Basically we know that IIR filters can always be more computationally efficient than FIR filters, sometimes dramatically; but we don't have a good theory of how to design them. There are probably a lot of tasty morsels hiding in IIR-space.

What's the dumbest register allocator that might give you reasonable performance?

Kragen Javier Sitaker, 2016-10-11 (15 minutes)

Programs compiled with Ur-Scheme are about five times slower than similar programs compiled with GCC. TCC is broadly similar.

It occurred to me that a big part of Ur-Scheme's slowness is probably its complete lack of register allocation. It treats the i386 as a stack machine with the top of stack in %eax. And so it occurred to me that even the dumbest register allocator would probably provide a big speedup, maybe up to a slowdown of less than 2.

What's the dumbest register allocator that might give you reasonable performance? Well, on amd64, as I understand it, you have 16 general-purpose registers, but one of them is the stack pointer. You could statically allocate 8 of these registers to local variables (the first 8 local variables) and 7 of them to an expression evaluation stack which is empty in between statements, assuming you have statements and that control flow is a per-statement thing. Then you can allocate the slots on the expression evaluation stack at compile time and spill to memory if your evaluation gets too deep.

I feel like that would probably work well enough, and it would be very simple to implement.

On i386, you don't have as many registers. You could have 4 levels of expression evaluation and 3 local variables held in registers.

Context: how well do programs get optimized?

Here's a Karplus-Strong string synthesis program I wrote in C, something over a year ago, in golfed form:

```
enum{n=72};s[n]={1<<15},i;main(){void*o=popen("aplay","w");
for(i=0;i<1<<14;i++)fputc((s[i%n]=s[i%n]*.9+s[(i+1)%n]*.1)>>8,o);}
```

Here's a deobfuscated version of the main loop:

```
for (i=0; i < 1<<14; i++) {
    int j = i % n, k = (i+1) % n;
    s[j] = s[j]*.9 + s[k]*.1;
    fputc(s[j] >> 8, output);
}
```

`n` here is 72, and `s` starts out with just an impulse in it. (If you're not familiar with KS synthesis, the weighted averaging of two samples there serves as a gentle low-pass IIR filter, attenuating all frequencies but especially the highest frequencies, while feeding the signal back into the delay line after 72 samples limits the original harmonic content to harmonics of 8000 Hz / 72 = 111 Hz, and the result sounds exactly like the string of a six-string guitar.)

I feel like this is a relatively typical piece of C code in some ways.

It has a for loop comparing against a constant expression that can be folded, some array accesses and a function call inside the loop, some floating point and integer math, some strength-reduction opportunities, and a local variable (or two, although `i` is technically a global).

So how badly does TCC do on this program?

First, what's our gold standard? It's actually pretty terrifying, both in terms of the optimizations achieved and the optimizations missed. On i386, here's a commented disassembly of the 48 instructions gcc 4.8.4 emits for the main loop with -O:

```
 804847d:   89 c6                   mov    %eax,%esi
 # This is the address of i; we are initializing it with 0.
 804847f:   c7 05 64 a1 04 08 00    movl   $0x0,0x804a164
 8048486:   00 00 00
 # And we also have i in %edi at the top of the loop.
 8048489:   bf 00 00 00 00          mov    $0x0,%edi
 # This magic number is the approximate multiplicative inverse of
 # 72.  72 times this number is 0x10,0000,0008.  That means that if
 # you multiply some 32-bit integer X by 0x38e38e39, then the high
 # word of the 64-bit result will contain the number divided by 72,
 # shifted four bits to the left.  So, for example, 0x38e38e39L *
 # 146 >> 36 = 2L.  So we save it in %ebx so we can multiply by it
 # in order to divide.  Multiplying is usually much faster than
 # division.
 804848e:   bb 39 8e e3 38          mov    $0x38e38e39,%ebx
mainloop:
 8048493:   89 f8                   mov    %edi,%eax
 # Now we divide %eax by 72 by multiplying it by the magic number in
 # %ebx.  %eax is the implicit argument of a one-argument imul in
 # i386.  I guess this means i was in %edi and %eax.
 8048495:   f7 eb                   imul   %ebx
 # The high dword of the result is in %edx, so put it in %ecx.
 8048497:   89 d1                   mov    %edx,%ecx
 # Eliminate those 4 extra bits on its low end so %ecx contains %eax/72.
 8048499:   c1 f9 04                sar    $0x4,%ecx
 # Another copy of i goes into %eax.
 804849c:   89 f8                   mov    %edi,%eax
 # Now we shift it 31 bits to the right, which means we are saving
 # off just its sign bit, which is a little bit stupid because it's
 # statically fairly trivial that it's always positive.
 804849e:   c1 f8 1f                sar    $0x1f,%eax
 # Now we do some kind of negative-number correction to our quotient
 # in %ecx with this.  This amounts to a no-op.
 80484a1:   29 c1                   sub    %eax,%ecx
 # Now we magically multiply %ecx (i/72) by 9 and put the result in
 # %eax.
 80484a3:   8d 04 c9                lea    (%ecx,%ecx,8),%eax
 # Then we shift it three more fucking bits, so guess what, now
 # we've multiplied it by fucking 72.  GCC factored 72 into 8*(8+1)
 # in order to multiply it with two obscure instructions instead of
 # just using an imul.  Now %eax is going to contain (i/72)*72,
 # which is to say, i-(i%n).
 80484a6:   c1 e0 03                shl    $0x3,%eax
 # Now we get another copy of i into %ecx.
```

```
80484a9:   89 f9                   mov    %edi,%ecx
# And now at last we compute i%n in %ecx, which took 11
# instructions.  This is the number I called "j" above.
80484ab:   29 c1                   sub    %eax,%ecx
# Now we load the integer at s[j] (s[i%n]) as a floating-point
# number.
80484ad:   db 04 8d 40 a0 04 08    fildl  0x804a040(,%ecx,4)
# This isn't in the listing but I bet the constant 0.9 is stored
# there.
80484b4:   dc 0d d8 85 04 08       fmull  0x80485d8
# Now we increment i, which makes a certain amount of sense because
# now we have to compute s[k], and we aren't going to use i again.
80484ba:   83 c7 01                add    $0x1,%edi
# Oh boy, here we go again.  Compute k as (new i) % n in another 11
# instructions, except now it's in %edi.
80484bd:   89 f8                   mov    %edi,%eax
80484bf:   f7 eb                   imul   %ebx
80484c1:   c1 fa 04                sar    $0x4,%edx
80484c4:   89 f8                   mov    %edi,%eax
80484c6:   c1 f8 1f                sar    $0x1f,%eax
80484c9:   29 c2                   sub    %eax,%edx
80484cb:   8d 04 d2                lea    (%edx,%edx,8),%eax
80484ce:   c1 e0 03                shl    $0x3,%eax
80484d1:   29 c7                   sub    %eax,%edi
# Compute the weighted sum, multiplying by a different constant in
# memory, presumably 0.1.
80484d3:   db 04 bd 40 a0 04 08    fildl  0x804a040(,%edi,4)
80484da:   dc 0d e0 85 04 08       fmull  0x80485e0
80484e0:   de c1                   faddp  %st,%st(1)
# Truncate the result back to an int by way of storing it in the
# stack frame and loading it into %eax.
80484e2:   d9 7c 24 0e             fnstcw 0xe(%esp)
80484e6:   0f b7 44 24 0e          movzwl 0xe(%esp),%eax
# Okay, I have no idea what is going on here, except that it
# results in storing the new value of s[j] at 0x8(%esp) and also in
# %eax.  Somehow this involves overwriting the high byte of
# some 16-bit number with 0xc!?
80484eb:   b4 0c                   mov    $0xc,%ah
80484ed:   66 89 44 24 0c          mov    %ax,0xc(%esp)
80484f2:   d9 6c 24 0c             fldcw  0xc(%esp)
80484f6:   db 5c 24 08             fistpl 0x8(%esp)
80484fa:   d9 6c 24 0e             fldcw  0xe(%esp)
80484fe:   8b 44 24 08             mov    0x8(%esp),%eax
# Now we store the result into s[j]; %ecx still has j in it, and
# 0x804a040 is the base address of s, as indicated by its use above
# in the fildls.
8048502:   89 04 8d 40 a0 04 08    mov    %eax,0x804a040(,%ecx,4)
8048509:   89 74 24 04             mov    %esi,0x4(%esp)
# Here we shift the s[j] result in %eax right by 8 bits and "push
# it" in order to call fputc with it.
804850d:   c1 f8 08                sar    $0x8,%eax
8048510:   89 04 24                mov    %eax,(%esp)
8048513:   e8 38 fe ff ff          call   8048350 <fputc@plt>
# Now we ignore fputc's return value and load the value of i again
# from memory and increment it, again.  fputc could have changed
```

```
 # it, after all, since it's a global variable.
 8048518:   a1 64 a1 04 08          mov    0x804a164,%eax
 804851d:   8d 78 01                lea    0x1(%eax),%edi
 # Save the incremented value to memory.  You never know, fputc
 # could be reading a global variable.
 8048520:   89 3d 64 a1 04 08       mov    %edi,0x804a164
 # Check to see if the loop is done.  It's interesting that the <
 # test got turned into a <= test.
 8048526:   81 ff ff 3f 00 00       cmp    $0x3fff,%edi
 804852c:   0f 8e 61 ff ff ff       jle    8048493 <main+0x36> (mainloop)
```

All right, so we can see GCC missed a *lot* of optimization opportunities there, although some of them were missed by the perverse choice to make i a global variable. But it did manage to compute i%72 without using any division instructions. It also manages to keep j and k in registers and avoid recomputing j --- common subexpression elimination. And the control flow is nice and clean, just a single conditional jump instruction at the end, because it can statically check that the loop will execute at least once.

How does TCC do? It's a bit messier but somewhat more straightforward, as you'd expect. tcc 0.9.25 emits 67 instructions:

```
# Initialize i to 0.  Note the unnecessary indirection through a
# register that isn't used afterwards.
     242:   b8 00 00 00 00          mov    $0x0,%eax
     247:   89 05 00 9f 04 08       mov    %eax,0x8049f00
looptest:
# Load i from memory and check it.  This is at the top of the loop
# so that it can run zero times if necessary.
     24d:   8b 05 00 9f 04 08       mov    0x8049f00,%eax
     253:   81 f8 00 40 00 00       cmp    $0x4000,%eax
     259:   0f 8d c8 00 00 00       jge    0x327 (exitloop)
     25f:   e9 11 00 00 00          jmp    0x275 (loopbody)
mainloop:
# This is "i++".  Neither %eax nor %ecx is used afterwards.  I have
# no idea why it makes a copy in %ecx.
     264:   8b 05 00 9f 04 08       mov    0x8049f00,%eax
     26a:   89 c1                   mov    %eax,%ecx
     26c:   40                      inc    %eax
     26d:   89 05 00 9f 04 08       mov    %eax,0x8049f00
     273:   eb d8                   jmp    0x24d (looptest)
loopbody:
# Load i from memory.
     275:   8b 05 00 9f 04 08       mov    0x8049f00,%eax
     27b:   b9 48 00 00 00          mov    $0x48,%ecx   # 0x48 == 72 == n
     280:   99                      cltd                # clears %edx?
# implicitly divides %edx:%eax by its operand; remainder is in %edx,
# quotient in %eax.
     281:   f7 f9                   idiv   %ecx
# Shift the quotient left two bits to use it to index dwords.
     283:   c1 e2 02                shl    $0x2,%edx
# Load base address of s into %eax and index it.
     286:   b8 44 9d 04 08          mov    $0x8049d44,%eax
     28b:   01 d0                   add    %edx,%eax
# Save the pointer into a temporary in the stack frame.  This is
```

```
# where we are going to store the result of the weighted sum.
    28d:   89 45 f8              mov    %eax,-0x8(%ebp)
# Load i from memory again.  This is the common subexpression s[i%n]
# not being eliminated.
    290:   8b 05 00 9f 04 08     mov    0x8049f00,%eax
    296:   b9 48 00 00 00        mov    $0x48,%ecx
    29b:   99                    cltd

    29e:   c1 e2 02              shl    $0x2,%edx
    2a1:   b8 44 9d 04 08        mov    $0x8049d44,%eax
    2a6:   01 d0                 add    %edx,%eax
# Load from s[i%n] into %ecx, then into a floating-point register by
# way of the stack, since that's apparently how we do things.
    2a8:   8b 08                 mov    (%eax),%ecx
    2aa:   51                    push   %ecx
    2ab:   db 04 24              fildl  (%esp)
# Pop it back off.
    2ae:   83 c4 04              add    $0x4,%esp
# Store the floating-point version of s[j] in an on-stack temporary?
    2b1:   dd 55 f0              fstl   -0x10(%ebp)
# Not sure what's going on here.
    2b4:   dd d8                 fstp   %st(0)
    2b6:   dd 05 6c 9e 04 08     fldl   0x8049e6c
    2bc:   dc 4d f0              fmull  -0x10(%ebp)
# Okay, now we load i from memory again, increment it, and divide it
# to compute (i+1)%n.
    2bf:   8b 05 00 9f 04 08     mov    0x8049f00,%eax
    2c5:   40                    inc    %eax
    2c6:   b9 48 00 00 00        mov    $0x48,%ecx
    2cb:   99                    cltd
    2cc:   f7 f9                 idiv   %ecx
# And then again we index off s.
    2ce:   c1 e2 02              shl    $0x2,%edx
    2d1:   b8 44 9d 04 08        mov    $0x8049d44,%eax
    2d6:   01 d0                 add    %edx,%eax
# Wait, what are we doing with the FPU?
    2d8:   dd 55 e8              fstl   -0x18(%ebp)
    2db:   dd d8                 fstp   %st(0)
# Okay, load s[k]
    2dd:   8b 08                 mov    (%eax),%ecx
    2df:   51                    push   %ecx
    2e0:   db 04 24              fildl  (%esp)
    2e3:   83 c4 04              add    $0x4,%esp
# I don't know what's going on here either.
    2e6:   dd 55 e0              fstl   -0x20(%ebp)  # ???
    2e9:   dd d8                 fstp   %st(0)       # ???
    2eb:   dd 05 74 9e 04 08     fldl   0x8049e74    # Maybe 0.1?
 # But this looks like the weighted sum.
    2f1:   dc 4d e0              fmull  -0x20(%ebp)
    2f4:   dc 45 e8              faddl  -0x18(%ebp)
    2f7:   d9 2d 7c 9e 04 08     fldcw  0x8049e7c  # ???
    2fd:   81 ec 04 00 00 00     sub    $0x4,%esp
 # Store the weighted-sum result at the stack pointer.
    303:   db 1c 24              fistpl (%esp)
    306:   d9 2d 7e 9e 04 08     fldcw  0x8049e7e  # ???
```

```
 # And now load it into %eax.
     30c:   58                      pop    %eax
# Load the pointer where we are going to save the result (stored at
# 0x28d above) into %ecx.
     30d:   8b 4d f8                mov    -0x8(%ebp),%ecx
# Save the result.
     310:   89 01                   mov    %eax,(%ecx)
# Shift the result before emitting it with fputc.  Note that we
# don't load it from memory again.
     312:   c1 f8 08                sar    $0x8,%eax
# Load o into %ecx to push it.
     315:   8b 4d fc                mov    -0x4(%ebp),%ecx
     318:   51                      push   %ecx
     319:   50                      push   %eax
     31a:   e8 f1 09 00 00          call   0xd10     # fputc
     31f:   83 c4 08                add    $0x8,%esp # pop fputc args
     322:   e9 3d ff ff ff          jmp    0x264 (mainloop)
exitloop:
     327:   c9                      leave
     328:   c3                      ret
```

The only real optimization TCC managed here was to keep a value in a register, once, and constant-fold the loop bound. It didn't attempt common subexpression elimination, and its FPU code is relatively horrible.

Low-power microcontrollers for a low-power computer

Kragen Javier Sitaker, 2016-09-06 (updated 2018-10-28) (18 minutes)

(See also Keyboard-powered computers (p. 2220).)

E-ink displays are capable of supporting continuous, comfortable reading at average power levels under 3 milliwatts. For this to be useful, we need a microcontroller to drive them at comparable power. But 5–20 watts might be available sometimes, and we'd like to be able to take advantage of it.

To build a computer that provides rapid UI response on very low average power (<10mW, >100 seconds per joule) I think you need, among other things, multiple processors: a low-speed, low-power "peripheral processor", probably designed as an embedded microcontroller, for normal real-time interaction, plus a higher-speed "central processor" that powers up occasionally, or when lots of power is available, to handle heavier-duty computation.

Computational power needed

Simply slinging pixel data around is a minimum; at 1 bit per pixel and 400 pixels per character (due to high-res screens), you need to send 50 bytes of data to the framebuffer to draw a single letter or space. That's probably about 100 instructions, so 100 instructions/glyph × 350 wpm × 6 glyphs / word = 3500 instructions/second. But that's like a theoretical minimum.

WordStar on a 2MHz (≈0.5MIPS) 8-bit CPU would sometimes fall behind your typing a bit. This suggests that one (8-bit) MIPS is adequate to provide real-time word processing.

A nanojoule (1000 pJ) per instruction is a microwatt per MIPS, which would be about 0.56 µA/MIPS (the unit microcontroller vendors like to use) at 1.8V. That's also 1000 giga-ops-per-second per watt. Low-power microcontrollers are usually 2–5 times better than this.

Atmel picoPower

Atmel ARMs can do 250 pJ per 32-bit instruction and 2µW in standby. However, they take forever to wake up, like tens of microseconds (and a microsecond is 12 to 48 instructions!). A full reboot from OFF takes 2.2 milliseconds.

At this energy cost, 10W would pay for 40 billion instructions per second, but that would require nearly a thousand microcontrollers.

These are Cortex-M0+s with single-cycle hardware (32×32!) multipliers. And also a tiny four-cell FPGA called "CCL", "configurable custom logic".

http://www.atmel.com/technologies/lowpower/picopower.aspx makes it hard to tell how low power can go. They say 1.62V.

http://www.atmel.com/Images/doc8349.pdf gives an example of how to lower power consumption by lowering clock frequency from 8MHz to 1.8432MHz, transmitting data at 115,200 baud instead of 19,200 baud, lowering the brownout voltage from the usual 2.7V to

1.8V, and going to sleep, increasing run-time off a capacitor from 6 seconds to 217 seconds. However, they never specify the capacitance!

http://www.atmel.com/products/microcontrollers/arm/sam-l.aspx#o
osaml21 says "power consumption down to 35 µA/MHz in active mode and 200nA in Sleep mode".
http://www.atmel.com/Images/Atmel-42385-SAM-L21_Datasheet.o
opdf says 48MHz (the Performance Level 2 model) or 12MHz (the PL0 model), 256kB flash, 40kB SRAM, 1.62 to 3.63 V, and typically 25 to 100 µA/MHz with the regulator in buck mode, lower for PL0 than PL2. 75 µA/MHz at 3.3V in the PL0 model seems like the worst-case performance. Normalizing that, we get 250pJ/inst. Also gives numbers in the 1 to 10 µA for STANDBY and BACKUP states, depending on temperature, and a bit lower for OFF.

More easily available is the https://www.digikey.com/product-detail/en/ATSAMD10D13A-MO
OUT/ATSAMD10D13A-MUTCT-ND/5226477 Atmel ATSAMD10D13A-MUT (US$2.24); datasheet at http://www.atmel.com/Images/Atmel-42242-SAM-D10_Datasheeto
o.pdf. 8 kB flash, 4 kB RAM, 22 GPIOs. Worst case 75 µA/MHz (+284µA), which normalizes to the same 250pJ/inst. Wakeup time is 4–20µs.

STM32

See also Notes on the STM32 microcontroller family (p. 3176), but the STM32L low-power ARM microcontroller series is supposedly 144 pJ/insn, and can reasonably do duty cycles down to 0.02%, while using 2 mA at 1.8 V at 16 MHz, and the STM32F0 range is 250 pJ/insn.

ATMega328

The familiar ATMega328 used in the Arduino isn't the highest-tech or lowest-power microcontroller out there, but it's very well known, and it's simple to get running. It runs at up to 20MHz, with most instructions in a single cycle, but only 8-bit ALU operations. In power-save mode, with a real-time clock enabled, it uses 0.75µA (at 1.8V, so 1.4 µW); at 8MHz and 5V, it uses up to 12mA, so 60mW, working out to 7500 pJ/instruction. This is about 30 times worse than the AT-SAM family and MSP430 family, even before you take into account that these are 8-bit operations.

Consequently, at 20MHz, this processor will gobble 150mW.

MSP430

The von Neumann MSP430 family is in the range of 300–500 pJ per instruction, 10–25 16-bit MIPS, and 220–4000nW idle, which means instruction consumption exceeds idle consumption above about three instructions per second or one wakeup per minute. At a power budget of 5mW, an MSP430 could average 12 16-bit MIPS.

These processors are generally the processors of choice for very-low-duty-cycle applications.

http://www.ti.com/lit/wp/slay015/slay015.pdf TI in 2012 explaining why they think MSP430 is better at low-power than Microchip XLP.

http://www.greenarraychips.com/home/documents/greg/WP003-100617-msp430.pdf says that in 2010 the F18 consumed 7 pJ per instruction or 450 pJ per 17×17-bit multiply; an MSP430 (at 8MHz) consumed 330 pJ per instruction or 2310 pJ per 16×16 multiply. It also gives a sleep/wakeup time of 4 ns for the F18, with an idle power consumption of 100 nW, and a sleep/wakeup time of 5µs for the MSP430, with an idle (LPM4 sleep state) power consumption of 3600 nW.

http://johann-glaser.blogspot.com.ar/2012/10/msp430-launchpad-with-debian.html says that an MSP430G2231 has 2kB flash, 128 bytes RAM, and runs at 16MHz (performing 16-bit operations). (Also, it gives a nice howto for getting a TI Launchpad device working with Debian.)

http://www.ti.com/tool/msp430-gcc-opensource is TI's deprecated but actively maintained port of GCC.

https://en.wikipedia.org/wiki/TI_MSP430A says the FRAM series of MSP430s has 320 nA RAM retention and 82 µA/MIPS, which is half the power consumption of other MSP430s, with up to 2 kB of RAM. Other MSP430s have up to 512kB of ROM or 10kB of RAM. Normalizing these numbers using 3.3V, which ought to be about right, we get 271 pJ/insn and 1100 nW. The MSP430G2xx series has sub-microsecond wakeup, 0.1µA RAM retention, and 220µA/MIPS at 2.2V, or 480 pJ/insn and 220nW idle.

Experimental subthreshold processor

http://www.eit.lth.se/fileadmin/eit/courses/eit095f/Hanson_Variability_J_2008.pfd describes an 8-bit processor that works at 350 mV and uses 3.5 pJ/instruction, two orders of magnitude less than the MSP430.
https://web.eecs.umich.edu/~taustin/papers/VLSI-subliminal.pdf describes it again more briefly.
https://web.eecs.umich.edu/~taustin/papers/VLSI06-sublim.pdf describes another one that reaches 2.6 pJ/inst at 833kHz. None of these processors are commercially available.

CoolRisc 81

http://citeseerx.ist.psu.edu/viewdoc/download?doi=10.1.1.25.1097&rep=rep1&type=pdf says the CoolRisc 81 uses 22 pJ/inst. In 2001!

Brains

http://icri-ci.technion.ac.il/files/2013/07/Karlheinz-Meier_red2.pdf Neurons use about 10 fJ (0.01 pJ) per neural spike (action potential) per synapse. It is not yet feasible to use them to build a portable computer.

Energy storage

A solar-powered computer could still be somewhat useful at night if it can store some energy. But standard batteries are flaky and break

after a few years, so fuck them. And we're talking about a super-low-power device, one that might use under 10mW when in active use, so even storing 1 joule of energy is potentially useful (100 seconds), 10 joules could last you 20 minutes, and 100 joules could last you three hours.

But how can you store 100 joules without batteries? I haven't found a good way.

If you can reduce the power consumption below 1mW, then a smaller amount of energy storage would be feasible.

Solid-state cell energy storage

http://www.mouser.com/pdfDocs/Cymbet-WP-EnerChips-vs-Supercaps.pdf claims that supercapacitors discharge at 10%–20% per day, while EnerChips (theoretically on the market but not in stock at Digi-Key) discharge at 1%–2% per *year*.

These solid-state batteries use a thin-film solid with ionic conduction as their electrolyte, so they are fully solid-state, despite the mobility of ions within them.

http://www.nature.com/nmat/journal/v14/n10/full/nmat4369.html discusses some new research on solid-state electrolytes for lithium batteries in more detail.

http://news.mit.edu/2015/solid-state-rechargeable-batteries-safer-longer-lasting-0817 is a press release about the paper.

Capacitor power storage

Solid-state capacitors are the physically stablest medium for storing a few joules of energy for short periods of time. They are low in capacity and expensive. To store 1J, a capacitor needs:

E <	C >
3V	0.2 F
10V	20000 µF
50V	800 µF
100V	200 µF
300V	22 µF
1000V	2 µF

Ceramics

Ceramic capacitors generally do not have the necessary energy capacity.

https://www.digikey.com/product-detail/en/C3216X5R0J476M160AC/445-1428-2-ND/569054 TDK Corporation C3216X5R0J476M160AC is 47µF, 6.3V, 3.20mm x 1.60mm, US$0.12. $CV^2/2$ = 1 mJ.

https://www.digikey.com/product-detail/en/AMK432BJ477MM-T/587-4368-1-ND/5405565 Taiyo Yuden AMK432BJ477MM-T is 470µF, 4V, 4.50mm x 3.20mm, US$5.34. $CV^2/2$ = 4 mJ.

https://www.digikey.com/product-detail/en/JMK325ABJ227MM-T/587-3980-1-ND/4950534 Taiyo Yuden JMK325ABJ227MM-T is

220μF, 6.3V, 3.20mm x 2.50mm, US$2.56. $CV^2/2$ = 4 mJ.

https://www.digikey.com/product-detail/en/B58033I5206M001/495-6706-5-ND/5039882 EPCOS (TDK) B58033I5206M001 is 20μF, 500V, 33.00mm x 22.00mm, 31g, US$89.90. $CV^2/2$ = 2.5J. Designed for industrial power inverters.

Films

Some film capacitors are designed for high voltages and consequently have substantial energy capacity. You could hook up the output side of an ordinary switchmode power supply (the part after the rectifier) designed for 240VAC line current to many of these, because in normal use a 240VAC-input SMPS's capacitors will be charged up to 340V.

http://www.righto.com/2014/05/a-look-inside-ipad-chargers-price-y.html gives an overview of these power supplies, and points out that you can get a crappy one with 5V output for US$3.

http://www.onsemi.com/pub_link/Collateral/SMPSRM-D.PDF explains a bit about how you could charge them from a low-voltage source such as solar panels.

https://www.digikey.com/product-detail/en/DS371506-CA/P9669-ND/821966 Panasonic Electronic Components DS371506-CA is 50μF, 370V, 50.50mm diameter × 112.00mm, US$7.87. $CV^2/2$ = 3.4 J. This capacitor is designed for shunting a motor.

https://media.digikey.com/pdf/Data%20Sheets/Panasonic%20Capacitors%20PDFs/AC%20Film%20Caps.pdf is the datasheet; specifies insulation resistance >1000 MΩ (giving $\tau > 14$h), explains it's an "oil wound metallized polypropylene film" capacitor.

https://www.digikey.com/product-detail/en/B32778G1276K/495-3933-ND/1884954 EPCOS (TDK) B32778G1276K is 27μF, 1300V, 57.50mm × 35.00mm × 50.00mm, US$14.48. $CV^2/2$ = 23 J.

http://en.tdk.eu/inf/20/20/db/fc_2009/MKP_B32774_778.pdf is the datasheet; gives lifetime expectancy of 100k hours (11 years) to 1M hours (110 years) at room temperature, but insulation resistance such that τ is only 10k seconds (3 hours).

https://www.digikey.com/product-detail/en/C44AFGP6200ZE0J/399-5955-ND/2704609 Kemet C44AFGP6200ZE0J is 200μF, 400V, 76.00mm diameter × 140.00mm, US$55.44. $CV^2/2$ = 16 J.

https://www.digikey.com/product-detail/en/B25620B1317K322/B25620B1317K322-ND/3489148 EPCOS (TDK) B25620B1317K322 is 310μF, 1320V, 116.00mm diameter × 103.00mm, US$82.83 (in quantity 16!). $CV^2/2$ = 270 J.

Tantalums

A few tantalum capacitors have reasonable energy capacity.

https://www.digikey.com/product-detail/en/T491B476K010AT/399-9728-2-ND/3724805 Kemet T491B476K010AT is 47 μF, 10V, 3.50mm x 2.80mm, US$0.12. $CV^2/2$ = 2 mJ.

https://www.digikey.com/product-detail/en/T491X476K035AT/39

o9-3821-2-ND/818681 Kemet T491X476K035AT is 47 µF, 35V, 7.30mm x 4.30mm, US$0.94 (in quantity 500!). CV²/2 = 30mJ.

https://www.digikey.com/product-detail/en/109D107X9060F2/7180-1226-ND/1559882 Vishay Sprague 109D107X9060F2 is 100µF, 60V, 7.92mm x 20.22mm, US$41.91. CV²/2 = 180mJ.

https://www.digikey.com/product-detail/en/TWDE503M006CB0Z0700/478-9404-ND/4990384 AVX Corporation TWDE503M006CB0Z0700 is supposedly 50 millifarads, but actually mislabeled; it's 50 microfarads. 6.3V, 9.52mm x 26.97mm, US$69.20. CV²/2 = 1 mJ. Also "wet tantalum".

https://www.digikey.com/product-detail/en/592D228X06R3X8T20H/592D228X06R3X8T20H-ND/2802652 Vishay Sprague 592D228X06R3X8T20H is 2200µF, 6.3V, 14.50mm x 7.37mm, US$3.69 (in quantity 500!). CV²/2 = 40mJ.

https://www.digikey.com/product-detail/en/TWAE228K025CBSZ0000/478-4966-ND/1879539 AVX Corporation TWAE228K025CBSZ0000 is 2200 µF, 25V, 9.52mm x 26.97mm, US$102.73, wet tantalum. CV²/2 = 700mJ.

https://www.digikey.com/product-detail/en/M39006%2F22-0660/1012-1025-MIL/2773731 Vishay Sprague [MIL] M39006/22-0660 is 56 µF, 125V, 10.31mm x 28.60mm, US$76.61. CV²/2 = 400mJ.

https://www.digikey.com/product-detail/en/TWAE157K125SBDZ0000/478-7301-ND/3451926 AVX Corporation TWAE157K125SBDZ0000 is 150 µF, 125V, 10.31mm x 26.97mm, US$87.20. CV²/2 = 1 J.

Supercapacitors

These are newish (like, the last 30 years). I'm not sure they can be trusted to last a long time; the numbers I'm seeing on Digi-Key's page are like "1000 hours at 70°".

http://www.murata.com/~/media/webrenewal/products/capacitor/edlc/techguide/electrical/c2m1cxs-053.ashx talks about the failure modes; it says they degrade little by little over time, although even after 5 years their 4.2V 470 mF supercap holds 2 J; they claim that their flat packages do a better job of keeping moisture out and electrolyte in than cylindrical packages, showing a degradation to 80% of capacity after 3000h (4 months). It also mentions that leakage current is around a microamp. On p.20 it shows a dryup lifetime graph, showing that even their DMT products will dry up in only 20 years at 70°, while their DMF products will dry up in only 5 years at 40°; on p.23 it explains that at 5.5V, their DMF will break after only 500 hours at 70° or 6400 hours (9 months) at 40°, while the DMT will last dramatically longer, like 40,000 hours at 70°.

https://www.digikey.com/product-search/en?pv13=1538&FV=fff40002%2Cfff8000c&mnonly=0&newproducts=0&ColumnSort=0&page=1&quantity=0&ptm=0&fid=0&pageSize=500 Nichicon JJD0E608MSEH is 6000 farads, 2.5V, 76.20mm × 168.00mm,

US$326. $CV^2/2$ = 18750 J. This sounds like science fiction.

https://www.digikey.com/product-detail/en/JUWT1105MCD/4930-4330-ND/2538684 Nichicon JUWT1105MCD is 1F, 2.7V, 6.30mm diameter × 10.50mm, US$0.86. $CV^2/2$ = 3.6 J.

https://www.digikey.com/product-detail/en/DSK-3R3H224U-HL/604-1020-1-ND/970232 Elna America DSK-3R3H224U-HL is 0.22F, 3.3V, 6.80mm × 3.00mm, US$2.16. $CV^2/2$ = 1 J.

Batteries

https://www.sparkfun.com/products/10319 is a 24.5 mm × 3.0 mm 3.6V LIR2450 rechargeable coin cell, rated for 110 mAh, which is 1430 J. It costs US$3.
https://electronics.stackexchange.com/questions/218655/running-3-03v-mcu-from-lir2032-lithium-ion-button-cell cites a LIR2032 (20 mm × 3.0 mm) cell with 40 mAh at 3–4.2 V, 520 J.

Horowitz & Hill (the 1989 edition with the micropower chapter) says that commonplace batteries (9-volt and AA batteries) "give nearly their full shelf life at drain currents less than 20μA." At 2 V and 200 pJ/insn (reasonable ballpark figures, though the STM32L does better) this works out to an average of 200 000 instructions per second. At 1400mAh for an ordinary 1.5 AA cell, of which you would need two (or a boost converter), this is 6 years, which is indeed comparable to the battery's shelf life. At 1 MIPS, the two-cell battery only lasts a year.

I bought a couple of rechargeable NiMH AA batteries the other day for some absurd price, like US$10 or something. They claim 2000 mAh, 1.2V, which is 8.6 kJ (per cell). At the full 3.5 mW power of a 16 MHz STM32L at 1.8V (see Notes on the STM32 microcontroller family (p. 3176)), that would run for 28 days.

Zamboni piles

A cell of the https://en.wikipedia.org/wiki/Zamboni_pile yields 0.8 volts, but only a few nA, and the Clarendon Dry Pile has been ringing its bell since 1840. The cell is perhaps 20mm in diameter, but <1mm thick; you could easily stack three of them to get 2.4 volts, perfectly adequate to run a microcontroller on without regulation. In particular, the Clarendon Dry Pile produces about 1 nA at 2 kV, consuming about 1 μg from each of its cells over the last 144 years, according to Croft's 1984 paper, "The Oxford electric bell." He doesn't give dimensions but the dry pile seems to be about 30mm in diameter, i.e. 700mm².

However, at least STM32s have a minimal current consumption of a few hundred nA (180 nA in standby mode with no RTC, 410 nA in standby mode with RTC). This would require, say, 500 times the cross-sectional area of the Clarendon battery: perhaps a 3-meter roll of 120mm-wide battery. If the total thickness were 1mm, the battery would be 350 mℓ. This seems like a small price to pay for a battery life measured in centuries, as long as the device doesn't have to be portable.

Memory

ISSI's IS62C256AL-45ULI-TR is 256 kilobits of parallel 5V 45ns SRAM for US$1.43 down to US$1.11 in quantity 500. It uses 150 μW

, or up to 15 mW in operation.

Microchip's 23K256-I/SN is 256 kilobits of SRAM in a little bitty 3.3V 8-pin 20MHz SPI SOIC for US$1.09 down to US$1.05. It uses 4 µA max for standby, which works out to 13.2 µW.

ISSI's IS62/65WVS2568FALL / IS62/65WVS2568FBLL is similar, 256 kiloBYTES of SRAM in a 3.3V SPI/SDI/SQI SOIC for US$2.20, but only available in quantity, running on 4 µA for standby.

The Adesto AT25SF041-SSHD-T is four megabits of 104MHz 2.5–3.6V Flash in the same 8-pin SOIC format, and it's much cheaper, US$0.36. Being Flash, it uses no power for "standby" but a lot of power to erase (10 mA for 500 ms to erase 32 kB ≈ 500 nJ/byte), but "only" 4 mA to read. It has quad outputs, so 104 MHz is pretty decent speed actually.

ISSI's IS62C1024AL-35QLI-TR is a megabit of parallel 5V 35ns SRAM for US$2.10 down to US$1.62 in quantity 500. It uses 20 µW, or up to 100 mW in operation.

In PSRAM, ISSI's IS66WV51216EBLL-55TLI is 8 megabits of parallel 55ns 2.5–3.6V DRAM, with all the refresh nonsense hidden inside the chip, for US$3.20 down to US$2.31 in quantity 1000. Because of the refresh nonsense, it uses more power, but not as much as you'd think — in CMOS standby mode (where presumably it retains the data) it uses 100 µA, which works out to 250–360 µW. That *is* about 80 times as much as the Microchip part, but it also has about 32 times as much memory, so the penalty isn't that bad.

Topics

Sparse filter optimization

Kragen Javier Sitaker, 2019-11-01 (5 minutes)

I've written a few items about "sparse filtering" previously, by which I mean factoring a DSP filter into some network of filters which requires very few total operations per sample. Generally I'm thinking in terms of single-rate LTI filtering, not multi-rate, nonlinear, or non-shift-invariant systems, and generally the nodes in the processing graph are basically comb filters of one kind or another.

This is a difficult optimization problem, being essentially combinatorial in nature: even for small numbers of operations per sample such as 10, the signal flow graph can have any of a large number of topologies, and each processing node in the graph can be configured in a large variety of different ways.

I just checked, and it seems that I haven't written down what now seems to me like the most straightforward way to handle this design problem, unless I'm not finding it.

Optimizing a fixed processing graph

Let's consider a processing graph made out of continuous-time delay, sum, and amplification nodes, and the problem to approximate a desired frequency and perhaps phase response with a fixed processing graph. The only parameters available are the delays and gains, and the frequency and phase response are continuous differentiable functions of them, so we can almost certainly use gradient descent and related methods (see, e.g., Using the method of secants for general optimization (p. 1773) and Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138)) to find a reasonable local optimum. In fact, for many problems, the dimensionality is small enough that I think we can use interval arithmetic to find the *global* optimum.

This is a continuous-time relaxation of the discrete-time problem we want to solve. Once a good solution to the relaxation has been found, imposing a penalty for fractional-sample delays is likely to be sufficient to find a good solution of the discrete-time problem; branch-and-bound is a surer approach, though exponential-time.

Deriving the processing graph

How can we derive the processing graph? A variety of approaches suggest themselves. We could start with a too-complex processing graph and use optimization penalties to drive most of the amplifier gains to 0, then remove the now-useless connections. We could start with a too-simple processing graph and alternate continuous-optimization phases with graph-mutation phases, which for example might replace a subgraph with two copies of that subgraph, each feeding to an attenuator, summed to form its original input, or insert a delay-0 element. Alternatively, we could just randomly generate a lot of graphs and try to optimize each of them separately.

A nontraditional choice that might improve the mutation properties of the graph is to use comb-filter nodes, which contain one delay, two gains, and a bit distinguishing whether they're feedforward

or feedback, rather than separate delay and gain nodes.

Databases and meet-in-the-middle

Of course, exploration of any optimization space can be facilitated by database and meet-in-the-middle approaches. In this case, we could begin any given search using a database of already-generated designs, starting the search from designs that already come close to meeting the desired specification; and, by dividing our desired frequency and phase response by that of every item in the database, we can get a set of frequency responses to search the database for.

For example, suppose we want a zero-phase gain of between 0.9 and 1.1 at 100 Hz and between 0.09 and 0.11 at 1000 Hz, and there's a signature in the database with a zero-phase gain of 0.5 at 100 Hz and 2.0 at 1000 Hz. So, if we found a system that had a zero-phase gain of between 1.8 and 2.2 at 100 Hz and between 0.045 and 0.055 at 1000 Hz, we could cascade the two together to get the desired response.

In practice, though, what we'd want to do is to find a database system or pair of database systems that get close to our objective (as measured by a response curve covering hundreds to millions of frequencies, or perhaps an affine-arithmetic approximation), then use local search as described earlier to converge precisely on that objective.

Even on modern hardware, the database can reasonably weigh terabytes, containing millions to billions of known inexpensive candidate systems. On future hardware we could conceivably tabulate trillions.

Cost functions

Aside from the penalty terms mentioned above, plus the penalty function for not meeting the desired response, there is some computational cost we're trying to minimize; this cost depends on the implementation technology. For digital computation, components of the cost function might include memory buffers, required bit width of those buffers, multiplications, and even additions. Analog signal processing is crucially limited by component precision and noise immunity, so you'd want to take the derivative of the system frequency response with respect to the vector of component values and injected noise and try to minimize that derivative; also, analog delay lines are not only bulky and expensive but also lossy. All of these situations can be handled by tweaking the cost function.

Lenticular deflector

Kragen Javier Sitaker, 2019-09-08 (updated 2019-09-09) (9 minutes)

I think I might have a solution to the problem of deflecting macroscopic light beams through large angles under electronic control at submicrosecond time scales, using a plano-convex lens and a plano-concave lens, which translate relative to each other — or, rather, an array of each, like the surface of a lenticular 3-D image. Then you can get large light deflections out of submicron movements.

The problem of electronically rapidly deflecting light

One of the problems I've frequently confronted — in, for example, Bokeh pointcasting (p. 92), Photodiode camera (p. 2265), and CCD oscilloscope (p. 1861) — is how to rapidly change the direction of light beams, such as laser beams, under the control of some kind of control system, such as an electronic circuit. This is a standard problem, and Michelson and Morley's 19th-century solution to it — a prismatic mirror spinning on an air bearing — led to new measurements of the speed of light and is used today in, among other things, supermarket scanners and laser printers. (I think it also led to the modern dentist's drill.). However, the spinning mirror has a lot of momentum, so while the movement is very predictable, it is not very controllable.

Modern laser light shows confront this problem with "laser galvos", descendants of the old instrument for measuring small currents — a galvanometer connected to a mirror rather than a needle. These are used in pairs, one for X deflection and one for Y deflection. Galvos for laser shows are rated in "kpps", thousands of points per second, and a few tens of kpps is typical.

Contrast this with the electron gun in a CRT. High-end mass-market CRT computer monitors in the early 2000s supported 1200 scan lines at a 72 Hz refresh rate, meaning that even with magnetic deflection, they could scan the electron beam across the screen in a sawtooth-wave pattern at 86 kHz. Analog oscilloscopes, using electrostatic deflection, routinely managed 20 MHz vertical deflections with 3 dB attenuation; high-end ones could reach 100 MHz. To look at it a certain way, that's 200 000 kpps.

The limitation on galvos is that mirrors have mass, which makes it harder to move them. If you try to make them smaller so that they have less mass, you suffer from divergence problems, where focusing the laser beam onto a smaller mirror narrows the beam waist and induces beam spreading through diffraction.

This is a serious problem: light can change direction in femtoseconds, and it's easy to switch electricity in nanoseconds, but changing the direction of light with electricity takes microseconds. Isn't there any way to get that number down to hundreds of nanoseconds or better, without suffering milliradians of divergence?

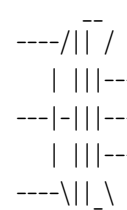
Well, there are lots of things that might work, like Kerr cells and dynamic LCD holography and ultrasonic gratings and whatnot, but I think I've found a good one.

Neutral meniscus lenses

A meniscus lens is concave on one side and convex on the other; it can be designed concave, convex, or neutral, so that collimated on-axis light entering the convex side comes out still collimated on the concave side. The exiting light is brighter and does not cover all of the lens; this effect gets stronger as the lens gets thicker, reaching a singularity when the lens thickness is the focal length of the convex side and, in the geometric-optics approximation, the light would come out in an infinitely thin pencil.

The sliced neutral meniscus lens

Take a neutral meniscus lens that is thick enough to be sliced along a flat plane parallel to its curved surfaces without interrupting either surface, and slice it in this way, dividing it into a plano-convex lens and a plano-concave lens. Separate the two halves by just enough air or oil to equal the delay of the glass removed. Aside from the stray light reflections at the new surfaces, this compound lens still behaves precisely as before, leaving collimated light collimated, but making it brighter.

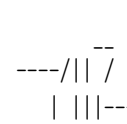


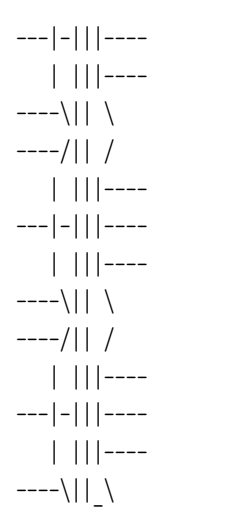
However, if we slide the two halves relative to each other, retaining flat-surface parallelism and distance, the collimated light exiting will change direction. If we slide the plano-concave half up, for example, the light passing through the center of the plano-convex lens, previously not deflected at all, now finds itself exiting just below the center of the plano-concave half, and so is refracted slightly down. The light a little above it enters the plano-convex lens and is refracted down, but exits through the center of the plano-concave lens, continuing its trajectory parallel to the other beam.

The beam remaining collimated depends on the deflection being linear with off-axis distance, and this linearity is not perfect. I think it's pretty good over ±30°, though, especially if the lens system is thick enough.

Microlens arrays

Consider the case where instead of one lens we have many, like two layers of that lenticular plastic covering that covers those 3-D parallax Jesus cards, except that the lenslets on one of them are concave:





This exhibits the same direction-changing behavior over the same angle with the same displacement as the single lens, but can handle a great deal more light.

You could fabricate this with little hexagonal lenslets in two dimensions, so that you can slide the two sheets relative to each other in two dimensions and deflect light on two axes, or you could fabricate it as two prismatic solids with complicated profiles amounting to many concatenated "cylindrical" lenses, like the typical 3-D lenticular parallax Jesus cards, and get only one dimension of displacement.

How fast can you move a thing? Tens of microseconds if it's 100 mm

The speed of sound in glass is commonly about 4500 m/s though it varies from 4000–6000 m/s for different glasses. Suppose you have a 100-mm-wide sheet of these lens things and you give it a shove on one edge, parallel to its surface, say with a piezoelectric actuator. That shove produces a sound wave that bounces back and forth through the glass about ten times before the whole thing has settled, in about 220 µs, using the above estimate of its speed of sound.

This sounds dismayingly slow, but I don't think the picture is that bleak. It's true that you have *latency* in the tens of microseconds, but it's very consistent, predictable latency. You can inverse-filter for the phase delay. XXX what about variation across the sheet while it's strained? Just turn the laser off except at key moments?

You might also be able to improve the situation with some acoustic impedance matching: some kind of matched resistance on the other side of the glass sheet that absorbs the shock and keeps it from bouncing back. That doesn't save you the initial 22-µs latency, but it means you don't have to contend with reflection.

This doesn't depend on the thickness of the sheet, as long as it's stiff enough not to buckle.

How small can you make the lenslets?

If you make the lenslets smaller than the wavelength of the light in question, they won't work at all. I think the variation in phase delay needs to be about half a wavelength from the center of the lenslet to its edge. That makes me think you should be able to make them on the order of 100 µm wide for visible light, even for fairly shallow

curvatures.

That means that the relative movements between the lenslet sheets to get light deflections can be on the order of 1 μm.

Uncertainty

Is it possible to deal with the acoustic delay somehow?

Will the light coming out of each lenslet have a different phase delay from the light coming out of the other lenslets? Does this mean that each individual beamlet will diffract on its own, giving a uselessly large divergence?

A survey of small TCP/IP implementations

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

Implementations

There are a few small TCP/IP implementations out there. Most recently, the Viewpoints Research Institute "STEPS toward the reinvention of programming" project has just done a "TinyTCP", including IP and TCP. [0] Although they claim it is "well under 200 lines of code" and provide some details about implementation techniques, it looks larger to me; see the section "TinyTCP" for details.

There have been a number of small TCP/IP implementations before. Adam Dunkels's 2001 "Miniweb", which is proprietary [1], supposedly implements a more or less working TCP, IP, and web server in about 400 lines of C.

Later, Dunkels wrote "uIP" and "lwIP", for "microIP" and "lightweight IP", which are complete and supposedly correct implementations of ARP, IP, UDP, and TCP. [2]

TinyTCP

I checked out TinyTCP r400 from Subversion:

```
svn co http://piumarta.com/svn2/idst/trunk/function/examples/tcp/
```

In the resulting directory, I counted the number of unique source lines:

```
cat *.k *.st | sort -u | wc -l
```

It counted 1270 lines of code, not "well under 200" as claimed. However, this includes the following (the listing is hand-annotated):

```
$ for x in *.k *.st; do printf "%30s " "$x"; sort -u "$x" | wc -l ; done
                  boot.k 152 construct the default environment (C iface)
               net-icmp.k 25  ICMP implementation
                 net-if.k 19  network pseudo interface
                 net-ip.k 62  the IP implementation
                net-tcp.k 81  TCP packet structure
             quasiquote.k 53  quasiquotation as userland syntax
              structure.k 87  the packet structure ASCII art parser
                   tcp2.k 78  TCP state machine, daytime, http
                    tcp.k 47  smaller version of the above
        Match-printing.st 74  COLA Smalltalk PEG parsing
                Match.st 221 more COLA Smalltalk PEG parsing
 NetworkPseudoInterface.st 108 TUN/TAP network interface in C and Smalltalk
               parse.st 275 more PEG parsing
          ParseStream.st 120 more PEG parsing
```

So the part that specifically pertains to TCP/IP, and not a particular network interface, or the system as a whole, and that isn't

duplicative, is much smaller:

```
$ sort -u net-icmp.k net-ip.k net-tcp.k structure.k tcp2.k | wc -l
311
```

A bit over 311 lines of code.

TCP Wrinkles

TCP itself is defined in RFC 793, STD 7 [3], which dates from 1981. But a number of problems have been discovered in TCP since then and worked around.

There's a full list of the specification documents in RFC 4614 [4]

RFC 896: where the term "congestion collapse" comes from.

Modeling trees with slices containing metaballs

Kragen Javier Sitaker, 2014-06-29 (updated 2014-07-02) (6 minutes)

So I'm doing this tree-growth simulation thing in slices, where theoretically we want the total cross-sectional area of the tree to stay constant through branch points. That is, the branch before a fork should have the same total cross-sectional area as the two branches after it, and also that every intermediate point in the forking process should have the same cross-sectional area.

The underlying structure is a set of branch center points that move around in the XY plane as a function of Z, but my current problem is how to convert that into a three-dimensional shape that has the right thicknesses, transitions smoothly from one layer to the next, and is approximately circular around the branch center points.

I've been trying to fake this by putting a circle around each branch center point and inflating it in such a way that two overlapping circles with the same center will have twice the area as if there were just one of them, and doing a radius linear interpolation thing as their radii get further apart, until they have no overlap at all. This is not working super well for a couple of reasons: the circles intersect one another and don't have a way to find corresponding points to join with a mesh, so they're only a step toward the two-dimensional shell I want, not the final result; and when more than two of them overlap because two branch events happened close together in time or because circles were forced to collide, the resulting circles are too big, and sometimes discontinuously so.

So it occurred to me that you could solve most of this problem with some variety of gradient descent. You have a bunch of boundary points linked into a bunch of loops. You're trying to optimize the following:

- The area of each loop is close to the sum of the weights of the branch center points contained inside it.
- The difference between the boundary points in this generation and in the last generation is small.
- The total length of each loop is as short as possible.
- The loops do not intersect or self-intersect.
- The loops have the right number of points: no more than necessary, but enough to keep their form well-defined.

Most of these can be optimized by continuously varying the boundary points' coordinates, but sometimes you might instead split or join loops or reorder the points of a loop, which might be done heuristically. If you can really differentiate the merit function with regard to the coordinates, you can do real gradient descent as such; otherwise, you're stuck with blind hill-climbing search or genetic algorithms.

Implicit functions

Unfortunately most of those things require a lot of geometric algorithms, and Sedgewick has impressed upon me how tricky those

are. As an alternative, maybe I could use an implicit function, a function whose zero is a circle of the correct area when it's fed with only a single branch center, which is computed from the sum of the functions of the different branch centers, and where the contribution of a branch center falls off rapidly to zero as you get far away from it.

As an example, you could use a sum of Gaussians centered on each center point, scaled to match the branch's radius, and subtract 1 from the sum to get a function with useful zeroes.

However, you'd also want it to be the case that the area of overlapping branches is the area that would be the sum of the individual branches, at least in the common case I'm looking at here where I divide a branch by making two new branches in the same place whose eventual cross-sectional area, once they separate, will sum to the cross-sectional area of the original branch.

A necessary but not sufficient condition for this is that the gaussian-like function of the distance from the center have the property that doubling the function makes the distance from the center at which the sum falls to 1 increase by a factor of $\sqrt{2}$. It happens that Gaussians do in fact have that property, at least if you double them! You can show it by algebra, but you can also do the experiment:

```
import math
def gaussian(r): return math.exp(-r**2)

def search(f, v, min, max, tolerance):
    fmin, fmax = f(min), f(max)
    assert (fmin - v) * (fmax - v) <= 0
    if tolerance >= abs(fmin - v): return min
    if tolerance >= abs(fmax - v): return max
    mid = (min+max)/2.0
    fmid = f(mid)
    if (fmid - v) * (fmin - v) <= 0:
        return search(f, v, min, mid, tolerance)
    else:
        return search(f, v, mid, max, tolerance)
```

This code shows that gaussian(.832554) ≈ 0.5, and 2*gaussian(1.17741) ≈ 0.5. The ratio between those two is indeed $\sqrt{2}$. However, it is not true in general that gaussian(x)/2 = gaussian(x$\sqrt{2}$), although that shouldn't stop us from using it here.

It seems like if there's an analytic function that has these properties (minimally, that in general f(x)/2 = f(x$\sqrt{2}$), that it's always positive and finite, that f(x) = 1 at exactly one positive x, and that its limit at infinity is zero) it should be unique.

I've already written an interval-arithmetic package in JS that could be used to efficiently divide the canvas into an implicit k-d tree to search for zero pixels. It may need to be enhanced somewhat to look harder for the zeroes, down into deep subpixel, in order to avoid false positives.

Topics

Regenerative fuel air cutting

Kragen Javier Sitaker, 2016-09-06 (4 minutes)

An oxy-acetylene flame can reach 3500°, which can easily heat steel past its kindling point of about 870°. Other oxy-fuel flames, like propane at 2800°, can also flame-cut steel. But single-tank torches that mix their fuel with air generally cannot, because they have to heat up a lot of inert nitrogen along with the active components, and even though the resulting temperature is higher than steel's kindling point, it's not hot enough to heat the steel fast enough; air-acetylene tops out at 2500°, propane at 1980°, gasoline at 2140°, hydrogen at 2250°, wood at 1980°.

You might be tempted to heat the air by running it through *two* flames, but that doesn't work, because the oxygen in the air has been used up; you'd have to mix oxygen back in, which lowers the temperature. What you need is a way to separate the heat from the gas and transfer it to fresh air, which you then use to burn a second flame.

You can do this with a regenerator. Taking propane as an example, you can heat the regenerator to 1980° with a first propane flame, and then heat fresh air to 1980° with the regenerator before using it to fuel a second propane flame. Propane has a specific heat capacity of 73.6 J/K/mol (and a molar mass of 44.1 g/mol), while air's is about 29.2 J/K/mol (and a molar mass of basically 30 g/mol), the stoichiometric mixture is $C_3H_8 + 10O_2 \rightarrow 3CO_2 + 4H_2O$, and air is only about 21% oxygen, so each mole of propane needs 10 moles of oxygen and 47.6 moles of air to burn. So the stoichiometric mixture is 97.9% air by volume, 97.0% air by mass, and 95.0% air by thermal mass, so if the air is at 1980° and the propane is at 20°, then the mixture would be at 1882° if it didn't immediately burn.

But it does immediately burn, which should raise its temperature by another 1960 K to about 3840°, quite a bit hotter than the oxy-acetylene flame, and plenty hot enough to cut steel.

For such a high temperature, both the regenerator and the combustion chamber would need to be of a material that can withstand the full 1980° produced by the propane-air flame. This is fairly demanding, and only a relatively small number of such refractory materials are available, including zirconia (melts at 2715°), urania (melts at 2865°), thoria (melts at 3300°), graphite or carbon (subliming at 6000°, but will burn at 700° if oxygen is available), and lime (melts at 2615°.) But if we only want to achieve the 2800° achieved by an oxy-propane flame, the regenerator only needs to withstand 840°, which is achievable by any number of everyday materials, including iron, steel, copper, and most kinds of dirt and rock.

It isn't necessary to use modern fuels like propane; syngas from a wood gasifier would work just as well.

(Other low-tech ways of flame-cutting steel are possible; Theodore Gray has demonstrated flame-cutting steel using thermic lances made of prosciutto and breadsticks and a cucumber, for example.)

There are several ways you could arrange the regenerator cycles;

for example, you could have two or three regenerators and alternate between them using valves, or you could mount the regenerators in a wheel like the desiccant wheel of a desiccant-type dehumidifier.

This approach should make it possible to flame-cut steel without using any exotic materials.

Optimizing for temperature

If we use the regenerator technique to optimize for high temperature rather than for easily-available materials, using a thoria regenerator to preheat oxygen for an oxy-acetylene flame should enable much higher temperatures, though not the 6800° you'd naïvely think, because the acetylene is a much larger fraction of the thermal mass entering such a flame, and the acetylene is by necessity not preheated.

This approach should make it possible to flame-cut stainless steels and aluminum, maybe glass and stone and other materials that cannot normally be flame-cut except with a plasma torch. (Plasma torches can reach over 20,000°.)

Optical lever thermometer

Kragen Javier Sitaker, 2015-09-03 (1 minute)

Was just watching Dan Gelbart's video on building large structures with adhesives (http://youtu.be/EeEhS3zmnDg), and he talks about the danger of mounting mirrors on silicone that changes size with temperature: if the adhesive layer is not of even thickness, its thermal expansion and contraction (an order of magnitude greater than that of metal or glass) will rotate the mirror, and the optical lever effect then can give you a substantial displacement! Maybe you can use this to get a thermometer, although liquids like mercury should have 3× greater coefficient in effect, since you're interested in the volumetric rather than linear coefficient of expansion there.

Some page about cleanrooms says that typically silicones have 30 to 300 ppm per kelvin expansion. So if you have a 1cm-wide mirror on a 5mm-thick wedge-shaped cushion of silicone, it should expand by half a micron per kelvin, or about 10 arc seconds per kelvin. That's half a millimeter of displacement at a distance of 10 meters.

This effect seems too small to make into a very useful thermometer.

Intro to algorithms

Kragen Javier Sitaker, 2016-09-06 (4 minutes)

If I want my paper-oriented algorithm notation to be useful, one avenue is to express algorithms that people are interested in in it. Perhaps introduction-to-algorithms classes would be a good place to find them. So here is a summary of some intro-to-algorithms classes, covering mostly only the algorithms, although in a few cases I've also included the problems because it wasn't clear which algorithm was being taught. I've probably missed a lot.

http://ocw.mit.edu/courses/electrical-engineering-and-computer-sci
ence/6-006-introduction-to-algorithms-spring-2008/calendar/ is an intro-to-algorithms syllabus. Algorithms it covers:

- document distance
- mergesort
- airplane scheduling
- binary search trees
- balanced binary search trees
- avl trees
- hashing
- hash table doubling
- karp-rabin hashing
- rolling hashes
- open addressing
- heaps
- heapsort
- stable sorting
- radix sort
- counting sort
- bucket sort
- graph search
- breadth-first search
- depth-first search
- topological sort
- shortest paths
- bellman-ford
- dijkstra's algorithm
- dynamic programming
- memoized fibonacci
- longest common subsequnce
- text justification
- knapsack
- maximum-sum subarray
- vertex cover
- dominating set
- integer multiplication
- matrix multiplication
- strassen's algorithm

http://www.cs.rpi.edu/~goldsd/spring2013-csci2300.php is another, in some sense much less comprehensive. It covers:

• graph coloring
• depth-first search
• breadth-first search
• binary search
• topological sort
• strongly-connected components
• shortest paths
• bellman-ford
• dijkstra's algorithm
• euler tour
• heaps
• minimum spanning tree
• kruskal
• prim
• dynamic programming
• memoized fibonacci
• longest increasing subsequence
• pascal's triangle
• sierpinski's triangle
• longest path
• hamiltonian cycle
• traveling salesman
• genetic algorithms
• satisfiability

http://www.cs.rit.edu/~anh/alg_resources.html is another. Unfortunately it doesn't give any significant detail on what is covered.

http://www.fas.harvard.edu/~libcs124/E124/syllabus.html is another, with rather nice lecture notes. It covers:

• debiasing coin
• mediation and duplation
• fibonacci by repeatedly squaring matrices
• mergesort
• depth-first search
• breadth-first search
• dijkstra's algorithm
• minimum spanning tree
• prim
• kruskal
• union-find with path compression
• satisfiability
• set cover
• huffman coding
• longest common subsequnce
• shortest paths
• all-pairs shortest paths
• traveling salesman
• matrix multiplication
• strassen's algorithm
• dynamic programming
• edit distance
• hashing

• bloom filters
• primality testing
• linear programming
• simplex algorithm
• vertex cover
• max cut
• factoring
• suffix trees
• one-time pad
• euclid's algorithm
• extended euclid's algorithm
• rsa
• least common ancestor
• range minimum query
• network flow

http://www.cse.msstate.edu/~swan/teaching/2008-3_CSE-4833-6830_Algs/schedule.htm is another, far less comprehensive:

• insertion sort
• mergesort
• heapsort
• quicksort
• dynamic programming
• minimum spanning tree
• shortest paths

http://cs.smith.edu/~streinu/Teaching/Courses/252.html is another:

• depth-first search
• breadth-first search
• connectivity
• minimum spanning tree
• shortest paths
• traveling salesman
• longest path
• hamiltonian cycle
• satisfiability
• clique
• vertex cover
• integer multiplication

Finally, http://courses.cs.washington.edu/courses/cse421/14su/ covers:

• fft
• matrix multiplication
• strassen's algorithm
• knapsack
• edit distance
• depth-first search
• breadth-first search
• strongly-connected components
• shortest paths
• minimum spanning tree

• satisfiability
• vertex cover
• graph coloring
• traveling salesman
• huffman coding
• connectivity
• topological sort
• bipartiteness
• fewest coins
• interval scheduling
• dijkstra's algorithm
• mergesort
• inversion counting
• closest pair of points
• integer multiplication
• karatsuba
• rsa
• dynamic programming
• memoized fibonacci
• dynamic programming fibonacci
• dynamic programming string alignment
• dynamic programming fewest coins
• weighted interval scheduling
• rna structure
• network flow

Here are the items that appear in more than 2 of those lists:

```
6 shortest paths
5 minimum spanning tree
5 dynamic programming
5 depth-first search
5 breadth-first search
4 vertex cover
4 traveling salesman
4 satisfiability
4 mergesort
4 dijkstra's algorithm
3 topological sort
3 strassen's algorithm
3 memoized fibonacci
3 matrix multiplication
3 integer multiplication
```

That's 15 algorithms or problems, which seems like a reasonably short list of things to cover; some of them are even redundant, like Strassen's algorithm to solve matrix multiplication.

It seems sort of bizarre to me that graph algorithms are given such great prominence in these introductory courses, since they seem, to me at least, to have relatively little importance in practical day-to-day programming. Certainly we work with graphs all the time, and we even occasionally topologically sort them. But shortest-path algorithms and minimum spanning trees almost never occur in my experience (except in Ethernet switches). Even dynamic programming is relatively uncommon, and search needs heuristics

most of the time to be useful.

Topics

A homoiconic language with a finite-map-based data model rather than lists?

Kragen Javier Sitaker, 2019-09-25 (updated 2019-09-28)
(46 minutes)

I wrote a mock Lisp the other night, which was a surprisingly pleasant experience. Thanks to LuaJIT, it took me only a couple of hours to get from nothing to generating reasonably fast native code — wasting only 70% of the CPU's performance rather than 80% as with Ur-Scheme or 95% as with CPython. The mock Lisp isn't powerful enough for a metacircular interpreter, since it lacks data structures, but it's powerful enough to write a recursive Fibonacci number function.

This led me to wonder whether an imperative homoiconic programming language based on maps rather than lists could be a better alternative to Lisp. I think it'll necessarily have more redundancy than Lisp, since a map with N keys has $N!$ equivalent permutations (so the parsing process discards lg (N!) bits), but that may not be a bad thing; after all, we can diminish redundancy further by dropping to Forth, PostScript, or APL.

After examining some clumsy alternatives, I think I have a reasonable alternative based on a forgotten SourceForge project for text munging.

The magic of READ and PRINT

Although LuaJIT is amazing, the experience of debugging things at the LuaJIT REPL made me wish for Python, JS, OCaml, or Lisp — languages where your data structures can be automatically serialized in a parseable form, a very handy feature not only for interactive testing but also for network communication, ad-hoc filesystem persistence, manual fixup of broken systems, primitive user interfaces, and shared-nothing message-passing parallel and concurrent processing, as with fork(). Here's a rehearsed interaction with the OCaml interpreter:

```
$ ocaml
        OCaml version 4.02.3

# type rope = Leaf of int * string | Cat of int * rope * rope ;;
type rope = Leaf of int * string | Cat of int * rope * rope
# let rope_length = function Leaf(a, _) -> a | Cat(a, _, _) -> a ;;
val rope_length : rope -> int = <fun>
#   let leaf s = Leaf(String.length s, s)
    let cat a b = Cat(rope_length a + rope_length b, a, b)
    let cat2 a b = match (a, b) with
    | (Leaf(n1, s1), Leaf(n2, s2)) when n1+n2 < 128 ->
        leaf(s1 ^ s2)
    | (Cat(_, x, Leaf(n1, s1)), Leaf(n2, s2)) when n1+n2 < 128 ->
        cat x (leaf(s1 ^ s2))
```

```
    | (Leaf(n1, s1), Cat(_, Leaf(n2, s2), x)) when n1+n2 < 128 ->
        cat (leaf(s1 ^ s2)) x
    | (_, _) ->
        cat a b
;;

val leaf : string -> rope = <fun>
val cat : rope -> rope -> rope = <fun>
val cat2 : rope -> rope -> rope = <fun>
# cat2 (cat2 (leaf "x") (cat2 (cat2 (leaf "x")
                                 (leaf (String.make 128 'h')))
                       (leaf "x")))
     (leaf "x")
;;
- : rope =
Cat (132,
 Cat (131, Leaf (1, "x"),
  Cat (130,
   Cat (129, Leaf (1, "x"),
    Leaf (128,

      "hhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhh")),
   Leaf (1, "x"))),
 Leaf (1, "x"))
#
```

(This experimentally confirms that the leafnode-coalescence strategy used by cat2, proposed in B-Tree ropes (p. 2762), does indeed experience pathological fragmentation for some workloads.)

Here's JS, though you can't see the pleasant syntax highlighting Node applied to its output:

```
$ node
> x = {a: [3, 4], b: 5}
{ a: [ 3, 4 ], b: 5 }
> x.b += 4
9
> x.c = ['okay']
[ 'okay' ]
> x.c.push('now')
2
> x
{ a: [ 3, 4 ], b: 9, c: [ 'okay', 'now' ] }
>
```

Here's the same interaction in Python, which is quite a bit fussier than JS, but still comes through:

```
>>> x = {"a": [3, 4], "b": 5}
>>> x["b"] += 4
>>> x["c"] = ['okay']
>>> x["c"].append('now')
>>> x
{'c': ['okay', 'now'], 'a': [3, 4], 'b': 9}
```

Lua has READ but not PRINT

Now contrast Lua, which is eminently capable of handling the same kind of flexible data structures, but doesn't come with any way to print them:

```
$ luajit
LuaJIT 2.0.4 -- Copyright (C) 2005-2015 Mike Pall. http://luajit.org/
JIT: ON CMOV SSE2 SSE3 SSE4.1 fold cse dce fwd dse narrow loop abc sink fuse
> x = {a = {3, 4}, b = 5}
> x.b = x.b + 4
> x.c = {'okay'}
> table.insert(x.c, 'now')
> =x
table: 0x40542160
> =x.a
table: 0x405485a8
> =x.a[1]
3
> =x.a[2]
4
> =x.b
9
> =#x.a
2
> =#x.c
2
> =x.c[1]
okay
> =x.c[2]
now
> =table.unpack(x)
stdin:1: attempt to call field 'unpack' (a nil value)
stack traceback:
        stdin:1: in main chunk
        [C]: at 0x004044a0
```

I guess `table.unpack` wasn't added until Lua 5.2, and LuaJIT is a Lua 5.1. Doesn't matter, because it wouldn't have helped anyway — `table.unpack` is only for lists, not for dictionaries. There's a `pairs` function in core Lua for iterating over dictionaries, but just printing it isn't useful; it returns an iteration state, not an unpacked sequence:

```
> =pairs(x)
function: builtin#4     table: 0x4163d160       nil
```

You actually have to write code to iterate over the pairs:

```
> for k, v in pairs(x) do print(k, v) end
b       9
a       table: 0x405485a8
c       table: 0x40548920
```

And of course it doesn't recurse; you have to do that yourself:

```
> for k, v in pairs(x.a) do print(k, v) end
1       3
2       4
> for k, v in pairs(x.c) do print(k, v) end
1       okay
2       now
>
```

S-expressions and their discontents

Lisp S-expressions are probably a sort of minimum-complexity way to give you fully general data structures that are readable and printable, with a syntax you can write in a single-rule BNF grammar:

```
sexp ::= [ \n]* "(" sexp* [ \n]* ")" | [ \n]* [-A-Za-z0-9*]+
```

And once you implement that, which is flexible enough to use for any kind of tree data structure, it's straightforward to use them for your source code as well as your data structures, although many people complain about the clarity of the resulting code. Here's the recursive-descent parser I hacked together in half an hour (plus a couple of cleanups), using Lua's built-in list structure and `string.match`, although I probably should have used LPEG:

```
function read_sexp(c, getc)
   while c:match("[%s]") do c = getc() end
   if c == '(' then return read_list(getc(), getc) end
   return read_atom(c, getc)
end

function read_list(c, getc)
   while c ~= nil and c:match("[%s]") do c = getc() end
   if c == ')' then return nil end

   local car, c2 = read_sexp(c, getc)
   if c2 == nil then c2 = getc() end

   return {car=car, cdr=read_list(c2, getc)}
end

function read_atom(c, getc)
   local name = {}

   while c ~= nil and c:match("[^%s()]") do
      table.insert(name, c)
      c = getc()
   end

   name = table.concat(name)
   if not name:match("[^%d.]") then return tonumber(name), c end
   return name, c
end
```

With this, the compiler can successfully parse and compile programs such as the following:

```
(letrec (fib (lambda (n)
               (if (< n 2)
                   1
                   (+ (fib (- n 1)) (fib (- n 2))))))
  (fib 40))
```

S-expressions have some real merits. They have great simplicity of implementation, and they're relatively light on delimiters, which makes them easy t type; compare JS's `{ a: [ 3, 4 ], b: 9, c: [ 'okay', 'now' ] }` or Python's `{'c': ['okay', 'now'], 'a': [3, 4], 'b': 9}` to `(a (3 4) b 9 c (okay now))` or even `((a (3 4)) (b 9) (c (okay now)))`.

The discontents

However, S-expressions also have some real drawbacks.

As you can see in the string `))))))` in the above mock Lisp program, they expose the deeply nested nature of the data structure rather crudely; this is often unhelpful to the humans. Tim Peters's line in the Zen of Python, "Flat is better than nested", is a response to this. Although the humans are capable of recursive thought, it is a lot of effort for them, so they do much better when they can stick to finite state machines and Markov chains.

Code that stores data as S-expressions can be somewhat inscrutable and therefore bug-prone; consider this Elisp snippet from files.el:

```
    (if (and mode
             (consp mode)
             (cadr mode))
        (setq mode (car mode)
          name (substring name 0 (match-beginning 0)))
      (setq name nil))
```

What are `(car mode)` and `(cadr mode)` (that is, the second item of the list `mode`)? They're some kind of fields of a data structure, but it's hard to tell what they intend. Fairly often Elisp will unpack such lists at the entry to a function or the top of a loop, which inflates the code a bit (this from Ken Manheimer's allout.el outliner mode):

```
  (while pairs
    (let* ((pair (pop pairs))
           (name (car pair))
           (value (cadr pair))
           (qualifier (if (> (length pair) 2)
                          (caddr pair)))
           prior-value)
      ...
```

A perhaps more subtle problem of S-expressions is their extensibility. The last example above handles tuples of the structure `(name value)`, which may be extended with an optional `qualifier` to become `(name value qualifier)`. Perhaps at some future point a `scope` or `mode` will be added.

As with Protocol Buffers, it's safe to add new items at the end of such tuple-shaped lists — but only if nobody else is doing so concurrently somewhere else, or you'll end up misinterpreting each other's data. That is, if I add a `scope` item as the fourth item, and you

add a `mode`, and for whatever reason I end up running my code on your data (from your .emacs.d/init.el, perhaps), something will go wrong.

(An example of this is how Racket doesn't really parse your program into cons nodes; instead it parses it into things that are similar to cons nodes but also contain file, line number, and column number information, so that it can report runtime errors in context. Adding such a feature using normal cons nodes in a way that wouldn't break existing users would be infeasible.)

Lists being used as lists are much worse, though — there's no way to add any extra data to them (other than per list item) without breaking backward compatibility.

Finally, S-expressions use a buttload of memory, especially on 64-bit machines: at least two pointers per list item, plus potentially extra space for type tags, garbage collection tags, locks, and so on.

These aren't really drawbacks of Lisp, except for))))))); Common Lisp, Scheme, Racket, Clojure, and even Elisp have a variety of other data structures and aren't limited to cons chains. It's a drawback of just storing data in cons chains.

Problems like these are why awk, Python, JS, and Lua privilege finite maps (also known as dictionaries, tables, associative arrays, or hashes) over lists or arrays, and OCaml is instead based on discriminated unions (although it has lists and tuples). Finite maps, sets of name-value pairs, have a sterling record of backward-compatibility in things like email headers, HTML element attributes, and library APIs.

However, none of these non-Lisp languages has attempted to use the same syntax for code and for data. I think it might be a fun thing to try.

Nested dicts

The simplest approach to a homoiconic language syntax consisting of finite maps is to just use S-expressions with an even number of items, and interpret them as finite maps. Clojure does something like this:

```
user=> {:a [3 4] :b 5}
{:b 5, :a [3 4]}
```

(The leading : in Clojure marks a keyword, which is autoquoted in much the same way as in Common Lisp or Ruby.)

The grammar for such a dictionary-expression approach is very nearly as simple as that for ordinary S-expressions:

```
dexp ::= [ \n]* "{" (dexp dexp)* [ \n]* "}" | [ \n]* [-A-Za-z0-9*]+
```

It remains to be seen how to encode programs in this form in a usable fashion. First, though, some exploration of a subtle point that can produce a lot of confusion.

Reading, evaluation, and auto-quoting

There's a subtle distinction which is glossed over above. Python reads "dictionary displays" like `{3: 4}` differently from the way Lisp parses S-expressions. Python, like Lua, JS, Ruby, and OCaml, is *evaluating* these expressions, with potentially Turing-complete

consequences. Lisp's READ, by contrast, just *parses* them, though if you type them in at the REPL prompt it will evaluate them, and they may evaluate to themselves. Here's an edited interaction with the SBCL implementation of Common Lisp:

```
* (read)
(x y z)
(X Y Z)
*
```

That is, I typed `(read)` at the prompt, and then it waited for another S-expression of input; I typed `(x y z)`, and it responded by parsing that and returning a list of those three symbols, which unfortunately it prefers to print in uppercase, as if it were still 1962. By contrast, if I type `(x y z)` at the prompt, first it parses ("reads") that into the same list as before, and then attempts to evaluate it, which fails because I haven't defined the variable `y`:

```
* (x y z)
; in: X Y
;     (X Y Z)
```

...(many lines omitted)...

```
debugger invoked on a UNBOUND-VARIABLE in thread
#<THREAD "main thread" RUNNING {100399C553}>:
  The variable Y is unbound.
```

If you actually want that list of three symbols, you can use `quote`, optionally abbreviated as `'`, both for input and for output:

```
* (quote (x y z))
(X Y Z)
* (list (quote x) (quote y) (quote z))
(X Y Z)
* '(x y z)
(X Y Z)
* (list 'x 'y 'z)
(X Y Z)
* '(quote (x y z))
'(X Y Z)
```

It happens that, in Common Lisp and in Elisp, evaluation of lists does things such as call functions and apply macros, but evaluation of other data such as integers or strings just returns that data (it is "auto-quoting"). In fact, this rule even extends to things like "vectors", which is to say, arrays:

```
* (defvar x 99)
X
* #(3 x 9)
#(3 X 9)
```

We got the symbol `X` rather than the value 99. What happened is that the whole vector `#(3 X 9)` was read, and vectors are auto-quoting,

so evaluating it simply returned the vector. If we want to build up a vector from values computed at run-time, we have to call the function `vector`:

```
* (vector 3 x 9)
#(3 99 9)
```

Smalltalk originally had the same problem, although Squeak has a fix. Clojure, on the other hand, follows Common Lisp by separating reading from evaluation, but follows Python by evaluating items inside of aggregate data structures unless they are explicitly quoted; like Elisp, JS, and Python, but unlike Common Lisp and Lua, it uses [] to delimit vectors/arrays:

```
$ clojure
Clojure 1.6.0
user=> (def x 99)
#'user/x
user=> [3 x 9]
[3 99 9]
user=> '[3 x 9]
[3 x 9]
user=> {x 3 (+ x 1) 4}
{99 3, 100 4}
user=> '{x 3 (+ x 1) 4}
{x 3, (+ x 1) 4}
user=> (type [3 x 9])
clojure.lang.PersistentVector
user=> (type '[3 x 9])
clojure.lang.PersistentVector
user=> ({x 3 (+ x 1) 4} x)
3
user=> ({x 3 (+ x 1) 4} 'x)
nil
user=> ('{x 3 (+ x 1) 4} 'x)
3
user=> (read)
[3 x 9]
[3 x 9]
```

In Clojure, only primitive atomic data types like numbers, strings, and keywords are auto-quoting. But it happens that, if the only things in your map or vector are auto-quoting, it evaluates to itself:

```
user=> {:x 3 :y 4}
{:y 4, :x 3}
```

(The comma is optional.)

This can be confusing because it obscures the fact that an evaluation is happening, as in Python, unlike in Common Lisp. Python is fussy enough to remind you of this if you forget, requiring a lot of extra line-noise punctuation in your literal "dictionary displays":

```
>>> x = {a: [3, 4], b: 5}
Traceback (most recent call last):
```

```
  File "<stdin>", line 1, in <module>
NameError: name 'a' is not defined
>>> x = {"a": [3, 4], "b": 5}
>>> x
{'a': [3, 4], 'b': 5}
```

JS and Lua, on the other hand, have special cases in their syntax so that you can forget most of the time:

```
> x = {a: [3, 4], b: 5}
{ a: [ 3, 4 ], b: 5 }
```

Lua:

```
> x = {a = {3, 4}, b = 5}
```

If you really want to force the evaluation of an expression for a key consisting of just a variable, there is special syntax for this in Lua:

```
> a = 5
> x = {[a] = 8}
> =x[5]
8
> =x.a
nil
```

And in JS:

```
> a = 8
8
> x = {a: 4}
{ a: 4 }
> x = {[a]: 4}
{ '8': 4 }
```

Encoding fundamental imperative-language constructs

An imperative programming language contains at least sequence, assignment, and looping; a normal programming language also contains identifiers, subroutine definitions, subroutine invocations, conditionals, and primitive operations. How can you encode these usably in a tree of maps?

I mean, obviously you can write an abstract syntax tree of the form

```
{nodetype binop operator +
 left {nodetype identifier name x}
 right {nodetype constant value 1}}
```

but this results in a very poor signal to noise ratio. Even if you don't use maps to represent the leafnodes, it's pretty bad:

```
{nodetype binop operator + left x right 1}
```

But can we do better?

Consider the example mock Lisp program I mentioned earlier:

```
(letrec (fib (lambda (n)
               (if (< n 2)
                   1
                   (+ (fib (- n 1)) (fib (- n 2))))))
  (fib 40))
```

Built-in operation invocations

A Smalltalk-like approach, treating things like addition like method calls, could reduce the noise factor somewhat:

```
{: x + 1}
```

We could treat function invocation in a similar way, providing named arguments. With this approach the Lisp expression

```
(+ (fib (- n 1)) (fib (- n 2)))
```

becomes

```
{: {: fib n {: n - 1}} + {: fib n {: n - 2}}}
```

which seems, if not ideal, at least potentially tolerable.

Because the sequence of name-value pairs is undefined, though, this could just as well be rendered as follows:

```
{+ {n {- 2 : n} : fib} : {n {- 1 : n} : fib}}
```

which seems pretty confusing; the interpreter is going to be looking for the : to see if the node is such a method-invocation node, and not having it first makes it harder to determine what is going to happen.

Conditionals

Lisp-style `cond` is not easy to obtain, but an if-then-else node is easy:

```
{if {: n < 2}
 then 1
 else {: {: fib n {: n - 1}} + {: fib n {: n - 2}}}}
```

Assignments

Lisp-like `let` or `letrec` fits very nicely into this sort of scheme; consider this Elisp (also from allout.el):

```
(let ((start (point))
      (ol-start (overlay-start ol))
      (ol-end (overlay-end ol))
      first)
  body)
```

This translates to

```
{let {start {: point}
      ol-start {: overlay-start overlay ol}
      ol-end {: overlay-end overlay ol}
```

```
     first nil}
 in body}
```

Imperative side-effecting assignments like this one (also from allout.el) demand a different approach:

```
(when (not first)
  (setq first (point)))
```

I mean there are lots of ways you could spell that:

```
{set first to {: point}}
{let first = {: point}}
{my first is {: point}}
{make first be {: point}}
```

However, I favor these, because they comfortably support parallel assignments (like the many-argument `setq` in one of the examples above) and have less noise words:

```
{= {first {: point}}}
{set! {first {: point}}}
```

Subroutine definitions

Darius Bacon has been working on a new dialect of Scheme called "Cant", previously "Squeam", in which the fundamental procedure-call mechanism uses a pattern-matching mechanism on the argument list to select a method to invoke on the receiver object. That is, you don't have procedures as such, just receivers. This provides a very nice unification of ML-style pattern matching and Smalltalk-style object orientation.

You could do something similar here, defining functions as sets of argument-list/body pairs. To guarantee determinism the compiler would have to verify that the argument lists were mutually exclusive.

This allows us to translate the Lisp above:

```
(letrec (fib (lambda (n)
               (if (< n 2)
                   1
                   (+ (fib (- n 1)) (fib (- n 2))))))
  (fib 40))
```

as

```
{let {fib {lambda {{n {}}
                   {if {: n < 2}
                    then 1
                    else {: {: fib n {: n - 1}}
                          + {: fib n {: n - 2}}}}}}}
 in {: fib n 40}}
```

which in this case contains only a single argument list, containing `n`. It's not clear what kind of values to associate with the arguments; maybe `{n {default 2}}` would be a valid specification.

Looping

The Common Lisp LOOP macro provides a good example of how you can usefully specify a loop as a set of name-value pairs: `{while foo do bar}` and `{for i = 1 to 10 do bar}` are simple examples, but it is reasonable to support also `{for x in mylist collect {: f n x} when {: x > 2}}` and the like.

Sequencing

I've saved the worst for last. In the language as described above the only obvious way to sequence is by nesting; things that aren't nested have no sequence. You could potentially use line numbers:

```
{prog {10 {print "HOWIE IS AWESOME"}
      20 {goto 10}}}
```

but failing that you are stuck with constructs of the form `{do x then y}`, which you must nest to get sequences of an arbitrary number of steps.

Flat dict syntax

So, what if we use infix syntax to build our dicts instead of circumfix syntax? I think I've written a bit about this before; the idea is that you use parentheses merely for grouping, and you have two operators `:` and `,` which you can use to build up an arbitrary dict. `x: y` is a single-entry dict in which the key `x` has the value `y`, and `a, b`, with lower operator precedence, is the union of the dicts `a` and `b`, with some kind of rule about key conflicts (either it's an error or there's a defined winner).

We need to change the name of the invocation-target tag `:` to something else, ideally something inoffensive; `.` is a reasonable candidate.

So our translation above

```
{let {fib {lambda {{n {}}
                  {if {: n < 2}
                   then 1
                   else {: {: fib n {: n - 1}}
                         + {: fib n {: n - 2}}}}}}}
 in {: fib n 40}}
```

could be spelled

```
let: (fib: (lambda: ((n: ()):
                     (if: (.: n, <: 2),
                      then: 1,
                      else: (.: (.: fib, n: (.: n, -: 1)),
                             +: (.: fib, n: (.: n, -: 2)))))))),
in: (.: fib, n: 40)
```

I think I've made it even worse, if that's possible! If we decree that `:` associates to the right, so `x: y: z` means `x: (y: z)`, we can remove all of the parentheses that neither contain a comma nor precede a colon:

```
let: fib: lambda: ((n: ()):
```

```
                  (if: (.: n, <: 2),
                   then: 1,
                   else: (.: (.: fib, n: (.: n, -: 1)),
                          +: (.: fib, n: (.: n, -: 2))))),
in: (.: fib, n: 40)
```

So far, so abysmal. But consider the above example:

```
{set! {first {: point}}}
```

Now we can write this example as

```
set!: first: .: point
```

This gives us a potential way to write semantically nested execution sequences as syntactically flat ones, but at the cost of putting our statements in the "name" field of name-value pairs, which means that there's no way to attach other data to these nodes in an unambiguous way. (This is something that is already true of, for example, argument lists.)

Consider this snippet of code from this bit of C++ 3-D ASCII-art animation:

```
  // Rotate by theta.
  nx = c*xs[i] + s*zs[i];
  zs[i] = -s * xs[i] + c*zs[i];
  xs[i] = nx;
```

It's necessary to either do the three statements in the order in which they're written or to do parallel assignment. For a moment let's disregard the much better option of parallel assignment and pretend it's a case where we have to write a sequence. Which of the following horrors is the less bad translation?

```
{do {= {nx {. {. c * {. xs at i}} + {. s * {. zs at i}}}}}
 then {do {. zs at i put {. {. {- s} * {. xs at i}}
                          + {. c * {. zs at i}}}}
       then {. xs at i put nx}}}
```

or

```
do: (=: nx: (.: (.: c, *: (.: xs, at: i)), +: (.: s, *: (.: zs, at: i)))):
    (.: zs, at: i, put: (.: (.: -: s, *: (.: xs, at: i)),
                        +: (.: c, *: (.: zs, at: i)))):
    (.: xs, at: i, put: nx)
```

Well, they're both pretty fucking bad compared to the FORTRAN-style code above, but I think the second one is worse.

Edge-labeled graphs: now is the winter of our discontent made glorious summer

Years ago I saw a project on SourceForge that treated text as an edge-labeled graph (similar to Suciu's UnQL unstructured query language) delimited by whitespace and structured by indentation, and

provided tools to query it and to reformat a number of Unix commands to make them more amenable to processing with it. (Unfortunately, I forget the name, and I haven't been able to find it again.) So, for example, given this input:

```
time    real    0m1.694s
        user    0m1.524s
        sys     0m0.168s
```

it would decide that from the start node there was an arc labeled "time", and from the node it led to three more arcs labeled "real", "user", and "sys", each of which led to a node with one further arc labeled with a string such as "0m1.524s". This of course means that you can easily query `time.user` and get that response.

(In a tree, it's immaterial whether the labels are on the arcs or on the nodes they lead to, but in a more general graph it can matter. It might make more sense to think of all of the following as having tags on nodes rather than edges.)

Note how this generalizes a subset of the finite-map-tree model: the names are just strings, as in JS and Perl, rather than general objects, as in Python, Lua, and Clojure, but there's no distinction between keys and values — the values are just the labels after the level where your query stopped traversing edges. Also, the keys need not be unique. (They may or may not be sequenced; those are different variants of the data model.)

Suppose we try to use this approach for our homoiconic language, although using parentheses rather than indentation to indicate side branches — the above graph comes out as `time (real 0m1.694s) (user 0m1.524s) sys 0m0.168s`.

The grammar here is something like

```
tree ::= [ \n]* ("(" tree [ \n]* ")" | [-A-Za-z0-9*]+) tree | ε
```

Here the three alternatives amount to three different ways to grow a tree: by branching it, by extending a branch by a segment, and by terminating a branch. This apparently has one more alternative than the original `sexp` grammar given above, but this is an illusion; the `sexp` grammar contained `sexp*`, which hides an alternative in its Kleene closure.

A homoiconic language using edge-labeled graphs?

In a sense, this is similar to the Lisp cons rotated 90°: nesting (car) is the default and parentheses turn it off! But let's say that the sequence of branches is not important, so the above example is equivalent to say `time (user 0m1.524s) (sys 0m0.168s) real 0m1.694s`.

Sequencing is now easy, but what do expressions look like?

With this approach, we could use sequencing not only for imperative statement sequences but also for argument lists. A sequence of statements might look like `(some action) ; (some other action) ; a third action`, with `;` edges connecting the sequence of statement nodes.

And the problem we previously had with difficulty determining what operation to invoke is gone — the label leading us into an expression node can be the variant tag that tells the interpreter

unambiguously how to handle that expression — or, as in Common Lisp, either an identifier of a special form or the name of a function. This suggests that, as in Forth, variables (and perhaps constants) are just zero-argument functions, but in this case — unlike in Forth — they can look to see if they're being invoked with arguments, such as maybe `=`. (And you can of course have a FUNCALL function as in Common Lisp or a `value` message as in Smalltalk, so if you store a function pointer in a variable, you can still invoke it.)

The fundamental benefit of property-list-like systems is that you can always attach new "properties" to some well-defined set of nodes without bothering the things that are already using those nodes, because they only look at the properties they care about. In this system this is somewhat vitiated by the fact that since property values are just arc labels, just like property names, there are inevitably a lot of nodes where this benefit does not obtain — any new property you attach at those nodes might be mistaken for the property value!

Function calls are kind of hairy

Unary operations and commutative, associative operations like `+` might conceivably just attach their arguments directly to their node: `+ (x) (y) * (a) b`, for example, for $x + y + a \times b$. But more general function calls might require named arguments `fib (n 10)` or an argument sequence analogous to statement sequences `cat2 (leaf "x") , leaf "y"`. Also, if duplicate edges are not allowed, `* (x) x` would be a problem.

What if math operators are messages sent to numbers?

As before, a possible alternative to applying (typically global and constant) functions to arguments is to send messages to objects, which would seem to allow syntax like `x + 1` or `xs (at i) put nx`. However, though the actors and closures models are formally equivalent, this poses a real problem for chains of operators of the kind we commonly see in mathematical expressions — it would seem to require the equivalent of Lisp's FUNCALL function, GlyphicScript's `;` operator, or Haskell's `$` function to separate the two operators. For example, $x + y - a \times b$ could be written, for example, as `(o (f x + y) - a * b)` or as `(x + y) $ - a * b`.

The problem with the obvious way of writing it `(x + y) - a * b` is, I think, that the root expression node has the `-` edge coming directly out of it, and we're considering here a universe where root expression nodes instead have edges coming out of them that denote message receivers, not operators, and it isn't clear who is supposed to be receiving the `-` message. Maybe it could be made to work, though, even for things like `(x + y) - (a * b) - 3` and `x + (y) - (a * b) - 3`, by making operators like `+` and `-` link together a sequence of expressions in the same way that `;` and `,` are suggested to do above.

This will inevitably lead to somewhat of an impedance mismatch with conventional mathematical precedence, as did the systematic rules of APL and Smalltalk, which may lead to bugs in programs. In this case, it might be possible to refuse to parse most expressions that have such problems, but not, for example, `a * b + c`.

How about currying?

If the difficulty only pertains to functions that must distinguish between their arguments, such as `<` or `÷`, can we solve it by currying?

In the function paradigm, this seems to require a function analogous to FUNCALL or APPLY:

```
funcall (< 2) x
```

Maybe in the message-receiver paradigm it works better?

```
x . (2 <)
```

This (equivalent to `x . 2 <`) doesn't seem promising.

The other programming constructs are simple enough

By contrast with primitive operations and function calls, there are relatively few difficulties with looping, conditionals, assignment, and function declarations.

A simple while loop poses no difficulty:

```
while (condition)
   do body
```

Perhaps we can use : as a tag for such bodies:

```
for (x in mylist): some body expression
```

More generally, looping can be written in a way quite analogous to Common Lisp, introduced with a `loop` tag and containing an unsequenced set of keyword-driven clauses:

```
loop (for i = 1 to 10)
     (for x in mylist)
     (if ((> x) (< 2)) then collect i)
```

Conditionals can be written either in a variant of the if-then-else style described earlier, with the `if` pulled out into an introductory tag, as

```
if ((< x) (> 2)) (then 1) else recursive expression
```

or in a cond sequence, since now we have a reasonable way of writing sequences:

```
cond ((condition a) -> consequent a)
   | ((condition b) -> consequent b)
   | else other consequent
```

Or

```
if ((condition a) then consequent a)
elseif ((condition b) then consequent b)
else other consequent
```

And lambda-expressions can be written with a delimiter to distinguish the body from the argument list:

```
fn (x y z) => some expression of x y z
λ (x y z) . some expression of x y z
```

Assignment could be written in a conventional way:

```
x = 3
x ← 3
x <- 3
x := 3
```

Or in a parallel-assignment way, like `letrec` or `setq`:

```
fn (a b) => (while (a): setq (b a) (a (b % a))); b
```

What if we represent branching with infix operators rather than parens?

It's rather jarring in the above that, for example, these two expressions are equivalent, even though the second looks like a typographical error:

```
while (a): setq (b a) (a (b % a))
while (: setq (b a) (a (b % a))) a
```

The fact that the associative and commutative operation of attaching two branches x and y to the same node is represented using the asymmetric syntax `(x) y` is, I think, the root of this difficulty. In a one-dimensional media it is unavoidable that we put them in some order, but we could imagine using a more visually symmetrical operator to separate the two symmetrical branches.

For example, ,, as explored briefly in the ill-fated "Flat dict syntax" section above. But we don't want to write

```
while a, do setq ...
```

because as long as comma binds more loosely than juxtaposition (as it should), that attaches the `setq` and `while` edges to the same root. Instead we get

```
while (a, do setq (b a, a b % a))
```

which seems potentially reasonable, though perhaps it gives us back the extreme nesting we were hoping to escape. It echoes Python's named-parameter syntax, but more placidly; instead of `f(g=h, i=j)` we have `f(g h, i j)`.

Maybe we should use indentation rather than parentheses to indicate side branches

A purely indentation-based version of this syntax is doable, replacing the line-noise punctuation and recursive nesting parentheses with preattentively-comprehensible horizontal juxtaposition for path concatenation and vertical juxtaposition for branching. Maybe using parentheses rather than indentation to indicate side branches wasn't such a hot idea after all!

```
while a
      do setq b a
             a b % a
```

Alternatively, with more vertical syntax:

```
while
  a
  do
    setq
      b a
      a b % a
```

These variants at last seem like they might actually be an ergonomic improvement over Lisp syntax rather than a regrettable compromise, at least if there's a solution to the problem with arithmetic expressions.

It unfortunately gets us back to the problem of representing sequences of statements with progressively increasing nesting:

```
do setq nx sum product c
              *      xs at i
          +   product s
              *      zs at i
   then do zs at i
             put sum product - s
                    *      xs at i
                +   product c
                    *      zs at i
          then xs at i
                 put nx
```

Or maybe

```
let nx sum product c
          *      xs at i
       +  product s
          *      zs at i
    in do zs at i
            put sum product - s
                   *      xs at i
               +   product c
                   *      zs at i
         then xs at i
                put nx
```

Or maybe, using , as an argument-sequencing graph label this time instead of a syntactic branching operator:

```
let nx + * c
          , xs at i
        , * s
            , zs at i
    in do zs at i
            put + * - s
                   , xs at i
                 , * c
                     , zs at i
```

```
        then xs at i
               put nx
```

This seems pretty bug-prone because it took me a couple of tries to get the `, zs at i` lines to the right indentation level.

This is less nauseatingly bloated than the earlier versions but it still compares poorly to the C++ version:

```
nx = c*xs[i] + s*zs[i];
zs[i] = -s * xs[i] + c*zs[i];
xs[i] = nx;
```

You could argue that maybe syntactic sugar can compensate, but the right syntactic sugar is precisely what I'm looking for here.

I may be asking too much, since even in Common Lisp it's still uglier and more bug-prone than the C++:

```
(let ((nx (+ (* c (aref xs i)) (* s (aref zs i)))))
  (setf (aref zs i) (+ (* (- s) (aref xs i)) (* c (aref zs i))))
  (setf (aref xs i) nx))
```

But that's not in the same league of noise bloat as most of the examples above.

We could imagine an infix-formula-evaluating macro like the ones in sh and Tcl, called, say, `[` (since `FORTRAN` would be a tasteless name, Σ is hard to type and too specific, and `eval` probably means something else):

```
let nx [ c
        * xs at i
        + [ s
            * zs at i ] ]
    in do zs at i
            put [ - s
                  * xs at i
                  + [ c
                      * zs at i ] ]
          then xs at i
                 put nx
```

However, that won't work as written; `[` has no way to tell whether you wrote `x * y + z` or `x + z * y`. If you want it to have a whole *sequence* of labels to compile, you have to put them on one line, which also means you can't inline-evaluate arbitrary bits of code like `xs at i` without some kind of magic tag. If you do it that way you could say

```
let nx [ c * [ xs at i ] + s * [ zs at i ] ]
    in do zs at i
            put [ - s * [ xs at i ] + c * [ zs at i ] ]
          then xs at i
                 put nx
```

In practice this is maybe not the best example since you would probably want array indexing in your numeric expression evaluator and also because a better way to do the whole calculation is

```
let xi xs at i
    zi zs at i
    in do xs at i
            put [ c * xi + s * zi ]
          then zs at i
                 put [ - s * xi + c * zi ]
```

or maybe even some kind of parallel assignment. I just picked an example that's too easy, I guess.

A potential problem with the proposed embedding syntax: what happens if you have branching inside the embedded expression? I mean, you could imagine something like

```
[ 2 * [ gcd a x ] + 3 ]
          b 2
```

where we invoke `gcd` with named arguments `a` and `b`, which upon some thought it can be seen can be made to work just fine — the `[` parser just needs to look down all the branches to find the terminating `]` of the embedded expression, not just one. This gets uglier if you have two such things; this will not work:

```
[ 2 * [ gcd a x ] + 3 * [ lcm a x ] ]
          b 2             b 2
```

But it will work if expressed this way:

```
[ 2 * [ gcd a x ] + 3 * [ lcm a x ] ]
                          b 2
          b 2
```

This is complex enough to be confusing.

How is that different from SRFI-49 I-expressions, Wisp, or LISPIN?

In the above proposal, as long as arcs out of a node remain unordered, these two expressions are equivalent:

```
a b c
   d
  e
```

and

```
a e
  b d
    c
```

as well as two more variations. Moreover, as mentioned toward the beginning, code written for the following structure will also work on the above structure without change:

```
a b c
```

An unpolished parser in Python

I just wrote the following simple parser in Python which seems to

handle the syntax outlined above properly and translates it into graphviz files you can view with, for example, `dot -Tx11`. It's maybe 50% longer than the S-expression parser above in Lua. It contains some duplication to factor out, would need to be extended to handle quoted strings, can break its graphviz output if you put special characters in the input, wastes memory, doesn't handle tabs, and (as always with Python) breaks on Unicode input in environmentally dependent ways, but hopefully it represents some kind of clarifying sketch.

```
from __future__ import print_function
import re
import sys

def parse(lines):
    stack = []
    node_counter = 1
    edges = []

    for line in lines:
        col = len(re.match(r'\s*', line).group(0))
        while stack and stack[-1][0] >= col:
            stack.pop()
        word, start, empty = [], col, ()

        while col < len(line):
            c = line[col]
            if word and re.match(r'\s', c):
                nw = ''.join(word)
                word[:] = empty
                if stack:
                    edges.append((stack[-1][2], nw, node_counter))
                else:
                    edges.append((0, nw, node_counter))
                assert start is not None
                stack.append((start, nw, node_counter))
                node_counter += 1
                start = None

            elif re.match(r'\S', c):
                if not word:
                    start = col
                word.append(c)

            col += 1

        if word:
            nw = ''.join(word)
            if stack:
                edges.append((stack[-1][2], nw, node_counter))
            else:
                edges.append((0, nw, node_counter))

            assert start is not None
            stack.append((start, nw, node_counter))
```

```
            node_counter += 1
            start = None

    return edges

def graphviz(edges, name='cosas'):
    yield 'digraph '; yield name; yield ' {\n'
    yield '    rankdir=LR;\n'
    yield '    node [label="", shape=circle];\n'
    for start, label, end in edges:
        yield '    '; yield str(start); yield ' -> '; yield str(end)
        yield ' [label="'; yield label; yield '"];\n'
    yield '}\n'

if __name__ == '__main__':
    sys.stdout.writelines(graphviz(parse(sys.stdin)))
```

So for example it renders the first example above as follows:

```
digraph cosas {
    rankdir=LR;
    node [label="", shape=circle];
    0 -> 1 [label="while"];
    1 -> 2 [label="a"];
    1 -> 3 [label="do"];
    3 -> 4 [label="setq"];
    4 -> 5 [label="b"];
    5 -> 6 [label="a"];
    4 -> 7 [label="a"];
    7 -> 8 [label="b"];
    8 -> 9 [label="%"];
    9 -> 10 [label="a"];
}
```

Since it took me about 40 minutes to write, test, and (mostly) debug that, including the graphviz output, this syntax is probably not too complex for a language whose first-draft compiler you want to write in an afternoon.

Functions for manipulating edge-labeled graphs

What is our equivalent of the ur-Lisp's CAR CDR CONS NULL ATOM QUOTE EQ? The fundamental traversal operation should presumably be `go(node, tag)`, which returns the node (if any) obtained by traversing the edge labeled `tag` from `node`, equivalent to `node[tag]` in JS or Lua syntax; if duplicate edges are allowed, probably both its `node` argument and its return value should be *sets* rather than individual nodes, and possibly `tag` should also be a set. Invoking the tag as a function `tag(node)` is an alternative possibility.

(If they are sets of nodes, we need to be able to iterate over them; we need to be able to test whether they are empty, but iterating over them with side effects may be an adequate interface for that.)

In the case where they are indeed individual nodes, there is the possibility of returning nil, in which case we need a way to detect nil — in a functional paradigm, `isnil(node)`, but alternatives include treating nil as false in conditionals (making the function implicit); a

pattern-matching `ifnil(node, consequent, alternate)` function which takes two functions to invoke, one with the node if it is not nil, and the other if it is; and the λ-calculus-like `node(consequent, alternate)`, which does the same without a separate function.

It's also necessary to iterate over the edges out of a node, since arbitrary values such as 57 are also stored as tags in the above model. (This wouldn't have to be the case — 57 could be a node, as it is in Lisp — but without this ability to iterate over edges you also can't write PRINT or the macro transformer for LETREC.) You can do this with a function `kids(node)` or `pairs(node)` which returns a list in the usual car–cdr or first–rest form; perhaps each node in the resulting list contains both a key — the edge label — and a value — the child node that it leads to. (That's superfluous, though, since `go(parent, tag)` will give you the child node.)

If we consider tags to attach to nodes rather than to the edges leading to them, we might be able to conflate nodes with tags, so that the `go()` function above takes two arbitrary node arguments. (The alternative is to have special "tag nodes".) But we still need to be able to compare tags for equality, thus `eq(tag1, tag2)` or `sametag(node1, node2)` is needed.

With `go`, `isnil`, `kids`, and `eq` (or the other alternatives discussed above), we can traverse the graph as we please, just as with CAR, CDR, NULL, ATOM, and EQ. However, constructing new graph structure — as with CONS — requires another operation: `add(node, tag, kid)`, which returns a new node identical to `node` except that it now has an edge with tag `tag` to node `kid`. However, this is not quite enough — it doesn't allow us to produce new nodes with no children. So we need `new()` to produce such a fresh node.

And of course we can provide QUOTE (and, more interestingly, quasiquote) just as Lisp does. That's what homoiconicity means!

Regenerator gas kiln

Kragen Javier Sitaker, 2016-09-05 (updated 2017-04-10) (9 minutes)

I want to start firing ceramics at home, but the mini-kilns I'm finding on MercadoLibre suck shit. They're electric and top out at low temperatures like a bit over 1200°. (Maybe this is a consequence of their heating elements?) Although earthenware can fire at as low as 1000°, temperatures in the 1350° range are needed for many other ceramics.

For example, in July, http://articulo.mercadolibre.com.ar/MLA-618696798-horno-para-vidrio-ceramica-gres-box-1-_JM was a 1200-watt kiln with a 160 mm × 160 mm × 115 mm inside space (2.8 ℓ) that cost US$500. And it only reached 1200°, but weighed 6 kg.

I was thinking that maybe a gas-fired kiln would work better, maybe fueled by a portable LP gas cylinder and with regenerators to keep noxious exhaust to a minimum.

I want to beat that shitty electric kiln handily on all axes except weight: energy usage, volume, temperature, and cost. I'm okay if it weighs a lot more, though. Let's shoot for a 320 mm cube inside capacity, 1400° max, cost under US$200, weight under 100 kg, and use under 600 W.

(See files Millikiln (p. 2581) and An electric furnace the size of a sake cup (p. 666) for versions of this with further reduced scope.)

Energy and power usage and efficiency

The gas heater we use to heat the living room is 8000 BTU/hour, which is 2300 watts. The little electric space heater I'm using to heat my office is 2000 watts. Suppose 2000 watts is a reasonable power envelope and we need to be able to heat at 300° per hour (0.083 K / second) once the ceramic is dry. Then the maximum thermal mass in the kiln is 24 kJ/K. The specific heat of water is 4.2 kJ/K per kilogram, so this is about 6 kilograms of water; other substances like quartz have lower specific heats like 0.83 kJ/K/kg, so it's in the neighborhood of 30 kg. This is pretty close to the amount of stuff you'd like to have on the inside of a kiln's insulation.

(Engineeringtoolbox lists specific heats of .70, .73, and .83 kJ/K/kg for different forms of quartz.)

This implies that you need pretty high efficiency; we can't afford to just spew out the vast majority of your heat in an exhaust and expect to get the kind of temperatures we need.

How much energy do you need at a minimum? The minimum would be when you heat your kiln up inadvisably fast. At 300° per hour (83 mK/s) you can reach 1200° in four hours, which would be 2000 W · 4 hours = 29 MJ. LP gas is 46.4 MJ/kg or 26 MJ/ℓ, so this is 630 g of gas, occupying 1.12 ℓ. A regular 10 kg gas cylinder would power 15 such firings before refilling, a cost of about US$6 per firing.

This doesn't take into account the heat lost while the kiln is hot, which depends on insulation and regenerator losses, or the energy lost in boiling off the water, which is about 2.3 kJ/kg and thus relatively small in this context.

Using regenerators in this context involves feeding the flame with

air preheated from the regenerators. LP gas burns at 1970° in cool air, which is hot enough, and presumably this temperature increases as the inlet temperature increases. This means, though, that the chamber where the flame is happening will need to be able to withstand such temperatures. Some amount of exhaust gas recirculation may reduce the load on the regenerators and lower the flame temperature.

You probably don't need to run the flame the whole time; the autoignition temperature of LP gas is around 400° or 500°, so you should be able to turn the gas back on and ignite it just from the walls of the burner chamber.

You need two regenerators because you need to pull the intake air through one while running the exhaust air through the other, periodically alternating direction. The use of a recuperator instead of regenerators would avoid this necessity, conventional (non-fractal) recuperator designs need to be fabricated from high-thermal-conductivity materials such as copper or aluminum, which can't withstand such high temperatures. (Copper melts at 1085°.)

What regenerator material can withstand 1350°, though? Lots. Alumina melts at 2072° and even quartz doesn't melt until 1670°, even though quartz-based felsic lavas and well-fluxed quartz-based glasses melt at much lower temperatures. Regular fireclay is good to 1515°. So a pebble bed of ordinary fireclay should work fine. Limestone would calcine to quicklime, which would also work, and would be a useful product in its own right, though it might be an unnecessary hazard. Quicklime could also perhaps eliminate some acid contaminants from the exhaust gases, such as HCl from salt firing.

Olivines are not suitable for the regenerator itself; although you might expect them to be much more refractory due to their role in raising the melting temperatures of mafic rocks, not to mention their foundry use as refractory sands, not only do some of them melt as low as 1200° (fayalites, though forsterites melt at higher temperatures up to 1900°), but they oxidize exothermically to quartz and magnesite when exposed to hot CO_2. This might be useful to get a zero-carbon-emission gas-fired kiln if the reaction is fast enough; the exhaust air could contain less CO_2 than the input air.

If the alternation time on the regenerators is 1 minute and the advection reaches 2000 watts (that must be retained), each regenerator must hold 120 kJ. If the temperature swing in the regenerator averages 600° (more for the innermost chunks, less for the outermost), then it would be sufficient to have 250 g of quartz per regenerator at 0.83 kJ/K/kg. This is very promising!

Let's suppose that we want the kiln to stay at 1350° for 12 hours without losing more than, say, 10% of the heat energy through its insulation, so that we run the burner at about 10% power to keep it warm. Earlier I said the inside should be a 320-mm cube, which gives it 0.61 m² surface area. R-values are m²·K/W, and in this case we want to lose under 200 W through 0.61 m² and a 1330-K difference, which means our R-value needs to be at least 4.1. Fiberglass is about 22 m·K/W, so that's about 190 mm of fiberglass. Loose-fill perlite is about 19 m·K/W, loose-fill vermiculite can be as low as 15 m·K/W, so you might need as much as 275 mm of vermiculite. This is eminently feasible, although it doesn't leave a lot of extra room.

NIST's data

http://ws680.nist.gov/bees/ProductListFiles/Generic%20Fiberglass.pdf says R-13 fiberglass batts (i.e. 13 m²·K/W, which is 3.2 times what we need) are 89 mm thick and weigh 12.1 kg/m³ (i.e. 12.1 g/ℓ). This works out to be 146 m·K/W, which is 6.6× as high as the value I calculated above and twice as high as the values I find online for silica aerogel, so it cannot possibly be correct.

Ah, this random CertainTeed™ brochure http://www.certainteed.com/resources/IGProductKnowledge20060008.pdf explains that "R-13" is actually 2.3 m²·K/W, giving a thermal resistivity for fiberglass of 25.8 m·K/W, which is correct. So we can probably take the density as correct.

Using such batts (minus their facing layer, I suppose) to achieve the insulation level needed would require two layers of them, providing 4.6 m²·K/W of insulation and increasing the dimensions of the kiln by 178 mm on each side, for a total of (178+320+178) mm = 676 mm. The total mass of the fiberglass then would be 3.3 kg, entirely reasonable.

But you can't actually use just those batts, because the innermost layers of insulation need to withstand 1400°, and glass won't. Glass will only handle up to 500° or so, so only the outer reaches can be made of glass. You need inner layers of kiln bricks or vermiculite or something, and that's going to drive up the weight considerably. (Or you could use ceramic fiber batts, which look like glass fiber batts but are made of alumina to withstand high temperatures.)

To observe the inside of the kiln without losing a ridiculous amount of heat, although peepholes are the traditional solution, you might want some kind of optics. I have no idea how this could work; wouldn't a mica window melt? Even if it doesn't melt, could you see through it while it's glowing?

Zombie contingency plan

Kragen Javier Sitaker, 2017-07-19 (9 minutes)

Suppose there were a zombie apocalypse (or similar event, such as a war or deadly epidemic). What could I do?

I live in a Buenos Aires apartment with two other people, about 29 meters from the street. If we could, it would be better not to leave the apartment if possible, preferring to conduct day-to-day life behind closed doors as long as possible.

Let's suppose for the time being that we don't need to provide our own air the way nuclear submarines and space stations do. What about the other necessities — food, water, medicine, warmth, coolth?

We have about 9m² of roof terrace and about 50m² of indoor space with 4m ceilings, a total of 200m³ of indoor space.

Food

A food reserve probably needs 2500 kcal per person per day for each of the two adults, plus 1500 kcal for the seven-year-old, a total of 6500 kcal/day. If we want it to last a year, that's 2.4 million kcal; if 40% of the calories are carbohydrate, 30% fat, and 30% protein — the desirable balance used in e.g. Clif bars — then that's 950 thousand kcal of carbohydrate and 700 thousand kcal each of fat and protein. At 5 kcal/g, that's 190 kg of carbohydrate and 142 kg of protein; at 9 kcal/g, that's 79 kg of fat. The total is 411 kg of dry mass, or probably 500 kg of dry food, probably occupying about 500 ℓ, or about 250 two-liter plastic coke bottles, if it's stored in that form.

We currently cook the food using the municipal natural gas supply; off-grid alternatives in case of catastrophe would include burners driven by LP gas cylinders, like the one that recently exploded the house of a friend of mine; alcohol burners; and solar cookers.

Lentils, as a representative cheap food, cost AR$5.20/kg in 10-kg bags. So 500kg of food would cost about AR$2600, which is currently about US$173. Of course, you wouldn't buy 500 kg of lentils; you would buy a mix of different cheap foods. But this would be super cheap.

Climate control

Right now I have a portable air conditioner set up in the bathroom drying my roommate's sheets and towels. Dry laundry is essential to maintaining body temperature when it gets cold and damp. This machine uses 6 amps of 220-volt single-phase AC and can evaporate and recondense between 1ℓ and 10ℓ per hour (I haven't measured carefully). (It also provides heat and cool when needed, although right now we're heating the apartment rather expensively with a gas heater run off the municipal natural gas supply.)

Devices like this one cost about AR$5000 = US$333. It would be good to have a spare.

However, running it requires electricity. Maintaining electricity in the event of a zombie apocalypse would require being able to generate it locally.

Electricity

We could drive the air conditioner off some car batteries and solar panels with an inverter, ideally on a pallet in a plastic tray under an awning on the roof terrace, so that if shit goes wrong it doesn't blow up the house. But how much would we need?

220V × 6A = 1320W; 1320W ÷ 12V = 110 A. So we'd need batteries capable of 110 amps, which is easy enough as far as it goes, but we probably also need to be able to run it for a couple of hours at a time, which works out to 9.5 MJ or 2600 watt-hours. That suggests we need something like three deep-cycle batteries like the Trojan 27TMX, which holds 3.2 MJ by my calculations and can supply 530 amps. This gives the electrical system a "burst" capacity of 19 kilowatts.

These batteries cost AR$5100 each, so this is AR$15300 of batteries. Probably you'd actually want four so that you can put them in series strings of two batteries to get 24V, for a total of AR$20400.

There are 2000W inverters on MercadoLibre for AR$7500; they require 24V input.

Such an electrical system could also be used to run a microwave for cooking, lights, even electric stove burners.

Somehow you'd also need to charge the batteries. A 250-watt (peak) solar panel is 1.62 m² and costs AR$7000. Since this is 5.3 times less power than the air conditioner, a single one of these would require 5.3 hours of midday sunlight to recharge from a single hour of air conditioner use; it would be better to have two of them, for 500 watts peak and AR$14000. The roof has space for about six of them at most.

You also need a charge controller, which I think is about AR$1000.

So the total is AR$20400 + AR$7500 + AR14000 + AR$1000 = AR$42900 = US$2860.

Water

Buenos Aires gets 1200 mm of rain per year, which is distributed fairly evenly through the year. That means our ≈9m² of roof terrace gets about 10.8 m³ of rain per year, or 10,800 liters; on average, that's almost 30 ℓ per day, or 10 ℓ per person per day. Even at Burning Man, you only need about 6 ℓ per day per person, and you lose less water when you're not in the hot sun in the desert.

So even a cistern system would work adequately, given adequate filtration and other measures against contamination. Transparent awnings covering 60% of the small terrace area would be adequate. Probably a month's worth of water is adequate; that would be 6 ℓ × 3 × 30 = 540 ℓ. 500-liter drinking water tanks are readily available and cost a bit under AR$1000 = US$67.

Additionally, though, the air conditioner I mentioned earlier condenses water from the air, somewhere between 1ℓ and 10ℓ per hour. (If we figure that all of the 3000 kcal/h of cooling provided by a machine like this are provided by the condensation of water, whose heat of vaporization is 2257 kJ/kg, it would be 5.6 ℓ/h.) That means we can get water even without the cistern. It seems to be a bit jelled, though, and tastes funny; I suspect it may have some kind of microbial slime in it.

This calls for a 400× microscope with slides (AR$1000 = US$67)

and a water tank.

Access control

Of course none of this is useful if the zombies can get in and bite us. The walls are concrete and therefore fairly zombie-proof, but it would be good to replace the apartment's front door with a metal door, and add another metal door at the bottom of the stairwell, since an inhabitant of any of the other dozen or so apartments in our passage could get bitten and become a zombie. The stairwell is shared between only three apartments and provides us access to our roof terrace.

"Armored" doors from vendors like Pentagono cost on the order of AR$10000, and we would need three of them. This costs AR$30000 = US$2000.

(We have wood floors, but I think there may be a concrete subfloor.)

Other safety equipment

We need fire extinguishers, probably three of them. These cost about AR$700 each, for a total of AR$2100 = US$140.

Carbon monoxide detectors and flammable-gas sniffer alarms would be a good idea.

Communication and interchange

A catapult launching guided gliders from the roof would make it possible to get a look at what's going on in the area and transmit radio signals to the rest of the city; the glider could return to the terrace to land, using a parachute to effect a vertical landing. If there are other survivors of the zombie apocalypse, we could send them small items.

Weapons

What, are you kidding? You can't kill zombies. Weapons are pointless. Just hide.

Total cost

```
US$ 200 food
US$ 666 two portable air conditioners (I already have one)
US$2860 solar electric system
US$  67 water tank
US$  67 microscope
US$2000 armored doors
US$ 140 fire extinguishers
-------------------------
US$6000 total
```

Why the Cartesian product of fields isn't a field

Kragen Javier Sitaker, 2019-05-02 (2 minutes)

If you have some underlying field like GF(2) you might think you could derive an infinite variety of other fields from it by way of taking arrays of some finite size which operate elementwise.

For example, GF(2) is just bits, using AND as multiplication and XOR as addition; considering the field axioms, these are associative, commutative, have identity, distribute (a & (b ^ c) = (a & b) ^ (a & c)) and have inverses (each element is its own inverse, trivially so in the case of AND: 1 & 1 = 1), so that's a finite field. You might think that you could extend this elementwise to "bitvectors" (not in the sense of a vector space, just in the sense of arrays of bits) but this fails when we get to the inverse: AND with a "bitvector" containing zeroes is information-destroying, so there can be no inverse. In the single-bit case, we get to escape by pleading division by zero, but not in the multibit case.

So "bitvectors" of some size form a commutative ring with unity, but not a field.

There *is* a field of size 2^8, though. It's GF(256), which is not just $\mathbb{Z}/256\mathbb{Z}$, arithmetic modulo 256, as you might think — that's, again, just a commutative ring with unity, since there are plenty of pairs of numbers that multiply to zero, like 2·128, so not every member has a multiplicative inverse. No, in some sense it *is* a vector of 8 bits, but I don't understand the construction of the operations; it's some kind of construction with monic irreducible polynomials.

Real-time bokeh algorithms, and other convolution tricks

Kragen Javier Sitaker, 2018-12-18 (updated 2019-08-15) (23 minutes)

It would be super neat if I could blur a video stream in real time with a realistic camera-like bokeh, like a flat circle or hexagon or octagon or something, with a diameter in the neighborhood of like 32 pixels or more.

By "flat" I mean that, within the area of the bokeh, the output transfer function is almost constant. (And, outside, it's zero.) This is very different from the Gaussian blur that is such a popular effect on computers, which has the advantage that it's isotropic (the PSF/OTF is circularly symmetric) and very fast to compute (as a cascade of box filters and/or separable X and Y Gaussian blurs). It's the *only* circularly symmetric separable convolution kernel.

On my laptop, the time budget for fullscreen full-resolution 60-fps video is 8 ns per pixel. So I think this is probably feasible on a GPU with enough work, but not on a CPU.

However, I have found some algorithms that are probably only *slightly* too slow, and are much faster than the state of the art.

Candidate approaches

Downsampled bokeh computation

Some of the algorithms described below may produce a bokeh whose edge is unrealistically sharp, or sharp in a way that is undesirable under some circumstances, or has visible aliasing artifacts. One way to ameliorate these problems is to downsample the image (using an algorithm more sophisticated than nearest-neighbor, but even decimating a first-order box filter ought to be sufficient), compute the bokeh, and then upsample the computed bokeh (with at least a second-order box filter). This of course also reduces the computational load of computing the bokeh itself.

Box filters

A box filter is pretty fast (using a prefix sum†), and it has the desirable camera-like flatness, but I've never seen a camera with a rectangular bokeh. You could use a set of 32 one-dimensional box filters for the bokeh on 32 scan lines, adding together the results, and that would work, but it might be pretty slow. (However, see the section below about "chord decomposition" for ways to improve this approach.)

And of course you can affinely texture-map the image to rotate it, box-filter the rotated version, and then texture-map it back to unrotate it. And that can get you a bokeh of a rotated rectangle or indeed an arbitrary parallelogram.

But is there some efficient way to get even, say, a paraxial trapezoid? With, like, less than a separate box filter for every 2–4 scan lines? (Yes, see the section below about efficient convolution with horizontal trapezoids.)

If you have successfully achieved two bokeh filters, one of which is

entirely contained in the other, you can subtract one from the other to get a bokeh with a hole in it.

You can get a spatially varying somewhat trapezoidal bokeh by a variation of the rotation method: do the texture mapping with perspective rather than just an affine transformation. This is a useful approach to get a bokeh of spatially varying size in general: spatially transform the image, apply the bokeh, and transform it back.

(See also the McIntosh et al. paper below for a hack that gives incorrect, but visually plausible, results for many interesting bokehs.)

Rounded corners by composing with hollow-circle convolution

A possibly useful approach to round the corners of the bokeh without blurring its edges much: add a stage to the bokeh pipeline whose PSF is a small hollow circle, e.g., this 28-pixel 11×11 circle, using . for 0:

```
. . . . 1 1 1 . . . .
. . 1 1 . . . 1 1 . .
. 1 . . . . . . . 1 .
. 1 . . . . . . . 1 .
1 . . . . . . . . . 1
1 . . . . . . . . . 1
1 . . . . . . . . . 1
. 1 . . . . . . . 1 .
. 1 . . . . . . . 1 .
. . 1 1 . . . 1 1 . .
. . . . 1 1 1 . . . .
```

This can be achieved with the difference of two one-dimensional box filters (using prefix sums) per distinct scan line. Note that in this case there are only four distinct scan lines, although there are 11 scan lines in total.

However, there's a more efficient way to compute this. We can divide the circle into slices of similar scan lines, then compute these slices with the composition of some sparse kernels without using prefix sums. For example, consider this slice of the above circle:

```
. 1 . . . . . . . 1 .
. 1 . . . . . . . 1 .
. . . . . . . . . . .
. . . . . . . . . . .
. . . . . . . . . . .
. 1 . . . . . . . 1 .
. 1 . . . . . . . 1 .
```

This convolution can be computed efficiently by the following composition of convolution kernels with three additions per pixel, plus an appropriate change of coordinates:

```
1 ∘ 1 . . . . . . . 1 ∘ 1
1                       .
                        .
                        .
                        .
```

The composition of the transposes of these kernels compute the transposed slice:

```
. . 1 1 . . . 1 1 . .           1
. . . . . . . . . . .           .
. . . . . . . . . . .           .
. . . . . . . . . . .           .
. . . . . . . . . . .  = 1 1 ∘  .  ∘ 1 . . . 1
. . . . . . . . . . .           .
. . . . . . . . . . .           .
. . . . . . . . . . .           .
. . 1 1 . . . 1 1 . .           1
```

The central slices also need three additions per pixel:

```
1 . . . . . . . . 1     1
1 . . . . . . . . 1  =  1  ∘  1 . . . . . . . . 1
1 . . . . . . . . 1     1
```

This might be useful in combination with some of the jaggy approaches, and an alternative that might work well for that in the case of an octagonal bokeh might be a 45° rotated hollow square, achieved through a difference of rotated box filters.

This works out to 3 and 3 additions for the horizontal and vertical central slices and 3 and 3 additions for the other two slices, plus 3 more additions to sum them all together, a total of 15 pixel additions.

Brute-force: Fourier convolution!

Finally, maybe doing the bokeh convolution in frequency space is the best available option. However, on my laptop's CPU, an FFT of a 640×480 grayscale image followed by an inverse FFT takes 96 ms, which is 312 ns per pixel. Much smaller FFTs should be significantly faster, but slightly larger FFTs (like a screenful) should be slightly slower (though for some reason 1024×1024 is actually often much slower on my laptop, possibly because of other CPU-intensive things I'm running).

Chord decomposition and per-scanline box filters

Consider a filled version of the 11-pixel hollow circle above:

```
. . . . 1 1 1 . . . .
. . 1 1 1 1 1 1 1 . .
. 1 1 1 1 1 1 1 1 1 .
. 1 1 1 1 1 1 1 1 1 .
1 1 1 1 1 1 1 1 1 1 1
1 1 1 1 1 1 1 1 1 1 1
1 1 1 1 1 1 1 1 1 1 1
. 1 1 1 1 1 1 1 1 1 .
. 1 1 1 1 1 1 1 1 1 .
. . 1 1 1 1 1 1 1 . .
. . . . 1 1 1 . . . .
```

If we wanted to convolve with that filled circle, we could do it by

convolving the following 12×11 sparse kernel (see Sparse filters (p. 834)) with a horizontal prefix sum of the pixels, thus applying a one-pixel-tall box filter to each scan line:

```
 . . . .-1 . . 1 . . . .
 . .-1 . . . . . . 1 . .
 .-1 . . . . . . . . 1 .
 .-1 . . . . . . . . 1 .
-1 . . . . . . . . . . 1
-1 . . . . . . . . . . 1
-1 . . . . . . . . . . 1
 .-1 . . . . . . . . 1 .
 .-1 . . . . . . . . 1 .
 . .-1 . . . . . . 1 . .
 . . . .-1 . . 1 . . . .
```

In this form this would require 22 additions and subtractions per pixel, but this, in turn, can be decomposed into pipelines of sparse kernels in a very similar way to that applied to the hollow circle above:

```
 .-1 . . . . . . . . 1 .
 .-1 . . . . . . . . 1 .                                  1
 . . . . . . . . . . . .                                  .
 . . . . . . . . . . . . = -1 . . . . . . . . 1 ∘ 1 ∘ .
 . . . . . . . . . . . .                        1    .
 .-1 . . . . . . . . 1 .                                  1
 .-1 . . . . . . . . 1 .
```

I think that, decomposed in this way, this circle decomposes into four kinds of scan lines; from the top, these require 2, 2, 3, and 3 per-pixel additions and subtractions each, plus the addition per pixel needed to compute the prefix sum. This works out to 11 operations per pixel, which is pretty good for a 121-pixel convolution kernel.

This is closely analogous to the Urbach–Wilkinson algorithm for erosion and dilation described in Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm (p. 216), with a few differences: Urbach and Wilkinson need to use a cascade of exponentially growing kernels rather than a simple prefix sum because of the inverseless nature of the max and min operations; and, because summation is not idempotent the way max and min are, overlap is significant to convolution in a way that it is not to the morphological operations. For example, 1 1 1 1 ∘ 1 0 0 1 = 1 1 1 1 1 1 1 when it comes to erosion or dilation, but 1 1 1 2 1 1 1 for convolution.

This approach generalizes to arbitrarily-shaped flat bokehs using, at most, two subtractions and additions per "chord" (Urbach and Wilkinson's term) of the convolution kernel. This should scale adequately to things like pentagonal bokeh.

In some cases, DAGs, rather than strict pipelines, of sparse kernels may be advantageous. For example, it wouldn't be unusual to have two blocks of lines that were both 3 pixels tall; a single vertical 1 1 1 kernel applied to the horizontal prefix sum can be shared among both of them. And consider the kernel 1 0 0 0 1; this can be implemented as `p[x] += p[x+4]`, and in this form it represents a convolution which could, for example, convert a convolution with 1 0 0 1 into a convolution with 1 0 0 1 1 0 0 1. But if instead we do `p[x] += q[x+4]`, we can get the pixels we're adding in from some other image — if

previously p is the convolution with 1 0 0 1, as before, and q is the original image, then this will convert p into the convolution with 1 0 0 1 1. Furthermore, I suspect it may be the most efficient way to compute that convolution.

Above I suggested computing bokeh on a downsampled version of the image to get blurry edges. An alternative is to compute the bokeh at full resolution, but using a jaggy approximation to a circle made out of a stack of rectangles, say 3 pixels tall, using 2-D box filters on a 2-D prefix sum; then a final blur pass might hide the worst of the resulting jaggies.

If the bokeh kernel has reflection symmetry around a vertical axis rather than a horizontal axis — for example, a pentagon with a point on top or on the bottom — it may be worthwhile to do all these computations using a vertical prefix sum in order to take advantage of that symmetry.

Efficient convolution with (some) horizontal trapezoids using prefix sums

Consider this convolution kernel:

```
-1 . . . . . . . 1
 .-1 . . . . . 1 .
 . .-1 . . . 1 . .
 . . .-1 . . 1 . . .
```

Composed with a horizontal prefix sum, this kernel computes the convolution with a 4-scanline-high trapezoid whose top and bottom are horizontal. But the tricks used above to divide circles into slices will avail us nothing here. However, barring overflow, the convolution with that kernel is clearly equivalent to the sum of convolutions with these two kernels:

```
-1 . . .      . . . . . . . . 1
 .-1 . .      . . . . . . . 1 .
 . .-1 .  +   . . . . . . 1 . .
 . . .-1      . . . . . 1 . . .
```

And this can be computed more efficiently as follows, with five additions and subtractions per pixel, plus some changes of coordinates:

```
                . . 1           1 . .
. . . . . . . 1  ∘  . . .  -  1 .  ∘  . . .
. . . . . . 1 .    1 . .      . 1     . . 1
```

This trick will work for trapezoid boundary lines of some angles, but maybe others are more problematic. Consider this decomposition to five per-pixel additions, similar to some of those discussed in Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm (p. 216):

```
1 . . .
1 . . .                   1 . .
1 . . .       . .         . . .
. 1 . .       . .   1     . . .
```

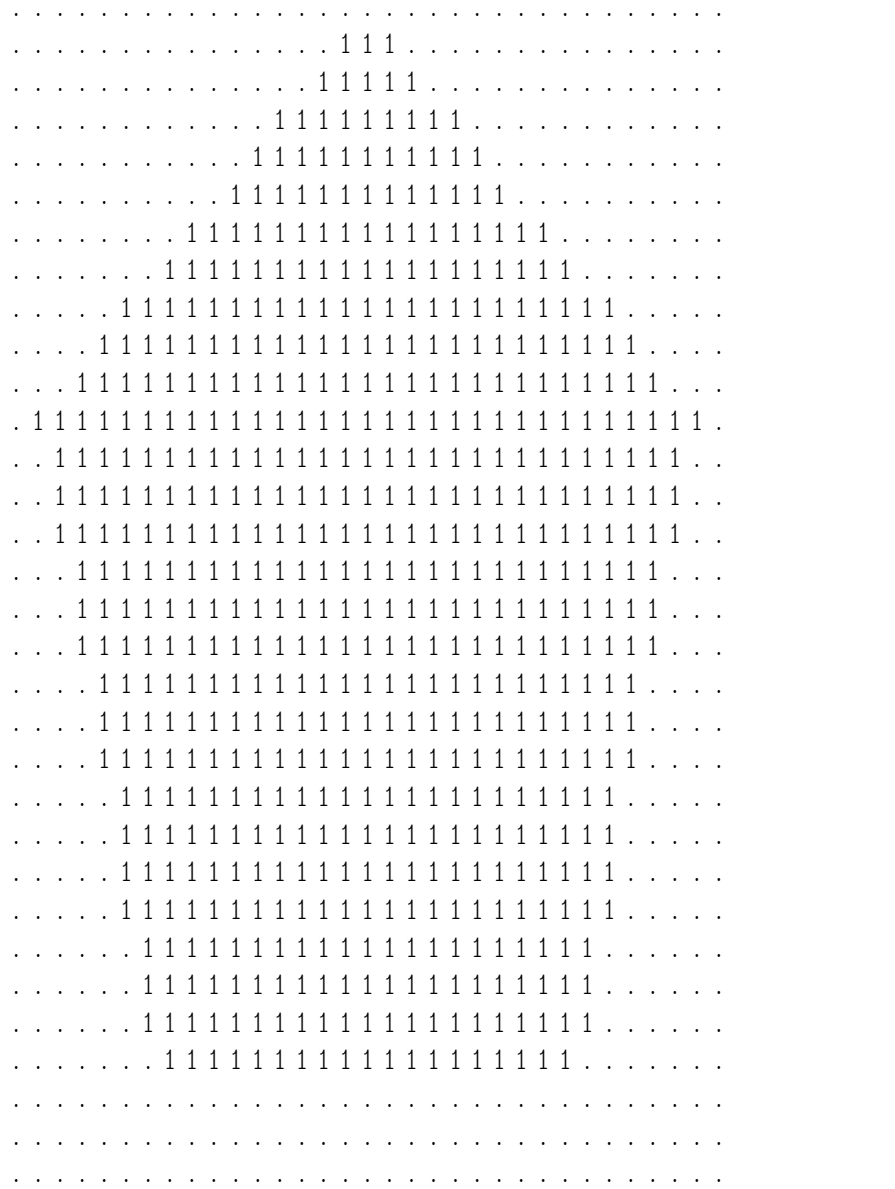
```
. 1 . .  =  (  . . + 1  ) ∘ . . .
. . 1 .        . 1   1      . . .
. . 1 .        . 1          . . 1
. . 1 .
. . . 1
. . . 1
```

Very nice, right? At first I thought you were fucked if the last scan line of the kernel is missing, but you can handle that just by subtracting it off. I don't have a fully general algorithm for finding efficient decompositions of this kind.

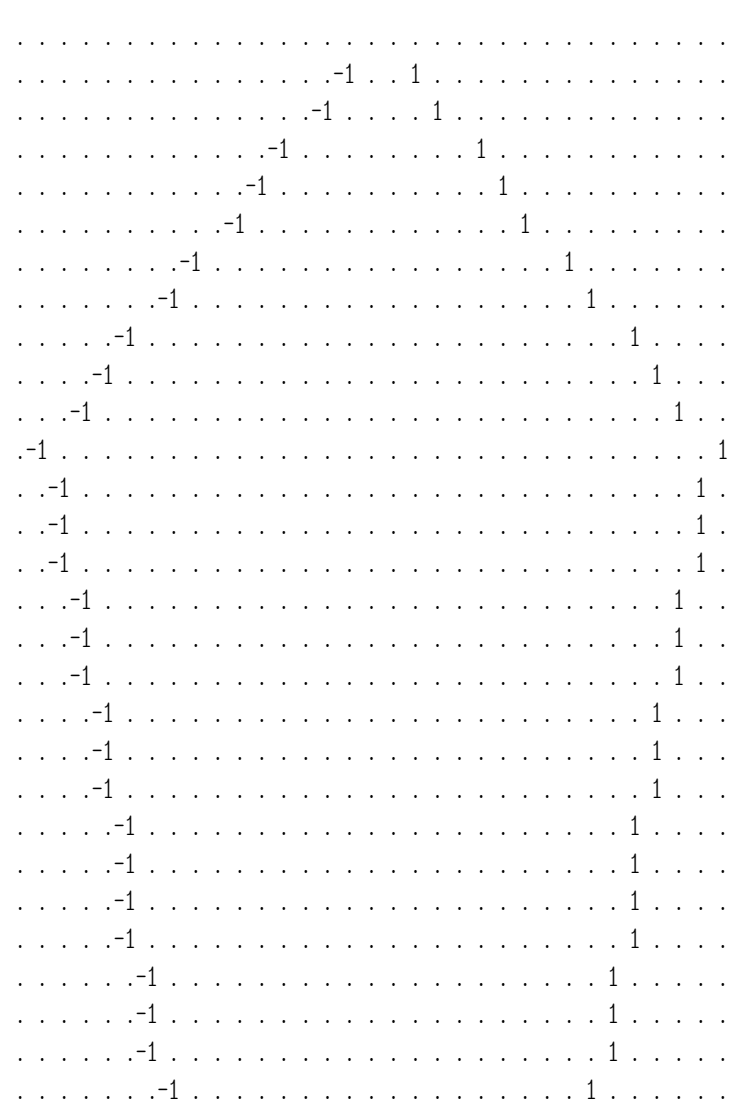
Since you can decompose any polygon into horizontal trapezoids in this fashion, using at most one trapezoid per polygon vertex, this potentially provides an efficient way to convolve with arbitrary flat polygonal bokeh. In particular, a pentagon with a point pointed up or down can be decomposed into two trapezoids, one degenerate in the sense that it is a triangle.

Convolving with a 32×32 pentagon with 600 pixels in 26 additions and subtractions

Here's a regular pentagon computed to fit into a 32×32 square:

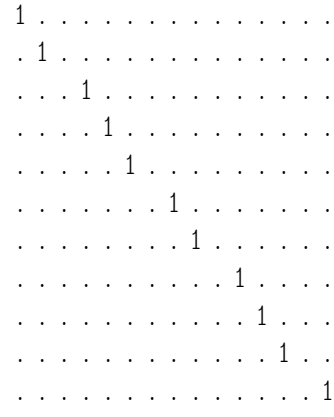


And here is the sparse delta kernel you would need to compute the convolution of the above with an image from a horizontal prefix sum of that image:

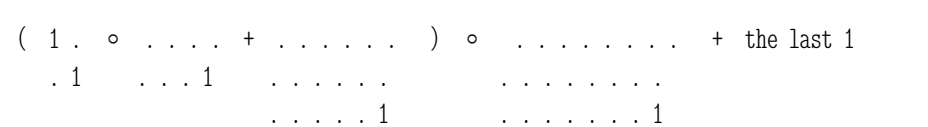


Since the left and right edges are the same in mirror image, I will just deal with the right edge.

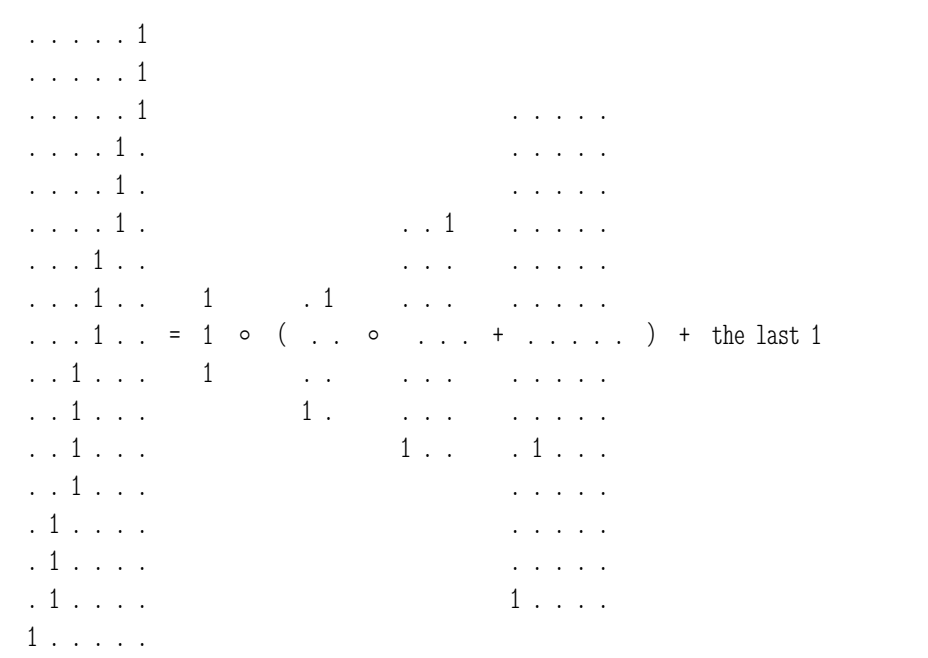
The upper right edge consists of these 11 lines:



I broke this down to the following, using a greedy algorithm:



That's five additions per pixel. The lower right edge is similar:



This works out to seven additions per pixel, so the whole right edge can be done in 12 additions per pixel; the left edge can then be done in 12 more, and the two subtracted, for a total of 26 operations per pixel, including the original prefix-sum calculation.

Not bad for a 600-tap bokeh kernel calculated to fit into 1024 pixels!

Plausibly, these numbers might scale linearly with the number of sides in the polygon, and logarithmically with the size of the kernel.

McGraw's singular-value-decomposition algorithm (see below) could probably produce a reasonable approximation of the same bokeh with a rank-3 reduced matrix; this amounts to summing three separable 32×32 filters, each requiring 64 multiply-accumulates, for a total of 192 multiply-accumulates. It has the advantage of not being limited to flat bokeh, but the additional disadvantage that its results are only approximate.

Pipelining

As described in Evaluating DSP operations in minimal buffer space by pipelining (p. 321), in cases where your dataflow topology *is* a strict pipeline of filters, and your filters only reach a limited distance into the past, you can pipeline them all into a single pass over a shared buffer, preserving just enough of the results of each stage in the pipeline to allow the next stage to run. This is especially important for low-computational-intensity algorithms like those explored here, because (at least on the CPU) it's likely that the algorithms' bottleneck will be memory bandwidth rather than the amount of time to add pixels together or whatever. Tiling is another related strategy for improving locality.

Floored Gaussian subtraction

Lenses with spherical aberration commonly produce bokeh that is

not completely flat; for example, it might be brighter or dimmer in the center. The above algorithms mostly cannot reproduce this, although the hollow-circle convolution will produce a brighter edge.

Maybe, to get a brighter or dimmer center, you could apply a Gaussian blur to the image (say, a third-order box filter) and add or subtract the attenuated blurred image from the bokeh image, using saturating subtraction when subtracting to prevent the creation of negative pixels where the support of the Gaussian extends beyond that of the bokeh. This is pretty imperfect since the darkness still leaks out to infect neighboring pixels, but might still look okay.

Previous work

The chord-decomposition and trapezoid algorithms above don't seem to have been published before, and in significant cases they seem to be dramatically more efficient than published algorithms.

Efficiently Simulating the Bokeh of Polygonal Apertures (McIntosh, Riecke, and DiPaola 2012) uses min between rotated and skewed box filters to get fairly realistic hexagonal and octagonal bokeh, also varying it with the depth of field and using max to get star-shaped polygons. This does produce visible artifacts, but they are fairly minimal. It cannot produce polygons with odd numbers of sides.

Fast Bokeh Effects Using Low-Rank Linear Filters (McGraw, 2014) used "low-rank linear approximations" to get linear approximations of arbitrary bokeh shapes. The best summary seems to be on p. 4:

> Our low rank filter approach for bokeh effects is to approximate an arbitrary filter kernel as a sum of separable kernels.

It criticizes the above paper as follows:

> McIntosh et al. [17] present a novel approach that is capable of generating polygonal bokeh, but their method has several restrictions that ours does not: the kernel is of uniform intensity throughout, the bokeh shape must be a union or intersection of parallelograms, and large overlapping bokeh do not blend properly.

In a way, it's similar to the various decomposition-based approaches I described above. He treats the rows and columns of the PSF as the rows and columns of a matrix, and then uses singular value decomposition to find a "best" rank-*N* approximation of that matrix; the vectors corresponding to the largest singular values then provide separable filters whose sum approximates the original filter kernel.

This is a very interesting approach to the problem of convolution in general, and it turns out there's a fair bit of research on it, although you wouldn't know that from reading McGraw's paper; see The miraculous low-rank SVD approximate convolution algorithm (p. 747) for details.

† Prefix sums are also known as scan or addition scan (+\ in APL), sum tables, integral images, cumulative sums, and summed area tables (SATs), the last especially when the prefix sum is taken along both the X and Y dimensions.

An IMGUI-style drawing API isn't necessarily just immediate-mode graphics

Kragen Javier Sitaker, 2015-09-03 (3 minutes)

There's this thing called "immediate-mode GUIs" floating around which is kind of related to immediate- versus retained-mode drawing systems. But it's not really. In an immediate-mode GUI, you supply the library with a function which draws your UI, and it invokes it when necessary, influencing its execution as needed.

A real drawing equivalent of immediate-mode GUIs might be how you would draw if you only had a single scan line of framebuffer. You could have a function that represented the image you wanted to draw, invoked with a drawing context object of type `dctx`, once every scan line:

```
void draw_stuff(dctx *c)
{
    draw_rect(c, 10, 10, 100, 100, DC_GREY);
    draw_circle(c, 10, 10, 100, 100, DC_BLACK);
    int baseline = 55;
    if (bbox(c, baseline - font_height, 0, baseline, 100)) {
        char *s = "Welcome";
        int text_width = text_escapement(s);  // for centering
        show_text(c, 55 - text_width/2, baseline, s, DC_RED, DC_BLACK);
    }
}
```

Note that this is almost entirely abstract over the question of whether you're drawing a scanline at a time or what.

The `bbox` function determines whether or not part of the currently-being-drawn area impinges on that bounding box. If not, the user-provided function above skips the potentially expensive calculations within. This is the same approach IMGUI libraries use to handle buttons being clicked, menus being open, and so on.

Serious IMGUI libraries do stuff to help you divide your GUI-drawing function into separately memoized parts, but I'm not going to touch on that here. Instead I'm going to focus on the idea of using this to make it usable to draw graphics scanline by scanline.

Let's consider what `show_text` has to do. It's being invoked with a `dctx`, a start point, some text, a foreground, and a background:

```
// in the dctx library:
void show_text(dctx *c, int x, int y, char *s, color fg, color bg)
{
    <<show_text implementation>>
}
```

Let's suppose for the moment that we only have one font, and it's a proportional bitmap font; and that this function in particular only has to draw a single line.

First, we ought to check to see if our bounding-box is being drawn, which means we have to compute it.

```
// in show_text implementation:
int width = text_escapement(s), max_x = x + width, min_y = y - font_height;
if (!bbox(c, x, min_y, max_x, y)) return;
```

Now, though, we need to copy the appropriate chunks of pixels into the scan line, in the appropriate color. This part inevitably depends on the fact that we're drawing a single scanline, rather than half a scanline or four scanlines.

```
int font_line = c->y - min_y;
char k;
for (char *p = s; (k = *p) != '\0'; p++) {
    short pixels = get_font_pixel_slice(k, font_line);
    char width = get_font_pixel_width(k);
    for (int i = 0; i < width; i++) {
        c->buf[x] = pixels & 1 ? fg : bg;
        x++;
        pixels >>= 1;
    }
}
```

And that's it, aside from some relatively mundane details about `get_font_pixel_width` and `get_font_pixel_slice`. That gives you the software equivalent of an old-style character generator, permitting color framebufferless rendering at arbitrary pixel offsets.

Personal notes from 2013-06-06

Kragen Javier Sitaker, 2013-06-06 (updated 2014-04-24) (11 minutes)

Well, the movie with Caro didn't work out, due to technical difficulties: she'd bought the tickets for the wrong day, so we ended up starting to see some kind of 3-D animated hero film for kids before going down to the ticket counter to buy new tickets. Her intense frustration at this state of affairs reminded me that she's one of the most organized and together people in my current inner circle. Maybe I can improve my conscientiousness by hanging out with her more.

Dinner with Naudy, however, was awesome; but afterwards I was sufficiently tired (and stuffed --- Los Sabios food tempts one to overindulge) that I'm not going to the hospital tonight.

I did my first experiments with frequency-domain convolution and sparse factorings of time-domain FIR kernels, but I don't know

I've stuffed the last of the moldy clothes in the wash bucket so I'll wash them tomorrow. And I've gotten some leads on roommates on the web, which I'll check out more tomorrow.

So for the morning here's my plan:

• Wake up 10:00.
• Bootup and fsck (1 hour):

• Put away bed.
• Flaxseed omelet with salsa golf, or something.
• Wash dishes and another bottle.
• Fold and put away dry laundry.
• Shower and laundry.
• Sweep floors. (Sisyphean: I swept them two days ago, and they're already dirty again. This is still an improvement over Augean, I suppose.)
• Optimization (1 hour):

• Bottle soybeans.
• Put away stray objects from living room floor.
• Reticulate splines:

• Read dspguide chapter on frequency-domain convolution.
• Networking:

• Go to Santi's.
• Call Telefónica to get the internet connection here fixed.
• Investigate housing possibilities: Craigslist, and followup on leads.
• Work project:

• Check status of server; do the needful.
• Talk with client.
• Look for a cellphone on Mercadolibre, Craigslist, OLX.
• Multimedia services:

• 17:50: go to movie with Caro.

Yeah, that was the plan. Here's what I actually did:

• Wake up 10:00. Reset alarm for 11:00. At 11:00, reset alarm for 12:00. Finally get up 16:00. Apparently I wasn't giving myself adequate sleep if I had built up a six-hour deficit. Put away bed.
• Eat a hurried breakfast: an alfajor maicena, a fried egg with soy sauce, a cup of English Breakfast tea, and a glass of pear-vinegar-flavored sugar water.
• Remember Violeta is coming today and would be arriving about the time I'd be going to the movie. We arranged that on Tuesday; I can hardly cancel it now on a whim. Also I need to go pick up my blankets from the laundry place (AR$50), but I don't have the money in pesos, and I doubt the laundry place will make change for US$100. I need to go change some dollars to pesos.
• Spend 50 minutes changing dollars to pesos, then pick up the laundry. Apologize to Caro.
• Buy a bottle of bleach (AR$22 for four liters), since I'm almost out, and the cleaning-supplies store is right across the street.

An interesting thing to note was my anxiety level while returning from money changing to go to the laundry place: I worried they might have already closed (I hadn't noted their hours), and that I'd have to spend the night tonight again under only the sheets and bedspread, inconveniencing Violeta as well as myself. My guilt at this possibility was kind of extreme. My relief upon coming in sight of the people sitting around inside the laundry's plate-glass windows was enormous.

This anxiety and guilt is a miniature version of the debilitating version I experience during procrastination.

As it turns out, Violeta is delayed, and so I could have gone to see the movie anyway, which I probably would have found out if I had messaged her to find out her schedule when I got up instead of after the movie had already started. So in this case my lack of communication exacerbated the situation caused by my lack of planning. Rationally, I know that all of this is much more important to me than to anyone else, and that the guilt I'm feeling is out of proportion to the real negative impact it's having on other people, and that that same guilt is what makes me reluctant to initiate those communications --- a vicious cycle.

Now it's 18:00, and I have time to make a revised plan for the rest of the day.

• Cooking:

• Make noodles with white sauce.
• Make lentils.
• Make a salad, using oil, pear vinegar, lettuce, celery, and tomato.
• For the above, buy onions, milk, lettuce, and celery, before house maintenance:
• House maintenance (before Violeta arrives, time permitting):

• Sweep floors. (Sisyphean: I swept them two days ago, and they're already dirty again. This is still an improvement over Augean, I suppose. But it's a very quick task.)
• Bottle soybeans.

• Fold and put away dry laundry.
• Shower and laundry.
• Wash dishes and another bottle, if there's still time.
• Put away stray objects from living room floor.
• Study (alongside Violeta):

• Read dspguide chapter on frequency-domain convolution.
• Read remaining dspguide chapters.

(Planning time: 7 minutes.)

An hour later, I've bought the foods, plus an off-brand Terma, a new kind of bottlable noodles, and some fresh tomatoes. I'm soaking some sun-dried tomatoes now; maybe I can use them in the salad, or maybe Violeta would prefer a tuco sauce rather than a roux.

While I was out, I met a little girl jumping rope on the sidewalk, across the street from the MACABI building, which is surrounded by heavy brick barricades in case of another truck bomb. I hung up the blankets on the patio to air out, since I forgot to specify not to soak them in nose-anesthetizing perfumes.

I was disappointed to find that the bottle I washed yesterday still isn't completely dry. I'd left it to air-dry rather than using alcohol as usual, which seems to have been ineffective. I filled it with about a kilogram and a half of soybeans anyway; hopefully the moisture will diffuse throughout the soybeans rather than just making a few moist spots that can harbor mold.

Violeta was very pleased with the dinner, with which she helped. To the basic roux (butter, flour, and milk) I added salt, pepper, dried parsley, and freshly-grated nutmeg, with excellent results.

We ended up not studying, instead going out for ice cream (AR$25 for a quarter-kilo) before dinner. Dinner ended a bit past midnight, and then we went to bed.

We took a shower; I soaked the laundry (this load is a bucket full of clothes that had gotten moldy from a flood) with sodium percarbonate, but I haven't washed it yet.

Rather than going to the hospital to get an appointment, I decided to sleep instead. (To get an appointment, you have to be in line when they open the doors at 5:00.) This was probably a good idea, because I had another night of sleeping over 12 hours. While my health probably needs the sleep, I worry that it could promote depression.

I woke up at 6:30 with her this morning and made her pancakes with dried apricots for breakfast. As I woke up, I was dreaming that a family of six weasels had divided up my nasopharynx for living space, which was my first sign that I had a ferocious sore throat. I went back to bed when she left at 7:15, sleeping another 7 hours. I had to put on 很愛很愛 by Sammi (an album I bought in Seattle in 2000) and Queen's Greatest Hits on a couple of occasions to enable me to sleep through the child abuse next door. At one point, the man was roaring "¡Callate!" over and over at the small child, and when the child began to cry, he began to laugh. Now he's emitting periodic falsetto screams.

I spent some time reading Wikipedia about different acid-base theories and anatomy.

My lunch (I suppose it's not a breakfast since I had pancakes with Violeta before sunrise) will be breadsticks with the roux, plus some of the lentils. Then I'll wash the laundry that's been soaking overnight,

wring it out to dry, go call Telefónica, and head over to Santiago's house.

To the lunch above I added sesame seeds on the lentils, English Breakfast tea with the rest of the orange syrup, celery, and two fried eggs. I guess maybe my body thinks it's time to stop losing weight. I've left the shower running on the laundry to give it a post-soak rinse; now it's time for a shower and a real wash for the laundry.

Things on my shopping list: sugar, laundry detergent, Scotch tape, milk, butter, light bulbs. I read in Wikipedia that the sale of incandescent light bulbs was banned in Argentina in 2010; if that's true, the light bulbs may be a bit of a challenge.

One of the molded garments, a light-colored pillowcase, seems to have suffered spotty staining from the mold. I'm going to try soaking it in bleach water overnight to see if that helps.

Walking to Santi's house, I stopped by a hardware store which sells replacement fan parts and fan service (of the hardware-repair type, not the anime type). They also sell new desk fans: AR$120. I bought three replacement 28W lightbulbs (to replace 40W bulbs) for the apartment, which cost AR$60 in total. It turns out that the traditional incandescent lights are no longer available, but halogen replacements are.

Since this represents an investment in repairing the furnishings (increasing the value over the original) of about 3% of the rent, I'm going to see if I can persuade José to reimburse me. I guess I should have asked for a receipt.

I bought a helium Mylar balloon from a clown on the sidewalk for AR$40. It has pictures of Mickey and Minnie Mouse, and says in English, "Best wishes". On the top, it has a similar message in Chinese which presumably says the same thing.

Gaim group chat

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

So I want to make a Gaim (um, I mean Pidgin) extension for group activities such as games. The first activity, of course, is group chat. So here are some thoughts on how to achieve that.

People on the channel are connected in some sort of connected graph and relay broadcast messages to each other. The graph doesn't need to be acyclic; every message has a unique ID and everyone's client remembers the unique IDs of the messages they've seen recently, and only forwards on or displays new messages. Eventually, every message should traverse every link that is live at the time in one direction or the other.

The first question is how much the people should be allowed to know about each other. Of course since they can send broadcast messages visible to one another, they can establish communications if they want; if my client colludes with someone, they can snoop on the channel without anyone else being able to find out that they are there; and if my client colludes with someone, my client can tell them all the people I'm talking to. So, in the framework above, there's no way to enforce either a policy of anonymity or the opposite in the protocol; the question is just what the default and advertised policy should be.

I think I will start with revealing the truenames of everyone on the channel --- truenames being something like "ksitaker on AOL" --- because it has four advantages. It makes it difficult to censor or falsify the utterances of a particular person when others can contact them directly; it can allow the channel to heal when somebody goes offline unexpectedly; it facilitates side-channel conversations; and it reduces the probability of accidentally saying something in front of the wrong person.

The conversations ought to be private, in the sense that the default should be that chat lines aren't transmitted unencrypted and aren't forwarded to unannounced third parties.

The encryption is a bit tricky. There are three straightforward possibilities:

- Encrypt point-to-point between connected clients;
- Encrypt each message with a fresh "session key" and include copies of the "session key" encrypted with the public key of each participating client;
- Negotiate a shared "session key" periodically (at least every time group membership changes) and encrypt all messages with that.

Solar system scale model

Kragen Javier Sitaker, 2017-04-18 (1 minute)

Suppose you wanted to build a scale model of the solar system at manageable scale. For example, 5 meters in diameter.

You probably have to include at least out to Neptune. The Oort Cloud maybe isn't really necessary. But omitting Neptune would be unreasonable. Neptune orbits at 30.1 AUs, and if your model only has one side of the solar system, then you could make 30.1 AUs correspond to 5 meters.

30.1 AUs is 4.5e12 meters, so the scale of the model is about 1e12:1. At this scale:

• Sun diameter: 1.4e9 meters becomes 1.4 mm (visible with the naked eye!)
• Earth diameter: 13e6 meters becomes 13 microns (will require a microscope)
• Earth orbital radius: 150e9 meters becomes 150 mm
• Jupiter diameter: 140e6 meters becomes 140 microns (visible with the naked eye, barely, but with a microscope you should be able to see the Great Red Spot)
• Jupiter orbital radius: 5.2 AU, 780e9 meters becomes 780 mm
• Neptune diameter: 25e6 meters becomes 25 microns (pretty much still requires a microscope)

It would be super awesome if you could continuously maintain a carbon arc or something similarly bright at the position of the Sun, so that you could see what the Sun looks like from different distances. This might be kind of dangerous though.

Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection

Kragen Javier Sitaker, 2019-06-16 (updated 2019-07-05) (39 minutes)

Windowing the results of the Goertzel algorithm, or the Minsky circle algorithm applied as a frequency detector, over different-sized windows, can provide frequency detection with variable levels of precision. Some kinds of PLLs can be used in the same way, and you can adapt the Goertzel algorithm or the Minsky algorithm into a PLL. The Hogenauer-filter approach can provide very nice windows very cheaply.

The Minsky algorithm applied as a frequency detector in the most obvious way turns out to be precisely equivalent to the Goertzel algorithm applied to the backward differences of the input signal.

This is a continuation of the exploration I began in Cheap frequency detection (p. 3026), but this note stands on its own, which is to say that it duplicates a lot of the material in that other note.

The Goertzel algorithm and windowing it with prefix sums

The Goertzel algorithm accumulates a sequence of values with a resonant frequency: $s_n = (2 \cos \omega)\, s_{n-1} - s_{n-2} + x_n$. You can verify that, if $x_n = 0$, this holds true of the sequence $s_n = a \sin(\omega n + \varphi)$ for any a and φ. First, consider the case $a = 1$, $\varphi = 0$, and suppose that it's true of s_j for all $j < n$; does it then hold true at n?

$$s_n = (2 \cos \omega)(\sin(\omega(n-1))) - \sin(\omega(n-2))$$

The formula above is a little more symmetrical if we rewrite it with $m = n - 1$:

$$s_{m+1} = (2 \cos \omega)(\sin(\omega m)) - \sin(\omega(m-1))$$

If you don't remember angle-sum formulas from high-school trigonometry, you can trivially rederive them from Euler's formula $e^{it} = \cos t + i \sin t$; if $t = h + j$, this becomes $e^{ih}e^{ij} = (\cos h + i \sin h)(\cos j + i \sin j) = (\cos h \cos j - \sin h \sin j + i(\cos h \sin j + \sin h \cos j))$, so $\cos(h + j) = \cos h \cos j - \sin h \sin j$, and $\sin(h + j) = \cos h \sin j + \sin h \cos j$.

Here, we're interested in these identities:

$$\sin(\omega(m+1)) = \sin(\omega m + \omega) = \sin(\omega m)\cos\omega + \cos(\omega m)\sin\omega$$
$$\sin(\omega(m-1)) = \sin(\omega m - \omega) = \sin(\omega m)\cos\omega - \cos(\omega m)\sin\omega$$

The second one gives us

$$\begin{aligned} s_{m-1} &= (2\cos\omega)(\sin(\omega m)) - \sin(\omega m)\cos\omega + \cos(\omega m)\sin\omega \\ &= (2\cos\omega)(\sin(\omega m)) - \cos\omega\sin(\omega m) + \cos(\omega m)\sin\omega \\ &= \cos\omega\sin(\omega m) + \cos(\omega m)\sin\omega \end{aligned}$$

which above is established as the value of $\sin(\omega(m+1))$, so $s_{m+1} = \sin(\omega(m+1))$.

To establish that this is true for all values of a and φ, we can simply

note that this is a linear time-invariant recurrence:

$s_n = (2 \cos \omega)\, s_{n-1} - s_{n-2} + x_n$

m or *n* does not enter into it except as an index, and the output on the left is linear in all the inputs on the right.

This is the unique way to get a sine wave of a fixed angular frequency ω as such a linear recurrence on the two previous terms, $\sin(\omega n) = s_n = a s_{n-1} + b s_{n-2}$; that is, if you solve that equation for *a* and *b*, the only possible values for *a* and *b* are $2 \cos \omega$ and -1.

I think it's somewhat trickier to show is that, if $s_0 = s_1 = 0$, s_n and s_{n-1} form a linear encoding of $\Sigma_j x_j \mathrm{cis}(\omega j)$ for $j \in [2, n]$. But it's true; unless I'm confusing something, $\Sigma_j x_j \mathrm{cis}(\omega(n-j)) = \gamma_k = s_k - \exp(-i\omega)\, s_{k-1}$. s_k is, of course, a linear function of any such previous sequence of s_n, s_{n-1} and the x_j since that point, since it's a linear function of x_k and s_{k-1} and s_{k-2}, which themselves are such a linear function.

The impulse response of this system makes it clear — an impulse in *x* will kick off a proportional sinusoidal oscillation in *s*.

So at any point along the accumulation of this sequence, we can extract the dot product between the complex exponential e^{ij} and the *x* samples so far. In effect, the Goertzel algorithm computes the prefix sum of a particular frequency component of our signal, just in a slightly obtusely-encoded form.

(Note that this is precisely one of the components of the Fourier transform of the signal over that interval.)

Using s_k as a prefix sum to rectangularly window a frequency component

This means that, if we want to know how much of a particular frequency was present during a given time interval, and we've saved off the s_k values for that time interval, we can just do the γ_k calculation for the two points above, perhaps apply a rotation to bring them into phase (if they aren't separated by an integer number of cycles), and take the difference. (This assumes that we aren't getting rounding errors, but since we're essentially computing a sum table here, our *s* values will grow without bound if the signal *x* contains a nonzero frequency component at the frequency of interest. As with Hogenauer filters, it might be wise to do the calculation in purely integer math to avoid this.)

This subtraction amounts to temporally windowing the signal with a rectangular window. So it convolves the spectral response of the filter with the Fourier transform of that rectangular window, which is a sinc. So, by using different widths of window on *the same* s_k *signal*, we can get different levels of frequency selectivity. And in fact we can do this with only a single multiply-subtract and addition per sample (since the factor $2 \cos \omega$ is fixed as long as we don't change the frequency), even though we're pulling out a number of different window widths from that single resonator.

Goertzel without multiplies and A440 even temperament

The multiply-subtract $(2 \cos \omega) s_{n-1} - s_{n-2}$ can, for some angles, be done with a couple of subtracts and bit shifts: $(s_{n-1} \ll 1) - (s_{n-1} \gg p) - s_{n-2}$. This works when $2 \cos \omega = 2 - (1 \gg p)$ and thus $\omega = \cos^{-1}(1 - (1 \gg (p+1)))$. This gives the following periods for shift lengths from 0 to 20 bits:

```
>>> 360/(numpy.arccos(1-2**-(1 + numpy.arange(20.0)))*180/numpy.pi)
array([    6.        ,     8.69363162,    12.43307536,    17.67813872,
          25.06699928,    35.49668062,    50.23272124,    71.06297418,
         100.51459792,   142.16068241,   201.05374803,   284.33872284,
         402.11976897,   568.68612356,   804.245674  ,  1137.37658591,
        1608.49441598,  2274.75534121,  3216.99036595,  4549.51176711])
```

For the particular case of 44.1-ksps audio, these work out to the following frequencies in Hz:

```
>>> 44100/(360/(numpy.arccos(1-2**-(1 + numpy.arange(20.0)))*180/numpy.pi))
array([ 7350.        ,  5072.67870839,  3546.99048555,  2494.60651377,
        1759.28516646,  1242.3696873 ,   877.91381613,   620.57633403,
         438.74224154,   310.21235444,   219.34433171,   155.09670846,
         109.6688186 ,    77.54717088,    54.83399094,    38.77343753,
          27.41694317,    19.38670028,    13.70846505,     9.69334783])
```

These are far closer to A440 musical note frequencies than we would have any right to expect; 438.7 Hz is about 5 cents flat of A_4 (A above middle C), and 877.9 is only about 4.1 cents flat of A_5, and the frequencies that are not As are even-tempered D♯/E♭ notes. It crosses over from being sharp to being flat in between 2494 and 3546 Hz, precisely where the human ear is most perceptive.

Better windows through Nth-order prefix sums

Usually we don't think of sinc as being a very good filter frequency response, because well into the stopbands, you keep getting these response peaks where an odd number of half-waves fit into your window. The Hogenauer-filter approach to solving this problem is to use N levels of sum tables to get an Nth-order approximation of a Gaussian window, which in theory has the optimal tradeoff between frequency precision and temporal precision — the minimal joint uncertainty, according to the uncertainty principle. If we consider the γ_k given above as representing values in a complex-valued sum table, we could compute running sums (prefix sums) of them to get Nth-order prefix sums, which we can then differentiate N times in the usual CIC-filter way to get a given frequency component with that window.

But calculating the γ_k is considerably more expensive than calculating the s_k: $\gamma_k = s_k - \exp(-i\,\omega)\,s_{k-1}$, so while calculating s_k required a single *real* multiply, addition, and subtraction (presuming all real x_j), calculating γ_k requires a *complex*–real multiply and then a complex–real subtraction: two real multiplies and a real subtraction, which is twice the multiplies. Normally we sweep this under the rug by presuming that we only calculate γ values occasionally, so this expense doesn't matter, but to compute the prefix sum ($+\backslash\gamma$, in APL notation) we would need to do those multiplications for every sample, and then it would matter. Also, computing complex prefix sums would involve twice as many real additions as computing real prefix sums.

But in fact we can avoid this hassle; $\Sigma_k\gamma_k = \Sigma_k(s_k - \exp(-i\,\omega)\,s_{k-1}) = \Sigma_k s_k - \exp(-i\,\omega)\Sigma_k s_{k-1}$, so we can do that whole computation using a sum table for s which we use twice, instead of computing separate real and imaginary Nth-order sums. Then we can compute a γ value windowed with an Nth-order approximation to a Gaussian window

using N real subtractions, a complex–real multiply, and a real subtraction. The same Nth-order sum table will serve for any window size. XXX is this right? Or do we need to either do N subtractions per sample or N(N-1)/2 subtractions per output? Or maybe decimate by the window width M and then do the N subtractions once every M samples?

Roundoff

However, this surely requires special measures to avoid roundoff for the Hogenauer-filter part of the computation; the values in a third-order sum table, over an interval where the signal is roughly constant, will grow proportional to the cube of the constant value. The standard approach is to implement Hogenauer filters using integer arithmetic with wraparound, thus entirely eliminating rounding error. Maybe an alternative exists, representing the sum tables using the tree constructed in the standard parallel prefix-sum algorithm, so that the values being added at each tree node are of comparable size and roundoff lossage is insignificant; but I suspect you need to traverse the tree at subtraction time, adding a logarithmic slowdown, and I'm not sure how this generalizes to second-order and higher sum tables.

Even without sum tables, it's a frequently noted observation that the Goertzel algorithm is prone to numerical error.

Frequency detection

So you could imagine using this approach to narrow down the frequency range where a particular signal might be in your input: first use very short windows to see if there's anything in the frequency range at all, then use longer windows at a larger number of frequencies (some of which might be the same frequency — just using the same prefix sums with a longer window width) to figure out where the signal or signals might be inside that window.

Alternatively, if your signal is sparse enough in frequency space, you can use a temporal window size long enough that only one significant frequency component will be within the corresponding frequency window, and then use its successive phases in successive overlapping windows to determine its real frequency, the way a phase vocoder does. So, for example, in The Bleep ultrasonic modem for local data communication (p. 966), I want to detect tones at 17640 Hz and 19110 Hz. I could very reasonably use the Goertzel algorithm with a frequency window centered on 18375 Hz, whose beat frequency with either 17640 or 19110 Hz is 735 Hz; that means that every 1.36 milliseconds (60 samples at 44.1ksps) the phase relationship between the reference frequency and the real frequency will shift by 90°. So if I perform Goertzel for that frequency over nominally 15-sample windows, I should get a nice clear phase that I can unwrap. I haven't tried this yet.

(18375 Hz is 2.6180 radians or 150° per sample, so the Goertzel recurrence becomes roughly $s_n = -1.732\ s_{n-1} - s_{n-2}$.)

Alternatively, suppose I'm trying to detect the tune I'm whistling as in Whistle detection (p. 357), in the band 600Hz to 1600Hz. Typically if I'm whistling it'll be the loudest sound in that band, maybe 20 to 40 dB louder than anything else nearby. Suppose we have a whistle at 1477Hz and we're trying to detect it by windowing a

1400Hz Goertzel filter; we'll get a phase spinning around the circle at 77Hz. So if our window mostly averages over, say, 3 ms (4.2 cycles of the 1400Hz reference), the phase will rotate around almost one quadrant, attenuating the phasor's average magnitude by about √2, or 1.5 dB. By unwrapping the phase (again, like a phase vocoder) we can determine the beat frequency and phase direction, and thus the real frequency. So windowing a single Goertzel filter about 500 times a second covers about 200Hz of bandwidth, so about five or ten of them should cover the whole band of interest.

As long as the window is pretty close to Gaussian, there's a relatively precise reciprocal relationship between the bandwidth and necessary number of windows per second for each filter. Using a window that's half as long requires us to use twice as many windows per second, but also covers twice the bandwidth in a single filter, so we need half as many filter center frequencies. In the limit, where our windowed filter kernel is just an impulse, we're just trying to "unwrap the phase" of individual samples (or perhaps pairs of samples, since y_k uses s_{k-1} as well). At the other extreme, with a very large number of very narrow frequency bands, each with windows tens or hundreds of milliseconds long, we only need check each band every hundred or more milliseconds, but we start losing temporal precision.

But at that point, wouldn't it be faster to window a downconverted signal and do a Fast Fourier Transform? Then we only have to do O(lg N) work per sample to get each of N frequency bands instead of O(N) work.

(Perhaps the best way to understand the CIC-windowed Goertzel filter in this context is precisely that it's providing a windowed downconverted signal, which we can then Fourier-transform if we like?)

In one line of C

Here's a one-line obfuscated C program from Cheap frequency detection (p. 3026) that generates a sine wave using Goertzel's algorithm:

```
main(s,t,u){for(t=32;u=s,1+putchar(128+(s-=t-s+s/8));t=u);}
```

If you compile it to an executable called `goertzel` on a Linux machine with ALSA or an ALSA emulation, you can run it with the command `./goertzel | aplay`.

(`arecord` and `aplay` default to 8000 unsigned 8-bit samples per second, which is convenient since it means we can use `getchar()` and `putchar()` to read and write samples.)

The Minsky algorithm

One way to think of the Goertzel algorithm's oscillator is by linearly extrapolating to the current sample, then subtracting a second-order correction to make it curve back towards zero at the desired frequency.

$$s_n = (2 \cos \omega)\, s_{n-1} - s_{n-2}$$
$$= s_{n-1} + (s_{n-1} - s_{n-2}) - 2(1 - \cos \omega) s_{n-1}$$

In essence, it's calculating the desired second derivative by multiplying a small negative number, $-2(1 - \cos \omega)$, by the latest

sample. While this is in theory exactly correct, it's easy to see that it could give rise to significant roundoff errors for sufficiently low frequencies. In the limit, where cos ω rounds to 1, it will stop oscillating entirely and merely linearly extrapolate. For angular velocities ω approaching 0, $1 - \cos\omega = \frac{1}{2}\omega^2 + O(\omega^4)$, which is why changing this correction by factors of 2 in the above note about multiplication-free Goertzel resulted in changing the frequency by roughly half an octave.

(However, don't be misled into thinking that this means Goertzel is merely a quadratic approximation that will fail at high frequencies. As shown earlier, if performed with exact arithmetic, it's exact.)

The Minsky algorithm is similar to the Goertzel algorithm, but while the Goertzel algorithm effectively calculates the current derivative of the oscillation from the difference between the last two samples, the Minsky algorithm reifies the first derivative as a separate variable:

$$s_n = s_{n-1} + \varepsilon c_{n-1} + x_n$$
$$c_n = c_{n-1} - \varepsilon s_n$$

XXX why does LaTeX give you a lunate epsilon ϵ by default, reserving normal epsilon for \varepsilon? Should I be using ϵ here?

This requires two real multiplications per input sample instead of Goertzel's one multiplication, but I hypothesize that it should have a smaller roundoff error; $\varepsilon \approx \sin\omega$, which means that for small angular velocities, it's proportional to the angular velocity rather than (as in Goertzel) the square of the angular velocity. So sometimes you can get more accurate results with Minsky.

ε is not precisely sin ω; more precisely, $\omega = 2\sin^{-1}(\varepsilon/2)$, so $\varepsilon = 2\sin(\omega/2)$, as explained in Cheap frequency detection (p. 3026) and *Minskys and Trinskys* and roughly in HAKMEM. For small angles, the approximation is very close.

One reason for roundoff error in Goertzel is that the energy of the resonator *s* alternates between being in the (square root of the) velocity — that is, the difference from one sample to the next — and being in the (square root of the) displacement — that is, the value of the latest sample. When the frequency is in the neighborhood of one radian per second, this doesn't cause much error, but for very low frequencies, the velocities, measured from one sample to the next, can be very small compared to the sample values. For one milliradian per sample, for example, at angles $\pi/4 + n\pi/2$, the velocity and the displacement are both at $\sqrt{2}$ of their maximum value, but the velocity there is 1000 times smaller than the displacement. So if you have eight decimal digits of precision, like a 32-bit IEEE-488 float, your velocity only has about five decimal digits of that precision, which means that every half cycle your signal has been rounded to five decimal digits. The Minsky algorithm doesn't have this problem in this form, since *s* and *c* are of similar magnitude, but it might have a similar problem in that the increments being added to *s* and *c* are potentially very small compared to their magnitude.

Both Minsky and Goertzel are stable, in the limited sense that they don't go to infinity over an infinite interval when the input is zero, if computed without roundoff. (They are *not* BIBO stable, of course.) The argument that Minsky is stable is that we can rewrite the above system as follows when $x_n = 0$:

$$s_n = s_{n-1} + \varepsilon c_{n-1}$$

$c_n = (1 - \varepsilon^2)c_{n-1} - \varepsilon s_{n-1}$

In Unicode-art matrix form:

```
⎡ sn ⎤ = ⎡  1    ε   ⎤ ⎡ sn-1 ⎤
⎣ cn ⎦   ⎣ -ε  1-ε² ⎦ ⎣ cn-1 ⎦
```

The determinant of that matrix is precisely 1. (XXX but its L^∞ norm is 1+ε; what's up with that?)

In a sense, s_n and c_n are temporally offset from one another by half a sample, and we are thus doing leapfrog integration of the harmonic-oscillator ODE $\ddot{s} = -\varepsilon s$. For slow oscillators, this is a small difference, so $s_n^2 + c_n^2$ is a fairly precise estimate of the energy in the system, but for fast oscillators it can be a large one. I think *Minskys and Trinskys* has calculated the exact expression for the correction, but I can't remember.

(It's easy enough to add an exponential decay to either Goertzel or Minsky, which results in the system state at any given time being an exponentially-windowed filter of the frequency of interest, but here I'm focusing on the prefix-sum-based approaches because I think they can produce nicer windows almost as cheaply.)

The Minsky algorithm in one line of C

Here's a one-liner obfuscated C Minsky-algorithm audio oscillator I wrote in 2017:

```
main(x,y){for(y=100;1+putchar(x+128);x-=y/4,y+=x/4);}
```

You can pipe it to `aplay` just as with the above Goertzel program. The tone is agreeable.

Varying ε, and efficiency

The canonical form of Minsky's algorithm above uses the same ε in both steps, but as is done in *Minskys and Trinskys*, you can scale c up and down relative to s by using a separate δ:

$s_n = s_{n-1} + \varepsilon c_{n-1} + x_n$
$c_n = c_{n-1} - \delta s_n$

(Here I have the ε and δ backwards from the use in Cheap frequency detection (p. 3026).)

If we're only interested in how s behaves, and $c_0 = 0$, then it turns out that only the product δε matters; if we vary δ while holding δε constant, the c_n values get scaled up or down by δ, but the sequence of s_n remains constant, barring roundoff errors. In particular, as explained in Cheap frequency detection (p. 3026), we can choose $\delta = 1$ or $\varepsilon = 1$. Say we choose $\delta = 1$; to get the same angular velocity of ω radians per sample, $\varepsilon = 4 \sin^2(\frac{1}{2}\omega)$. So our new equations are:

$s_n = s_{n-1} + (4 \sin^2(\frac{1}{2}\omega))c_{n-1} + x_n$
$c_n = c_{n-1} - s_n$

So now we need one subtraction, two additions, and a multiplication per sample. The Goertzel algorithm requires one subtraction, one addition, and a multiplication. So our multiplication penalty has disappeared, but I think the rounding-error advantage has disappeared with it: c can now have peak values much larger or smaller than s, so we can lose precision when energy moves from one to the other.

If we instead choose $\varepsilon = 1$, we get this equivalent version:

$$s_n = s_{n-1} + c_{n-1} + x_n$$
$$c_n = c_{n-1} - (4 \sin^2(\tfrac{1}{2}\omega))s_n$$

We can reverse the order of the updates, as is usually done, which shifts the indices of c by 1:

$$c_n = c_{n-1} - (4 \sin^2(\tfrac{1}{2}\omega))s_{n-1}$$
$$s_n = s_{n-1} + c_n + x_n$$

We can expand this out a bit:

$$c_n = c_{n-1} - (4 \sin^2(\tfrac{1}{2}\omega))s_{n-1}$$
$$s_n = (1 - (4 \sin^2(\tfrac{1}{2}\omega)))s_{n-1} + c_{n-1} + x_n$$

This is looking suspiciously familiar! What is $4 \sin^2(\tfrac{1}{2}\omega)$, anyway? Well, $\sin(\tfrac{1}{2}\omega) = \pm\sqrt{(\tfrac{1}{2}(1 - \cos \omega))}$, so it ends up being $2 - 2 \cos \omega$. Which means that this is actually:

$$s_n = (-1 + 2 \cos \omega)s_{n-1} + c_{n-1} + x_n$$

If we want to express this purely in terms of s, we need to eliminate c_{n-1}. Since $s_n = s_{n-1} + c_n + x_n$, $s_{n-1} = s_{n-2} + c_{n-1} + x_{n-1}$, so $c_{n-1} = s_{n-1} - s_{n-2} - x_{n-1}$. So we have

$$s_n = (-1 + 2 \cos \omega)s_{n-1} + s_{n-1} - s_{n-2} - x_{n-1} + x_n$$
$$s_n = (2 \cos \omega)s_{n-1} - s_{n-2} + x_n - x_{n-1}$$

We have the not entirely unexpected result that using Minsky's algorithm in this way as a signal filter is equivalent to using Goertzel's algorithm on *the backward differences of* the input signal, which in this context can be understood as a high-pass prefilter introducing a 90° phase shift.

Since the tricks we were playing with scaling c up and down don't affect the sequence of values in s, this result applies to using the vanilla form of Minsky's algorithm, too.

This means that if we want to precisely reproduce the results of Goertzel's algorithm using Minsky's algorithm in the straightforward way, we need to run Minsky's algorithm on *the prefix sum of* the signal. This may be a practical problem in situations where using a prefix sum may result in roundoff errors. Perhaps adding the input samples into c instead, while still reading the output from s (updated after c) would solve that problem? XXX investigate further.

A PLL in one line of C

In 2012, after struggling with software PLLs ("SPLLs") for a while, I wrote this obfuscated one-line first-order PLL in C:

```
main(a,b){for(;;)putchar(b+=16+(a+=(b&256?1:-1)*getchar()-a/512)/1024);}
```

If you compile it to an executable called `tinypll` on a Linux machine with ALSA or an ALSA emulation, you can run it with the command `arecord | ./tinypll | aplay`; it tries to emit a tone that tracks the pitch of your voice, but one octave higher. This works better with headphones, so that the microphone isn't picking up the tone it's emitting.

This isn't a very good PLL, but I think it's an excellent way to show the anatomy of a PLL. It contains two continuously-varying state variables, `a` and `b`. `b`, or rather the low 9 bits of `b`, is the phase accumulator of an oscillator, while `a` is the low-pass-filtered error from the phase detector.

When the program gets an input sample with `getchar()`, it feeds it into a "chopper":

```
(b&256 ? 1 : -1) * getchar()
```

Since the low 9 bits of `b` are the phase accumulator for the oscillator, its bit 8 tells us which half of the oscillation we're in. And, as the oscillator alternates between the halves, it either inverts the input signal, or it doesn't.

How does that chopper compute a phase error? Well, if we suppose that the input signal is an oscillation whose frequency is close to that of the PLL's oscillator, then the sum of that chopped signal over a whole cycle tells us the relative phase. If the two oscillations are perfectly in phase, then we're inverting precisely the negative part of the input signal, and so we get a large positive number. If they're perfectly out of phase, then we're inverting precisely its positive part, so we get a large negative number. And if they're in perfect quadrature, then the samples we inverted are half negative and half positive (and cancel each other out), and so are the samples we didn't invert, so we get zero. If there's a small phase error from quadrature, say so that we're inverting a little more of the negative signal than the positive one, we'll get a small negative number. And any DC bias cancels out.

So a sum over a whole oscillation of this chopped signal gives us some kind of indication of how far away we are from quadrature, and close to quadrature it's linear. So naturally the next thing we do is to add that phase-error sample into our phase-error accumulator:

```
a += … - a/512
```

To sum over precisely a whole oscillation would require keeping in memory an array of values to run a rectangular window over, so here we just use an exponential filter with a time constant of 512 samples, which is 64 milliseconds. (This is guaranteed to be several cycles long over the frequency range we can reach here.) Note that this also means that the magnitude of `a` is about 512 times bigger than the chopped input samples getting fed into it — if our average phase error is about 3 per sample, say, then `a` reaches a steady state at $a \approx 1536$.

So, then we want to drive our oscillator at a frequency that depends on this filtered phase error:

```
b += 16 + (a …)/1024
```

If our input signal is always 0, `a` will decay to 0, and this simply reduces to `b += 16`, which means it will reach 512 and its low 9 bits will wrap around every 32 samples, which is 250 Hz. So that's the "natural frequency" of the chopping. But if `a` is in the range, say, 1024 to 2047, then this is `b += 17` and it pitches up to 265 Hz. On most systems C division rounds towards 0, so if `a` is slightly negative, it doesn't lower the pitch, but once it gets to -1024, the pitch drops to 234 Hz.

So if you're screeching at your computer at 234 Hz, the chopper will initially drift in and out of phase with your screech 16 times a second, but if it ever manages to accumulate a phase error of -1024 in `a`, it enters a steady state where it's chopping your signal just enough out of quadrature to maintain that -1024. If it falls behind your screeching, `a` will decay and the chopping will speed up until `a` is

growing again, and if it gets ahead of your screeching, `a` will grow to an even more negative value and its chopping will slow down.

This sounds ridiculously crude, but there's a certain amount of noise on `a` from the regular increases and decreases of the phase error accumulator four times per cycle (about every 8 samples), plus actual signal noise, so it works better than you would think. Not that well, but better than you'd think.

Finally, it emits an output tone:

```
for (;;) putchar(b…);
```

This is the low 8 bits of the 9-bit phase accumulator in `b`, so it produces a triangle wave at twice the chopping frequency, so, in the neighborhood of 500 Hz. Triangle waves sound really harsh, but because they're so harmonics-rich, they make it easier to hear pitch changes than smoother waveforms would.

Notes on SPLLs in general, and using real sinusoids with them

The ramp up and down of the phase error accumulator at twice the frequency being detected is called "VCO control line ripple" or "reference spurious" in analog PLLs. This is often a thing you want to minimize, though in this case the noise it adds probably improves system performance through stochastic resonance. You could notch-filter this frequency out with a simple feedforward comb filter by the simple expedient of averaging two samples from the phase error signal half an oscillation apart (adjusting this, ideally, to the current oscillation frequency); or, since doing this requires a table of past phase-error samples anyway, use a prefix sum to calculate a simple moving average, a box filter, of that width, and dispense with the exponential. Box filters have a better noise-suppression/tracking-latency tradeoff than exponentials anyway.

I think there's an even simpler solution, though: in a digital system, it probably isn't necessary to update the phase error after every input sample anyway; you can do that processing at a lower sample rate, which filters out fast oscillations by construction.

Although the overall system isn't linear, it has a lot of linear pieces in it. This phase detector, for example, produces an output signal that's proportional to the amplitude of the waveform it's locking onto. If the waveform is near a local extremum where it gets chopped from negative to positive, then the phase-detector output is also locally linear in the phase error. The chopper frequency shift is linear in the filtered phase error signal, and the exponential filter on that signal is linear and time invariant.

Each of these components — the phase detector, the feedback-loop low-pass filter, the variable-frequency oscillator, and the feedback path from the oscillator to the phase detector — has lots of possible realizations. This particular phase detector is called a "type I" phase detector, but there are also "type II" phase detctors. And there are higher-order PLLs, which I don't understand at all. I'm pretty much just sticking to basic PLLs here because that's all I understand at all.

Chopping with a square wave means your PLL is sensitive not only

to its nominal frequency but also its odd harmonics. There are cases where this doesn't matter, but in particular if you're doing this on a sampled signal, the odd harmonics can alias down to other strange frequencies. In my 18375-Hz example above, for example, the third harmonic would be 55125 Hz — probably heavily attenuated by the antialiasing filter on your sound card, but at 44.1ksps, it aliases down to 11025 Hz. The fifth harmonic is even worse: it aliases to 3675 Hz. (Subsequent harmonics repeat this cycle backwards and forwards.)

And, indeed, that's what you see if you analyze the output of this program:

```
#include <stdio.h>
int i;
int main(){for(;;)putchar(i++*18375*16/44100&8?0:128);}
```

Feed it to `head -c 44100 | sox -r 44100 -t raw -u1 - sqwv.wav`, hit ^C, run `audacity sqwv.wav`, and plot the spectrum, and there are three sharp peaks at 18375 Hz, 11025 Hz, and 3675 Hz, just as predicted. And if you were multiplying that oscillation pointwise by an input signal to try to do phase detection, you'd be detecting all three of those frequencies, too.

So you may actually prefer to multiply by a real sine wave at the frequency of oscillation, which of course is what the Goertzel and Minsky resonators do; they also both have the advantage that they can give you a phase readout fairly directly, rather than using these subtle arguments about halves of chopped waves canceling each other out. But to use them for this application, you need to be able to adjust their resonant frequency.

A thing to notice is that, in this single-line SPLL, there's nothing left over that tells you if you actually have a signal or just silence. `a` will be 0 if you're perfectly locked onto a strong 250-Hz signal or if the signal is all zeroes. `a` might be 2048 because it's locked onto a really strong signal around 281 Hz, or a weak one, or because it's randomly being buffeted by strong random noise. To get the signal amplitude, you can chop the input signal with a second chopper in quadrature with the one you use for phase detection; this chopper will be in phase with the input signal instead of in quadrature with it, and so it amounts to synchronous rectification of the input signal. (The Goertzel or Minsky approach does this implicitly.)

This in-phase-chopped signal gives you the amplitude of the oscillation at the frequency of interest (and, as noted above, potentially some other frequencies too). Earlier I had suggested using a box filter in the feedback path to eliminate phase-error ripple, using a prefix sum calculated over some segment of the quadrature-chopped signal. By computing an analogous prefix sum of the in-phase-chopped signal, you can enable the same kind of after-the-fact frequency selectivity described in the earlier sections about fixed-frequency Minsky and Goertzel resonators: by subtracting two nearby samples on the I-chopped and Q-chopped prefix sums, you can detect signals over a wider bandwidth, or by subtracting prefix-sum samples with a large lag between them, you can detect them over a very narrow bandwidth. For better or worse, your detection band chirps along with your PLL oscillator.

There is presumably no PLL equivalent to the phase-vocoder-like

use of the fixed-frequency oscillators that I mentioned above, since the whole point of using a PLL is that it finds the frequency of the signal of interest and follows it.

Altering the frequency has some subtle effects which may introduce numerical errors here. As mentioned earlier, for fast Minsky oscillators, the half-sample offset between the two state variables becomes significant; altering the frequency will alter that relationship, and might rob energy from the system or add energy to it. Similarly, with Goertzel, lowering the frequency can add energy to the system, but won't always — it depends on what part of the oscillation *s* is in. (I don't know if it can also rob energy from it.) Presumably we can work out how to correct these errors.

Related work; contributions?

I ran across a 2015 paper by Sridharan, Chitti Babu, MuthuKannana, and Krithika entitled "Modelling of Sliding Goertzel DFT (SGDFT)…" which seems to have some things in common with the above. They're using a Goertzel oscillator in their PLL, but it isn't the oscillator; it's in the feedback path between the oscillator and the phase detector. They're also using a moving-average filter (a box filter). Moreover, they're using a PI controller in the loop to set the oscillator frequency in order to drive the phase error to zero (since their application is power grid synchronization), rather than the proportional control I used in the example above. As far as I can tell, by "SGDFT" they just mean the Goertzel algorithm.

I haven't found anybody talking about the relationship between the Goertzel algorithm and the Minsky algorithm, about using prefix sums to get variable tradeoffs between precision in the frequency domain and in the time domain without having to redo the multiplications, about using the Goertzel or Minsky algorithm as a combination phase-detector and oscillator in a PLL, or about the fortuitously nearly-A440 Goertzel frequencies we get with just a bit shift. I've never seen anybody talk about doing the Goertzel algorithm in wrapping integer math to avoid roundoff error (though, admittedly, it probably only makes sense in the context of Hogenauer-style windowing). I've never seen a discussion of using the Goertzel algorithm to detect a frequency *near* the target frequency and precisely identify it by unwrapping the phase. But it's possible that that's just because I'm just not that familiar with the literature. Or that the ideas are wrong.

However, most of the PLL and Minsky-algorithm and Goertzel-algorithm stuff is very well known. As far as I can tell, the relationship between the Minsky algorithm and the Goertzel algorithm hasn't been published, but quite possibly it's just too obvious to those skilled in the art to be considered novel.

Autism is overfitting

Kragen Javier Sitaker, 2019-08-31 (1 minute)

Many of the perceptual deficits of autism — difficulty recognizing familiar faces when a hat or beard is added or removed, stress and meltdown when facing departures from routines or minor changes in environment such as a book out of place on a bookshelf, memory of perceptual details neurotypicals don't notice or consider unimportant, difficulty distinguishing signals in the presence of background noise or environmental chaos, inflexible behavior — while commonly attributed to executive-function deficits, bear a suggestive similarity to a pathology in machine learning and in particular artificial neural networks called "overfitting", in which a learner adapts itself to particular examples from its training set at the expense of generalizability. Perhaps, at the human neural level, overfitting is a general mechanism that causes many of the different characteristic manifestations of autism.

Quasimode keyboard

Kragen Javier Sitaker, 2018-07-14 (24 minutes)

Jef Raskin invented the word "quasimode" to describe the user interface technique of setting a mode only as long as a certain key is held down, like Shift, Control, or ⌘. Quasimodes can multiply the expressivity of user interfaces without the usability problems created by full-blown input modes like Caps Lock or Vim's command mode.

I'm going to focus here on text editors, which (for better or worse) are the predominant medium for human expression through computers in 2018, whether you're typing a WhatsApp message, a Tweet, a Facebook status, a spreadsheet formula, or a YouTube comment. And I'm largely focusing on environments for computer programming, because those are the most expressive text editing environments.

Modes

Modes are a usability problem for a couple of reasons. First, because of "mode errors": if the consequences of an action such as pressing the "B" key depends on what mode you're in, and you don't know what mode you're in, you don't know what will happen when you take the action. (The classic example is when you can't figure out how to log in because your Caps Lock key is on when you're typing your password). Second, because of the "gulf of execution" — even if you know that the "B" key can cause the consequences you want in some mode, it can be hard to figure out how to get into that mode.

Emacs is mostly modeless in the sense that the same keys usually do the same thing; its "editing modes" usually have more effect on things like syntax highlighting and where the tab stops are than on what will happen if you press the "b" key, although there are exceptions. Vim, on the other hand, has a "normal mode" for most editing commands and "insert mode" and "replace mode" for actually writing stuff.

Quasimodes in common practice

Emacs uses quasimodes in its user interface to the extent that was possible with the "space cadet" keyboards that were common at MIT when it was designed in the 1970s and 1980s, which is to say that it uses "key chords". The "B" key, for example, inserts "b", except that if Shift is held, it inserts "B"; if Control is held, it moves to the left by one character; if Alt ("Meta") is held, it moves left by one word; if both Control and Alt are held, it moves left by one parenthesized expression; and if Shift is also held while using control-B ("C-b"), alt-B ("M-b"), or control-alt-B ("C-M-b"), the cursor movement creates or extends a text selection ("region"). So the "B" key can invoke eight different functions modelessly — or, let's say, quasimodally. But some of those functions require holding down as many as four keys at a time. This is commonly held to make Emacs a risk factor for repetitive stress injuries, although I don't know of any rigorous studies demonstrating this.

Space-cadet keyboards did not send any data when these

quasimode or "modifier" keys (Control, Meta, Shift, and also Hyper and Super) were pressed and released by themselves, nor when a modifier was released after pressing some modified keys. Neither did ASCII terminals of the 1970s and 1980s, and neither do ASCII terminal emulators today in 2018, 45 years later. Consequently, any editors that aspire to being used through such things are unable to take actions when a modifier key is initially pressed or when it is released, nor can they distinguish between, for example, holding Control and typing "XB" and separately typing control-X and then control-S, releasing Control in between. (Also, in ASCII terminals, the Control key collapses many characters together, typically three, so control-shift-b will do the same thing as control-b, and control-@ does the same thing as control-space, so keys distinguished only by such distinctions are typically assigned to less important commands.)

This means that some of the user-interface conveniences personal-computer users got used to during the 1980s are impossible to implement in this environment. For example, some MS-DOS programs display an on-screen menu listing the functions available on the various function keys, and the menu changes when Control, Alt, or both Control and Alt are pressed, displaying the function that will actually be invoked if you press, say, F8. Likewise, the Macintosh Key Caps applet displays a picture of the keyboard labeled with the characters that will be produced if you press a given key; the labels change if you press Shift or Option. And the task-switching key sequence in Microsoft Windows, introduced I think in Windows 95, cycles through the most-recently-used windows as long as you hold Alt and press Tab repeatedly; no window is activated until you release the Alt key.

The limits of key chording

Emacs and Vim both have a large number of commands. The Emacs I'm typing this in is currently configured with 14165 different commands, which is too many to assign to key chords on the keyboard — even if you have four modifier keys, so that each non-modifier key had 16 different chords, a 105-key keyboard would only have 1616 distinct chords in this way. Also, since the editor can't provide any visual feedback related to modifier keys that are currently held down, the memory load would be quite heavy. So, instead, they use three alternative approaches: prefix keys, a command line, and command mode.

Prefix keys

Prefix keys are sort of like modes that only last for a single keystroke. For example, in Emacs, as I said, control-B moves left by one character, and B by itself inserts "b". But control-X control-B opens up a window listing all the things that are open in Emacs, and control-X B prompts you for the name of the thing you would like to switch to. In effect, control-X puts Emacs into a mode which changes the effect of the next keystroke. Analogously, in Vim, typing "?" (as shift-/ on Qwerty keyboards) does a search backwards, but "g?" decrypts the current selection with the rot13 cipher. The "g" key puts Vim into a mode which changes the meaning of the next keystroke.

GNOME and Microsoft Windows applications can typically be

keyboard-operated by using the Alt key and a letter to select a pull-down menu, then further letters or arrow keys to select submenus or menu commands. This is also an implementation of prefix keys. It shows how modes can actually be more usable than having hundreds of commands on modified keys: it's feasible to display breadcrumbs and guidance.

However, prefix keys still cause mode errors, which are still frustrating, and even in the best cases, they don't help to reduce the gulf of execution much. Among the key sequences currently defined in my Emacs are things like control-X 8 / A (which inserts the letter "Å"), control-X control-K B (which binds the last-defined keyboard macro to a key or key sequence), control-X Enter shift-F (which changes the character encoding used for the filename of the currently open file), and over a thousand others, most of which I've never heard of even though I've been using Emacs almost daily for a quarter century. It can be hard to find out that these even exist, even though Emacs has an active community, comprehensive documentation, and many ways to explore and query.

Command lines

In Vim, you invoke the command line by typing ":"; Emacs has several command lines, including the Lisp command line invoked by alt-:, the editor-command selector invoked by alt-X, and the shell command line invoked by the command "shell". In Firefox and other web browsers, you type control-L or ⌘L to edit the URL, and in Gnumeric or Excel, you can invoke the command line with the F2 key or "=".

The command line is sort of a mode, but the B key generally causes a "b" to appear on the screen, just like in normal life, and the normal editing commands do normal editing things; the difference is that what you're editing is a command which will eventually be executed, usually when you hit Enter. Command lines can still cause mode errors where you want to be typing stuff into a document and you end up typing commands instead, but generally they support more usability features than prefix keys.

The "alt-:" command line in Emacs is for evaluating Lisp expressions, which can invoke editor commands, define new functions, or do useful computations. For example, I recently evaluated "(* 16 101)", the product of 16 and 101, to see how many commands a 105-key keyboard with four modifier keys could invoke. Earlier I evaluated "(+ (* 9 .40) (* 4 .59))", which calculated the BOM cost of a possible circuit design that used 9 chips that cost 40¢ and 4 chips that cost 59¢.

Emacs also supports a different way of evaluating Lisp expressions. Its `*scratch*` buffer is by default in an editing mode called "lisp-interaction-mode" in which the key chord control-J scans backwards from the cursor for a complete Lisp expression, evaluates it, and inserts the results into the buffer on a new line. So, instead of typing `alt-: (* 16 101) Enter`, you can switch to `*scratch*` and type `(* 16 101) control-J`, with the following result:

```
(* 16 101)
1616
```

In "lisp-interaction-mode", control-J is bound to the command "eval-print-last-sexp", which does what I explained above. Also, by default, throughout Emacs, control-X control-E is bound to "eval-last-sexp", which does the same thing except that it doesn't insert the result into the buffer. This is especially useful when you are programming in Emacs Lisp, because it allows you to point at pieces of your code and instantly run them to see if they do what you think they should.

This is a more modeless way of providing a command line; it was pioneered in Smalltalk, where "Do it!" and "Print it!" are commands available on key chords and on menus in every text editing window, and have been since the 1970s. These work on either the current selection or, if none, the current line, treating it as a Smalltalk sentence and inserting the result as a new selection. This is a little bit clumsier than the Lisp approach because Smalltalk sentences are not self-delimiting, but you also don't need it as often — my most common use of this facility in Emacs is to recompile a function I just edited so I can try it out, and Smalltalk has an even smoother way to do that.

However, in a sense precisely because it is more modeless, this approach to providing a command line has suboptimal usability. If I type `(* 16 101) control-X control-E` in this document, it isn't until the last chord that Emacs knows that `(* 16 101)` is intended as Lisp code. If I accidentally type `(*16 101)`, Emacs doesn't know to highlight `*16` as an undefined function until then. If I start typing `(backw` in this buffer and ask for completions of the partially-typed function name, Emacs doesn't know I'm intending to type Emacs Lisp and so can't complete that to `backward-` and list the 18 functions whose name starts with that. By contrast, in the alt-: command line, it can and does.

The alt-X command line in Emacs just allows you to select among the 14165 already-defined commands I mentioned earlier; if you select a command that needs arguments, it either obtains them from context (such as from the current selection) or prompts you for them afterwards (yet another mode).

The alt-X equivalent in Oberon is modeless; it works like the Smalltalk "Do it!" or Emacs `lisp-interaction-mode` — if you click a certain mouse button, it looks for a command name in the text around the point where you clicked, and if it names a procedure, it calls that procedure with no arguments. I think `File.save` is one example, although I don't have my Oberon book here (see A review of Wirth's Project Oberon book (p. 431) for my notes from reading it). The command is not permitted to prompt the user and await input, because Oberon is a single-threaded event-driven system, but it can do things like open a new window for further interaction and put more command texts into that window, or some other window.

Repetition and adjustment

If I want to type a line of asterisks on this Qwerty keyboard, it's pretty easy; I put my left pinky on a Shift key and bang on the 8 key with my right middle finger until I have the right number of asterisks, possibly adjusting at the end with a few backspaces if I overshot. By contrast, if I want a line of alternating periods and colons, it's a real pain to type by hand; I need to use my right ring finger on the period key and coordinate my two pinkies on the semicolon and Shift keys to

get the colon. Repeating a single key is much, much easier than repeating a two-key sequence, and repeating a sequence of a chord and a key is even harder.

Now, Emacs has a keyboard macro facility. Keyboard macros are good for repeating something a number of times. I can type “F3 .: F4”, with the F3 and F4 keys, to define a keyboard macro that inserts “.:”. The traditional key sequence to run the macro is control-X E, and it takes a count, so if I want a line of 20 of them, I can type “control-U 20 control-X E” and then add a trailing period:

.:.

The trouble is that it’s usually a real pain to figure out what 20 should be until you see it. (Why am I counting things when I have a computer to count things for me?)

Vim, and vi, were better at this; you could type “a.: Esc .....”, and each “.” you typed would append another “.:”. You could also type “a.: Esc 20.” or even “20a.: Esc” if you knew the count.

Emacs’s “indent-rigidly” command had the same problem; you had to figure out how many spaces you wanted to indent by ahead of time, say by multiplying 3 by 4 in your head, and type “control-U 12 control-X Tab”. Worse still was “undo”, which used to be just “control-X U”, and which you almost always want to repeat a difficult-to-calculate number of times.

Modern Emacs has a feature called “transient modes” or “transient maps” which temporarily change the meanings of only a few keys — like prefix keys, but leaving most of the key functions undisturbed. In particular, now you can type “control-X E E E” to repeat the macro three times: “.:.:.:”. (Also, you can type F4 to repeat a macro, and control-/ or control-_ to undo.) What they did with indent-rigidly is more interesting: now, if you just type control-X Tab without giving a count first, the right and left arrows indent and outdent the selected region by one space, or by a whole tab stop if you use shift. Because this mode only alters the meanings of a few keys, it rarely causes mode errors, but they do happen occasionally.

The interesting thing here is that these are ways of interactively and almost continuously varying a parameter in either direction while observing the results, much like Bret Victor’s “Kill Math” proposal (and some of his other ideas).

WordStar’s late-1970s approach to this problem, by the way, was interestingly different: you would ask it to start repeating a command, which it would do at a rate you could vary interactively with the keys 0 to 9, with a key to stop it — much like the autoscroll feature on some web sites. I suspect that this was not a viable approach on the timesharing machines where Emacs and vi were born because of the unpredictability of their response times and the high costs of context switches and terminal-screen repaints.

The Cat, LEAP and THE

The Canon Cat was a text-based personal computer whose user interface Jef Raskin designed after being pushed out of the Macintosh project at Apple. Among its daring user-interface innovations was that, not only did it have no mouse, it also had no vertical arrow keys. Instead, it had two “LEAP” keys, one for moving forward and one

for moving backward, which were quasimodal, like modifier keys, but for incremental text search, like Emacs's control-S and control-R commands. Like Emacs's control-R, when the search terminated, you would be left at the beginning of the search hit, but unlike Emacs, the search terminated when you released the LEAP key, making LEAP both faster to invoke and less error-prone — because it wasn't a mode.

Raskin claimed that experiments showed that it was substantially faster for navigating text than a mouse.

Canon mass-produced the Cat and sold a number of them, but it was pretty much a failure in the market. In later years, Raskin was working on an extended reimplementation of the concept as free software, called "The Humane Environment" or "THE", before being struck down with a few weeks' worth of warning by pancreatic cancer. THE never gained significant adoption and has largely been forgotten.

Thoughts about modifier keys for quasimodes

So, that's the historical background. Here's some wild speculation about how to apply it.

You can quite reasonably substitute quasimodes for the search modes used by Emacs and Vim; you could maybe control-F (for PARC bindings; control-S for Emacs bindings) to start a search, which would continue only as long as you held the control key. You wouldn't be able to disambiguate searching for control characters without some kind of additional escaping, but for the common cases of searching for Enter and Esc, both Vim and Emacs already need the additional escape sequence (control-V and control-Q respectively, or control-J to search for Enter in Emacs), so this would actually be an improvement. I'm not sure what to do for next and previous match other than arrow keys; maybe alt-K and alt-J.

For calculations — the thing I most use Emacs M-: for — an RPN calculator quasimode would be quite handy. You could type control-= to launch it, and it would persist as long as you held the Control key, fading away when released. Numbers would be pushed on the stack, separated by spaces; `*+-/^` would do their usual things, but `%` would do divmod; `,` could perform vector concatenation; `dxr` would dup, swap, and rotate; backspace would delete; `pqtscale` would compute π, square roots, tangents, sines, cosines, arctangents, logarithms, and exponentials; `i` would generate sequences; and `(` and `)` would respectively take numbers from the document you were editing and put numbers into it. So to double a number you would type `control-= (2*)`, although it might be snatched from somewhere other than where you were. The stack would remain persistent between invocations, and values on the stack would retain their provenance, operations being reversible with `z`. Vectors would be graphed by default, toggled with `g`. This would be substantially more convenient than the nonsense I'm using now with alt-: and running `units` in a shell.

More ideal still would be the ability to edit input values after the fact and watch the changes propagate, like in a spreadsheet. And it would be nice to have access to more mathematical functions than

there are letters, and to be able to search for them.

Of course, substituting a quasimode for the Emacs alt-X named-command invocation is straightforward; control-X would show you the available commands matching your search (and some kind of visualization of their results) and you could invoke one with Enter.

The Tab key is pretty much off limits for these things because both of my Control keys are on my left pinky.

Substituting a quasimode for the indentation stuff is also super easy; I'm currently using control-< and control-> for this, though control-H and control-L would work if I weren't using Emacs standard keybindings. Mouse movement might be best for providing the input for things like this, and also maybe navigating through undo history.

Some kind of thing that would insert a "form" into your current document, with like fields and stuff, would be super handy. Especially if you could like search through a list of currently defined forms and maybe fill in some fields with default values and already existing context data, and maybe have a command button or two to take actions that had side effects, and if the fields could recompute automatically and maybe satisfy constraints. And also if this was a generalization that included mathematical relationships (cylinder volume is $2\pi rl$, surface is $4\pi r + 2\pi rl$, from which you can deduce any two of those variables from the other two; see Relational modeling (p. 1102) for more thoughts on this) and values in mutable tables that you could assert and retract from. Maybe this is a different idea that doesn't really have to do with quasimodes at all.

Window switching, task switching, and so on is probably the most common fully-quasimodal keyboard interaction technique in use today, via the Microsoft Windows alt-Tab keybinding that has been widely adopted since then. The standard approach is to cycle through a least-recently-used list of windows, displaying thumbnails; the iswitchb-mode and ido-mode alternatives to this in Emacs are modal rather than quasimodal, but also winnow the list according to a search string as you type it. Now that I've been using iswitchb-mode for ten years (I'm trying ido-mode) this winnowing seems like the obviously right thing. But it would be better if it were quasimodal.

Similarly, term lookup (whether library functions, dictionary words, or Wikipedia articles) is a possible useful quasimode.

Multiple-cursor editing, as implemented in Sublime and IDEA, is arguably a "mode," but it may be difficult to make it a quasimode; it's sort of an alternative to keyboard macros, which means that you need to be able to use all the usual editing commands.

Mice, multitouch and quasimodes

I've focused on keyboard interfaces, but of course mouse drags and touchmoves are even more common interactions than switching windows with the mouse, and they're quasimodal. But I think quasimodes are even more promising for multitouch interaction than for keyboard interaction.

Improvising high-temperature refractory materials for pottery kilns

Kragen Javier Sitaker, 2013-05-17 (4 minutes)

We were talking today at a "natural construction techniques" workshop about how to build a ceramics-firing kiln. We'd spent the weekend making adobe from materials found onsite and making buildings out of it.

A pottery kiln needs to withstand heating to at least 1050° for earthenware and bricks, and at least 1200° for stoneware or porcelain.

The most common way to build a kiln is apparently by lining it with kaolin-derived refractory brick. But there's no kaolin in the native dirt on site. What could be done about that, aside from going to the ceramics supply store to buy some kaolin?

Well, it might be possible to extract kaolin from glossy paper; it's one of the two minerals used to give common magazine paper its gloss, the other being calcite. Or it might be possible to mill porcelain to powder (known as "grog" when it's sand-sized, or "pitchers" when coarser) and then sinter the powder. But I think wet milled porcelain powder isn't going to have the plasticity of kaolin. You'd have to stick it together with something that will hold it in place until it fires.

My first idea for such a binder was salt, because I had the mistaken idea that sodium chloride didn't melt until 1500° or so. But in fact its melting point is only 801°. But kaolin won't sinter until 1200° or more. It's possible that the salt-binder idea might happen to work --- if the salt lets the porcelain chunks sinter at a lower temperature, but doesn't flux them enough for them to melt entirely at the temperatures the refractory must withstand --- but it's likely to fail one way or the other.

A somewhat more likely binder candidate is simply the other clays available. You'd mix a small amount of clay into a large amount of milled porcelain.

You might be able to press the milled porcelain into bricks using something like a compressed-earth brick press, then firing the bricks. This way, the porcelain particles are in direct contact with each other, and there's no possible flux in the way. Achieving porosity might be difficult, because I think you couldn't simply mix in sawdust, the normal way; its elasticity would force the porcelain particles apart when you took the brick press. Charcoal or carbon black might work.

Another possible alternative would be to make the refractory bricks from some other mineral found onsite. Quartz, for example, is abundant almost anywhere, and if you can purify it and get it to sinter, its melting point is 1670°; in theory, you could also turn quartz and alumina into kaolin, but I have no idea how. ("Chemical weathering of rock", says Wikipedia. But what reactions chemically weather quartz and corundum into dust?) Magnesium oxide (periclase) might work? It doesn't melt until 2852°, and you can presumably make it from electrolyzed seawater, but I don't know

how to separate it out from dirt, or if it's common.

The traditional refractory used for gas lantern mantles is a mixture of uranium and thorium oxides, made from monazite, a common ingredient of sand. However, even if we could practically separate those out (separating the monazite should be easy because of its high density, but separating the rare earths involves lye and hydrochloric acid at above-boiling temperatures), people might complain that the furnace was too radioactive.

Calcium oxide (quicklime) doesn't melt until 2572° and would therefore work, and it's easily made by heating limestone to 825°, if there's limestone onsite, which there probably is. However, it's dangerously reactive with human bodies and other sources of water.

Magnetite is maybe the easiest mineral to separate out of sand. It oxidizes to hematite, ferric oxide, if heated with oxygen, and that doesn't melt until 1566°. I haven't heard of it being used for refractories, but it seems like it would work.

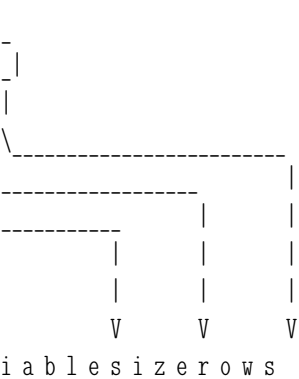
Raggedcolumns

Kragen Javier Sitaker, 2015-08-28 (3 minutes)

The standard C way of doing two-dimensional arrays accommodates two possibilities in the same syntax `c[i][j]`: arrays of arrays like `int c[10][7];` and arrays of pointers like `int *c[10];`. The first representation wastes no memory on pointers, but requires each row to be the same length, while the second one allows each row to be of a different length, but spends a pointer and often a dynamic memory allocation on each row. Also, it needs to store the lengths of the rows somewhere, unless they're NUL-terminated strings or something, which has problems of its own. So the overhead is something like two or three words per row.

Historically, array languages like APL and libraries like Numpy have preferred rectangular N-dimensional arrays rather than ragged ones. This isn't ideal for things like lists of strings, where each string may be of a different size. I've been thinking about how to extend array languages consistently to such objects, both in abstract semantics and in practical machine implementation.

Speaking of practical implementation, it occurred to me that if your N rows are stored one after another in a contiguous block, as in the C array-of-arrays case, but you have a pointer to the beginning of each one, as in the C array-of-pointers case, then for N+1 pointers, you can store N variable-size rows. Like this:



Here, we've stored four strings with no delimiters between them, with an array of five pointers. This allows optimally efficient multidimensional indexing with range-checking.

(As a digression, if you're really hard up for space, you could block the array into 16-string-or-so blocks, store an array of block start offsets, and store the 16 string lengths in another array, either limiting each individual string to 64KiB or 256 bytes or something, or using a variable-length encoding in the other array and an array of pointers to every 16th string length. Then a typical block of 16 short strings like the above will cost you about 64 bytes of string data, 4 bytes of offset into the array, 4 bytes of offset into the lengths array, and 16 bytes of string length data, for a total of 88 bytes. That is, assuming that no single array is over 4 GiB.)

This ragged-array thing can be multidimensional: you can store a list of variable-length lists of variable-length strings in the same way, with the first level of pointers pointing to the beginning of each string list pointer array, and the pointers in the string list pointer array pointing to the string starts. Only three allocations and all the lengths available at run-time.

Additionally, and importantly for use in array languages that tend to construct new large arrays by applying operations to existing large arrays, this multidimensional ragged structure can be constructed incrementally, one character at a time, without knowing ahead of time the size of any of the rows.

Clisweep

Kragen Javier Sitaker, 2018-06-06 (3 minutes)

The first relatively modern file manager I used was a thing on CP/M called "NSWEEP". Like the CP/M command line, it was designed essentially for a teletype interface, but it used a completely different paradigm, one rather similar to the Macintosh Finder, which I think came somewhat later: it displayed you a list of files (one at a time, normally), and you would issue it keystroke commands to invoke operations on the current selection — normally a single file, but optionally some set of "tagged" files. ("The selection" was not, I think, NSWEEP's terminology; it's the modern terminology.) To respect the speed limitations of the teletype interface, it would normally only display you a single filename after each action — most actions, including tagging and untagging, moved to the next file, but you could also move to the previous file. And, if I recall correctly, there was a command to list all the files (with asterisks to indicate whether they were tagged) without requiring keystrokes in between each one.

This was about halfway to the direct-manipulation noun-verb user interface the Macintosh Finder used, which was of course prefigured by GUI work on the Alto and Star at PARC, which probably preceded and may have inspired NSWEEP. You would first select the file you wanted to act on, perhaps by moving down to it one line at a time with keystrokes (I think Enter or N would move to the next file?), then invoke the action you wanted to invoke on it. The Unix editor `ed` worked fairly similar, but with lines of text in a file rather than entire files, and with less feedback by default.

Speaking of strange user interfaces, the MH mail reader was, in the late 1980s and early 1990s, a relatively popular way to read email. I never used it, but as I understand it, you had short commands to do things like list the messages in the current folder, display the next and previous message in a folder, reply to the current message, or move it to another folder. The novelty is that these commands were invoked from the Unix command line, rather than a separate CLI like Berkeley mailx, or a screen interface like elm or mutt. So it was easier to script them, and you changed folders with the usual `cd` command, and so on.

So I was thinking it would be interesting to try something like this for file management: a set of commands you could use from the Unix command line that would give you a noun-verb next-prev kind of user interface for file management. And I was thinking it would be nice to support some kind of hashtags for saving, editing, and combining previously defined selections, since it's 2018.

Food storage

Kragen Javier Sitaker, 2013-05-11 (updated 2013-05-17) (54 minutes)

Storing food at home

A related post, Only a constant factor worse (p. 1648), discussed a food-buying strategy that would give you an unboundedly-expanding stored-food supply, as long as you're spending more than about US$0.64 per day (US$234/year) on food, and advocated doing so if you're poor, for several reasons: you can buy food only when it's on sale or free, you can buy food in bulk for better prices, and you can keep a wide variety of food on hand to avoid dangerous dietary monotony. Even if you accept that it would be a good idea, it's reasonable to ask how you can practically store such a stockpile.

First off, let's cap the stockpile at a year's supply. Not even the Mormons store up more than a year's supply of food; many people just store up 72 hours' worth for disaster-preparedness. So let's not even consider the possibility of storing two, five, or ten years' worth of food.

Second, let's consider how much space we can reasonably use. I think it's reasonable to dedicate some constant fraction of your living space to food storage, not too much. If 25% of your house is full of stored food, it's likely to significantly diminish your quality of life. Let's figure 6.25% as a reasonable upper limit.

Would you suffer a lot if your house were 6.25% smaller? The smallest house I've lived in was a Volkswagen Vanagon camper bus, which was about two meters by four meters by one and a half meters (although you could put the top up to get a ceiling of over two meters in part of the bus when you were stopped). Getting at daily-use stuff was trivially easy; it was almost always within arm's reach. Getting at more specialized stuff (tools for putting the damn muffler back on again, say) required reconfiguring the furniture, which was kind of a pain.

That was 12 cubic meters of space. 6.25% of it would be three-quarters of a cubic meter, which was about the size of the humongous toolbox we lugged around to fix the thing. Another three-quarters of a cubic meter would have been feasible, but it would have blocked the back windshield; we would have had to put it on the floor when driving or sleeping, and in the bed space when we needed the floor. That is, we could have done it, but it would have been a pain.

However, if your house contains 12¾ cubic meters, you can damn well spare those extra three-quarters of a cubic meter for food storage. If that's useful, which it is, and if it's necessary, which as we'll see, it isn't.

The apartment I'm living in at the moment has a living room, a kitchen, a bathroom, and a storage room, which was intended as the bedroom but has a weird mold smell, so I don't want to sleep in it. I basically live in the living room, which is about four meters by six meters by three meters tall, a total of 72 cubic meters, six times the size of the Vanagon. 6.25% of this would be 4.5 cubic meters; if it's

vertical to the ceiling, it would be 1.5 square meters; along the four-meter-long wall, it would shorten the six meters of the room by 38 centimeters. Eminently livable. How much food can you store in 4.5 cubic meters?

In that related post, I was talking about foods like flour, polenta, brown rice, soybeans, salt, and sunflower oil, with total consumption between 600g and 700g per day. These have somewhat varying densities, but they're generally around the density of water: 1kg/ℓ, or one tonne per cubic meter. Which means you can store about four or five tonnes of food in 4.5 cubic meters. That would be about 19 years' worth!

In fact, storing 650 grams of dry food per day, a year's worth of food is only 237 kg. That's not even the three-quarters of a cubic meter that would be 6.25% of the Vanagon. It's more like *one* quarter of a cubic meter.

Lifetime and spoilage

This brings us to the problem of the lifetime of stored food. If you just buy bags of food and pile it up in a corner, you will not have a food stockpile that eliminates risks to your food budget; you will have a serious vermin infestation, maybe a mold problem, and probably a lot of expired food. Plus, if you have to move, you'll have one more heavy thing to bring with you. At different times and in different places, I've had to cope with cockroaches, rancid oil, weevils, red flour beetles (or confused flour beetles), and moths in my food. This is where I explain how you can make sure you never have these problems.

I know nine basic strategies for managing the limited-food-lifetime problem:

- Rotation: first in, first out.
- Hermetic sealing.
- Vermin-proof packaging.
- Cold.
- Dehydration.
- Darkness.
- Chemical preservation.
- Sterility.
- Liveness.

Rotation

Things like rice are typically guaranteed good for 18 months from packaging. Even unopened, unrefrigerated mayonnaise is guaranteed good for nine months. So if you consume your rice within 18 months of buying it, you're all good. But that means that, if you open up the pantry and pick between a two-month-old bag and a 17-month-old container of rice, you'd better pick the 17-month-old one. Otherwise, it's going to expire before you finish the last one.

This is known as "proper stock rotation" or "first in, first out" in business. You need to mark each item you have in stock with a date (either its date of origin or its date of expiration) and always use the oldest item.

That means that, if you manage to work your way up to a one-year stockpile, you'll always be eating year-old food. The alternative is to keep buying more food than you need and just throw out the

year-old food, wasting it.

You can mark items in lots of ways. I like to use polyester cloth ribbon, tied around the necks of bottles, marked in ballpoint pen. It looks pretty, it's easy to read, it's easy to make, and it's pretty cheap.

Hermetic sealing

Most spoilage problems are caused by stuff getting into food from the outside: moisture, bugs, or in the case of rancidity, mere oxygen. So to keep your food from spoiling, it helps a lot to keep it hermetically sealed. Historically, this was really difficult, and that was a major cause of food spoilage. Now, there are lots of ways to do this: heat-sealed bags, cans, jars with hermetically-sealing tops, Ziploc bags, bottles with corks, and my favorite, screw-top soft-drink bottles.

Screw-top bottles typically have a soft plastic gasket on the inside of the screw-top lid, which the thread compresses against the top of the bottle neck. This seal must be sufficiently airtight to keep the soft drink from going flat. Some, but not all, bottled-water bottles are inferior. You can test a candidate bottle by filling it with water and freezing it, which will stretch the bottle and put the contents under a lot of pressure; if the bottlecap doesn't seal well, the last of the water will be forced out and drip past the cap, forming an icicle in your freezer.

One thing to beware of is that hermetic sealing means that odors and contamination won't have a chance to dissipate. This means that if your hermetic container is leaching stuff into your food, it will build up, rather than bubbling out. This is why "tin cans" traditionally were coated in tin and nowadays are coated in plastic: to keep the steel from ending up in the food. Soft-drink bottles probably won't leach anything toxic into your food (they don't contain bisphenol-A, and the concerns about leaching of antimony-based catalysts have not proven out so far) but they might make it taste like Coca-Cola.

Oxygen rancidifies oils and helps to spoil beer (I think by souring it), and most plastics are fairly permeable to oxygen, including the polyethylene terephthalate used for soft-drink bottles and the polyethylene and polypropylene used for most plastic bags. This is the major reason that beer has not been sold in plastic bottles until recently. Some new formulations of polyethylene terephthalate include a bentonite clay filler to dramatically reduce their oxygen permeability, which has made it possible for plastic-bottled beer to keep. I have no idea how to tell if you have such a bottle. Multiple layers of enclosure, perhaps including a layer that's not plastic, may be a useful way to reduce oxygen permeability.

Latex condoms --- preferably unlubricated --- or gloves may provide a useful level of additional sealing for storage that you don't expect to open and close repeatedly. They have the advantage that they can be stored in very little space when empty.

Vermin-proof packaging

You can have a container that's hermetically sealed but not vermin-proof. In particular, weevils and flour beetles can tunnel through even fairly thick polyethylene plastic bags, so if one bag in a pile is infested, they will eventually colonize the other bags. So far, I haven't had them chew through soft-drink bottles. (This is one of the

reasons soft-drink bottles are my favorite.) I'm sure they can't chew through ceramic, glass, or metal.

Some varieties of cockroaches can chew through wood, so wood may not be a good choice for vermin-proof packaging. It's hard to get wood to seal hermetically anyway.

The Anasazi had a kind of container called a "seed pot" which was vermin-proof but not hermetically sealed. It was a small pot with a tiny hole on top --- maybe 2mm in diameter --- to fill it with dried seeds. Apparently the vermin they had to deal with were mostly mice, not flour beetles, and mice are far too big to get in through such a hole. You break the pot to get access to the seeds.

Mice and rats will not have much trouble chewing through soft-drink bottles, I think, so if you have to deal with them, it might be a good idea to keep your soft-drink bottles inside something mouse-proof, like a metal box.

Because your food might already have vermin in it when you put it into storage, it's a good idea to have at least one level of vermin-proof packaging that's fairly small, say, around a kilogram or so. It would be a real shame if the progeny of two tiny flour beetles were able to spoil 20 kilograms of your stored-up flour. The Anasazi seed pots held about 100 grams. I typically use soft-drink bottles of 1½ liters, although I occasonally use 2¼ℓ and 3ℓ bottles too.

Cold

Most kinds of spoilage follow the Arrhenius law, increasing exponentially with temperature; so dropping the temperature even a few degrees can slow a spoilage process to the point where it's effectively stopped --- where it won't proceed to the point of mattering by the time you eat the food. This also means that what matters is not the *average* temperature at which food is stored, but the *maximum* temperature, so simply reducing the size of temperature variations will extend the lifetime of food.

Refrigerators, of course, are the most ubiquitous manifestation of this storage strategy in the modern world, but wine cellars are another. Deep-freezes --- large, low-temperature freezers that open on top rather than to the side --- are among the most effective ways of storing food.

I've speculated in the past on kragen-tol about using a superinsulated icebox in place of a refrigerator, and have actually done some experiments with freezing two soft-drink two-liter bottles of water in a freezer and transferring them daily to a 2cm-thick styrofoam cooler in the Buenos Aires summer. Heat leakage was enough to melt about one of them per day. This suggests that 10 or 20 centimeters of styrofoam, or twice that of straw, would be sufficient to give you a low-cost major expansion of your refrigerator capacity, at the cost of transferring ice bottles once or a few times a week.

I also recently did some calculations about using a drying-closet to evaporatively cool air to near the wet-bulb temperature, using the temperature change of the air to drive a constant airflow down a cold-air drain, thus accelerating the drying process. Preliminary psychrometric-table consultations suggest that this could lower the temperature of whatever is below the drain by some 5 degrees under ordinary circumstances.

A pot-in-pot evaporative cooler design won some design awards a few years back. Basically you fill the space between an inner terra-cotta pot and an outer terra-cotta pot with sand, and you keep the sand damp with a watering can so that the inner pot remains at the wet-bulb temperature. This doesn't keep things as cold as an actual refrigerator --- and in humid places it doesn't do much at all --- but in many circumstances it can preserve food substantially longer than nothing.

Dehydration

Dehydrating food for storage has some drawbacks --- the flavor and texture changes, and in most food, not for the better; you typically need to rehydrate it to cook it; and it can be labor-intensive, since only occasionally will food dehydrate without human intervention. Usually you have to spread it out, perhaps cut it into slices, perhaps warm it up, and perhaps drive airflow over it. On the other hand, it dramatically reduces the mass of food, making it more portable; and only a very few kinds of spoilage can attack dry food: rancidity, of course; weevils, flour beetles, and moths, which can get sufficient water by digesting its carbohydrates; and large vermin such as mice and rats, which I fortunately have never yet had to deal with, can drink water elsewhere and then eat your food.

Lack of proper dehydration for storage is a major risk factor for cancer, because aflatoxin-producing molds will infest grains and legumes that are stored insufficiently dry.

One thing to keep in mind is that, once vermin have infested food, they tend to moisten it. Flour beetles and weevils are not, in themselves, toxic, although flour beetles do produce nasty flavors --- but if present in sufficiently high quantities, they will moisten the remaining food enough that it will spoil soon, even if you kill them. (Some people think they add protein to the food, but they do not. They probably do slightly increase the protein fraction of the food, but by reducing its carbohydrate content, not by increasing its protein content. Animals, such as humans and confused flour beetles, do not produce protein. We must get it from our food.)

Some foods have a hard, dry shell protecting a tasty inner core, such as nuts, flax seeds, sesame seeds, sunflower seeds (unshelled), and so on. This only works as long as the outer shell remains dry.

I speculate that empanadas and their kin in other lands originally gained popularity in part because of long shelf life. The surface of the empanada is completely dry when you finish cooking it, and it's impregnated with oil to keep it from moistening from either within or without. The interior, having just been cooked thoroughly, is sterile. I suspect that an unpunctured empanada, especially of the fried type, would have a shelf life measured in weeks or months if you can keep vermin off of it, but I have not yet dared to do the experiment.

Darkness

A few kinds of spoilage are caused by exposure to light, especially ultraviolet light. Potatoes exposed to light will produce potentially deadly levels of solanine and turn green; beer exposed to light will sour faster; and I think oils exposed to light will rancidify faster. Refrigerators conveniently provide darkness, but other kinds of enclosures may also be useful. And, of course, light produces heat,

which can dispel cold and accelerate spoilage.

Even a cardboard box with holes in it can provide useful levels of darkness.

Chemical preservation

Aside from the obvious and noxious chemical preservation methods, using nitrites, sulfites, formaldehyde, and so on, we have jellying, salting, pickling, alkaline preservation, spicing, and antioxidants --- methods which were more ubiquitous before the advent of refrigeration, but which still extend food lifetimes in concert with refrigeration.

Jelly, jam, syrup, and preserves have too much sugar for much life to survive in them, although they can sometimes grow mold on their surface, where perhaps condensation locally reduced the relative sugar content. I think this kind of preservation works by reducing the osmotic pressure to the point that any invading microorganisms are sucked dry. (Unlike with my stores of beans, rice, legumes, flour, and spices, I've never had an insect infestation in my sugar; the most that happens is that ants may come to carry it back to their anthill, grain by grain.)

Salting works similarly, by reducing osmotic pressure. Thus both jellying and salting work synergetically with dehydration --- dehydration reduces the salt or sugar needed, and salt or sugar reduces the dehydration needed, to reach a given level of longevity.

Mayonnaise is, in part, a way to pickle eggs so they can last for months without refrigeration; and many vegetables can be enjoyed for months or years by pickling them, producing an environment too acid for bacteria to grow in.

Alkaline preservation is not as widely used, but, for instance, from the stench, I think thousand-year eggs are preserved with ammonia, and lutefisk, also notoriously stinky, is preserved and softened with lye.

Many spices are poisonous enough to retard food spoilage. Capsaicin, which makes chile peppers hot, is also a fungicide; and cloves and bay leaves, among others, are sufficiently poisonous to discourage many kinds of spoilage-causing organisms.

Antioxidants such as BHA, BHT, and vitamins A, C, and E (IIRC) can slow down rancidification dramatically, even in the presence of ample oxygen. Palm and camellia oils supposedly have very long shelf lives in part because of their high levels of naturally present antioxidants. I don't know if you can use this property of theirs to impart longer shelf lives to other prepared foods. (Nitrites, I think, are antioxidants too, which is why they keep preserved meat pink. But, in meat, they generate carcinogenic nitrosamines, and the consumption of nitrite-containing meat is associated with a significantly higher risk of stomach cancer, so I don't think the risk is worth it.)

Sterility

Many food spoilage problems are caused by life forms, like beetles, bacteria, or fungi; some other food health problems are caused by the survival of parasites in the food. Contrary to the medieval and earlier hypothesis of spontaneous generation, if these life forms are initially absent from the food and have no opportunity to get into it, they will never be present, and the food will never experience that kind of

spoilage. (It might still get eaten by rats or go rancid.)

So ensuring that the food contains no spoilage-causing life forms is one way to prevent it from spoiling. This is, of course, the main thrust of canning: you cook the can thoroughly after sealing it. Approaches other than cooking include irradiation (sadly, not practical to do at home) and deep-freezing. If you have a small number of weevils or other beetles in your flour or rice or whatever, freezing it for a couple of days can be sufficient to kill them. (If you have a large number, you may still want to freeze the container before you throw it out, to keep them from spreading from it.)

Liveness

In the opposite direction, many foods are still alive when you harvest them, for example because they are seeds or fruits. They have their own immune systems to fight off disease and spoilage, for a while at least. Green beans can survive and remain free of spoilage for weeks under even fairly unfavorable conditions. Winter squash and potatoes can last for months.

Physical structure

So suppose you have 250 kilograms of dry food with a density of 1kg/ℓ. You need to rotate it properly so as to keep it from expiring, and keep it in hermetically-sealed vermin-proof containers of around a kilogram each, ideally in the dark, at a consistent, low temperature. How do you do it?

A big part of the solution is to store most of the food in 1¼-ℓ soft-drink bottles, making sure it's in pieces small enough to fit through the necks without jamming. These bottles are about 32 cm tall and about 9 cm across. You need about 200 of them, or to allow for the fact that some of them will be partly empty at any given time, 300.

These bottles have a few other advantages over other alternative food storage methods that I haven't mentioned above: they're very difficult to break (I've watched a bus drive over an empty soft-drink bottle without breaking it), they're designed to be food-safe, they're very lightweight, they come in a variety of pleasing shapes and colors, they can be deflated when empty for compact storage and transport (at some cost to their sturdiness and pleasing shape), and they're free, in the sense that they're discarded in huge numbers.

300 of these bottles standing next to each other on the floor would occupy a rhombus consisting of two equilateral triangles some 162 cm on a side, which would actually hold 324 such bottles; its total area is about 2.3 square meters, for a total volume of about 0.73 cubic meters. (That means this arrangement is mostly empty space, which is because the bottles are partly empty and in themselves only occupy about 61% of the volume of the hexagonal prism enclosing them).

The coffee-table pantry

These 2.3 square meters (say, a rectangle of 1.6 meters by 1.4 meters) could fit inside a coffee table, for example, which could have doors on the side that open or a top that swings open. 162 cm provides 18 bottles per long row and 17 bottles per short row; 140 cm provides 18 rows, half short and half long. The total is then 315 bottles. A hexagonal or rhomboid coffee table would be both more space-efficient and more entertaining. A few centimeters of

styrofoam around the outside and thermal mass such as sand in the bottom would go a long way to keeping temperatures consistent. (If you labeled the bottle bottoms, you could stick them neck-down into the sand, so the sand wouldn't diminish the bottle storage capacity. An average depth of 5cm of sand would need 114 liters of sand, which would weigh about 260 kg, doubling the mass of the coffee table, and probably roughly doubling its thermal mass as well.)

The curtained-wall pantry

What if you want to shelve the bottles instead? If you divided that area into eight equal-area shelves (spaced 37½ cm apart, floor to ceiling) each shelf would need to be about 0.28 square meters. At a minimal shelf depth of 9 cm --- one bottle --- it would cover a bit over three meters of three-meter-high wall space. If you extended the 9-cm shelving to fill the whole four-meter wall of my living room, you'd have space for 44 bottles per shelf, 352 in all. You'd probably want to hang a curtain in front of it to provide insulation, darkness, and aesthetics. (Although orderly rows of shapely bottles filled with dried foodstuffs of varying visual textures has its own aesthetic appeal.)

The loft pantry

While both of these approaches are livable, they still do reduce the available living space somewhat. Your 500-kilogram coffee table would be a hell of a thing to stub your toe on. An approach that would enhance rather than compromise the architectural merits of this living room would be an overhead loft space for the bottles: a single shelf of the 2.3 square meters, some 40 cm below the ceiling, would be 47 centimeters wide, providing an alcove at one end of the living room. Rather than ensmallening the living space, this would just transform a part of it into a cozy nook, enhancing the rest of the room. The ceiling in the nook might be 2½ meters high instead of the 3 meters of the rest of the room.

The chest pantry

If you wanted to reduce the physical dimensions of your year's worth of stored food to a minimum without abandoning the bottle strategy, for example to make it more portable, you could probably have an upper layer of bottles neck-down, sticking through round holes in an upper shelf, with their conical necks nestling into the gaps between the necks of the bottles in the lower layer. Arranged this way, I think the second layer of bottles would add only about 22 cm of height to the thing, for a total of about 54 cm high in 1.14 square meters of floor area: 107 cm square, or a hexagon of around 120 cm from corner to corner.

You'd probably want to build the upper shelf in four to six pieces that could be lifted separately, since it would contain 125 kg of food when full, and you'd need to lift it off to access the bottles below. Each of four pieces would weigh at most 32 kg, which most people can lift safely.

Adding a third layer of bottles neck up would increase the total height to some 86 cm and diminish the floor area to about 87 cm by 87 cm. This is probably close to the minimal-dimension configuration, so let's work out the details a bit more.

If you have at least 300 bottles, at least 100 in each layer, you could

make the bottom and top layer hexagons of 127 bottles --- 7 bottles on each side of the hexagon, 13 from corner to corner. Then the middle layer would be an uneven hexagon of 101 bottles.

This gives you a total of 355 bottles, a distance across the corners of 117 cm, and a distance across the flats of 101 cm. Not as small as you might hope.

But 355 seems a little excessive if we just want to accommodate 200 bottles plus some extra to compensate for some bottles being partly empty. Suppose we use smaller hexagons: 6 bottles on each side of the regular top and bottom hexagons, for a total of 91 each, and 75 in the irregular middle layer:

Then we have 257 bottles, still 86 cm tall, 11 bottles (99 cm) across the corners, and about 86 cm across the flats. This is probably the minimal-dimension configuration.

With the Terma bottles I'm using for my estimates here, you can get a full 10 cm of interpenetration of layers by putting the second layer neck down. But without putting the second layer neck down, just spreading out the spacing of the bottles by about half a centimeter, you can still get about 8 cm, and you can get it with both of the upper layers, instead of just one. This turns out not to be an improvement.

If you actually built this chest full of potentially 321 liters of stored food, you'd probably want to put it on heavy casters so you could move it around. Otherwise it still wouldn't be very portable unless it was mostly empty. 320 kilograms is not a weight you can reasonably lift.

The underground pantry

If you don't live up in the air somewhere (I'm about four meters off the ground as I write this), you can get extremely consistent temperatures, constant darkness, and little oxygen just by burying things less than a meter into the ground. Many vegetables can keep at least a year this way, and roots like potatoes, ginger, onions, beets, manioc, and turnips have the additional advantage that they will do the work of burying themselves for you, if you just let them grow. And if vermin attack your root vegetables, well, it's a shame, but at least they're not inside your house.

Geopolitically, root vegetables are credited as a major force in peasants' attempts to evade conquest and taxation in, for example, Zomia (if I recall the name correctly) and Ireland. You can't burn a field of potatoes, you can't tell how many potatoes there are in it, and you can't confiscate them if the farmer won't tell you where they are.

I suspect that you can get some of these root vegetables to last longer than a year by burying them deeper so they don't sprout in the spring.

Growing food at home

This brings me to growing food at home, instead of storing it. Among my earliest memories, I remember my mother plowing the back yard with a Roto-Tiller to plant a garden, mostly corn. All my life she's had at least tomato plants, and often sunflowers too; and last I saw, my father (who left her decades ago) had a few rows of corn in his backyard in Minnesota.

That is not the way to save time and money. That's gardening as a hobby, not gardening for frugality and resilience.

To garden for frugality and resilience, you need to focus on the things that provide the highest return --- the least effort for the greatest benefit. As I documented in the other post, you can buy all the corn you can eat for two years for about US$200, at retail. Unless you have less than a few hundred dollars a year to spend on food, or you're preparing for a total collapse of civilization, you shouldn't spend your scarce gardening time on raising more corn or potatoes.

Instead, focus on foods that require very little effort and very little land area, and are difficult to store instead of growing. Don't grow anything you can easily buy dry in quantities you'd eat in a week. For example, here in Buenos Aires's temperate climate:

- Sprouts. My first attempt at sprouting turned about 100g of dry, boring, high-carbohydrate mung beans into about 400g of crunchy, fresh, low-carbohydrate, high-protein, juicy stir-fryable vegetables, which lasted several days. It took a few minutes a day for three or four days. My second attempt turned about 100g of dry, boring, high-protein soybeans into a moldy mess. If I figure out how to do this right, I'll be eating some bean sprouts every week, year round.
- Rosemary. It's nearly impossible to kill, and although you can dry it for storage, dry rosemary is a pale shadow of fresh rosemary. A single plant in a pot can give you enough rosemary to spice every meal. I think I've heard you can use it to keep moths out of clothing, too, but I haven't tested that.
- Hot peppers. Really hot varieties can also provide you more than enough spice for every meal from a single plant in a pot. Some

varieties are also spectacularly gorgeous.

• Mints. Similarly, a small pot can provide enough mint to spice every meal, and it's hard to kill; the usual problem is that if it's not in a pot, you have to police it aggressively to keep it from choking out everything else in the area. There are a lot of different mint varieties with widely varying flavors.

• Basil. Likewise, but you'll need several large pots rather than one small one if you like pesto. Try to keep it from going to seed.

• Squash. Squash vines are also quite aggressive and hard to kill, and when their season comes, they tend to produce volumes of squash that go beyond anything reasonable. You can't really raise them in a small pot. Summer squash, once picked, goes bad quickly enough that I fear buying it if I'm not planning to use it immediately, but I think it stays good for weeks on the vine.

• Nasturtium. Better known as a decorative flower, it's also edible with a kind of mustard-like spicy flavor. Both the leaves and the flowers are edible, and the flowers are gorgeous. It requires very little care.

• Bay, aka laurel. It's a hardy evergreen tree, and its leaves can be used to keep moths away and to spice food; they're strong enough that you usually only need a fraction of a leaf per serving.

• Tomatoes. If you have a few meters of fence that you can plant thickly with tomato vines, when they come into season, you can easily have thousands of tomatoes. This requires more care than the other plants mentioned, since the tomatoes are pretty attractive to pests, and they don't keep nearly as long on the vine as the other plants mentioned.

• Other herbs: oregano, parsley, cilantro, thyme, sage, lavender, lemon verbena, and so on. Many herbs are much better fresh than dry, will rot if you cut them and don't dry them, and can't be bought in small enough quantities for a single meal. If you have a dozen pots of a dozen different herbs, you can choose among a dozen different fresh herbs for every meal. This can go a long way toward making frugal food palatable.

• I've heard that chard also has pretty good frugality performance, is dead easy to grow, and grows year round, but I haven't tried growing it yet myself.

• Olives, if you inherited an olive tree. Otherwise, maybe plant one and hope your grandkids will benefit.

• Mushrooms, maybe? I don't know how to grow mushrooms, but they don't need access to sunlight, they can live on garbage (right?) and one or two of them really dramatically improve the flavor of a lot of foods. But they don't last long, and you often can't buy just one or two.

• Blackberries, if you have a lot of land, or mulberries. Blackberries are thorny, but otherwise easy to pick, and they're very hard to kill; you don't need to worry about pampering them. They make a wonderful jam, which you can eat year-round if you can it when they're in season. I haven't seen them growing in Buenos Aires, but they grew wild and abundant in the Presidio in San Francisco, whose climate is similar. Mulberry trees are also quite hardy once established --- IIRC they can grow deep taproots to survive long droughts --- but they take years to mature, and your chances of getting a male tree that produces no fruit is 50-50. Mulberries essentially cannot be

bought, because they don't last long enough once picked.

Storing water at home

Stockpiling food, as explained above, is a potent weapon against poverty and geopolitical uncertainty. Stockpiling water will probably not help you get out of poverty, since you already buy it in bulk, you don't benefit from variety, and it's never on sale. And water supplies typically remain available anywhere inhabited by people, except for short periods of time, even when your city is being bombed to smithereens.

A week's worth of water in the bathtub

Sometimes, however, a "short period of time" might be three or four days, or a week, due to nothing more serious than a power outage. A sufficient stockpile of water can improve your resilience against power outages. It's really hard to cook dried food without water.

At Burning Man, we had to bring our own water. The recommendation was 8 ℓ/day, for cooking, drinking, and showering in an extremely hot, dry climate. A week's worth would then be 56 ℓ. That's about half a bathtub full, and if you have a bathtub and forewarning of a possible interruption, filling up the bathtub is a reasonable response.

If you want to be prepared for a week-long water interruption without forewarning, it's not reasonable to keep your bathtub full of clean water all the time. The water will go stagnant and breed algae, mold, and mosquitoes. You'll stink from not bathing. Instead, you need containers, you need to be able to seal them, and you need to remember to rotate them.

Water bottles

For Burning Man, we actually used 56-liter military-surplus bacteriostatic plastic water bottles. Rotating 56 liters of water every few months is going to be a huge pain in the ass if you're trying to use containers much smaller than this. 20-liter bottles might be reasonable, and they're a lot easier to move around than the 56-liter ones are. 3-liter bottles are not reasonable.

Barrels

A 200-liter barrel is probably a thoroughly reasonable and widely available solution. Food-safe, sturdy 200-liter plastic barrels with sealing screw tops are a standard item all over the world, as are devices for moving them around when they're full. They go for about US$10 to US$20 used in the US.

For your house, though, you'll probably want to fill and empty the barrel with a hose.

Soy-sauce bottles

A more ghetto, but also quite effective, container is the 20-liter soy-sauce bottle, which is small enough that you can carry it around when full, rectangular, and unlike the mil-surplus bottles we took to Burning Man, stackable. I wash my laundry in a bucket cut from the bottom of one of these that I found near a dumpster outside a Chinese restaurant last month, labeled "DO NOT REUSE". They're made of thoroughly unbreakable polyethylene, they have handles to lug them

around with, they're food-safe, and originally they ship with a hermetically-sealed screw top. They're not bacteriostatic, though, and the one I fished out of the trash stream had been long separated from its screw top.

Three 20-liter soy-sauce bottles, a week's supply of water, would occupy a little less space than the year's supply of food considered earlier.

Chlorination

It's recommended to chlorinate your stored drinking water with bleach to a level where it's not really safe to drink, I think 100ppm or 200ppm. Water thus chlorinated should last for months or years. (I forget what the official recommendation on rotation for water thus chlorinated is, but I think it's six months or a year.) Before you drink it, you dechlorinate it by letting it sit in an open jar overnight. (I think you can boil it, too, if you're in a hurry.)

There are other poisons you could put in the water to keep it sterile, but they're harder to remove.

Storing a year's worth of water

If you wanted to store enough drinking water for a year, perhaps because you were insane, the 8 liters a day multiplies out to 2920 liters for the year: fifteen 200-liter barrels whose contents you'll have to rotate once or twice a year. This is three tonnes of water, occupying three cubic meters. This would occupy less than 6.25% of my living room, so it might be a reasonable thing to have in your house --- or, better, outside your house where it won't wreck everything if it springs a leak --- if you had some other use for it, other than preparing for a disaster that is unlikely ever to happen.

For example, three tonnes of water is a fairly large thermal mass, and eminently capable of internal convection. Raising or lowering its temperature by a degree requires 13 megajoules, which is 3.5 kilowatt hours. Freezing or thawing it requires almost a gigajoule, 260 kilowatt hours. This could allow you to time-shift the use of energy to warm or cool something to a time of day when energy is easily available, or to harvest ambient temperature at a reasonable time of day.

Or you could put it in a swimming pool and filter it if you wanted to drink it. Swimming pools are still a pain to maintain, but at least they're fun, in a way that a psycho apocalypse water barrel complex isn't.

Speaking of the same thing more prosaically, if you have a tank of hundreds of liters of water, it's not going to change temperature much between day and night unless it's really, really shallow, so you can take a cold bath any time, day or night. In a heat wave, this can save your life.

Storing fuel at home

A lot of the food I've described here isn't edible without cooking. Some commonly-eaten legumes are actually dangerous to eat raw, especially kidney beans. But if you can't pay the bill one month and they turn off your gas or electricity, or if there's an earthquake, or if somebody's air force bombs your city's power plants or transmission lines, or there's a heat wave and consequent power outages, you could

be out of luck forever if you don't have fuel stored up.

And energy is important for other things as well as cooking.

Wood and charcoal

The most common response to this situation is to cook with wood, dried poop, or charcoal, which isn't very convenient and is dangerous --- it produces carbon monoxide and, except for charcoal, carcinogenic and irritating smoke. (This is the biggest cause of childhood death today, now that we've dramatically ameliorated the diarrhea situation.) The fuel is also kind of a pain to keep stored, and it can harbor wildlife, including termites, deadly spiders, mice, rats, and cockroaches.

Compressed gas

The next-most-common response is to store LP gas or CNG in a tank, either inside or outside your house. This works fine, is reasonably safe, and is extremely convenient because you can adjust the flame instantly. It does involve a certain amount of up-front investment if you're not renting the tank, and it's not completely safe; people have produced spectacular explosions by accidentally driving cars into LP gas tanks.

Alcohol

A less-common approch is to cook with alcohol. The Penny Stove is a stove burner which can cook a meal with tens of milliliters of alcohol, weighs a few grams, and can be made from two discarded aluminum cans and a worthless coin. Ethanol is a particularly safe fuel: it won't explode if its container is breached, doesn't usually burn the surface it's burning on top of (so it probably won't burn your skin if you get splashed with it), can be extinguished with water, produces very little carbon monoxide when burning, and is much less toxic than alternatives like gasoline or methanol. It's also usable for disinfecting water or wounds and as a solvent for some things, and because it doesn't require high-pressure containment, it's more portable than LP gas or CNG. It's much more expensive than those fuels, though. Ethanol here currently costs about AR$20 per liter, and that liter might cook 50 meals --- AR$0.40 per meal. In the Penny Stove, it's also less controllable than gas fuels, but I think there are camping stoves that provide similar levels of control to a regular gas stove.

If you're poor enough to worry about US$1 per day of food costs, cooking on alcohol may be a low-upfront-investment alternative to buying a gas cylinder or hookup and gas stove. It's a lot more convenient and safer than wood or charcoal. It might even be cheaper than those fuels if you have to buy them, but most people scavenge them instead.

I've previously written on kragen-tol about inherently-safe ethanol storage XXX by floating your ethanol bottles in your water stockpile, so that almost any conceivable storage accident will result in the ethanol mixing with the water and becoming nonflammable.

Solar cooking

Solar cooking is a zero-fuel-consumption alternative, but it's less convenient than cooking with fire unless you have a bunch of heat-storage bits that are not very frugal yet. Still, I think you can

make reasonable solar cookers entirely out of garbage, assuming you have sunlight access.

Specifically, if you have a thermal storage tank for molten salt, you can use that to cook with solar heat whenever you want; the eutectic mixture of nitrates of potassium and sodium melts at 221°, hot enough to bake with, and has a heat of fusion near that of water, so you can store a huge amount of heat in a tiny space. But this is very far from being a practical option to save money.

Refrigeration

Refrigeration also suffers when energy supplies are interrupted. If you have a superinsulated icebox as I suggested earlier, or even if you keep your refrigerator and freezer full of bottles of water when they have available space, you may be able to weather some days without refrigeration power.

In our Vanagon, we had a dual-fuel refrigerator, which could run off the 12-volt van electricity (for hours) or the 12-liter LP gas tank (for days or weeks). It was of the ammonia-absorption type, which is somewhat more hazardous than the usual HCFC-compression type to have inside your house, but has no moving parts other than the gas valve. Gas-fueled refrigerators are common in houses in rural parts of the US.

With a somewhat more elaborate system, I think you could run an ammonia-absorption chiller from a solar concentrator to freeze ice (maybe salted) during the day, and use the ice with a secondary heat transfer circuit to keep your food cold. This is not very practical for individual frugality unless somebody commercializes it.

Space heating

Jesus, you think it's cold in your house without the heat on? Do you have a medical problem with body-temperature regulation? Otherwise, you know, in igloos, people get naked, even though the igloos aren't melting. You can adjust. Insulate your house, chink the cracks, put on a sweater, put a mylar blanket over your regular blanket, snuggle up to somebody, and quitcher complaining.

(Some solar thermal mass might help too.)

Air conditioning

This is a bigger problem; many more people die in heat waves than in cold waves. Their houses get too hot, because they don't have air conditioning or because the power went out, and they die. As the climate changes, we'll see more and more heat waves, and more and more mass deaths as a result. Air conditioners require a lot of energy; you need a hefty generator to run one, and it will gobble up lots of generator fuel. In theory you could run one off solar heat (see earlier comment under Refrigeration) but it's simpler to just have lots of thermal mass around you, thick enough that it'll stay cool past the end of the heat wave. Traditional adobe construction was about a meter thick, and solved that problem.

In theory, you could build a Thermal Mass Stockpile in your house just like an emergency food or water stockpile. In practice, it's considerably more difficult and not really practical. It would be a little alcove of adobe (or brick, or stone, or concrete), just big enough for you to be comfortable inside, with meter-thick walls, ceiling, and floor, and a closeable door. If you made it horizontal --- a

thermal-refuge version of a Kapuseru Hoteru bunk --- you could probably get by with a one-meter by one-meter by two-and-a-half-meter inside volume, enough of a sturdy metal frame to keep it safe from collapse, a mattress, and a light. The outside dimensions would be 3 m × 3 m × 3½ m, for a total volume of 31½ cubic meters, of which 29 cubic meters would be adobe. About 64 tonnes of adobe. This is going to be more than 6.25% of your living space, and your downstairs neighbors are going to raise hell about the cracks in their ceiling.

(You could actually keep your food and water stockpiles inside of it, keeping them at a consistent temperature and slightly cutting down on the adobe requirements all at once.)

Failing that, if you have, or recently had, a working refrigerator, soft-drink bottles filled with frozen water can make a huge difference. Sleep with one, wrapped in a towel, at night; snuggle up to one during the day. If the air temperature gets above about 35°, snuggle up to an ice bottle or two under blankets; instead of keeping your body heat from escaping into the air, the blankets keep the air's heat from escaping into your body and the ice bottles. In a sense, your ice bottles are your "stockpile of air conditioning".

Or you could take a cool bath, if you have or can get cool water.

If you live on the ground instead of up in the air like me, you can just dig a meter-deep trench in the ground, shore it up to keep it from collapsing, put a cover over the top, and lie down in it. This has its potential problems (radon, groundwater, propane or freon) but digging out five or six tons of dirt beats the hell out of molding 64 tons of it into bricks or heaping 64 tons of it on top of your box.

All of these thermal-mass stockpile approaches become slightly more practical when they're for more than one person. If you have four people, you can build a 4×2½×1 meter capsule with a meter of adobe around it, and instead of 64 tons of adobe for one person, you have 5×3½×3 - 4×2½×1 = 42½ cubic meters of adobe, or 93½ tonnes for four --- less than 25 tons each!

Topics

Why John Backus Was on the Wrong Track

Kragen Javier Sitaker, 2007 (updated 2019-05-05) (48 minutes)

(This document is unfinished.)

So I've been reading John Backus's Turing Award paper from 1977 [Backus 1977], and a lot of the assertions he makes therein seem dubious to me. Perhaps this is a little unfair, since von Neumann computers are now 60 years old, and were only 30 years old when Backus wrote; and much of the interesting stuff in the intervening 30 years has been elaboration on Backus's ideas. And I'm just some wanker, while Backus was a Turing Award winner, so probably whatever I can say here is pretty obvious now; but quite a bit of it was anticipated by Dijkstra's EWD-692 response immediately afterwards.

According to Eliezer Yudkowsky, Max Gluckman once said: "A science is any discipline in which the fool of this generation can go beyond the point reached by the genius of the last generation."

So maybe this article is a demonstration that computer programming is a science.

Still, I thought it would be useful to collect 30 years of perspective on the very influential ideas he expresses in this paper.

Summary

Backus's initial complaint about the obesity of von Neumann languages was myopic, coming as it did on the heels of five years of remarkable innovation in the invention of small von Neumann languages. Although he correctly identifies "word-at-a-time thinking" as a serious obstacle to good programming, its cure is garbage collection, not the removal of the assignment statement.

The point-free style he advocates could have been adopted a decade or more before he wrote his paper, but it wasn't, apparently because programs in that style are fucking hard to read. Many languages available today reduce the problems he identified with von Neumann languages of the time, as illustrated by his inner product example, but without using that point-free style; some of those languages were already available when he wrote, but were not in the mainstream.

Most people who have commented on the paper don't seem to have read most of the meat of the paper, probably because it's badly presented. I suggest another order of presentation that I think makes them easier.

Backus's pessimism that formal semantics would make von Neumann languages more tractable was wrong, although this is in part because those languages have been redesigned over the years to be analytically tractable. Similarly, his assertion that the word-at-a-time nature of von Neumann languages makes them non-extensible is both unsupported and simply mistaken, as illustrated by ample counterexamples from his time and our own.

Myopia About Existing Languages

Backus: "Each successive language incorporates, with a little

cleaning up, all the features of its predecessors plus a few more. Some languages have manuals exceeding 500 pages; others cram a complex description into shorter manuals by using dense formalisms. . . . For twenty years programming languages have been steadily progressing toward their present condition of obesity; as a result, the study and invention of programming languages has lost much of its excitement."

The C programming language was already in use at Bell Labs and a few universities when he wrote this, although Kernighan and Ritchie's manual (120 pages, I think?) didn't come out until, I think, the next year. C is not a minimal language, but as K&R says, it demonstrates that a language that doesn't have everything can be easier to use than those that do. Other smallish languages in use in 1977 — almost all substantially created during the previous five years — included BLISS-10 and BLISS-11, Scheme [Sussman 1975], Prolog, Smalltalk, and, of course, Forth, which is perhaps the ultimate in simplicity of mechanism among high-level languages.

Backus does say, in the next paragraph, "Since large increases in size bring only small increases in power, smaller, more elegant languages such as Pascal continue to be popular." But I think this dramatically understates the reality of 1977, as seen from 2007; there had been a renaissance in small, elegant languages over the several years immediately preceding Backus's paper, languages whose simplicity, elegance, and power has kept many of them in use until the present day. Some of them were not widely known at the time, but perhaps Backus's disgust owes more to overexposure to PL/1, which had been standardized the previous year after 13 years of drafts, and to Algol 68, than to a paucity of alternatives.

Dijkstra makes a similar comment in EWD-692:

He writes that "smaller, more elegant languages than Pascal continue to be popular", where in the case of Pascal "rapidly gaining in popularity" would be more accurate.

The Intellectual von Neumann Bottleneck Isn't

Backus says, "Not only is the tube [between the processor and memory] a literal bottleneck for the data traffic of a problem, but, more importantly, it is an intellectual bottleneck that has kept us tied to word-at-a-time thinking instead of encouraging us to think in terms of the larger conceptual units of the task at hand."

This is necessarily true of programs for the Altair 8800, which shipped with 256 bytes of memory and could run Altair BASIC in 4096 bytes, or an un-upgraded Apple][, which I think had shipped around the time of Backus's talk. But, as demonstrated by APL, the various FP and FL systems that came after this paper, and the "Lambda: The Ultimate" series of papers around the same time, the limitation is not really imposed by the hardware architecture; it takes some cleverness but not a huge amount of code to allow those single words to represent the larger conceptual units in question.

In a sense, McCarthy's 1960 Lisp article that Backus cites also showed this — or rather, the Lisp implementation that followed it in the next few months. That Lisp (modulo its bugs and its dynamic scoping, which had to be papered over with the FUNARGS (XXX?)

form) was capable of more or less directly implementing all of the primitive functions and functional forms that Backus presents in this paper.

His sample program from section 5.2 is:

```
Def Innerproduct = (Insert +)o(ApplyToAll ×)o Transpose
```

or

```
Def IP = (/+)o(α ×)o Trans.
```

where "o" is the function composition operator, "×" multiplication, and "α" the alpha he uses for ApplyToAll. We can define the operations needed to write this quite concisely in modern Scheme, with lists for vectors, as follows. (Remember that Backus's functions are to be applied to a single argument which is a vector of its arguments.)

```
(define (plus args) (apply + args))
(define (x args) (apply * args))
(define (o f g) (lambda (x) (f (g x))))
; Note that this implementation doesn't discover whether its
; argument has a unit so that it can do the right thing in the
; case of an empty vector.
(define (insert fn)
  (lambda (args) (if (null? (cdr args)) (car args)
                     (fn `(,(car args)
                           ,((insert fn) (cdr args)))))))
(define (alpha fn)
  (lambda (args) (if (null? args) '()
                     `(,(fn (car args)) .
                       ,((alpha fn) (cdr args))))))
(define (transpose1 heads tails)
  (if (null? tails) '()
      (cons (cons (car heads) (car tails))
            (transpose1 (cdr heads) (cdr tails)))))
(define (transpose0 lst)
  (if (null? lst) '() (cons '() (transpose0 (cdr lst)))))
(define (transpose lst)
  (transpose1 (car lst) (if (null? (cdr lst)) (transpose0 (car lst))
                            (transpose (cdr lst)))))
(define ip (o (o (insert plus) (alpha x)) transpose))
(begin (display (ip '((1 2 3) (6 5 4)))) (newline))  ; outputs "28"
```

You will notice that the definition of "ip" here is identical to the one from Backus's paper, except for being in prefix order with parentheses. This code makes heavy use of closures, but with some cost in readability could use the Lisp 1.5 FUNARGS (XXX?) form instead, and similarly quasiquotation could be replaced with explicit calls to "cons". Maybe it would be 30 lines of code instead of 22. (I don't have a Lisp 1.5 implementation handy to test on, so I can't say for sure.)

So, however tied we may have been to "word-at-a-time thinking" in the first 30 years of von Neumann computers, there had been systems in use since 1964 or so that could express Backus's functional forms in a few lines of code each.

And APL had already shown some of the way from the mid-1960s on. While APL expressions' values were internally represented as pointers, they were presented to the user in a very non-word-at-a-time fashion; and indeed, in many cases, they represented finite maps with domains of integers less than some limit, or integer pairs, and so on.

And, of course, Church's SK-combinators (which Backus mentions in his paper) are straightforward to implement even in ancient Lisp, sufficient to express any computable function, support the writing of higher-order functions, and don't name their arguments. (But I think the first efficient implementations of SK-combinators on computers, using graph reduction instead of tree reduction, either did not precede Backus's paper by much, or actually followed it.) XXX find out, asshole

So why had programming with higher-order functions that don't name their arguments — what we now call "point-free style" — not taken off in the 1960s? Was it really because programmers were too tied to "word-at-a-time thinking"? That doesn't seem plausible to me.

The alternative I suggest — after 40 years of our collective experience with "point-free style" in Forth, as well as 30 years in languages inspired by this very paper, languages such as Miranda, Haskell, and ML, plus more than 50 years of APL one-liners that are nearly point-free — is that while point-free programs are indeed much easier to "refactor" (i.e. perform semantics-preserving transformations on), they are fucking hard to read, maybe because they're too abstract.

This is based not only on my own limited experience, but the experiences of other hackers who have spent years programming in point-free style. Even the HaskellWiki Pointfree page [HaskellWiki Pointfree] admits that it can sometimes be hard to read:

> Point-free style can (clearly) lead to Obfuscation when used unwisely. As higher-order functions are chained together, it can become harder to mentally infer the types of expressions. The mental cues to an expression's type (explicit function arguments, and the number of arguments) go missing.
>
> Point-free style often times leads to code which is difficult to modify. A function written in a pointfree style may have to be radically changed to make minor changes in functionality. This is because the function becomes more complicated than a composition of lambdas and other functions, and compositions must be changed to application for a pointful function.
>
> Perhaps these are why pointfree style is sometimes (often?) referred to as pointless style.

(However, other parts of the same page advocate point-free style as "clearer", "cleaner", and "good discipline".)

Today's Programs for Inner Product

So today, the state of the art (due largely to work in languages inspired by Backus's paper) is something like this Python program:

```
def innerproduct(a, b): return sum(ai * bi for ai, bi in zip(a, b))
```

Which compares favorably to Backus's 1977 "von Neumann program for Inner Product":

```
c := 0
for i := 1 step 1 until n do
  c := c + a[i] × b[i]
```

(This could be translated to C as follows, gaining a bit of clarity but not changing in any substantial way:)

```
c = 0;
for (i = 0; i < n; i++) c += a[i] * b[i];
```

Backus lists seven undesirable properties of this program:

a) Its statements operate on an invisible "state" according to complex rules.

This is not really true of the Python program above. Although it is a user-visible feature that the expression `(ai*bi for ai, bi in zip(a, b))` results in a stateful iterator that eventually runs out of values, this program does not make use of that property.

The rules that govern the evaluation of the program are more complex than those of Backus's FP, though.

b) It is not hierarchical. Except for the right side of the assignment statement, it does not construct complex entities from simpler ones.

Actually, the assignment statement contains four nested compound expressions, made out of five atomic variables and one another. The Python program contains `zip(a, b)`, `ai * bi`, the generator expression, and the `sum` expression — exactly the same number; but perhaps `zip(a, b)` and the generator expression would be more to Backus's liking, since they express exactly the return values of the Trans and (α ×) operations in his functional IP program.

c) It is dynamic and repetitive. One must mentally execute it to understand it.

This is not true of this Python program, although it is true of many Python programs. Incidentally, this is exactly Guido van Rossum's reason for wanting to remove Backus's "insert", called `reduce`, from Python [van Rossum XXX] — he finds he has to mentally execute the reduction process to understand it.

d) It computes word-at-a-time by repetition (of the assignment) and by modification (of variable i).

This is true of the actual execution of the Python program, as it is of the execution of Backus's FP programs or any other programs on a von Neumann machine; but if you try to interpret it as a statement about the user-level semantics of the code, it reduces to criticism (c).

e) Part of the data, `n`, is in the program; thus it lacks generality and works only for vectors of length `n`.

Not true of the Python program.

f) It names its arguments; it can only be used for vectors `a` and `b`. To become general, it requires a procedure declaration. These involve complex issues (e.g. call-by-name versus call-by-value.)

Almost as true of the Python program as of the C version; in fact, the procedure declaration constitutes fully half of my program as written.

"Call-by-name" here refers to evaluating procedure parameters when their values are needed, rather than before entering the procedure; it's like lazy evaluation, but may evaluate the procedure parameter more than once. In effect, this allows you to construct any arbitrary zero-argument closure, called a "thunk", subject to the limitations of what you can express in an expression in the language in question.

In the cases where the parameter will always evaluate to the same value, it is therefore just a gratuitously inefficient version of lazy evaluation; in the cases where it can evaluate to different values, its value therefore depends on some information that could be thought of as a parameter to the thunk, but which generally needs to be passed in by mutating some apparently-unrelated variable, and so in those cases, it is just a gratuitously bug-prone version of a general closure facility (limited to passing the closures downward through the stack).

"Call-by-name" was therefore replaced by a combination of call-by-reference and a general closure facility, albeit one limited to "downward funargs", in Pascal (XXX did Algol-60 have downward funargs? I think so); and C and most languages designed since then have simply stuck to call-by-value. So, although call-by-name does indeed involve complex issues, it should have been an irrelevancy long before 1977, and merely adding procedure declarations to your language does not imply that your semantics will suffer the slings and arrows of outrageous call-by-name.

XXX sometimes people say "call-by-name" when they mean "lazy evaluation"; maybe that's what Backus meant?

(Of the other languages I've used or mentioned in this note, C, Scheme, Python, Smalltalk-80, APL, OCaml, 1960 Lisp, Miranda, Haskell, ML, and Forth just use call-by-value; Perl 5 just uses call-by-reference; C++ has both call-by-value and call-by-reference; Algol 60 has both call-by-value and call-by-name; Prolog uses something else entirely; Altair BASIC didn't have procedures; I'm not sure about BLISS-10 and BLISS-11; Lisp 1.5 had call-by-value and, I think, also FEXPRs; I think Smalltalk-72 did something vaguely FEXPR-like; and PL/1 and (I think) Algol 68, consistent with the rest of the language design, have every horrifying deformed argument-passing convention you can imagine.)

However, the distinction between call-by-value and call-by-name includes another complexity — strictness. A function "f" is strict in some parameter if it can't compute its return value without getting the value of that parameter. Backus calls this property "bottom-preserving", and not having procedure declarations has not saved him from strictness; throughout the paper there are a number of minor logical errors having to do with this particular extra complexity.

Backus implies that procedure declarations import some other complexities that he hasn't mentioned; the ones I can think of are variable scoping (lexical vs. dynamic vs. broken) and the creation of closures (downward-only or generalized; interchangeability with non-closure function pointers; etc.).

This absence of variables is the central difference, as I read it, between Backus's proposed programming system and most of the purely applicative systems that preceded it: unlike them, it doesn't have lambda substitution. It is interesting to note that nearly all of the systems inspired by Backus's paper over the ensuing 30 years have acquired lambda substitution rather quickly.

g) Its "housekeeping" operations are represented by symbols in scattered places (in the for statement and the subscripts in the assignment). This makes it impossible to consolidate housekeeping operations, the most common of all, into single, powerful, widely used operators.

This is still somewhat true of the generator expression (`... for ... in ...`) but not the `sum` and `zip` operations. Backus never defines "housekeeping" anywhere in his paper, but as additional examples, he gives function composition, matrix transposition, apply-to-all, and "insert", more commonly known as "reduce" or "fold".

A modern C++ program, using the STL, is somewhat similar in structure, although dramatically wordier. C++ is probably the poster child for obese von Neumann languages; here I have included the entire file with a `main()` function, because that turned out to be a little tricky for me to write concisely with my limited knowledge of C++, and I would hate for anyone else to have to suffer the same way. It's only the 4 lines inside `innerproduct` that correspond to the 2-3 lines of C given at the top of this section or the half-line of Python.

```
#include <iostream>
#include <vector>
#include <numeric>
using namespace std;

template<typename T>
T innerproduct(vector<T> a, vector<T> b) {
  vector<T> result;
  transform(a.begin(), a.end(), b.begin(),
            back_insert_iterator<vector<T> >(result), multiplies<T>());
  return accumulate(result.begin() + 1, result.end(), result[0], plus<T>());
}

#define arrayend(array) ((array)+sizeof(array)/sizeof((array)[0]))
int main(int argc, char **argv) {
  int aa[] = {1, 2, 3};
  int bb[] = {6, 5, 4};
  vector<int> a(aa, arrayend(aa)), b(bb, arrayend(bb));
  cout << innerproduct(a, b) << endl;
  return 0;
}
```

(I think that's purely standard C++. I tested it with g++ 4.1.2. There's no particular reason `transform()` couldn't have been defined to produce an `InputIterator` instead of consuming an `OutputIterator`, but it wasn't. Oh, and the STL contains an `inner_product()` template function that does this already, but you have to give it a starting value, as with `accumulate()`, so it's hard to make a call to it generic across element types.)

(A note about performance: the above program compiles to 3632 bytes of machine code, on the order of 750 instructions, containing obvious inefficiencies; the inner-product function itself, instantiated for vectors of integers, is 86 instructions, and on my laptop, it takes 3300 nanoseconds on Backus's example vectors. By comparison, the analogous non-generic C function, with the code at the top of this section, is 23 instructions, contains no calls to other functions, and consequently executes in 54 nanoseconds. So much for the STL's vaunted "absolute efficiency". The C++ version also requires four dynamic libraries at run-time.)

In "A Short History of STL" [Stepanov 2007], Stepanov writes about how his work was inspired by Backus's FP work.

In OCaml, which is very much inspired by Backus's paper, we could write:

```
List.fold_left2 (fun a b c -> a + b * c) 0
```

Although that's not generic across numeric types the way the Python and C++ versions are.

In Squeak Smalltalk, it looks like this, as a method on `SequenceableCollection`:

```
innerProduct: aCollection
    ^ (self with: aCollection collect: [:a :b | a * b ]) sum.
```

I don't know if `with:collect:` and `sum` existed in Smalltalk-80, let alone the Smalltalk that existed in 1977; the oldest version in Squeak was in 1999 by "di", which is presumably Dan Ingalls, but older versions may exist.

In R5RS Scheme, if I don't restrict myself to trying to reproduce the structure of Backus's program exactly using facilities that I'm sure were present in early Lisp, I can write it quite concisely as well:

```
(define (innerproduct a b) (apply + (map * a b)))
```

I don't know when Scheme's map acquired the ability to apply to an arbitrary number of arguments, but I suspect it was a bit later than Backus's paper.

The Smalltalk and Scheme versions, too, are generic across all numeric types; although the Scheme version, unlike the Python, C++, and Smalltalk versions, doesn't support user-defined numeric types.

These programs are improvements over the C version along Backus's criteria in the following ways: Python: abceg; C++: beg; OCaml: abceg; Squeak: abceg; Scheme: aceg.

So, in sum, von Neumann programming languages — the avant-garde, if not yet the mainstream — have adopted features that provide most of Backus's desiderata, but without requiring the point-free style he considers crucial. Some of them, I think, had those features before his paper.

Garbage Collection is the Key to Not Thinking Word-at-a-Time

In section 4, Backus writes, "The assignment statement is the von Neumann bottleneck of programming languages and keeps us thinking in word-at-a-time terms in much the same way the computer's bottleneck does. Consider a typical program; at its center are a number of assignment statements containing some subscripted variables. Each assignment statement produces a one-word result."

But actually, even years before Backus wrote his paper, PL/1 supported assignment statements that copied entire arrays, and C

eventually acquired the ability to copy `structs` in simple assignment statements as well. But you can't write the functional forms used in Backus's "InnerProduct" program in those languages, the way you can in Python, OCaml, Smalltalk, or Scheme. The key is that, even though assignment statements in Python or Scheme only copy single words (unlike those in C and PL/1!) those single words can effectively stand for much larger data structures that they point to.

In C, a single word can point to a much larger data structure, but you must constantly be aware of the difference between the pointer and the thing it points to, because you must be careful to free the thing it points to before overwriting the last copy of the pointer, or letting it go out of scope. C++ can do better here because its destructors and copy-constructors allow you to automate that work.

So, even though C's assignment statements and parameter-passing can copy entire `structs` (say, complex numbers, or begin-end pointer pairs), they can't copy structures of irregular and unpredictable size, such as the transposed list of pairs in the inner-product function. Garbage-collected languages can universally pass structures of irregular and unpredictable size without worrying about who deallocates them, and so you can toss around a list, or a parse tree, or an arbitrary-precision number, or an arbitrary-size matrix, or a drawing, as easily if it were a single byte.

(As long as you don't mutate it. Once you start mutating it, you have to worry about aliasing. But most of the time, that doesn't impose a large practical complexity penalty on your programs — just your proofs.)

In sum, Backus misidentified the source of word-at-a-time thinking; it is not the assignment statement and its ability to transfer only a word at a time, but rather the hassle of manual memory management.

This is perhaps somewhat surprising; garbage collection had been invented for Lisp in 1958 or 1959, and Algol-68 implementations were required to provide it. But it seems that in 1977, Backus didn't have much experience programming in garbage-collection languages. Perhaps this is because, despite Algol-68's mandate, garbage-collected programming environments weren't in wide use by 1977, largely because garbage collection was grossly inefficient until the invention of generational garbage collection (in 1982? XXX).

However, this myopia about garbage collection was not limited to Backus; Dijkstra comments in EWD692, about this very paper:

> In the first step [of the program MM] each of the component functions in the construction ("1" and "trans o 2" , respectively) is combined with the total operand —a sequence of two matrices— from which in the last step (Selection) each extracts the half it really needs. If the matrices m and n are sizeable [sic], a naive [sic] implementation that first copies those matrices and then kicks out half of it again seems absolutely unacceptable on *any* machine —von Neumann or not—.

But That's Not the Point!

But the "abcdefg" desiderata in section 5 aren't the real point of the paper! The real point of the paper, found in section 9, is that languages that are more mathematically tractable permit "algebraic laws" to be "used in a rather mechanical way to transform a problem into its solution." Backus proposes to solve this problem by inventing a new programming style that is particularly easy to manipulate

mathematically.

There is definitely merit in using programming styles that make it easy to prove things and to mechanically transform programs without changing their semantics; this was the idea of Dijkstra's "structured programming", which Backus mentions in passing.

Unfortunately, while I think Backus was correct that purely-applicative programs in general, and point-free purely-applicative programs in particular, are particularly amenable to formal manipulation, he doesn't do a very good job of presenting this in the paper.

Backus's Pessimism About Formal Semantics Was Wrong

In section 9, Backus writes:

> Axiomatic semantics [Hoare 1969] precisely restates the inelegant properties of von Neumann programs (i.e. transformations on states) as transformations on predicates. ... [Its practitioners'] success rests on two factors in addition to their ingenuity: First, the game is restricted to small, weak subsets of full von Neumann languages that have states vastly simpler than real ones. Second, the new playing field (predicates and their transformations) is richer, more orderly and effective than the old (states and their transformations). But restricting the game and transferring it to a more effective domain does not enable it to handle real programs (with the necessary complexities of procedure calls and aliasing) ... As axiomatic semantics is extended to cover more of a typical von Neumann language, it begins to lose its effectiveness with the increasing complexity that is required.

Although Scheme contains a large and useful applicative subset, it is certainly a von Neumann language in the sense that Backus is describing. R5RS includes a formal denotational semantics for Scheme. It's only two and a half pages, and handles the primitive forms of the whole language; another two pages are concerned with formal definitions of rewrite rules that reduce the other special forms in the system to those primitive forms. Real programs in Scheme have had useful properties proved of them, or so I hear. I haven't written or read any of those proofs myself. XXX PreScheme

(Axiomatic semantics is a different approach from the denotational semantics used by R5RS, as Backus points out in section 12, but his skepticism is not confined to one or the other.)

More recently [Leroy 2006], Xavier Leroy's team at INRIA has constructed a compiler in OCaml from a large subset of C, which they call Clight, to PowerPC assembly. The compiler is automatically extracted from a machine-checked proof of its correctness written in Coq. While the source language Clight is, at this point, still a toy language (it lacks `structs`, `unions`, `typedef`, `goto`, `switch`, and, I believe, casts) its compiler is definitely a "real program".

On the other hand, while the problems Backus identifies are not as severe as he thought, neither are they nonexistent. Apparently [Leroy 2006] it is still the case that nobody has published a formal semantics for C, which was the most-widely-used von-Neumann-style language during much of the 30 years since Backus's paper (say, 1984 to 1994, or possibly even until today). So the early hopes accompanying formal denotational semantics work were overoptimistic, essentially for the reasons Backus identifies.

And Backus's other skepticism expressed later has turned out to be correct: "If the average programmer is to prove his programs correct,

he will need much simpler techniques than those the professionals have so far put forward." And point-free purely-applicative programs have indeed turned out to be among the easiest to manipulate in this way.

Dijkstra writes in EWD-692:

...his objection is less against von Neumann programs than against his own clumsy way of trying to understand them.

(But over the next few dozen EWD notices, Dijkstra seems to have changed his mind about the ease of proving properties of functional programs.)

Von Neumann Languages Can Be Powerfully Extensible

Backus writes:

Let us distinguish two parts of a programming language. First, its *framework* which gives the overall rules of the system, and second, its *changeable parts*, whose existence is anticipated by the framework but whose particular behavior is not specified by it. For example, the for statement, and almost all other statements, are part of Algol's framework but library functions and user-defined procedures are changeable parts...

Now suppose a language had a small framework which could easily accommodate a great variety of changeable features entirely as changeable parts. Then such a framework could support many different features and styles without being changed itself. In contrast to this pleasant possibility, von Neumann languages always seem to have an immense framework and very limited changeable parts. What causes this to happen? The answer concerns two problems of von Neumann languages.

The first problem...a von Neumann language must have a semantics closely coupled to the state, in which every detail of a computation changes the state. The consequence of this semantics closely coupled to states is that every detail of every feature must be built into the state and its transition rules.

Thus every feature of a von Neumann language must be spelled out in stupefying detail in its framework. ...many complex features are needed... The result is the inevitable rigid and enormous framework of a von Neumann language. . . .

The second problem of von Neumann languages is that their changeable parts have so little expressive power. Their gargantuan size is eloquent proof of this; after all, if the designer knew that all those complicated features, which he now builds into the framework, could be added later on as changeable parts, he would not be so eager to build them into the framework.

His "first problem" is a non sequitur. Why would having every detail of a computation change the state, and therefore semantics being closely coupled to states, result in not being able to define "features" such as the `for` statement? Backus never explains what "feature" means, nor does he explain any kind of connection between operational semantics and lack of extensibility.

The only additional complication operational semantics bring to extensibility is that when you define a new expression or statement type — such as a `for` statement — you must specify if, when, and how many times each subexpression is executed, while purely-applicative languages need only specify what to do with their results.

In fact, there already existed many highly-extensible von Neumann languages when he wrote this, Lisp and Forth being among the prime examples of the type. Smalltalk-72 was more extensible than Smalltalk-80, but even Smalltalk-80 supports easy user-level definitions of things such as the Algol `for` statement. Here's the definition of Number>>#to:do: from Squeak, which is a

Smalltalk-80 implementation:

```
to: stop do: aBlock
        "Normally compiled in-line, and therefore not overridable.
        Evaluate aBlock for each element of the interval
        (self to: stop by: 1)."
        | nextValue |
        nextValue _ self.
        [nextValue <= stop]
                whileTrue:
                        [aBlock value: nextValue.
                        nextValue _ nextValue + 1]
```

This allows you to write a for loop like this:

```
1 to: 10 do: [:i | Transcript show: ('item ', i asString); cr]
```

As the comment explains, the compiler specially recognizes the #to:do: selector and inlines an implementation equivalent to this one; but you can use the code to define another loop structure that does the same thing under another name.

There are several different approaches to defining highly extensible von Neumann languages:

• Lisp macros: by running arbitrary user-defined code at compile-time, you can add arbitrarily complex language features. R5RS defines Scheme in terms of only six primitive expression types: variables, `quote`-expressions, procedure calls, `lambda` expressions, `if`, and assignments. Everything else — `cond`, `case`, `let`, `let*`, `letrec`, `begin` (sequencing), `do` (the `for` loop), even access to the macro system — is defined in terms of the macro system. While Lisp macros had their shortcomings at the time Backus wrote (hygienic macros wouldn't be successfully implemented for, I think, another ten years) they were already in heavy use in, at least, MacLisp. R5RS defines `do` in the following fairly tricky way:

```
(define-syntax do
  (syntax-rules ()
    ((do ((var init step ...) ...)
         (test expr ...)
         command ...)
     (letrec ((loop
               (lambda (var ...)
                 (if test
                     (begin (if #f #f) expr ...)
                     (begin command ...
                            (loop (do "step" var step ...) ...))))))
       (loop init ...)))
    ((do "step" x) x)
    ((do "step" x y) y)))
```

(Some Scheme dialects also have a Common-Lisp-style macro

system in which the code to rewrite the tree is normal Scheme rather than this `syntax-rules` crap, but it's somewhat trickier to use because of name-capture problems.)

C++ uses a similar approach; like standard Scheme, it has, in effect, a completely different programming language that runs at compile-time, based on pattern-matching of C++ types.

Forth uses this approach to the extreme. The Forth equivalent of the `for` loop is the `DO LOOP` loop, which looks like `10 0 DO I . LOOP` — 10 is the loop limit, 0 is the starting value, `I .` is the body of the loop (which prints the value of the loop counter), and `LOOP` ends the loop. There are variants, but that's the basic structure. Here's the implementation of `DO LOOP` in F-83, a 1983 implementation of Forth; this version is for MS-DOS, and so some structures are written in an RPN version of 8086 assembly for speed. (I gathered this together from several different parts of `KERNEL86.BLK`.)

```
ASSEMBLER HEX
CODE (DO)   (S l i -- )   AX POP   BX POP
LABEL PDO   RP DEC   RP DEC   0 [IP] DX MOV   DX 0 [RP] MOV
  IP INC   IP INC   8000 # BX ADD   RP DEC   RP DEC
  BX 0 [RP] MOV   BX AX SUB   RP DEC   RP DEC   AX 0 [RP] MOV
  NEXT END-CODE
CODE BRANCH   (S -- )
LABEL BRAN1   0 [IP] IP MOV   NEXT END-CODE
CODE (LOOP)   (S -- )   1 # AX MOV
LABEL PLOOP   AX 0 [RP] ADD   BRAN1 JNO
  6 # RP ADD   IP INC   IP INC   NEXT END-CODE
FORTH
: DO      COMPILE (DO)   ?>MARK                    ; IMMEDIATE
: LOOP
    COMPILE (LOOP)  2DUP 2+ ?<RESOLVE ?>RESOLVE    ; IMMEDIATE
```

Essentially everything is the "changeable parts" in Forth. The eForth 1.0 model from 1990, in an effort to define a maximally portable Forth, has 171 instructions of actual machine code constituting a two-instruction "interpreter" and 31 primitive "words" or procedures.

I want to emphasize that, although some of these words are written in assembly, and some run at compile-time, in no way do they form an unchangeable part of the framework in the sense that Backus deplores; any user of the system can define new words in assembly at any time, or define new words that run at compile-time to define new control structures, and those words are immediately available.

Although the above exercise in archaeology is from six years after 1977, the relevant attributes of Forth were in place from some time before Backus wrote.

• Lightweight closures: Smalltalk-80 gets most of its extensibility from a very lightweight syntax for (restricted) closures, as shown in the above code for Number>>#to:do:. This has undesirable effects occasionally — in `((index <= limit) & (anArray at: index))`, the second half of the conjunction is evaluated regardless of the value of the first half. There's another method that allows you to write `((index <= limit) and:`

`[anArray at: index]`) and only evaluate the second part if the first one is true; but the notation is undesirably asymmetrical and non-infix.

Perl 5's prototypes and Ruby's block arguments give them a similarly lightweight closure syntax in some circumstances, which can provide similar facilities.

• Reflection: if there's very little done at compile-time that your code can't change at run-time, such as constructing new classes, enumerating the methods of classes, constructing method names and calling the named methods, evaluating strings of source code, and so on, you can get a certain amount of extensibility without any special features of the actual language. Smalltalk's #doesNotUnderstand: method, for example, allows classes to reuse the method namespace for their own purposes.

In sum, Backus's assertion that the changeable parts of von Neumann languages are necessarily quite limited in their expressiveness is poorly reasoned and simply wrong, and ample counterexamples existed even before he wrote it, although he may not have been aware of them.

The Design of His FP System

Backus's FP system is a bit different from modern "functional programming" systems, although it inspired the explosion in them over the next few years. They are generally based on the lambda-calculus, and so it is easy to define new higher-order functions in them, and they incorporate parameter substitution as a fundamental mechanism.

Space Usage

Backus writes, "[This MM program] is an inherently inefficient program for von Neumann computers (with regard to the use of space), but efficient ones can be derived from it and realizations of FP systems can be imagined that could execute MM without the prodigal use of space it implies."

Here's the MM program:

```
Def MM = (α α(/+)∘(α ×)∘ trans))∘(α distl)∘ distr ∘[1,trans ∘ 2]
```

The most obvious interpretation of his remark follows, and under that interpretation, the remark is wrong.

What he means is that the result of the next-to-last step of MM is a four-dimensional array with dimensions (A, B, C, 2), where the the original matrices have dimensions (A, C) and (C, B) and the result has dimensions (A, B). So, for instance, taking the product of two 1000×1000 matrices, producing a million-number result, would require a two-billion-number intermediate result, which is then reduced to a million numbers in a billion multiplications.

Dijkstra made a similar assumption; see the quote from him above in the section about garbage collection.

But, as he says, there's no reason to physically realize all the values of that intermediate result. "An APL Machine" [Abrams 1970], written several years before Backus began his work, describes an architecture for evaluating APL programs that avoids materializing many such intermediate results. In this case, it's sufficient to copy the

sequences by reference, even if you materialize them all.

I was thinking that linear logic was going to be helpful here, since obviously there's no point in materializing a sequence of values that gets used only once when you might as well produce it on the fly (modulo locality of reference and instruction-level parallelism concerns), but actually the values of concern here are the rows and columns, which are indeed used multiple times; distl and distr are not "linear" in Girard's sense.

This straightforward Python translation of the above MM program can multiply a 10000×40 matrix by a 40×10000 matrix, producing a 40×40 result, in 5MB. If it created an intermediate 40 × 40 × 2 × 10000 matrix with no sharing, as Backus seems to have envisioned, that intermediate matrix would contain 32 million values. It takes about five minutes on my computer.

```
#!/usr/bin/python
# A Python implementation of some of John Backus's "FP" system.
def selector(n):
    return lambda x: x[n-1]
def insert(f):
    def rv(x):
        rv = x[-1]
        for xi in x[-2::-1]: rv = f([xi, rv])
        return rv
    return rv
def apply_to_all(f):
    return lambda x: [f(xi) for xi in x]
def compose(*fs):
    if len(fs) == 1: return fs[0]
    f = fs[0]
    g = compose(*fs[1:])
    return lambda x: f(g(x))
def construct(*fs):
    return lambda x: [fi(x) for fi in fs]
def transpose(x):
    return [[x[i][j] for i in range(len(x))]
            for j in range(len(x[0]))]
plus =  lambda (x, y): x + y
times = lambda (x, y): x * y
distl = lambda (y, z): [(y, zi) for zi in z]
distr = lambda (y, z): [(yi, z) for yi in y]
innerproduct = compose(insert(plus), apply_to_all(times), transpose)
print innerproduct([[1, 2, 3], [6, 5, 4]])
mm = compose(apply_to_all(apply_to_all(innerproduct)),
             apply_to_all(distl),
             distr,
             construct(selector(1), compose(transpose, selector(2))))
matrices = [[[1, 0, 1], [0, 1, 0]], [[1, 2], [3, 4], [0, 0]]]
print mm(matrices)
bigmatrices = [[range(10000)] * 40, [range(40)] * 10000]
print mm(bigmatrices)
```

It could be that Backus was merely considering the necessity to allocate *any* variable-sized space for intermediate results as an

"inefficient" use of space, since all you really need for a matrix multiply is three loop counters and an accumulator.

Presenting Some of Backus's Results Better

Backus's section 12.5.1 is a correctness proof for a recursive factorial function, defined as follows:

```
f = eq0 -> constant(1); times o [id, f o s]
s = - o [id, constant(1)]
eq0 = eq o [id, constant(0)]          [from section 11.3]
```

XXX so the idea here is to work through the proof from section 12.5 to get f = / times o [id, id o s, id o s o s, ... constant(1) o crap] and then generalize it. But I'm too sleepy right now. And I probably want a "recursion lemma for f" and a "linearly expansive lemma for f". `p = eq0;  g = constant(1);  h = times;  i = id;  j = s`

Misc Crap

Topics

Golang has a *lot* built in, compared to C; for example, it has garbage collection, an interesting new way to do ad-hoc polymorphism, parametrically polymorphic finite maps, a range type, lightweight and relatively safe concurrency constructs, complex numbers, type-safe variadic parameters, run-time type identification, exception handling with FIFO automatic cleanup, a string type with equality and concatenation, and a print statement. However, without importing at least some packages, there's no way for a Go program to obtain input, and there are a lot of facilities that are easily accessible in the standard library that can save you a lot of time.

I'm just starting to learn Golang, so I'm taking some notes on the standard library from http://localhost:6060/pkg/, which is unfortunately organized alphabetically, which means that really recondite stuff is mixed in with really basic stuff. So this is my attempt to summarize what I think is most important.

The standard Golang library seems to be entirely lacking facilities for interactive terminal I/O and GUIs.

Really basic packages

Kragen Javier Sitaker, 2019-02-08 (20 minutes)

These are all you need for a pretty wide range of stuff: `testing`, `io`, `fmt`, `os`, `strconv`, `bytes`, `strings`, `math`, and `sort`. Without any one of these, you'd be pretty handicapped.

testing

`go test` runs automated test suites written using functions named `TestFoo`, that take pointers to `testing.T` objects, in `foo_test.go` files. It also has benchmarking and doctest-like functionality. I have to admit I haven't tried this yet because so far I haven't written any Golang packages, just standalone programs, and I'm not sure how to use it with those.

The `test/quick` subpackage does generative property-based testing, like Hypothesis.

fmt

`fmt` does formatted I/O, including `Printf`. It can use reflection to dump out structs (`%v`, applicable to any type, or `%+v` to see field names) and even Golang-syntax representations (`%#v`). Naturally there's a `fmt.Formatter` interface you can implement to override the default formatting.

Because of reflection, `fmt.Fscan`, `fmt.Scan`, `fmt.Sscan`, etc., don't need a format string at all — you just give them some interface values pointing at where you want to store the results — and the same is true of `fmt.Print`. Scanning can be overridden with a custom `Scan` method.

There's also a `print` function you can use without importing `fmt`.

io

`io` is where you find the Reader and Writer protocols, among others; `fmt.Fprintf` takes an `io.Writer` rather than a file. It also contains things like `io.Copy`, which normally copies a `Reader` to a `Writer`, but when possible uses more efficient methods, which I assume means `sendfile(2)`; plumbing utilities like `io.LimitReader`, `io.LimitWriter`, `io.Pipe`,

`io.MultiReader` (cat), `io.MultiWriter` (tee), and `io.TeeReader` (tee); `io.ReaderAt`, suitable for concurrent random-access record I/O from multiple goroutines; etc.

An interesting difference from Unix (or Python) is that `Read()` is supposed to return the error `io.EOF` at EOF rather than just an empty byte count. This has the annoying result that if you `import "os"` and do file I/O with it, you probably also need to `import "io"`.

The subpackage `io/ioutil` contains `ReadFile`, `WriteFile`, and tempfiles.

os

`os` is where you find `Args` and most of the Unix API, including things like `Open(filename)`, `Getpid()`, and `os.Stdout`, which is an unbuffered `io.Writer`, which you can buffer using `bufio`. Opening a file for writing requires calling either `os.Create` or `os.OpenFile`.

There's a separate `File.WriteString` method for when you have a `string` rather than a `[]byte` to write to a file. This is sort of strange because you can convert from `string` to `[]byte` with `[]byte(s)`, which makes me think this method may be left over from an earlier version of Golang where you couldn't do that.

The design is a mix of very Unixy and somewhat portable. File permissions are a 32-bit int with no place to put, for example, a separate "delete" permission bit, as on VMS. But the inode returned by `os.Stat` (`FileInfo`) isn't even a concrete type at all, but an interface. (And it includes the file's basename, but not e.g. ctime, so it's only sort of an inode.)

The `os.Process` API is an interesting design, clearly designed with non-Unix systems in mind. (There's no `os.Fork`!) It's somewhat weak; there's no nonblocking `waitpid`, for example, and thus no way to get an `os.ProcessState` for a running process! `os.exec` has a more convenient interface, but it's apparently built on `os.Process` and therefore can't do anything `os.Process` can't.

There also doesn't seem to be a way to call select(2), although of course you can spawn off a goroutine or two per fire descriptor.

strconv

`strconv` is where you look for conversion to and from strings, although `fmt.Sprintf` gives you a more capable way to build strings.

bytes

Things you would expect to be utility methods on strings (`ToUpper`, `Join`, `Split`, `TrimRight`, `Compare`, `HasPrefix`) are here, as are `io.Reader` and `io.Writer` interfaces for in-memory "files". There's a corresponding `strings` module for strings.

There are actually two different `io.Reader` implementations: the read-write `bytes.Buffer` and the seekable `bytes.Reader`. `bytes.Buffer`, in addition to converting output-generation functions into string-building functions, also allows you to buffer your output in a more controllable way than the `bufio` module mentioned below — it guarantees to return no errors when you write to it (it will `panic` instead if it runs out of memory) and allows you to accumulate the bytes written until you're ready to do something more interesting with them, like send them over a socket.

strings

This is almost the same as the `bytes` package, but for strings, even to the point of including the unnecessary `Compare` function. Naturally, though, it omits the read-write `Buffer` interface.

math

This has the usual set of floating-point functions; you know, `Acosh`, `Cos`, `Ceil`, `IsNaN`, `Max`, Bessel functions, `Erfc`, and so on. Angles are in radians, logarithms are natural where not otherwise specified. There are functions to convert floats to and from raw bits.

sort

`sort` provides an exchange sort, with stable and unstable variants, and it's somewhat less comfortable than its Python equivalent not only because you have to import it explicitly, but because it requires that the sequence you're sorting implement `sort.Interface`, which is impossible for raw slices. (The *sequence* implements the interface, not the data items being sorted.)

This module contains heapsort, insertion sort, binary quicksort with some optimized pivot selection, and mergesort; the quicksort fails over to heapsort if it goes badly, an approach sometimes known as "introsort".

The mergesort is apparently a 21st-century optimization of binary mergesort which uses only logarithmic space rather than the usual linear space, at the cost of some extra swaps.

The package also implements binary search as `sort.Search`, generalized to the case of a general function over integers 0..n (i.e. not just for searching sorted sequences in memory).

For convenience, there are a number of wrappers for sorting and searching built-in data types.

Somewhat less basic packages

These are very common things but not quite as absolutely basic as the ones listed above. These are `flag`, `log`, `bufio`, `math/rand`, `time`, `net/http`, `net/url`, `net/mail`, `mime`, `regexp`, `encoding/gob`, `encoding/json`, `encoding/binary`, `image`, `C`, and `yacc`.

flag

This is the standard way to implement command-line parsing. For better or worse, it doesn't support combinable Unix-style single-letter flags, just long-only options, and it doesn't support GNU-style options following non-option arguments.

log

`log` is the standard way to log errors and other messages. This is how you debug your programs, and `log.Fatal` or `log.Fatalf` is how you report fatal errors and exit. There's no tagging, logging levels, complex object serialization, or filtering, but you can set a prefix and twiddle a couple of formatting flags. You can create different `log.Logger` objects with `log.New`, sending information to the same or different files, and pass them around as you like.

I wanted to put this in the "Really basic packages" category, since I import it in every Golang program I write, but the truth is that you

can get by without it a lot more easily than you can get by without `math`, `sort`, or `strconv`.

bufio

This adds I/O buffering to an `io.Writer` (for performance) or an `io.Reader` (so you can put back already-read bytes or runes, for parsing reasons, as `fmt.Fscan` does). It also contains `bufio.Scanner`, which parses things like (limited) CSV. (There's also a CSV parser in `encoding/csv`.)

math/rand

This is a random number generator, which includes a shuffler in the form of `rand.Perm`.

time

This package mixes together access to the real-time clock (`time.Now()`), calendrical calculations, formatting, time zones, and scheduling. The time format used internally is nanosecond-precision and has its zero value at the beginning of year 1 CE in UTC.

This package includes a syntax for durations, which are int64 nanosecond counts; the syntax accepts "300µs". ♥

Because Go has no operator overloading, the Time type has .Add and .Sub methods to interact with Duration.

net/http

This includes a fairly easy HTTP/1.1 and HTTP/2 client and server with TLS support. An HTTP server fits in a Tweet:

```
package main

import . "net/http"

func main() {

        HandleFunc("/", func(w ResponseWriter, r *Request) { w.Write([]byte("hello
oo")) })
        ListenAndServe(":8080", nil)
}
```

This also provides a convenient interface to the query-string parsing in `net/url`; the `http.Request` object above has a `FormValue` method.

net/url

`net/url` does URL parsing, construction, escaping, unescaping, relative URL resolution, and query-string encoding and decoding.

```
u, err := url.Parse("http://bing.com/search?q=dotnet")
```

net/mail

`net/mail` parses RFC-822 (well, RFC-5322) mail messages and addresses, but not MIME, and it doesn't format mail messages, just parses them.

mime

`mime` implements "parts of the MIME spec", including reading /etc/mime.types and the b-encoding and q-encoding used in mail headers. Subpackages implement quoted-printable and multipart encoding, but I don't think there's anything here that will give you a decoded email message body directly; this package is more aimed at handling mail headers and HTTP messages.

regexp

This implements a fairly Perl-compatible regexp engine, including non-greediness and the Python extension of named `(?P<foo>bar)` capture groups, but with no backreferences. Given the history of Russ Cox and Ken Thompson in writing high-performance regular expression libraries, using DFAs that can't handle backreferences, you would think that this library would be super fast, but usually it seems to be noticeably slower than Python's and Perl's. It does, however, avoid the exponential behavior characteristic of NFA engines in cases like this:

```
// Pathological regexp.
// The Python equivalent takes exponentially long:

// __import__('re').compile('(x|xx)*y').match('xxxxxxxxxxxxxxxxxxxxxxxxxxxxxxxxxo
oxxxxxxxxxxx')
package main

import "regexp"

func main() {

        regexp.MustCompile("(x|xx)*y").FindString("xxxxxxxxxxxxxxxxxxxxxxxxxxxxxxxxo
oxxxxxxxxxxxxxxx")
}
```

encoding/gob

This is a generic serialization/deserialization system, using a Go-specific serialization, and it seems to be the closest equivalent to Python's `pickle`, though it doesn't support circular references. It supports maps, structs, arrays, slices, bools, signed and unsigned integers, floating-point numbers, complex numbers, and strings; structs include only exported fields, and functions and channels are omitted. Interface types are supported with a little more hassle.

It is not necessary to register user-defined types before sending them or for them to implement any particular interface, although there is an interface that they *can* define to override the default marshaling. There is some limited support for schema evolution even in the default marshaling.

encoding/json

`json.Marshal` converts a Golang value into JSON; it supports bool, numbers, strings, arrays, slices, maps from string, and structs (except for unexported fields or fields tagged with "-".) This is actually the only use I've seen so far of struct field tags.

Naturally, of course you can override the JSON serialization by implementing an interface.

`json.Unmarshal` takes an optionally-nil destination argument, which I suppose allows it to determine what types to deserialize things as.

This module *does* support reading a sequence of JSON values from the same input stream; perhaps more interestingly, it has some minimal support for sequentially reading JSON items inside an outer JSON wrapper.

encoding/binary

`encoding/binary` contains functions `Read` and `Write` which can be used to parse and generate binary data in an externally-imposed format. They're slow because they use reflection ("Python-class slow," as Tommi Virtanen explained to me). This provides an easy way to do what the Perl `pack` and `unpack` functions do, or `struct.pack` and `struct.unpack` from Python.

image

This module and its submodules provide support for encoding and decoding PNG, GIF (including animation), and JPEG files. You generally will load the images by calling `image.Decode` without explicitly mentioning the specific image format module, except to import it, but to save e.g. a PNG you need to call `png.Encode`.

The `image.Image` interface looks impossibly inefficient, requiring an indirect function call and some coordinate arithmetic for every pixel.

It looks like the PNG loading is eager and ahead-of-time, storing the image in RAM, although `image.Image` doesn't strictly require that.

The `image` module also contains some basic 2-D graphics stuff, like `image.Rectangle` (bounding boxes) and `image.Point`.

C

cgo isn't actually a Golang package; it's a way to invoke statically-linked C libraries. But you import it as a package named "C", and you add some special comments before that import in order to link in the stuff you want.

...and then the Go compiler searches your directory for files named `*.c`, `*.s`, `*.S`, `*.cc`, `*.cpp`, or `*.cxx` (but not `*.C`) to compile with the C, C++, or assembly compiler. Except that I'm not clear which compiler it uses for this: GCC or the Plan9 C compiler?

Presumably if you want to load and invoke shared libraries written in C, this is the way to do it.

yacc

If you want to parse something more than regular languages, `go tool yacc` is probably the thing to use. It's mostly undocumented, but it's similar enough to Bison, ocamlyacc, etc., that it should be reasonably attainable.

Somewhat more recondite packages

I've also taken some notes on some other packages that seem less central to me.

html/template

`html/template` gives you convenient XSS-safe HTML templating. Its capabilities are fairly elaborate, and there's also a `text/template` package for doing the same kind of thing without the HTML escaping.

syscall

This deprecated package provides access to basically the entire Linux (or other) native system call interface, including weird things like epoll(7), `ETH_P_IRDA`, inotify(7), `SCM_RIGHTS`, and openat(2). The `unsafe` package has some details on directly invoking Linux system calls.

This is also the package where you get errno values, if you want to test those against the `Err` attribute of e.g. an `os.PathError`.

encoding/xml

`encoding/xml` contains an XML parser and emitter, some HTML parsing, and something that looks suspiciously like another generic serialization system like Gob and the one in `encoding/json`, but really isn't.

The serialization system handles arrays, slices, structs, and interfaces, but not maps, and like the JSON serializer, it optionally uses struct field tags. It seems to be designed to allow you to produce arbitrary XML by marshalling structs, and parse almost arbitrary XML by unmarshalling.

This module doesn't provide DOM or SAX interfaces, but it has interfaces that are sort of similar.

net

This library provides sockets, basically, but with a somewhat nicer interface. Like, actually a dramatically nicer interface. TCP sockets have SetNoDelay and SetLinger methods, for example, and you can invoke `net.Dial("tcp", "google.com:http")` to open a connection.

index/suffixarray

`suffixarray` provides an in-RAM search index that supports regular expression searches, though using a log-linear-time construction algorithm rather than a linear-time one. On my laptop, it takes about 1.8 seconds to index a megabyte, about 26 seconds to index 10 megabytes, and 540 seconds to index 100 megabytes; then, each match for a simple regexp in the 10MB index takes 1.3 ms, and each match in the 100MB index takes 2.5 ms. It uses 1.6 GB of RAM to index 100 megabytes, which is maybe a bit excessive.

You can write the index to a file, which is about 4.8 bytes for each byte that you originally indexed. My laptop can then read the index in at about 100 megabytes a second, which is a necessary prerequisite to doing searches with it.

As a point of comparison, I tried `index/suffixarray`, the raw regexp engine, and the Python regexp engine to find the '^From ' lines delimiting messages in a 100MB mbox. The indexed search found the 3593 `From_` lines in 17.5 seconds. Just reading the file in and running the regexp engine over it found them in 12.6 seconds. The Python version took 2.0 seconds.

This seemed like unreasonably poor performance, so I tried searching for a spammer's email address. The Python version found

the three matches in 430 ms; the Golang brute-force version found them in 210 ms; and the indexed version found them in 4.3 seconds, of which 4.0 seconds were spent reading the index.

Just for kicks, I tried a Perl version. It produced the 3593 `From_` lines in 220 ms and the three hits for the spammer's address in 195 ms, but upon trying to find all the lines *containing* the address (regexp `^.*VanceE.McCray.*`), I killed it after 21 minutes. Python managed to finish that job in 2.7 seconds, the Golang brute force version in 36 seconds, and the Golang indexed version in 45 seconds.

So I haven't been able to find any cases where `index/suffixarray` is faster than doing a brute-force regexp search on the file data in RAM, even though it uses several times as much RAM.

runtime

`runtime` provides control over the garbage collector (including setting finalizers), a `Caller` function to walk the stack, and a bunch of profiling stuff I don't know how to use yet. (I guess I could call the `runtime.debug.PrintStack` function periodically and save the results, and that would be a crude profiler.)

net/rpc

`net/rpc` is an RPC system using the `encoding/gob` serialization; a JSON-serialized variant is in `net/rpc/jsonrpc`. It doesn't enjoy a lot of syntactic sugar.

zip

`zip` lets you read and write zipfiles, but only items compressed with the "store" and "deflate" methods. It uses the same `io.Reader` and `io.Writer` interfaces everything else does (or rather `io.ReadCloser` and `io.Writer`.)

Topics

Ghettobotics: making robots out of trash

Kragen Javier Sitaker, 2013-05-17 (41 minutes)

I've been thinking for a while about low-cost electronics projects. What could you make out of the garbage? People throw away electronics all the time, and recycling it is an interesting sustainability and autonomy experiment.

The ultimate goal of Ghettobotics is a self-sustaining industrial economy that consumes nothing but discarded electronics and other trash and produces, with a minimal amount of human effort, useful robots. To this end, every tool and material used in the Ghettobotics program can be made out of trash, by Ghettobotics itself.

A big part of the problem is that you can't make much out of electronics without some fairly specialized tools. So the first problem is how to build the tools out of garbage --- maybe using a previous generation of tools you bought in a store.

So what tools do you need? These would be desirable:

- A soldering iron.
- Desoldering equipment.
- A basic VOM: volt-ohm-milliammeter.
- An LCR meter.
- An oscilloscope.
- A display.
- Current-limited variable-voltage power supplies.
- A logic analyzer.
- A JTAG board.
- A serial terminal.
- A PROM burner.
- A pick-and-place robot.
- A solder stencil cutter.
- A reflow oven.
- A CNC mold cutter.

You also need some basic electronic and mechanical parts; the following are desirable:

- Solder.
- Wires.
- Connectors.
- Resistors, capacitors, inductors, transistors, diodes.
- Displays.
- Speakers.
- Cases.
- Motors and motor controllers.
- Amplifiers.
- Analog-to-digital converters.
- Digital-to-analog converters.
- Presence sensors.
- Light sensors (pixel array or otherwise).
- Motion measurement.

• Microcontrollers.
• Memory.
• Batteries.
• LEDs.
• Other lights.
• Buttons.
• Touchpads.
• Wireless communications modules.
• Range measurement devices.
• Power supplies.
• Solder paste.
• Temperature sensors.
• Relays.
• Shift registers.
• Wheels.

In taking apart and buying electronics, I'm highly impressed by the degree to which they seem to have been designed by people who can't program, and therefore prefer electronic or even mechanical complexity to simplify software. Now that you can get low-power microcontrollers for under a dollar, this seems absolutely idiotic to me, except in cases where software simply won't cut it. I conclude that knowing how to program is an incredible secret weapon in electronics design.

A soldering iron

This is basically a resistive wire that can get hot and has a pointed tip. This should be relatively easy to improvise, I haven't tried. In a pinch you don't even need the resistive part; you can heat up a chunk of metal with fire.

For cleaning the tip, if cellulose sponges are hard to find, you can use wet paper or cardboard.

A temperature-controlled soldering iron would be really useful; you can use a thermal-resistance "voltage divider" with your hand as the known-temperature "ground" to measure the tip temperature with pretty much any old temperature sensor. Then you just need a little hysteresis and something to turn mains power on and off with; a triac? Not sure. A high-power relay would work.

Desoldering equipment

Desoldering parts with just a soldering iron is feasible, but tricky and messy. It's especially difficult using just a low-wattage pencil-type iron, which simply can't handle desoldering high-current or heat-sinking connections; a high-power soldering gun would have less risk of damaging chips. Hot-air heating is apparently the standard approach here for rework stations, but I imagine you could also use a reflow oven or hot plate.

Rework stations also have desoldering irons different-shaped tips for desoldering different parts quickly, heating up all their pads at once. I don't know how to improvise this.

Beyond just heating solder up, it's also handy to have other metals to mix into it to lower its melting point. Standard lead-tin solder alone can help if you're trying to desolder modern lead-free devices; lead might work too. The other alternatives that occur to me sound either expensive or, in the case of mercury, dangerous.

Solder braid or a solder sucker also helps a lot. Presumably if you have some copper wire sitting around you can braid it into solder braid, but a solder sucker would help more if you want to be able to recycle the solder. An improvised solder sucker could maybe be made from a metal tip with heatsink fins on it and a rubber squeeze-bulb, but it's going to be difficult to make something that performs as well as a standard Teflon tip.

A VOM

The traditional way to build a VOM is with a galvanometer, a network of resistors with a selector switch, and a battery for the ohmmeter bit. You can still do this (hard disks are built around voice-coil actuators that should work well for the galvo) but it's probably more reasonable to use a cheap analog-to-digital converter that measures voltage directly, then use a microcontroller to convert the reading to something comprehensible.

Historically, VOMs have been designed around linear components, because nonlinearity is hard to compensate for in the analog realm. It's really easy to compensate for in the digital realm, so it probably makes more sense to not worry so much about linearity.

The electrically simplest design for a VOM is something like a microcontroller with a built-in ADC, a voltage divider (one large resistor between the voltage input and the ADC pin, and one small resistor from there to ground), a speaker or piezoelectric sounder, and a battery; total of five components. Current inputs connect directly to the ADC pin and ground; voltage inputs go through the large resistor, enabling the measurement of voltages much larger than the microcontroller can deal with directly. An additional input pin with a pullup resistor and ADC input is used to measure resistance. The microcontroller uses speech synthesis to communicate the results of the measurement.

If you're willing to require an external display, you can ditch the speaker and send the measurement results over a serial or USB connection; if you're willing to require an external power supply (say, an unplugged laptop on battery, connected via serial or USB), you can ditch the battery too, getting down to three components, two of which are resistors.

Back-of-the-envelope calculation says that with a 10-bit ADC with selectable 5V and 1.1V range (like what you get on an Arduino) and a 50:1 voltage divider, you can measure up to 250V with 0.25V precision and up to 55V with 0.05V precision. If you then manually connect smaller voltages (below 5V) directly to the ADC pins, you can get up to 5V with 0.005V precision and up to 1.1V with 0.001V precision.

You can use a microcontroller without an ADC if you can convert the quantity you want to measure to a measurement of time to exceed a digital threshold; for example, you can hook up a capacitor between a couple of pins of the microcontroller, instead of a resistor, and measure an RC time constant. You may be able to get better precision this way, but it depends on your capacitor's temperature-constancy and on your oscillator's constancy. You may be able to calibrate to temperature, both by charging the capacitor under microcontroller control at start time, and by using a temperature sensor. (Many microcontrollers have temperature sensors

built in.)

A very useful feature of VOMs in general, lacking in the normal ones, is to correct for noisy connections. If you average over time, a shaky connection to a 10-volt power source might look like 9 volts, 5 volts, or 1 volt; but if you look at the voltage waveform at microsecond resolution, you can tell that it's 10 volts with a shaky connection, not 5 volts or whatever. VOMs (and LCR meters) built around ADCs should be intelligent enough to do this correction.

Nonlinear frontend

It would be interesting to examine some diode-resistor networks to see if you can get a wider range with good precision by building a nonlinear input circuit, avoiding the need to switch ranges in order to measure large and small voltages --- and, perhaps more importantly, the possibility of blowing up your meter by hooking it up to a too-large input signal. I'm thinking something like using a high-current power-rectifier diode in place of the low-value resistor in the voltage divider, so that the voltage signal you measure is the diode's minimal turn-on voltage drop, plus an additional voltage that's nearly logarithmic in the current that passes through (which is more or less the input voltage E divided by the larger resistance R between the input and the ADC pin).

Something like the ON Semiconductor MBRAF1100T3G Schottky power rectifier diode would be ideal: assuming 25°C, at 20 mA it drops 0.42 volts; at 200 mA it drops 0.54 volts; at 2000 mA, which is above its maximum rating, it drops 0.70 volts; and at 20 A, it drops 0.98 volts. (Serious temperature compensation would be needed to get a reasonably accurate measurement, because the voltage varies by more than a millivolt per °C.) It would be very difficult to drive the voltage across this diode into a range that would damage a microcontroller, even one without 5V-tolerant inputs.

If your ADC precision were 1mV, this would give you measurement precision of around 1% for currents in this range, at the cost of imposing a significant voltage drop.

If we assume that the diode doesn't turn on until 0.42 volts, which is probably about right, then you'd have effectively an ideal voltmeter up to 0.42 volts, and above that, nonlinear response depending on your input resistor. You probably want your input resistor to be quite large, since the diode isn't going to provide much input impedance above half a volt, but you can't make it too large or you won't be able to measure voltage at all. With an absolutely minimal requirement of being able to measure a doubling of input voltage per 1mV increase at the ADC pin, and only trying to measure up to 100V (the maximum reverse-bias rating for this diode), you need 100V to give you 0.428 volts at the ADC pin, which would be about 23mA through the diode, so your input resistor can be at most about 4kΩ. With this network, you can get better voltage precision than the quarter-of-a-digit that this implies, but only at the cost of a lower input impedance.

I have no idea how common Schottky power rectifiers are. I've found lots of power rectifier diodes in the garbage but I have no idea what kind they are. I assume most of them are large standard silicon diodes.

So you might be able to do better with a more elaborate network,

or using a separate input pin for voltage measurement. You probably want a diode that's rated for a lot less than an amp. The Vishay SD101A, for example, goes from 200mV at 0.01mA to 1000mV at 15mA, and is rated for 60V max reverse voltage; the same 4kΩ input resistor and 1mV measurement precision at the ADC pin would then give you some ±2% precision on your voltage measurement over that range and down to 50mV, rather than the +100%,-50% you'd get with the power rectifier. That is, with this configuration, your meter can measure voltages covering three orders of magnitude with a consistent ±2% error. That's probably better than the analog multimeter I normally use.

(Incidentally, this configuration might also be useful for digitizing audio and other signals; you only get about 34dB of SNR, but it's a consistent 34dB across 60dB of dynamic range, instead of having a noise floor 34dB below the strongest possible signal. You get 94dB separation between the strongest measurable signal and the weakest measurable signal, as if you were using a 17-bit ADC instead of a 10-bit ADC. Analog Devices recommends this in their application note MT-018, and explains that this resistor-diode configuration is how Bell originally implemented μ-law for voice digitization!)

An LCR meter

If you're fishing inductors and capacitors out of the trash, or even just using surface-mount ones, you probably need to be able to measure them; the device you need is an "LCR meter", and they are available new for less than US$40. But variants on the previous section's ohmmeter circuit should be able to provide reasonable measurements.

A really handy physical design for this is the "smart tweezers" design, where the probes for your LCR meter are flexible and elastic, so you can pick up the component under test between them, or even touch them to the component in-circuit before bothering to desolder it.

Many microcontrollers have ADCs but no DACs, which means that stimulating a device under test with a sine wave is out of the question without further hardware. Measuring the impulse response of the component is theoretically sufficient, but you can also generate digital white noise to stimulate the component with, then compute the Fourier transform of the noise and the measured current waveform.

This test provides enough information that you can automatically test the hypothesis that the component you're measuring is actually just an RL or RC circuit, and rather than giving dubious numbers when it's clearly not, you should try some more elaborate hypotheses --- more elaborate network models, or nonlinear components like diodes and transistors.

There are several articles about homebrewing LCR meters with microcontrollers:
http://www.kerrywong.com/2010/10/16/avr-lc-meter-with-frequency-measurement/, http://electronics-diy.com/lc_meter.php,
http://web.archive.org/web/20080405215220/http://ironbark.bendigo.latrobe.edu.au/~rice/lc/,
http://py2wm.qsl.br/LC_meter/LC_meter-e.html,
http://reibot.org/2011/07/19/measuring-inductance/. Cypress has

an example project using their analog PSoC chips at http://www.cypress.com/?app=forum&id=2492&rID=76890.

An oscilloscope

This can be usefully separated into data acquisition and display.

Data acquisition

At times I've had some success using my sound card in place of an oscilloscope. If the signals are within the audio range, a standard 8Ω speaker can also provide some valuable information about them. But what you really want is to digitize the signal and display it on a screen.

You can, of course, use any ADC. But a standard cheap analog oscilloscope has 20MHz bandwidth, which would require a 40Msps ADC, and actually a 20MHz analog oscilloscope can still detect signals much higher than 20MHz. 40Msps ADCs are not commonplace. AVR ADCs can be run at up to a couple of Msps with reduced resolution (about 6 bits), and I found a three-channel 12-bit 2Msps ADC in a discarded flatbed scanner. Some such scanner ADCs can digitize a single channel at three times their three-channel speed.

Many of the remarks about cheap-shit VOM frontends apply here too. You can use a nonlinear input network and restore linearity in software.

If you want to examine a high-frequency signal that is repetitive or nearly so, you should be able to downconvert it into a lower frequency band in order to digitize it with a lower-data-rate ADC. In fact, if the sample-and-hold circuit on your ADC is fast enough, you may be able to do this with no extra analog circuitry!

Another approach is to use many ADCs in parallel, triggering them in a round-robin fashion. The guts of about 8 scanners would suffice to produce a 40Msps data-acquisition system this way, with a little bit of coordinating circuitry. This, however, also depends on the sample-and-hold circuits being sufficiently fast.

Oscilloscope display

If you have a laptop, you should use that, because you can afford dramatically greater amounts of computation and storage for display that way than if you build it yourself out of garbage. See below.

Analog oscilloscopes provide great variation in intensity, carrying additional information. Oona Räisänen demonstrated the rather impressive difference in her post Rendering PCM with simulated phosphor persistence:

Now how cool is that? It looks like an X-ray of the signal. We can see right away that the beep is roughly a square wave, because there's light on top and bottom of the oscillation envelope but mostly darkness in between. Minute changes in the harmonic content are also visible as interesting banding and ribbons.

A display

For lots of measuring-equipment stuff, you need a display. The traditional approach is to integrate the display into the measuring instrument, but it probably makes more sense to separate them, so that you can amortize the effort of building a good display over several measuring instruments, each of which can then be extremely

simple. You may want a simple seven-segment display on the measuring instrument itself (easily recoverable from discarded calculators or watches) but more detailed data display is probably better with a separate display device.

People are throwing out CRTs all over the place, but here in Buenos Aires, it's difficult to find an intact discarded CRT --- cartoneros break off the yoke to recycle, ruining the tube. But if you can find an intact CRT, you can probably drive it with a VGA or composite NTSC or PAL video signal from a microcontroller, without having to worry about any of the electronics inside the case.

The TVout library for AVR microcontrollers works quite well with just two output pins and a couple of resistors to generate a blocky one-bit black-and-white NTSC video signal, which is dramatically better than nothing, but I think you can do better with even a few bits of ADC. A three-bit or four-bit R-2R ladder DAC is easy to construct.

Trickier is that the TVout library uses a lot of memory (kilobytes) for a framebuffer. This dramatically limits the resolution, and inhibits the use of grayscale. More elaborate software could display higher-resolution vector graphics.

A perhaps more interesting approach is to use displays from discarded cellphones, which typically have their own framebuffer. You send them commands to write (and maybe even read) their framebuffer, so you don't need to have enough memory yourself.

Audio output is another, cheaper option. Aside from simple approaches like beeps for continuity testers, there are several implementations of speech synthesis on AVR microcontrollers, one of which is Cantarino (LGPL); I think you can get comprehensible speech at under 100k 8-bit multiply-accumulates per second, which is within the capability of many microcontrollers; it should be about 0.2% of the CPU cycles of an Arduino. Arjo Chakravarty has even done speech *recognition* on an AVR, called µSpeech.

Bench power supplies

For testing, you need a bench power supply with selectable output voltage, one that's not necessarily highly efficient, but is hard to burn out. I found an adjustable-voltage DC-DC converter chip in a discarded scanner, but I haven't yet tried using it for anything.

I don't know how to build robust power supplies, but I assume that big power clamping diodes and big current-limiting resistors are involved.

A logic analyzer

This is especially important for reverse-engineering the undocumented controllers often found in discarded electronics, but you also need it to diagnose problems in the things you build. You can make a slow logic analyzer (say, a few million samples per second) with just a microcontroller using its GPIOs; what remains is only to view the waveforms.

A fast logic analyzer probably needs shift registers or something.

A JTAG board

Lots of embedded systems can be put into debug mode and even

reprogrammed with a JTAG interface; you can also use JTAG's boundary-scan functionality to map out board connectivity and diagnose connectivity faults in your own devices. Four pins on a microcontroller, hooked up to a standard 6-pin JTAG header, suffices to control other things through JTAG.

One of the most common JTAG cable chips is the FTDI FT2232, which you're not likely to find in the garbage, unless it's garbage from an electronics lab. But you probably want to emulate it in software so you can use existing JTAG software on your laptop.

Felix Domke wrote a paper about JTAG for reverse engineering in 2009, which he presented in much more detail in a talk at 26C3, and the NSA@home project used JTAG to reverse-engineer boards that had FPGAs on them to repurpose the FPGAs for hash cracking; they published software for this called "jrev".

Among other things, JTAG lets you identify JTAG-attached chips automatically and use them as shift registers.

A serial terminal

Any old computer will work as a serial terminal, with its own display; but you may want a microcontroller-based serial terminal. A "terminal emulator" program that does what the Arduino's serial monitor does is quite simple; it doesn't even support backspace. A more full-featured serial terminal can easily fit into a microcontroller.

A PROM burner

If you're recycling old garbage electronics, their ROMs can be useful for several different purposes:

• Dumping the ROM can allow you to repair other instances of the same device that have damaged ROMs, or to reverse-engineer the controller that runs the program found in the ROM.
• If the ROM is reprogrammable, you can use it to store other data, or even...
• if the ROM is programmable and asynchronous, use the ROM as a programmable logic device whose inputs are the address lines and whose outputs are the data lines.

To reprogram an EPROM or EEPROM you need at least a PROM burner and possibly an EPROM eraser, which is a shortwave ultraviolet light. PROM burners are relatively straightforward to build with a microcontroller, although they do often need control of 12-volt voltage, which you can achieve with many of the chips you'd use for motor control.

A pick-and-place robot

If you're building your own circuits, eventually you will benefit from being able to assemble them automatically instead of by hand. I don't know all of what is involved in this, but I think that a lot of the mechanical and electronic difficulties of high-precision X-Y positioning are already dealt with by many inkjet printers.o

A solder stencil cutter

This lets you squeegee solder paste onto a printed circuit board so you can solder your surface-mount components all at once with a

reflow oven instead of one at a time. It's basically a plotter. You should be able to use overhead-projector transparency film for the stencils themselves, but X-ray film might be an alternative where you don't have sufficient overhead transparency film handy.

I don't know what's involved in actually cutting these. I think a vinyl-cutting machine might work.

A reflow oven

A reflow oven bakes your circuit board until the solder paste melts and all of your components are glued into place. SparkFun has a tutorial on their site on how to use a hot plate for this instead, but presumably you can also build your own reflow oven from a metal box, some heating elements, and a thermostat.

A CNC mold cutter

Michal Zalewski's "Guerrilla guide to CNC" explains that often it's more reasonable to make even one-off robot parts by cutting molds for them and then casting them than to cut the parts directly. You can go a long way with a three-axis robot for this, which might be the same one that does your pick-and-place.

Long ago I saw a video of an X-Y robot that avoided the difficulties of gantry construction by using two turntables in parallel planes, one of whose edge passes over the center of the other; by this means, you need only rotary motion rather than linear motion. This way, X-Y positioning needs no more mechanical complexity than a couple of bicycle wheels driven by belts from motors, which is considerably less than the mechanical complexity of an inkjet printer.

Solder

Recycling solder is a little tricky, but I think a solder sucker is probably sufficient. You probably need to add new flux; I think pine pitch is sufficient, but haven't tried it. You probably also want to keep your RoHS lead-free solder separate from your traditional lead-tin solder.

Wires

Ethernet cables typically have nice solid wires that are easy to work with.

Connectors

It's a pain in the ass to deal with multi-board circuits that are connected by wires soldered to all the boards; they tend to break easily. Connectors are easily recyclable. The most robust connectors are from automotive systems.

It's also valuable to be able to connect to standard cables: audio, video, network, etc. Ethernet cables are especially useful for unintended uses, since they tend to be long.

Resistors, capacitors, inductors, transistors, diodes

Small ones of these are all over the place (many of them are literally a dime a dozen new from Digi-Key). The tricky part is keeping them

categorized, since you need so many of them. It may be worthwhile to catalog them with an LCR meter in situ, only desoldering them from their original board when you need them after looking in a search engine. Smart tweezers on a pick-and-place robot could theoretically categorize them into little boxes.

Larger items are somewhat harder to find. Discarded old fluorescent light fixtures typically contain large inductors as "ballast"; I've found large resistors in discarded microwave ovens, and of course they're often used as heating elements; large diodes are often found in power supplies. Large transistors, capacitors, and transistors, I have no idea.

Displays

As components rather than tools --- I've mentioned CRTs, cellphone displays, and 7-segment displays from calculators and watches, but there are many other premade displays out there.

LCDs can be recovered from broken laptops.

I haven't yet tried to connect new wires to a broken e-ink screen, but if it's feasible, broken Kindles would be a rich source of excellent displays.

Vacuum fluorescent displays are among the most visually appealing to me, but they also require a high-voltage source, so they're tricky to work with.

Laser displays are traditionally done with a couple of galvanometer-driven mirrors, and they look awesome. I've speculated about building laser displays by deflecting mirrors using speaker cones instead, which would make them cheap as dirt; and you could use a laser display with a light sensor as a camera or scanner, too.

Speakers

These are the easiest components to scavenge: half-broken earphones, dynamic speakers in broken TVs, piezoelectric speakers from greeting cards, and so on.

Cases

When I was a kid, we used cardboard boxes for our electronic projects; but nearly anything can be used as a case: empty bleach bottles, books, tin cans, discarded pots, blocks of wood, hunks of styrofoam (modulo ESD issues). Many discarded electronics include particularly robust steel cases, but toys provide plastic cases that are easier to drill.

Motors and motor controllers

Inkjet printers typically have two relatively powerful (around 20W) stepper motors and PWM-controlled H-bridges to run them. Flatbed scanners will have one, which will be lower power. Laser printers have motors too. Power-supply fans have brushless DC motors. CD drives need at least two motors, one to spin the CD and one to move the head, but may have a third one to open and close. Disk drives have high-speed motors with the finest bearings in the world. Washing machines, refrigerators, and the like have much higher power motors, into the hundreds of watts and beyond; car

starter motors are *really* high power, into the tens of kilowatts, but only work on a very short duty cycle.

Even small stepper motors probably need more than 5 volts. Chips like the ULN2003 can help with this, but then there are PWM H-bridge chips like the LB1845.

Recent Epson inkjet printers use proprietary motor control chips which seem like they'd be really useful if they can be reverse-engineered.

Bigger motors need things that can control several amps of electricity, often relays.

Amplifiers

You need amplifiers for lots of things: driving speakers, controlling motors, and boosting delicate analog signals so they can get to where you digitize them. Amplifiers tend to be fairly specialized. Audio equipment tends to have lots of amplifiers in it, including opamp chips, that won't work much outside the audio range; but an awful lot of useful signals are in the audio range.

Analog-to-digital converters

ADCs are fundamental to interfacing with the outside world. Some microcontrollers have them built in; if not, you may be able to do delta-sigma DAC with not much more than an analog comparator, such as an opamp, and a resistor and capacitor. But lots of discarded electronics has separate ADCs in it, because keeping the ADC on a separate chip reduces electromagnetic interference. So you can find separate high-quality ADCs in scanners and some audio equipment, at least.

Digital-to-analog converters

Even more audio equipment has high-quality digital-to-analog converters, and you can cheat by using PWM or PDM at a high frequency; just be careful your high carrier frequency isn't going to blow up any tweeters.

Presence sensors

Optical presence sensors are ubiquitous in printers and scanners; the light from an infrared LED is blocked, or not, on its way to a phototransistor. Typically they use them as a "home position" sensor.

Light sensors

Scanners, digital cameras, cellphones with digital cameras, and optical mice contain light sensors. LEDs can also be used as (slow, noise-sensitive) light sensors. (I haven't been able to reproduce the Mitsubishi paper that reported microsecond-range sensing times with reverse-biased LEDs; I get more like hundreds of milliseconds.)

Motion measurement

Robotics involves being able to measure how far things have moved and where they are --- at least parts of the robot, and maybe things the robot interacts with. There are lots of ways to do this. Stepper motors emit pulses as you turn their shafts; servomotors typically use integrated potentiometers; optical encoders like those

used in ball mice give you a quadrature-encoded signal that tell you how fast things move; optical mice take a high-frame-rate video of the table the mouse is sitting on. I've seen inkjet printers that use linear optical quadrature sensors to sense the printhead position, as well. At the high end, shaft encoders give you an absolute shaft position readout, typically using Gray code.

Digital cameras in general can be used with machine vision algorithms to measure position and motion. This is easier with structured illumination, e.g. a laser pointer.

Binary chain codes are a promising alternative to quadrature encoding to measure absolute positions instead of just relative motion, with some bootstrapping time. Random noise, as long as it's repeatable, should work almost as well as a designed binary chain code.

Accelerometers and gyroscopes are a particularly important kind of position sensor for many purposes: balancing on wheels, flight control, and protection from falls, for example. Off-the-shelf MEMS accelerometers and gyros are what current cellphones and laptops use, but they aren't old enough for many of them to have made their way into the trash stream yet. The traditional kind of accelerometer is a sprung weight controlling a potentiometer slider, and it seems like that sort of thing shouldn't be too hard to improvise, given other kinds of position and distance measurements.

Microcontrollers

This is one of the biggest problems for actually bootstrapping with garbage. You need *something* you can program to take advantage of all the amazing digital circuitry you can fish out of the garbage. You can get really awesome Flash microcontrollers from Digi-Key for under a dollar these days, but options in garbage are more limited; garbage electronics tend to be old, and mass-produced microcontrollers often use mask ROM instead of Flash, or have fuses blown that prevent them from being reprogrammed.

One option is to use a regular old computer running a real-time operating system like Linux-CNC's EMC2.

Another option is to find something that has the controller program stored in a separate ROM chip, and replace that ROM chip. This requires you to understand the instruction set of the controller, which is often not documented. Lots of reverse engineering is required here.

It turns out that lots of interesting devices from the last few decades actually do keep their program in a separate chip.

Memory

Lots of devices have RAM, though usually small; fewer have Flash. It might make more sense to look for discarded SD cards, which will be hard to notice in garbage, just because they're so tiny; but they're supposedly easy to interface with, because they support SPI. I've encountered a DVD player with a one-megabyte Flash chip in it, and a discarded cellphone with a 1GiB mini-SD card.

Actual old disks might make more sense for heavier robots. A disk that's "only" ten gigabytes is too small to be worth bothering with if you have any money; but ten gigabytes is quite a bit compared to what microcontrollers typically have built in. I'm not completely

sure, but I suspect SATA is easier to deal with than parallel IDE/ATA.

Batteries

Few discarded devices have working batteries. Some have marginal batteries. Fewer have workable rechargeable batteries.

Really building batteries out of trash will probably require re-purifying the materials from dead batteries and building fresh cells.

LEDs

LEDs are in just about every discarded electronic device. They wear out a bit after long use, but they remain useful.
High-brightness, blue, and white LEDs are recent (since about 1990), but you can still find them in trash occasionally.

Other lights

LCD displays and flatbed scanners typically include tiny cold-cathode tubes and high-voltage power supplies for them.

Occasionally you might find neon lamps and the like. Neon lights last *forever*.

When fluorescent tube filaments burn out, people typically discard the tubes. But I think it's possible to still run them as cold-cathode tubes; you just need a high-voltage power supply.

Buttons

You can use capacitive touch sensing to make buttons out of aluminum foil and paint; but also many devices contain multiplexed button matrices. Any light sensor can be used as a button.

PS/2 keyboards are commonly discarded and easy to interface to microcontrollers. Sometimes the discarded keyboards themselves work fine; at other times it is more to your advantage to hook up a couple of the keyboard matrix wires to some other kind of buttons.

Touchpads

I think you can make a resistive touchpad that works like a touchscreen out of pencil lead on paper.

Wireless communication modules

Only occasionally will you find a discarded device with working radio communication, other than cellphones, which are useless except for talking to the cellphone network, but there are DIY options: infrared, ultrasound, 900MHz, 2.4GHz; software-defined radio? Basically any discarded audio or video device (or, here, air conditioner) will have an IR receiver for the remote control, which will also have been discarded --- but possibly separately.

(Recent cellphones also have Wi-Fi, but I'm not seeing them yet in the trash.)

Presumably you could also use the parts of optical presence sensors as infrared transmitters and receivers.

Range measurement devices

Not only do you need to be able to tell where parts of your robot

are, you also need to be able to tell what's nearby.

Aside from the camera approaches mentioned earlier, ultrasound is a common ranging approach. I think you can do ultrasonic ranging with a couple of piezoelectric sounders, but I haven't tried it yet.

Power supplies

Nearly every discarded electronic device has some kind of power supply. Often it's broken, and fixing it or replacing it will fix the entire device. Sometimes it's partly broken, and some of its output voltages work fine. Power-supply chips are versatile and useful for many things.

Solder paste

If you want to reflow solder a surface-mount board, you need solder paste. You aren't going to find solder paste in discarded electronics, and in fact it has a quite limited shelf life. It's also difficult to buy in small quantities. I have no idea how to make solder paste out of garbage.

Temperature sensors

A lot of things (reflow ovens, temperature-compensated measurement, emergency scram on overheat) benefit from measuring temperature. Essentially every electronic component has significant behavior changes when its temperature changes, so in theory any electronic component can be used to measure the temperature!

Some current microcontrollers have built-in temperature sensors, but if not, you can probably build a bridge circuit with a couple of different kinds of resistors to give you a voltage that changes dramatically with temperature. Carbon-composition and wire-wound resistors have temperature coefficients that are opposite in sign. Alternatively, you could measure the RC constant of an RC constant.

Relays

All kinds of high-power devices (microwaves, refrigerators, washing machines, etc.) have relays controlling them. These are handy for robots too. Typical relays are only good up to a few kHz, but reed relays are good up to tens of kHz.

Shift registers

A crucial limitation on microcontrollers in general is the number of available digital GPIO pins. You can use a shift register to turn two or three GPIO pins into an arbitrarily large number of slower GPIO pins. But you aren't going to find a lot of discrete shift-register chips in modern discarded electronics.

JTAG to the rescue! Basically any JTAG-enabled device can be used as a shift register by using JTAG's "boundary scan" functionality. That piece of shit undocumented SoC you ripped out of some scanner, which won't even let you read its program from Flash, will work fine as a 200-bit shift register driven through JTAG!

Wheels

This is skipping quite a bit of mechanical stuff, but wheels are

important for mobility. Wheels are often available from discarded cars or discarded bicycles; bicycle wheels are likely more practical, and back wheels already come with sprockets attached, dramatically reducing the need for gearboxes.

Heavy robots probably need fairly powerful motors to propel their wheels.

Topics

B-Tree ropes

Kragen Javier Sitaker, 2019-09-24 (updated 2019-09-25) (19 minutes)

I just hacked together a quick rope-based string system in Lua, but it has rather alarming worst-case performance characteristics. I was thinking about improving such characteristics with B-trees.

The string and rope problem

If you build up a long string through successive concatenations, many string systems will suffer an $O(N^2)$ slowdown; for example, in LuaJIT this takes 2.4 seconds, which works out to 42 kilobytes per second; PUC Lua 5.2.4 is only slightly faster at 1.9 seconds:

```
N = 100000
s = ''
for i = 1, N do s = s .. 'x' end
```

CPython used to be really slow at this, but has a special optimization for this case now, so it takes such a small amount of time that it is difficult to measure accurately; the following slight variation still takes 700 ms, which works out to 140 kilobytes per second:

```
N = 100000
s = ''
for i in range(N): s = t = s + 'x'
```

This shows the expected $O(N^2)$ curve, taking 2.5 seconds for $N = 200\,000$ instead of $N = 100\,000$.

Moreover, in these systems, if the same large string occurs as part of M other strings, it uses up M times the space, and many of the concatenation operations are redundant.

It's common for such string-concatenation operations to consist of essentially variable interpolation — filling variable holes in otherwise-constant templates. Ideally we wouldn't be looping over all that unchanging data every time we render a web page or whatever.

Ropes

Ropes are trees representing immutable trees which originated in Cedar; you could describe the essential core of the idea in OCaml as follows:

```
type rope = Leaf of string | Cat of rope * rope
```

The idea is that `Leaf "foo"` represents the constant string `"foo"`, while Cat represents the concatenation of two ropes; `Cat (Leaf "foo", Leaf "bar")` is one possible representation of the immutable string `"foobar"`. This gives you constant-time string concatenation (if garbage collection is okay) and plenty of structure sharing, and you can convert the rope to a flat string in linear time when necessary — or just a `struct iovec` to send over the network with `writev`.

If the leaves are nonempty, this data structure has worst-case linear

space overhead, although it can be quite large, on the order of 64× the plain string.

If you augment this structure with lengths, you can additionally index and slice it in logarithmic time, if it's well balanced:

```
type rope = Leaf of int * string | Cat of int * rope * rope
```

If we define the function `rope_length`

```
let rope_length = function Leaf(a, _) -> a | Cat(a, _, _) -> a
```

we can state the invariant that `rope_length (Cat(a, g, d)) == rope_length g + rope_length d` (using "g" and "d" for *gauche* and *droit*) and maintain this with concatenation and lifting functions:

```
let leaf s = Leaf(String.length s, s)
let cat a b = Cat(rope_length a + rope_length b, a, b)
```

and define a function to drop the first *n* bytes:

```
let rec rope_drop n = function
 | Leaf(a, s) -> leaf (String.sub s n (a - n))
 | Cat(a, g, d) -> if n < rope_length g
     then cat (rope_drop n g) d
     else rope_drop (n - rope_length g) d
```

It is straightforward to define analogous functions to take the first *n* bytes, etc.

These functions will take logarithmic time and space if the tree is well balanced, but they can take linear time and space if the tree is imbalanced. Looking at the structure of `rope_drop` we can see that it's closely analogous to a binary-tree search where the search key in each `Cat(a, g, d)` node is `rope_length g`, though augmented by the past search keys. It's binary-searching the tree for the breakpoint.

It's also straightforward to write a function that converts a `rope` as defined above into a flat byte sequence; in OCaml, we invoke `Bytes.create` with the size of the string to be created, use `Bytes.blit_string` to copy each of the leaf nodes into the new sequence, and finally invoke `Bytes.to_string`; alternatively you can build up a string list and invoke `String.concat ""` on it, which does the same thing under the covers. This takes linear time and linear space regardless of the balance or imbalance of the tree, but it is necessary to be somewhat careful to avoid stack overflows.

My Lua implementation `macrope`

This implementation has four kinds of nodes rather than two — it additionally contains "variable nodes", representing template variables to be replaced, and "environment nodes", which provide values for those variables. This allows you to instantiate a template rope once and then use it repeatedly with different variable bindings without having to copy it around to modify it.

Because the size of the variable nodes can vary depending on their environment, the nodes don't know their size, so these ropes can't be sliced and indexed efficiently as the above OCaml code does.

The module exports a function `var` to define variable nodes and a

function `macrope` which idempotently coerces strings to macropes. Concatenation and parameter passing are done with the Lua `..` concatenation operator and the normal parameter-passing mechanism:

```
> macrope = require 'macrope'
> v = macrope.var 'name'
> s = v .. ' is the best friend of ' .. v
> = s { name='Bob' }
Bob is the best friend of Bob
```

Macropes can support large strings with linear, though poor, efficiency:

```
> x = macrope.macrope 'x'
> for i = 1, 25 do x = x .. x end
> =#tostring(x)
33554432
```

The first two lines execute instantaneously; the third line takes about 30–40 seconds on my laptop. No attempt is made to cache the results.

The $O(N^2)$ code above runs faster with `macrope` as follows, for N above about 10,000:

```
> s = macrope.macrope ''
> for i = 1, N do s = s .. 'x' end
> s = tostring(s)
```

The source code is organized as follows. `macrope` calls a `const` function if necessary, which is forward declared because I'm leery of Lua's scoping. Each node type has its own metatable:

```
# (in macrope.lua)
local catmeta, envmeta, varmeta, constmeta, const, macrope
```

All these metatables "inherit from" a common prototype metatable, but using a function that generates copies from it, rather than delegating to it using `__index`. They *do* share an `is_macrope` property via `__index`, which allows the `macrope` function to be idempotent.

```
local function meta()
   return {
      __index = {is_macrope = true},
```

The string concatenation operation is overridden to construct concatenation nodes:

```
      __concat = function(car, cdr)
         return setmetatable({car=macrope(car), cdr=macrope(cdr)}, catmeta)
      end,
```

The function-call operation is overridden as follows to create an environment node; note that each variable binding is coerced to a `macrope`:

```
      __call = function(self, vars)
         local nvars = {}
         for k, v in pairs(vars) do nvars[k] = macrope(v) end
         return setmetatable({vars=nvars, child=self}, envmeta)
      end,
```

Finally, coercion to a string as implemented by the standard `tostring` function (invoked implicitly by `print`) is done by using an explicit stack — because the worst cases I was alluding to above cause LuaJIT to kill the function if the stack gets more than a few tens of thousands of stack frames deep:

```
      __tostring = function(self)
         local items, stack, env = {}, {}, {}
         local function put(item) table.insert(items, item) end

         self:visit(put, stack, env)

         while #stack > 0 do
            local item = table.remove(stack)
            item(put, stack, env)
         end

         return table.concat(items)
      end,
   }
end
```

Mostly what remains are the `visit()` methods, which avoid recursion by pushing continuation closures on the explicit stack — which I managed to do in the wrong order at one point:

```
catmeta = meta()
function catmeta.__index.visit(self, put, stack, env)
   table.insert(stack, function(...) self.cdr:visit(...) end)
   return self.car:visit(put, stack, env)
end
```

The environment node needs to modify the environment, then arrange to restore it after its descendants finish executing:

```
envmeta = meta()
function envmeta.__index.visit(self, put, stack, env)
   local saved = {}
   for k, v in pairs(self.vars) do
      saved[k] = env[k]
      env[k] = v
   end

   table.insert(stack, function(put, stack, env)
                  for k in pairs(self.vars) do env[k] = saved[k] end
   end)
   return self.child:visit(put, stack, env)
end
```

Note that it's not safe to do `for k, v in pairs(saved)` because the saved value may have been a `nil`, in which case Lua would skip it in the iteration!

Variable nodes just delegate to their value (which, remember, was coerced to a `macrope` when the environment node was created), assuming the value exists:

```
varmeta = meta()
function varmeta.__index.visit(self, put, stack, env)
   local val = env[self.name]
   if val == nil then error("name not found: " .. self.name) end
   return val:visit(put, stack, env)
end
```

We need a function to export from the module to instantiate variables:

```
local function var(name)
   return setmetatable({name=name}, varmeta)
end
```

Constant nodes, the `Leaf` of the OCaml implementation above, simply invoke `put` to append their contents to the growing output buffer:

```
constmeta = meta()
function constmeta.__index.visit(self, put, stack, env)
   put(self.value)
end
```

There is a `const` constructor which could perhaps be inlined into the `macrope` coercion function:

```
const = function(value)
   return setmetatable({value=value}, constmeta)
end
```

Finally, the main entry point to the module does this type-testing DWIM magic:

```
macrope = function(thing)
   if type(thing) == 'number' then thing = tostring(thing) end
   if type(thing) == 'string' then return const(thing) end
   if thing.is_macrope then return thing end
   -- XXX maybe try to invoke tostring on it?
   error("not a macrope or string: " .. thing)
end
```

And the module exports:

```
return { macrope = macrope, var = var }
```

How worst-case ropes arise

One worst case is building up an extremely imbalanced tree of

single bytes:

```
macrope = require 'macrope'
N = 100000
s = macrope.macrope ''
for i = 1, N do s = s .. 'x' end
s = tostring(s)
```

As I said above, this takes 250 milliseconds, working out to 400 kilobytes per second. Although at this scale this is 12 times faster than the $O(N^2)$ native-Lua implementation, it's still ridiculously slow, and three times slower than when I wasn't using an explicit stack. For perspective, this takes about the same time, with 1000 times as many iterations:

```
macrope = require 'macrope'
function doit(N)
    s = 0
    for i = 1, N do s = s + i end
    s = tostring(s)
    return s
end
=doit(100*1000*1000)
```

Building the same string this way instead gets a further 5× speedup:

```
macrope = require 'macrope'
N = 10000
s = macrope.macrope ''
for i = 1, N do s = s .. 'xxxxxxxxxx' end
s = tostring(s)
```

Most of this speedup is in the explicit loop there, which took two thirds of the time before and now runs one tenth as many iterations.

This is the linear-search worst case that forced me to use an explicit stack in the `__tostring` function to avoid stack overflows, at the cost of a 2.5× slowdown in the `tostring` call. If you did some kind of tree balancing during the construction of the graph, it probably wouldn't speed it up (doing more work on each iteration would probably slow it down instead, even if the working set shrank) but it could speed the final tree traversal substantially.

A different kind of worst case is the other example above:

```
macrope = require 'macrope'
x = macrope.macrope 'x'
for i = 1, 25 do x = x .. x end
tostring(x)
```

This doesn't take long to construct, because there are only 26 nodes in the DAG, but in the `tostring` call the single leafnode is visited 33 million times; that's why it takes 30–40 seconds. Constructing the same string as follows instead takes 1.3 seconds, about 30 times faster:

```
macrope = require 'macrope'
```

```
x = macrope.macrope 'xxxxxxxxxxxxxxxxxxxxxxxxxxxxxxxx'
for i = 1, 20 do x = x .. x end
#tostring(x)
```

So it wouldn't take a lot of tree optimization to speed things up by quite a lot in this case.

Leafnode coalescence, and when it isn't enough

The simplest measure would be to have a special case for concatenating short const leafnodes: if the total length of the result is under some threshold, somewhere in the range of 16–128 bytes, it's better to just copy all the bytes into a new const node instead of making a concatenation node. This would help a lot with the million-laughs DAG above but would only slightly worsen the problem of successive concatenation at the end.

You could be a little more sophisticated and get a linear improvement by having your concatenation operator coalesce with non-root leafnodes, something that's dramatically easier to expressin a language with pattern-matching (here ^ is OCaml's string concatenation operator):

```
let cat2 a b = match (a, b) with
| (Leaf(n1, s1), Leaf(n2, s2)) when n1+n2 < 128 ->
    leaf(s1 ^ s2)
| (Cat(_, x, Leaf(n1, s1)), Leaf(n2, s2)) when n1+n2 < 128 ->
    cat x (leaf(s1 ^ s2))
| (Leaf(n1, s1), Cat(_, Leaf(n2, s2), x)) when n1+n2 < 128 ->
    cat (leaf(s1 ^ s2)) x
| (_, _) ->
    cat a b
```

This successfully reduces the tree depth by a linear factor — 128 in this case — in the simple scenarios considered above. It might speed up or slow down the tree construction, though if it does slow it down, that's probably just because 128 is a bit too big. However, it doesn't help in all cases — consider the case of alternately adding to the beginning and the end of the string:

```
cat2 (cat2 (leaf "x") (cat2 (cat2 (leaf "x")
                             (leaf (String.make 128 'h')))
                      (leaf "x")))
     (leaf "x")
```

The initial `String.make 128 'h'` produces a large leafnode, and the following operations of appending or prepending a single character are then blocked from coalescing.

Evidently it would be useful to have a tree structure with rigorous guarantees on worst-case behavior.

B-tree ropes

B-trees are great for worst-case performance. The tree has a uniform depth on every path from the root to the branches, and the high branching factor minimizes the number of internal nodes on

which we must waste storage space and the amount of memory needed for tree traversal. And, at least in principle, they're simpler than other popular self-balancing trees such as red-black trees, AVL trees, and treaps. (They also tend to be much faster, especially on modern deep memory hierarchies.)

But can we use B-trees for ropes like the above? I started an OCaml implementation in 2015 and never finished it but I think that in principle it's straightforward. To concatenate, you may need to add tree levels to the smaller rope, and then you can merge (by concatenating) newly-adjacent nodes moving down from the root until you encounter a place where merging would make the new node too big; then you stop.

I still need to read Okasaki's masterwork and the follow-on work in the decades since, but there's a trap in amortized analysis of FP-persistent data structures — typically, amortized complexity analysis assumes that once you've done some big messy reorganization, like rehashing a hash table into a larger array of buckets, you can be sure that you won't need to do it again anytime soon. But with FP-persistent data structures (like ropes!) the state of the data structure immediately prior to the reorganization may still be accessible, and so it may be possible to provoke the reorganization over and over again by deriving new states from it.

This suggests that to get good amortized performance from FP-persistent data structures, either you need mutability behind the curtain or you need good *worst-case* performance per update operation. This is a connection I hadn't previously suspected between the world of FP-persistent algorithms and the world of bounded-time algorithms, which are usually on opposite ends of the universe.

B-trees in particular are relatively friendly to this. Suppose you decide on nodes of about 128 bytes: 64–256 bytes of text for leafnodes, 8–32 pointers for internal nodes†. The worst-case B-tree for a 4-gibibyte rope is $2^{26} = 67108864$ leaf nodes, which is at worst 9 levels of internal nodes. So, to concatenate it with another such rope, at worst you'd have to merge together 9 pairs of nodes, about 2 KiB of memory traffic. This is definitely worse than the 32 bytes or so of memory traffic used by `cat` or `__concat` above, by about a factor of 64, but it's also fairly closely bounded. Note that with a minimal branching factor of 8, the internal nodes are guaranteed to use no more than ⅐ of the leafnode memory.

For smaller strings the cost is smaller — with those parameters, everything up to 512 bytes is guaranteed to fit into a single level of B-tree.

For perspective, this suggests that the process of inserting a character (or arbitrary string) into the middle of an FP-persistent 4-gibibyte rope will require on the order of a microsecond and ten kilobytes of allocation:

- 18 new nodes, totaling 4 kilobytes in cache to break the tree into two slices at the insertion point;
- 9 new nodes, totaling 2 kilobytes in cache, to create the tree for the new byte;
- 9 new nodes, totaling 2 kilobytes in cache, to concatenate the new byte to the left tree fragment;
- 9 new nodes, totaling 2 kilobytes in cache, to concatenate the right

tree fragment onto that.

Filling up these 10 newly allocated kilobytes of memory is going to take a few thousand instructions, which takes about a microsecond on modern CPUs. You could probably reduce this cost in the average case with a simplified "buffer gap" approach in which you maintain separate left and right trees, so that you normally only pay the cost of creating the new byte's tree and concatenating it onto the left tree.

I feel like there may still be aspects of B-tree rebalancing I'm not appreciating, even without slicing.

† CLRS claims that allowing nodes to be less than ½ full, as in the factor of ¼ in this example configuration, makes it no longer really a B-tree, and if we don't allow nodes to be less than ⅔ full it becomes a "B*-tree". However, CLRS gets terminology wrong pretty often, so this might not be right. My rationale for the extra factor of 2 slack, which probably doesn't really apply in an FP-persistent context (at least not without more work), is to prevent pathological modification sequences from thrashing between splitting and joining the same node.

Interactive calculator

Kragen Javier Sitaker, 2018-04-26 (16 minutes)

I've written a keyboard-driven interactive calculator at http://canonical.org/~kragen/sw/dev3/rpn-edit, but it's really more of a prototype than anything else, and using it on a cellphone is painfully clumsy. But it's already pretty useful.

It interprets an RPN program to produce a sequence of formulas and their corresponding numerical results, displaying both the formulas and the results; the values can be vectors, and vectors are plotted as sequences of numbers.

So I've been thinking about how to take advantage of multitouch and small screens, and I've come up with some ideas that I think will be substantially easier than what I have now, even without a keyboard.

One of the problems with the current approach I'm taking is that what you're editing is really the RPN representation of the set of formulas. This is particularly tricky when you're rearranging a formula, because it's hard to tell if you're going in the direction you want; you have to go through a lot of disorienting intermediate states first.

Another problem is that it's pretty time-consuming to select existing sub-terms. A third is that DAGs aren't really supported, because the stack machine doesn't have variables or operations like DUP, OVER, or PICK.

So here are a few ideas that are generic to multitouch in general which I haven't seen tried much or at all:

• Quasimode buttons which, while held down with one finger (and possibly pushed in some direction), cause touches with the other finger to have some unusual effect. For example, a trashcan button which, while held, sends everything you touch into the trash; a break-apart button which, while held, splits subnodes out of formulas and turns them into formulas themselves at the top level; a push-up button which, while held, factors subexpressions out of function definitions, copying them into all callers; etc. In a photo manager, you might have a rotate-90° quasimode, or a quasimode to apply a given filter. Quasimode buttons have the advantage over pie menus (mentioned later) that you can drag your finger around the display until you have the right thing selected, taking advantage of visual feedback to allow you to accurately select deeply nested subexpressions. Quasimode buttons should visually highlight the objects they are applicable to while they are pressed; they can also display a transparent, non-interactible message that explains what they do. And of course some of the buttons can be non-displayed at any given time, using scrolling or tabs to bring the desired buttons into view. Foucault et al.'s "SPad" prototype uses this approach. In Surale, Matulic, and Vogel's 2017 paper, it's called "non-dominant hand" or "non-preferred hand", a term they took from Li et al.'s 2005 pen-based paper; they found it was the fastest of all mode-switching alternatives tested except for two-finger strokes, although it had a higher error rate when the user was standing; users

rated it as the easiest to learn and most accurate when sitting, though it suffered somewhat on some other measures.

• A single primary selection or focus, as with Macintosh-style GUIs, which can be set by tapping an object; but unlike Macintosh-style GUIs, the selection of an object results in action buttons popping out of the sides of other objects for binary operations that combine the two objects. For example, if you have an expression "5" sitting around and another expression "[11, 12]" gets selected, the "5" should grow buttons for +, -, ÷, ×, ↑, and maybe some other things. Originally I was thinking that you should just use two fingers to select two objects, and that might be worth trying, but then I realized that in cases like these, most of the time you want to select newly created objects to do more things with them, and it's probably easier if that happens automatically without having to locate the new object and move your finger to it.

• Another kind of quasimode that turns the whole area of the display into a two-dimensional input for the currently selected item until the quasimode button (or perhaps just the drag) is released. For example, this could allow using the whole display to spin through enumerated alternatives, rather than the half of the screen that iOS Safari uses for `<select>` elements. This technique applies also to the sliders and dials mentioned later. Some FPS games may use this for aiming; Bret Victor's animation demos use it.

• To take advantage of multitouch's higher precision in motion direction than initial touch position, like the typical lower-left-hand corner movement pad in video games which centers on your initial tap, we can use pie menus — while your finger is on an object (perhaps with no quasimode active, or perhaps with a special menu quasimode active), a pie menu pops up around it to offer applicable unary operations. In the calculator, this is probably better for top-level formulas than for subexpressions, because selecting a subexpression could be finicky. The Banovic et al. multitouch variation of pie menus uses a second finger to select the menu item, which seems like it should work a lot better actually, since it's the distance and angle between the two fingers that determines the command. Gupta & McGuffin's 2016 pie menu paper is similar to the pin-and-cross method mentioned in #10, but by using two separate fingers to open the menu (selecting the object) and to select the menu items, it has two touchpoints to use to control the resulting operation once it's begun, allowing simultaneous rotation, scaling, and translation. Bitwig Studio's "radial gesture menu" uses motion to select one of a small number of "inner ring" menu items or a second finger touch to select items from an "outer ring".

• Operation previews, providing one step of lookahead: the arithmetic operation buttons sticking out of the "5" in the above example should show the results — "+ [16, 17]", "↑ [48828125, 244140625]", "× [55, 60]", and so on. Once the operation is selected, a new object is created, and it becomes the selected object. In the calculator, though maybe not in other contexts, the objects that went into it disappear (you can break it back apart if you want).

• In addition to the usual keyboard entry of numbers, entering univariate functions by drawing graphs of them with your finger is a very useful feature. You probably want some kind of weighted average of recent and nearby finger strokes in order to not introduce

discontinuities unintentionally and in order to allow changes that are small compared to your finger positioning precision. For discrete sequences of numbers, lollipop charts may be a reasonable alternative.

• Each object has multiple possible views: in the case of the calculator, for example, as a formula, as a sequence of computed numeric values, as a graph, and so on. Some past experimental user interfaces have used "lenses" that could be dragged over objects in order to provide these different views, but I think that's probably kind of gimmicky and clumsy, except for cases where you actually want to scrub a boundary back and forth over small parts of an image; it's better to just display all the views for the currently selected object, when there is one, and allow the user to "pin" views they want to keep visible. Video games actually do provide multiple views of the same data fairly often, but they usually aren't all interactive.
• A transparent overlay keyboard. An overlay keyboard for typing is an honest-to-goodness mode, rather than a quasimode, but it's probably necessary on current cellphones due to their small screens. But there's no reason it has to obscure your view of the workspace. (GTA 3 has a slightly transparent keyboard.) For the calculator application, you probably want to be able to enter several numbers in a row without stopping. Given sufficient scrollability, the always-visible quasimode buttons could be transparent as well, like most buttons and most status displays in most 3-D cellphone games, so that they effectively take up less screen real estate.
• Sliders and dials: in addition to entering numbers with the keyboard, we want to be able to adjust them interactively with a movement, as in Bret Victor's work. So two of the views available on any number literal are as a linear slider and as a logarithmic dial with one decade per rotation, plus a button in the middle for negation. These two views are quasimodal in the sense that while you press on them, the entire screen can be used for the interaction. The logarithmic dial in particular allows access to a large range of values without having to define the range ahead of time. Making these quasimodal allows us to use multiple strokes with the adjusting finger across the display. On the other hand, non-quasimodal sliders would allow us to use several fingers at once to control several different quantities.
• The fidget-spinner-like pin-and-cross interaction technique presented by Yuexing Luo and Daniel Vogel is maybe a better alternative to pie menus; it preserves the high spatial resolution of being able to drag your finger around until you find the right thing with the screen real-estate advantages of pie menus. The disadvantage is that (it looks to me like) really only angles almost directly to the left and right of the target object are really usable, giving you four commands, although they went a bit further and used a few different angles on each side, including one at 45° above the X-axis which I have to think would be super uncomfortable if you were left-handed. Distinguishing between different distances seems like it would multiply the number of alternatives. Gupta & McGuffin's approach mentioned above might allow further degrees of freedom, and could be used one-handed within limited angles.
• Focused-item zooming: the currently-selected item should be displayed larger, maybe by an areal factor of 2–4, so that you can

normally display things at a slightly uncomfortably small size, and then make them amply large when they're selected. Some games do do this.
• Indirect input, like Pfeuffer et al.'s "gaze-touch" and "gaze shifting", either through a draggable lens (since gaze-tracking on cellphones is an unsolved problem), or through something like Käser, Agrawala, and Pauly's 2011 FingerGlass, which defines the area of interest using a pair of nearby fingers. These approaches dramatically improve effective display resolution and reduce the occlusion problem for drawing and selection precision.

Upon observing some people in the subway using their phones, I came up with some observations:

• By far the most frequent interaction types were vertical scrolling without taking advantage of momentum and typing a letter on the onscreen keyboard. These clustered; it was common to see 20 interactions in a row of the same type.
• The third most common interaction type was tapping buttons, list items, or menu items.
• The fourth most common interaction type was quasimodally recording an audio message in WhatsApp.
• Occasionally I saw horizontal scrolling. Once I saw a double-click to zoom. I saw no photo-taking, drawing, or pinch-zooming.
• Around 95% of the people were using their phones in portrait mode.

• Most people typed using two thumbs on the onscreen keyboard, even though the phone was in portrait mode; sometimes they even let go of the subway straps while standing to do this. They just bought phones big enough that this was comfortable for their hand size. The only person I saw using their phone in landscape mode was playing an immersive video game.
• Social interaction through cellphones, such as WhatsApp, Instagram, and Fecebutt, was much more popular than solo video gaming, such as Candy Crush.

I tentatively conclude that a new interface needs to be operable with two thumbs in portrait mode and not break single-finger vertical scrolling in order to be avoid large usability problems.

Some ideas specific to the calculator application

In a good calculator, there is some way to use a computed value more than once; the dataflow forms a DAG, not a tree. In the language of formulas, we do this with variables. I think there should be a quasimode button that allows you to factor out a subexpression into a variable so you can use it again. At one point, I thought that probably it would be best to do this implicitly: if you selected a subexpression as an operand, then that would pull out the subexpression into a variable and use it twice. But then I realized that it would be more intuitive to use that approach to edit the existing formula — same interaction, but sucking the standalone operand into the existing formula, replacing the selected subexpression with the newly created subexpression. This is similar to how function composition worked in early versions of Subtext.

Aside from adding complexity to existing subexpressions, we often want to simplify them or replace them altogether. I think simple replacement is likely to be frequent enough to warrant the use of drag-and-drop of a formula for it — which, if we make it mean "swap", can also function to swap arguments around and rearrange parts of an expression. Simplification can be done with the inverse of the above-mentioned combining operation — a user-interface action that removes an operator and expels one of its arguments to be an independent formula.

Given the ability to define variables like x = 2+3×4, a very incremental way to define functions is to select a subexpression and convert it into an argument; for example, if the 3, we would transform the definition into x(y) = 2+y×4, replacing all the existing references to x with x(3). This refactoring pulls the argument into the caller (every caller); if the whole definition of x is selected, it reduces x to the identity function, and we could as a special case remove x entirely, thus allowing this single extract-argument refactoring to also serve as inline-function.

The inverse refactoring is not always possible, since different arguments may be passed at different locations.

derivatives, integrals
optimization
vertical layout
reduction (?)
different views

• Temporal univariate function input and output: in addition to a static two-dimensional display of a sequence or continuous function, we can cycle through the values of the independent variable with time, as, for example, we do when it's an audio waveform we're playing back. But we can use this to choose a single numerical value to display at any given time, stepping a cursor visibly through the values; for an input variable, if augmented with a slider, we can use the slider to "push" the value up or down in a given region, or just to set it.

Cheap shit ultrawideband

Kragen Javier Sitaker, 2013-05-17 (10 minutes)

So, pulse radio, huh?

If you want to do short-range wireless communication among really cheap circuits, maybe made out of garbage and running off batteries, you could in theory use something like CW oscillations at some arbitrary carrier frequency, like 101.3 MHz. A Q=100 fixed-frequency resonator circuit is relatively easy to build (three or four components), will accumulate RF energy over some 100 oscillations, and will allow you a modulation bandwidth of about 100 times less than the carrier frequency, in this example 1MHz. Then you could transmit pulses using, say, Manchester encoding, and do clock and data recovery in software. Your filter circuit gives you some 20dB of rejection of wideband noise like lightning and sparks and stuff.

This has a couple of big problems:

- 20dB isn't very much, so you have to use a lot of power.
- If you're using a single frequency, your signal will be easily picked up by accident by e.g. standard FM radios for listening to music. This will provoke complaints if you happen to be close to a standard radio station.
- By the same token, if you're near a strong source of RF noise at a given frequency, such as a radio station, it will make it impossible to receive data.
- Even though it's easy to build a fixed-frequency resonator with Q=100, it's hard to tune its frequency to 1% precision, for thermal and fabrication-error reasons. That means you'll have a hard time getting two such devices to communicate with each other without some kind of tuning component, like a varactor, unless you use something like a quartz crystal or a mechanical resonator for your filter.

Instead, you could build a low-Q resonator and transmit occasional pulses spread across a wide band. Here in ITU region 2, which includes the Americas, we have a 902–928 MHz ISM band (Q=35) commonly used for cordless phones, plus the 2.4–2.5 GHz ISM band (Q=25) also used by Wi-Fi and Bluetooth, both of which have reasonable penetration of building materials.

The lower your pulse rate, the less interference you'll cause with other radio applications. But now, instead of high-precision resonators, you need high-precision clocks. A common quartz clock crystal oscillator has a precision of below 300ppm (I think 100ppm is actually typical) but most of this error is due to temperature and voltage variation. If you can measure and compensate for the temperature and voltage, producing a "temperature-compensated crystal oscillator" ("TCXO") you can straightforwardly get precisions close to 1ppm. If you're counting cycles with a microcontroller, increasing or decreasing the cycle count is a simple way to compensate.

(You don't really need the resonator to make the communication work, but it might help to prevent your generated RF interference from straying outside the ISM band.)

If your average time between pulses is, say, 262144 clock cycles, then you can transmit up to some 18 bits per pulse. If your clock rate is 20MHz, easily achievable with off-the-shelf microcontrollers, you'll be transmitting an average of 80 pulses per second, working out to a maximum of 1.44 kilobits per second. The 262144 is limited by the precision of your clock speed; you need an oscillator with a precision of 4ppm, which will require temperature compensation, to get such a sparse pulse rate.

I think this is also the limit on your receiver selectivity --- those 18 bits have to be allocated between rejecting interference and transmitting information. You could get 50dB of receiver selectivity at the cost of only transmitting one bit per pulse; or you could get down to 3dB of receiver selectivity with the benefit of transmitting 17 bits per pulse.

I think it's reasonable to assume temperature compensation for the duration of a communication; the transmitter can transmit a series of pulses that allow the receiver to estimate the difference between their two clocks. A reasonable initiating pulse pattern for this might include a series of exponentially-increasing intervals: first 2 clock cycles, then 3, then 4, 6, 8, 12, 16, 24, 32, 48, 64, 96, 128, 192, 256, 384, 512, and so on, each pulse allowing the receiver to more precisely calibrate their expectations for the timing of the next pulse. You don't even need to start at 2 cycles. You could start at whatever you think the worst-case clock-rate skew is likely to be. Suppose you're reasonably sure your clocks are accurate to within 1000ppm, for example; then you could start with 512 cycles between pulses and go up from there.

Because of the need for coding-gain receiver selectivity, I think you probably need to transmit many more than 80 pulses per second to get a reasonable data rate. For example, if you transmit an average of 1024 pulses per second, a 16.777MHz clock gives you some 14 bits per pulse. If you allocate 11 of these bits to receiver selectivity and use the other 3 to encode information, you get three kilobits per second and 33dB receiver selectivity. Your signal could in theory also be rejected by some 30dB by someone using the same frequency band with frequency-division multiplexing, but this will be limited by their receiver Q. If you're talking about a regular FM radio, I don't think you're going to hit 30dB.

In a two-way communication, you could negotiate this allocation dynamically, so that you get higher data rates when there's less interference, in this case from fractional kilobits up to tens of kilobits.

To improve rejection of narrowband interference, your receiver (but not your transmitter) could be several concurrent channels handled by different analog filters with slightly higher Q. For example, you could divide the 902–928MHz band (Q=35) into four bands of some 6MHz, each handled by a separate Q=140 analog resonator. Any single source of narrowband interference will be limited to only one or two of these four bands, and you can simply ignore that band when decoding.

You may even be able to get some of your frequency selectivity from your antenna. A 900MHz quarter-wave antenna is some 8.3 cm in length. Unfortunately, I don't know how much selectivity you can get out of an antenna. Q=2, maybe?

Such cheap-shit electronics might often need to maintain very low

energy usage with extremely intermittent communication, for example in mobile-sensor-network applications. Achieving this probably requires maintaining a very low duty cycle for the receiver circuit, which effectively means you need some kind of time-domain multiplexing, with each device only listening for transmissions to it inside of a narrow time window.

Complicating this picture is the problem that the individual devices may be radio-isolated from each other for long periods of time and have clocks of limited accuracy, or even occasionally run out of power. If you want them to still be able to communicate when they come in contact, one of them needs to happen to transmit at a time when the other happens to have its receiver turned on.

A reasonable duty cycle for the receiver might be 1/1000 or so, if the receiver needs 1000 times the idle power of the rest of the device.

If you can depend on clocks continuing to operate and on occasional contact, then you can just use large timeslots. For example, if your worst-case clock drift is 15 seconds in a month, which is around what you'd get from a watch crystal, and your worst-case delay between resynchronization is a month, then each device can listen in a designated 30-second interval. With a duty cycle of 1/1000, the total cycle will be about 8 hours. So evidently this approach (which Elaine Chao told me about; I don't know if she invented it) works fine for wireless sensor networks that are relatively static, but it won't work well in the dynamic-topology case, unless 8 hours is "dynamic".

Elaine's solution was that when a new device is joining an existing network, it keeps its receiver turned on all the time until it receives a beacon from an existing device, which lets it synchronize with the network's timeslots. This could work well if you have mobile nodes with much higher available energy: they can listen constantly for beacons from fixed low-power nodes announcing their listening timeslots.

A different approach, suitable for a more symmetric system, is to transmit beacons and listen at random. Suppose we want a 10-second average-case synchronization lag; then we need to arrange for the transmitting node to transmit at the same time that the receiving node is receiving, on average, every 10 seconds. Suppose that the fastest that you could notice that you might have received a beacon, and therefore ought to keep listening to see if it's a new node you can talk to, is 1 microsecond. Now you have to coincidentally synchronize with a probability of about 1 microsecond in 10 million microseconds. If you listen a random 1/3000 of the time and the other node transmits a beacon another random 1/3000 of the time, then once every 9 million microseconds, you will happen to synchronize.

This implies, however, that you're transmitting 3333 beacons per second, which is a lot, since the entire beacon frame will take a lot more than a microsecond. If you're willing to accept a longer synchronization time, like 1000 seconds, then you can transmit only 333 beacons per second and listen 333 times per second.

Ostinatto

Kragen Javier Sitaker, 2014-04-24 (4 minutes)

I'm in the lobby of Ostinatto hostel in Buenos Aires, where Stace has come to see if she can get a job. Eminem from 2000 is blasting on the stereo, the fridge is full of Quilmes and Corona beer and Speed Unlimited energy drink. Blue-LED Christmas lights festoon the railings.

I just took Stace to see her first milonga. She'd never seen people dancing tango in real life before. It was under the summer night sky and full moon in Plaza Dorrego, also known as Plaza Bethlem. Across the Plaza, Candombe Monserrat was finishing up their weekly ambulatory performance of candombe drum music, the blessing and curse of living in San Telmo, but we could still clearly hear the golden-age tango recordings booming from the loudspeakers. I'd been suggesting she take tango lessons; within about ten seconds of arriving at the milonga, she had decided: this is a thing she must learn.

The lobby of Ostinatto is some seven stories tall, with wire staircases crisscrossing in the air under the skylight, which is dark with the night. Stace is hoping to get a job here.

Later we cross over to Tanguera Hostel, where Beatrice and I lived for some weeks, one of a dozen different places in Buenos Aires I've called home. It's beautiful with its marble and tile floors and its elaborate wall carvings, but we stopped recommending that friends stay there when they had a problem a few years back with bedbugs.

I show Stace the fiberglass statues of cartoon characters that decorate San Telmo, and tell her the little I know of each one; but my Argentine comic strip knowledge is pretty limited, and even if it weren't, it's hard to evoke the spirit of a comic strip in words. The statues speak more eloquently than I manage to.

On the bus home, a group of Boca fans are singing and whistling about how River fans are faggots lacking a testicle, and how they are going to kill them. Stace is enjoying it, since that's the kind of thing she goes in for, in fact the kind of thing she likes to organize, but I'm not --- I'm reminded of the last time a group of people called me a faggot and threatened to kill me, which was the crackheads who robbed me on the train in November. And the whistling hurts my ears, but I'm afraid that putting in earplugs will single me out as a target. After about 10 minutes, I get off early and take a separate bus home, angering her, because she feels I am abandoning her; but at the same time, she was complaining I was harshing her buzz from the bouncy football hooligan song. The adrenaline has mostly gone down by the time the other bus arrives.

Earler today, I spent some time with my coworker trying to qualify some off-the-shelf software for a $work task, hoping it can help me to avoid reimplementing its supposed functionality from scratch. So far it's something like fifty times slower than the software we've written ourselves, although our software doesn't yet do as much. I'm not sure if I'm doing something stupidly wrong or if it's really that slow.

I spent most of Saturday sitting in Starbucks reading *The Grammar*

Of Graphics, a book about data graphics, an influential book highly recommended by a couple of different widely-used pieces of data-graphics software. I'm finding it slow going, in part because the abstractions they define are all slightly different from the related abstractions I'm used to. Time alone in the café — all afternoon until it closed at midnight — was helpful in keeping my focus on the book.

Tomorrow I have more off-the-shelf software to try out for the $work task. Or I could try spending some more time with this software.

Heckballs: a laser-cuttable MDF set of building blocks

Kragen Javier Sitaker, 2016-08-17 (updated 2016-08-30) (24 minutes)

In part since I'm living with a seven-year-old, I've been thinking about laser-cutting a construction set based on a design Matt Heck showed me at TechShop something like a decade ago. If I recall, he had some things laser-cut from Masonite. I can't find anything he's put online about it.

Although the original was laser-cut from I think high-density fiberboard, you could realize this design with any sheet-cutting process, including scrollsaw cutting, plasma cutting, oxy-fuel cutting, laser-cutting of plastic or metal, waterjet cutting, hot-wire cutting, wire EDM, or sheet-metal shearing.

The basic Heckballs unit is a square with rectangular slots cut halfway from its edge to its center, with the width of the slot being the same as the thickness of the square. By slotting squares into each other's slots (edge-lap joints), so that their edges match up with each other's centers, you can easily assemble a somewhat free-form 3-D lattice. 80 mm is a reasonable size for the squares; 1.5 mm is a reasonable thickness.

To be somewhat concrete about costs, in the most basic Heckballs form, you can cut an 810 mm × 450 mm sheet of 1.5 mm MDF into 10×5 = 50 squares using 10×5 cuts totaling 10·400 mm + 5·800 mm = 8 m of cutting; each slot is 20 mm + 1.5 mm + 20 mm = 41.5 mm, and there are 200 of them, for another 8.3 m of slot cutting, a total of 16.3 m. At 30 mm/s, this is 543 s ≈ 1 hour ÷ 6.6, which is probably about US$6 of laser cutting time, or about 12¢ per Heckballs square.

MDF costs AR$179 ≈ US$12 for 1830 mm × 2600 mm of 3 mm-thick MDF, which works out to about US$2.50/m², or AR$40 for 300 mm × 600 mm of 1.5 mm thick MDF, which works out to about US$14/m². So the cutting is probably the bulk of the expense, which suggests it might be worth trying to cut stacked MDF.

(Steel is supposedly around US$300 per tonne right now, which would be US$7.20/m² at 3 mm, which rather surprisingly suggests that ASTM A36 steel only costs about twice what MDF does per unit volume, despite having 210 GPa of Young's modulus, which is 50× MDF's stiffness, and 290 MPa yield stress, which is 16× MDF's strength.)

In this form, this has a few drawbacks:

- The lattice is entirely made of perpendicular and parallel planes, which is the worst possible configuration for rigidity. More liberty of form would allow much more efficient material use.
- There's no way to make a flat surface without stuff sticking out of it, like for a shelf, chair seat, table top, or foot.
- The slot width is unforgiving of imprecision; if the material is slightly thicker or thinner than spec, or if the slot is cut slightly narrower or wider, it's easy to get parts that won't fit together or don't stay together reliably.
- If you fill all the slots of a square, the other squares collide in the

middle.
• The tensile strength of the joint is low because it is entirely dependent on friction.
• The square corners of the slot create stress risers in the material, resulting in much lower resistance to cracking than is necessary.
• Covering a long distance demands a lot of material, because you can't make a "beam" of joined squares that's less than 80 mm wide in both dimensions.
• Covering a long distance creates a lot of angular slop, because there are a lot of serial degrees of freedom in all the slot joints.
• There's no way to make joints that are free to turn or slide, only rigid connections.

To provide tensile strength, the joints can be provided with tapered clips (i.e. snap joints). To eliminate stress risers, the internal corners of the slots can be replaced with rounded divots, or better for laser cutting, chamfered divots. The tapered clips should also allow making the slots a bit wider, eliminating the sensitivity to precision, but curving the slots slightly might also solve the problem without introducing more play. Curving the tapered clips could make it easier to fit a fingernail or whatever between them and what they're clipping onto so that you can unclip them.

To prevent the collisions at the centers, it probably makes sense to chop off the edges of the squares, so that the distance between the centers of two edge-lapped squares is still 40 mm, but the squares are only 77 mm wide.

To permit covering a longer distance, I think probably the right solution is to have more than one kind of unit. For example, a long beam with 20 mm slots only at its ends, could hold the centers of the two squares at its ends 320 mm apart instead of 80 mm apart. This gives it a total length of 320 mm (or 317 mm to avoid collisions).

If the beams are 8 mm wide, we can cut an 80 mm × 320 mm rectangle into either 4 squares (roughly) or 10 beams. We probably want to have more beams than squares, because even in a 2D square grid, you have twice as many beams as vertices. The 4 squares require 320 mm + 4·80 mm + 4·4·21.5 mm = 984 mm of cut (although adding clips might add another 300 mm or more to that). The 10 beams require 10·320 mm + 80 mm + 2·4·21.5 mm = 3452 mm of cutting, which suggests a certain cost disequilibrium, pressuring the scale to increase to avoid wasting expensive laser to conserve cheap MDF.

Solving the rigidity problem involves using a different lattice. The incremental change is to add diagonals: convert the squares into octagons with eight slots and add beams of $320\sqrt{2}$ mm ≈ 452.5 mm. Alternatively, you could try to switch to a sphere-close-packing lattice.

Once you have 8-mm-wide beams, you could enable rotation by cutting circular holes through the centers of some octagons or squares. Curves are much slower to cut on typical laser cutters, so you probably don't want to do this for all the octagons, just some of them. The diameter of the hole should probably be about 8.2 mm.

Making flat panels that can fit snugly onto the coplanar edges of some octagons shouldn't be very difficult, although they won't be watertight. You just cut slots for the edges of the octagons to peek through.

These beams will be somewhat prone to buckling, since their slenderness ratio 320:1.5 is over 200; although the column effective length factor K is probably 0.5, this is still plenty long enough to enable buckling. If you could strengthen the beam into a T-beam with another 8 mm beam, the problem would probably be solved.

The aforementioned pressure to increase the scale adds more pressure to do the T-beam thing, since at a larger linear scale, buckling becomes a bigger problem.

What would the face-centered-cubic close packing solution look like? The unit cell is a cuboctahedron; in different planes, the number of lines coming out of a vertex are 0, 2, 4, or 6, all evenly spaced. If you think of the face-centered cubic arrangement as being a stacking of square layers, the connections within a given layer are at 0°, 90°, 180°, and 270°, while the connections to the layer above or below are at 45°, 135°, 225°, and 315°. Unfortunately, both the layer above and the layer below are at exactly the same angle, so they can't both connect. Still, you could enable a double-layer close-packed truss with this arrangement by simply having octagon joints and extra unit-length beams whose end slots are angled at 45°. For the moment I think I'll give up on fcc and hcp.

So, what does the most basic Heckballs kit look like? Let's say I want to be able to make a cube with diagonals on most faces. Four vertices, four regular beams, and one long beam make a square (320mm side plus an extra 40mm stickout). But then there's no immediate way to extend the lattice in a perpendicular direction. By adding more joints onto the edge, we could get a perpendicular direction and thus a sort of cube, but now some of the diagonals are the wrong length.

So here's the part where Heckballs actually become balls. We eliminate rotational symmetry from the octagon; one of its slots now extends to its center, and the opposite one is eliminated. Two such octagons can be edge-lapped together to form something approximating a sphere with 12 available valences, 8 of which are among the 12 directions needed for the fcc crystalline structure. To make the cube with some diagonals, we can use the three valences along one edge of one octagon to make the two sides and diagonal of one square, and the valence in the center of the side of the other octagon to make the side of a perpendicular square. Two corners of the top square must be made in this way, with their axes coplanar with and at 45° to the square's sides. The other two corners could be made with their axes coplanar to the perpendicular square and perpendicular to *its* diagonal, thus enabling four of the six cube squares to have diagonals. The other two faces are not thus diagonalizable.

If it is our priority to have three *adjacent* square faces diagonalized, neither this structure nor any similar structure can solve that problem, because connecting to the ends of the axis is impossible. A possible solution is to make some beams integral with joints, enabling them to connect axially.

Another possibility is to avoid connecting *at* vertices and instead connect *around* vertices, forming a polygon or polyhedron enclosing the vertex. For example, beams could penetrate into one another at some angle near their ends. It's easy for me to imagine how this would work for 90° in a single plane around a vertex, but harder for

me to imagine other angles.

Oh, wait, it's not that hard. You can get an arbitrary angle with the plane of each beam rotated by some amount with respect to the plane of the angle; as long as the beam's plane is neither parallel nor perpendicular to the angle plane, it's workable (though more so if it's not nearly so). Hmm, I have to think about that some more.

Anyway, back to the cube. Here we have eight vertices, each of which needs two half-slitted octagonal joints, sixteen octagons in all, plus 12 short beams and 4 long beams. Let's suppose we scale up a little bit to respond to the cost-optimization thing to ⅛m (125 mm) for the octagon nominal width, and add another 4 long beams for extra flexibility, and cut down the beam length to half the octagon width. Now we have:

- 16 122 mm × 122 mm octagons
- 12 250 mm × 31¼ mm short beams
- 8 353.6 mm × 31¼ mm long beams

That all adds up to about 0.42 m², slightly more than a single 810 mm × 450 mm cut at Max58, even before worrying about packing. Maybe to get quicker feedback I should scale down by a factor of √2 to 88.4 mm as the basic unit? This is getting fiddly, I should probably just use 100 mm, and go back to 4× for the beams. Also I don't need to leave a whole 3 mm off at the end; I only need ¾ mm off each end, or 1.5 mm in total:

- 16 98½ mm × 98½ mm octagons
- 12 398½ mm × 25 mm short beams
- 8 564.2 mm × 25 mm long beams

That's 0.39 m², still slightly too big, argh.

All right, let's bite the bullet and go down to a basic unit of 62.5 mm:

- 16 61 mm × 61 mm octagons
- 12 248½ mm × 15 mm short beams
- 8 352.1 mm × 15 mm long beams

That's 0.147 square meters, so I should be able to nearly double it.

It's about 41% octagons, 31% short beams, and 28% long beams. We could probably do with a higher proportion of beams: maybe 24 octagons, 28 short beams, and 20 long beams.

(Actually the octagons could still be squares maybe, although the slot ends should still be radially symmetric.)

A thing to somewhat worry about with these small octagons is that the slot ends will be awfully close together, and especially close to the deepened slot. The distance from the center of the joint to the end of the slot is 31.25 mm, with another 29.75 mm to the edge of the octagon. The clip hole needs to be at least 1.5 mm further in, probably better 3 mm further in, and the clip hole and slot probably need to be 1.7 mm across, and the clip hole probably needs to be 3 mm long, so the innermost part of the clip hole will be (31.25 − 3 − 3) mm = 25.25 mm from the center. But the slots at 45° from the deepened slot will have the center of the innermost end of their clip hole only √½ 25.25 mm = 17.9 mm from the deepened slot, and the 0.85 mm diagonal reduction from the width of the clip hole reduces that by 0.6 mm further down to 17.3 mm. Actually that's the distance the

clip hole corners will be from one another, but the deepened slot will also have its own clip on one side.

What should the clip dimensions look like?

The maximum tensile strength we can expect is the compressive strength of the 1.5 mm × 1.5 mm maximum possible contact area, 10 MPa · (1.5 mm)² = 22.5 N, or 45 N when we take into account the clips on both sides, which is pretty wimpy. Ideally this thing would withstand my harshest pulls without breaking, and with my legs I can pull close to twice my body weight, so about 2000 N. So this is about 44 times weaker than it needs to be.

It's possible to get some improvement there with multiple clips in multiple holes, but there isn't room for 44 sequential holes. At 6 mm per hole, there's really only room for 3 at most. So this is probably unattainable. It does rather strongly suggest that 1.5 mm MDF is suboptimally thin and will result in assemblies that are far too easily broken. Indeed, probably even 3 mm is too thin. The next size up stocked by Max58 is 5.5 mm, giving us about 13× as much contact area.

So what if it's 5.5 mm thick? 10 MPa · (5.5 mm)² · 2 = 600 N, about a third of what we'd like it to withstand. So maybe a double hole in 5.5 mm and call it a day at 1200 N of compressive strength.

But for that double hole, we probably need 22 mm from the center to the inside of the slot, even if the hook holes are absolutely square. So we probably need to make our octagons bigger, more like 150 mm. 15 such octagons would occupy our entire 810 mm × 450 mm sporting area, so we don't have room for anything else on the first pass. Which is fine, because this is already taking me forever.

What about tensile strength? MDF's UTS is only 18 MPa, so to withstand the 600 N of tension on either of the double hooks, we need 6.1 mm of width on the 5.5-mm-thick clip at the first hook to keep it from simply breaking from tension. That's going to make it kind of tough to unclip by hand, I think.

(I have a new design to keep the clip head from tearing off due to a tension concentration on the hook side of the clip; it involves a bar on the other side sliding into a slot, preventing the clip from rotating. But the clip still needs to withstand the tensile stress.)

What about the force and energy needed to unclip the clip? Patrick Fenner tells us that if we don't taper,

> the force to deflect the tip by a set distance is $F = dEta^3/(4l^3)$, where d is deflection, E is the Young's modulus of the material, t is beam thickness and a is the depth of the beam.

In this case, d is at least 5.5 mm, E is 4 GPa, t is 5.5 mm, and a is 6.1 mm. So if l = 75 mm, which is kind of an absolute limit if the diameter of the thing is 150 mm, then we need 16 N, which is doable without tools. For a more reasonable value of 40 mm, we get 107 N, which is going to require a screwdriver or something.

We may be able to improve the situation by tapering the clip down to 3.1 mm at the second hook, which should still be enough to resist the tensile force there, starting from a thicker root.

The clips and clip holes shouldn't extend all the way to the center, to avoid colliding with the deepened slot or excessively weakening the overall joint, nor should they extend all the way to the edge, in order to keep the angle properly controlled. The clip beam can extend deeper than the slot, but not by too much.

I don't know, maybe I'm being too demanding of the tensile strength of a clip joint. Suppose that instead of designing for 1200 N we settle for 360 N, 90 N per hook, which we can get with 3 mm MDF instead of 5.5 mm, so we don't need 11 mm of depth per hook hole, only 6 mm; we can now get 180 N tensile strength out of <3.4 mm of beam. And maybe we go back down to truncated 100 mm squares for our octagons. If the hook holes end 12 mm after the end of the slot, and we extend the clip beam by those same 12 mm, then its total length is 24 mm. So $dEta^3/(4l^3) = 3\text{ mm} \cdot 4\text{ GPa} \cdot 3\text{ mm} \cdot (3.4\text{ mm})^3 / (4\ (24\text{ mm})^3) = 25$ N, which you can operate with your fingers. It should get even better with tapering.

(ETA: actually it's totally reasonable to have arbitrarily low unclipping force with arbitrarily high tensile strength. Among the things you can do are to fold up the spring serpentine-style or to cut lengthwise slits in it to make it less stiff, in the limit becoming like the pages of a book.)

Plasma-cutting clips like these in steel might be feasible, but they'd have to be much thinner, since steel's stiffness is 50× higher; about 3.7 times thinner to retain the same operating force they had in MDF. Plasma has tolerances in the 300-micron range, so if your steel clip's nominal thickness was 1.5 mm, it might come out as 1.2 mm (and have 51% of the desired operating force) or 1.8 mm (and have 173%). So the 920-micron clip width indicated ought to be doable, and its 290 MPa yield stress would give it a tensile strength of 800 N (or as low as 540 N if it came out thin). The steel's 0.13% elongation at yield is only a fourth the MDF's 0.45% or so elongation at break, so steel flexures have to be quite a bit thinner in order to work at all.

Anyway, back in MDF-land, the whole clip/slot perforation extends to 13 mm from the center, which is only 8 mm in the case of the corners of the 45° and 315° diagonal slots next to the deepened slot. I'm getting less worried about that, though.

Bending strength of the joint should be good. If you have octagon A and octagon B edge-lapped and B tries to rotate around its axis, it's pressing against A at almost A's center (like uh 2 1.5 mm $\sqrt{2} = 4.2$ mm from the center I think?) and has one of A's hooks in it at 25 mm + 12 mm = 37 mm out. It's not totally easy to predict how that's going to end up, but let's say we have a 15 mm lever arm from where the fulcrum ends up being and something like 30 mm² effective surface area; then the surface will start to be damaged at about four or five newton-meters. Hmm, that suggests that maybe the double clips are overkill?

Trying to squish the two octagons against each other may break them more easily. The surface only has a 1.5 mm lever arm at most to resist the 50 mm lever arm where you can apply torque.

The 400 mm × 400 mm area devoted to the 16 100 mm octagons in the starter kit leaves a spare 400 mm × 10 mm area along one side and another 450 mm × 410 mm area for beams. No long beams will fit that way! We could fit long beams if we have a 200 × 400 area with 8 octagons, and then 8 more octagons in a 400 × 200 area to the right, leaving a 610 × 250 area above it into which we pack 10 564.2 × 25 long beams, leaving a 45 × 250 area to its right, and a 200 × 200 area below, or something. So then one short beam can fit vertically on the right. Blegh.

Alternatively the second group of octagons could be 600 × 100,

cutting the total octagons to 14, and leaving space for plenty of short beams above it. Actually no none of this makes any sense. I should drag and drop stuff or some shit.

Erlang musings

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

Learning Erlang for the first time. A few notes --- mostly the language and especially the runtime system are lovely, so to keep these notes short, I haven't listed the many things I like about them.

The syntax for tuples and records is just too bad. Maybe the record syntax was unavoidable, but the tuple syntax is bad.

Selective receive seems like it could lead to deadlock.

It seems like client-server responses ought to be tagged with a request-ID, not the server's PID.

It's kind of bizarre that the ugly "registered process" mechanism, which introduces a mutable global namespace into an Erlang node, is built into the message-sending machinery, but you must build at user-level the machinery to include your PID in a request if you want a response and figuring out which of your pending responses corresponds to which request.

Distributed performance isn't particularly good. Ping-pong time between processes in a single OS process is on the order of 12-15us on my machine, but between processes in different OS processes, it's about 1000-3000us.

It seems like the system tries to hide a lot of the crucial issues related to distribution: fault-tolerance, tolerance for partitions, security. There's a magic "epmd" process ("Erlang portmapper daemon") that gets started on a node by the first guy who starts a distributed Erlang process, and then the other Erlang processes connect to it (on TCP port 4369 --- what, was 4269 taken? 4369 is 0x1111.) and use it to figure out how to talk to each other. Even if another user stars running Erlang processes later on on the same node, they will use this same "epmd" for their nameservice.

I used Wireshark to see what they're saying to each other. None of the conversations are encrypted, but they all use some ugly binary protocol that makes them a bit hard to read. (Not sure why they bother with a binary protocol if it's going to take on the order of a millisecond each way to do a simple RPC containing a timestamp anyway.) The "epmd" conversations are pretty concise, but the "RPC" conversation between the two Erlang processes is a bit more verbose.

Apparently there's some kind of shared-secret authentication involved as well...

It seems like it would be better to just layer on top of some other system for actually making, authenticating, and encrypting the connections in the first place --- ssh, named pipes in the filesystem, HTTPS, or whatever.

There also doesn't seem to be any documentation for the security properties of binary_to_term/1.

Topics

Rubber air conditioner

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

Stretching rubber or other hyperelastic material heats it; allowing it to relax cools it. If you have a set of concentric rubber tubes you can twist, with metal rings embedded at intervals in the tubes to keep them from collapsing, then the torsion should manifest as heat which could be carried away by a fluid passed through them; allowing the torsion to relax should cool the tubes, which can be used to cool a fluid passed through them at that time.

This allows the construction of a refrigerator whose refrigerant is solid and thus very safe. By passing the same air (or other fluid) through the tubes during successive cooling cycles, it should be possible to cool it to lower and lower temperatures, until whatever leakage is inherent in the system cancels it out.

The cooled, stretched rubber has lower tension than the stretched rubber did when warm, so the relaxation cycle returns less energy to the motor than was put into it originally, which is where the ability to reduce the entropy of the air comes from. Still, it's likely to be significant, so it may be desirable to use a flywheel or something in harmonic motion to recover that energy for the next stretching cycle.

Fatigue is potentially a major problem for this device, since the rubber needs to last through at least tens of thousands of stretch-and-release cycles to be useful at all, if not millions; and the degree to which the rubber can be stretched safely determines the achievable ΔT.

Topics

Camera flash extrapolation

Kragen Javier Sitaker, 2019-11-12 (6 minutes)

One hot summer night recently, I guided a tourist through the streets of Palermo, the chichi Buenos Aires neighborhood. She was enthralled by the colorful murals that cover the walls of many of the alleyways (*pasajes*) and stopped to take many photos. (Incredibly, during her entire trip, she didn't get even a single hand computer stolen, just a jacket and some colored pencils.)

Her hand computer camera's wimpy LED flash was not enough to illuminate the murals clearly; unfortunately she wasn't able to visit them during the day. It occurred to me that it should be possible with multiple coregistered camera frames to artificially amplify the brightness of the flash somewhat.

The scheme is as follows. First, we take some frames with the flash and other frames without it, and perhaps frames with different quantities of flash or different exposure times (and variation in "ISO" gain to compensate for the exposure time). Then, we coregister them to find the corresponding pixels. For each pixel, we compute a linear regression of its color in each frame against the amount of flash in that frame; this resolves the various frames into a frame of "biases" representing the color of the pixel under existing lighting, a frame of "slopes" representing the per-spectral-band reflectance of the pixel to the flash, and what we hypothesize is random noise.

This allows us to extrapolate what the image would look like if the flash had been brighter than it was in fact. This will amplify errors and measurement noise to some degree, but if we are amplifying the flash signal by less than an order of magnitude, the effect should be small enough not to overwhelm the quality improvement from the added light.

The flash may cause some pixels to saturate, and saturated or near-saturated pixels should either be excluded from the linear regression or given a very small regression weight. A potentially worse problem is that the extrapolated image may saturate pixels that were not saturated in the input images. This can be handled by doing the extrapolation with extra bits of precision or in floating point to handle the larger dynamic range, then translating these linear high-dynamic-range values to the final image in a way that preserves as much information as possible. As I understand it, ACES recommends using a sigmoid curve per color channel to imitate the gradual-saturation nonlinear behavior of film emulsions, thus avoiding the total loss of information in particularly dark or light areas, providing higher dynamic range in digital images without the spatial filtering we usually see in HDR images.

Pixels spatially closer to the camera will experience more flash illumination, at least if we're using an on-camera flash (typical for photos from hand computers). However, they will also experience more flash illumination if they have higher reflectance, so by itself this does not turn a camera with an on-camera flash into a depth camera; it cannot untangle reflectance from closeness to the camera. If the non-flash illumination were constant everywhere in the scene, like a naïve ambient light source in a raytracer without ambient

occlusion, then we could use the ambient light source to derive the raw reflectance, then divide the flash slope of each pixel by its reflectance to derive its (inverse square) distance. However, this seems unlikely to work in practice.

A different way to take advantage of this phenomenon that might work better is to use even fairly imprecise SfM depth data derived from camera parallax to figure out which parts of the image are unusually close to the camera, then artificially attenuate the flash on them. This give the effect of a flash positioned further from the scene than it really is, thus evening out the flash illumination across the scene somewhat.

If we have this crude SfM data available, we should also be able to determine that certain pixels are at very nearly the same depth — for example, nearby pixels on the surface of a single object — so they should be receiving very nearly the same illumination from the flash. This means that differences in their flash slopes reliably indicate differences in their reflectances; this enables local correction of the "bias" image for reflectance to get an image that is purely a map of non-flash ilumination (plus non-Lambertian phenomena such as specular glints). Since we're talking about pixels that are close together in three-space, the *intensity* of non-flash illumination on them should be the nearly the same, except in shadows; only its *direction* varies. So we can use this to get information about the angle between the surface and the non-flash illumination and thus about its geometry.

Of course, if we have multiple flashes in different positions available, we can use them to illuminate the scene from different angles in different frames, thus giving us lots of great information about surface geometry. This might sound like an expensive setup that is unrealistic in most circumstances, but in fact with the advent of widespread forward-facing cameras on hand computers, it's eminently feasible for small objects: the different "flashes" are just different regions of the screen. (Some researchers also noted that this allows you to get nine or twelve channels of spectral information rather than the usual three, since the spectra of the RGB or RGBW filters on the screen will usually imperfectly match the spectra of the RGB filters on the camera focal plane. Unfortunately, some shithead reporter mischaracterized the research as providing "hyperspectral" capabilities, and so most of the commentary I saw focused on debunking the lie rather than the actual research.)

Ideas to explore

Kragen Javier Sitaker, 2017-05-29 (updated 2019-09-15) (3 minutes)

• Portals: can I get some kind of usable windowing/hypertext system out of circular rotating scaling portals?
• Laser-cut omnitriangulation: can I use tusk tenons to make light, airy lattices out of cheap, thin laser-cut MDF?
• Reduced affine arithmetic raytracing: can I make a fast ray tracer with it?
• Reduced affine database: can I do a fast query on gobs of time-series data with it? (See An affine-arithmetic database index for rapid historical securities formula queries (p. 2275).)
• Circuit simulation: can I get SPICE working in a reasonable way with a Falstad-like UI?
• Database exploration: what does it look like to load my mail into Kafka/Samza, SQLite, Elasticsearch, LevelDB, Redis, Datomic, or just MySQL?
• Home kiln: can I get a reasonably efficient kiln working?
• Programmable logic: can I whip these 2114s and PALCE16V8s into some kind of useful logic circuit?
• Fabribot: can I get some kind of fabricating bot working? Clay cutting, 3-D printing, etc.
• Calculator rebraining: can I replace a calculator brain with an AVR running my software and get a super-calculator? (See Reflections on rebraining calculators with this RPN calculator code I just wrote (p. 1717).)
• Self-sustaining personal computer: can I wedge a Nokia cellphone display into a PS/2 keyboard and SD card and get a self-hosting computer out of the deal, one that can reprogram itself?
• Moiré servomechanism: can I use moiré patterns between sparse random screens with webcams to get high-resolution feedback on where a thing is?
• Garbage oscilloscope: can I make a reasonable oscilloscope out of common garbage? (See files VCR oscilloscope (p. 213), TV oscilloscope (p. 1253), Laser printer oscilloscope (p. 449), and Disk oscilloscope (p. 713).)
• Digraph notation: can I come up with a much better way of describing finite state machines, electrical circuit schematics, dataflow graphs, and similar graphs? (See files Graph construction (p. 3226) and Circuit notation (p. 1161).)
• Card-based hypertext: what does it look like to re-envision a text as a set of linked "cards" small enough that several can be on the screen at once, even on a cellphone? Is this Smallest Federated Wiki?
• RPN UI: can I extend rpn-edit to be powerful enough to handle most everyday calculations, maybe better than Excel and Python? (See An RPN CPU instruction set doubling as user interface (p. 177) .)
• Synthgramelodia: can I repackage synthgramelodia into a form that makes it easy to run and shows what it's doing?
• Magic Kazoo: can I get a prototype Magic Kazoo running, maybe as an Android app? (See The Magic Kazoo: a synthesizer you stick in

your mouth (p. 1873).)
• Power supply hacking: can I make an adjustable benchtop power supply that won't catch on fire and displays the output voltage with an AVR on an LED display?
• Life clock: can I make an LED display of how many days someone likely has left to live?
• AVR programmer: can I make a serial programmer to load the Arduino bootloader into the various AVR chips I have lying around? Using ArduinoISP, say?
• Tiny bytecode machine: can I implement a tiny bytecode engine that allows me to do any further programming in a flexible way?
• Logarithm table memorization: can I practice mental logarithms enough to make them a useful calculation shortcut?
• Machine-learning/optimization stuff: what can I do in this area? Maybe I need someone else to suggest exercises. All kinds of physical and information design, plus control systems, seem like appropriate things to try.
• Tile grid systems: can I make a maze out of user-drawn tiles in DHTML?

Freeze distillation at 1 Hz

Kragen Javier Sitaker, 2016-10-06 (5 minutes)

How can you do process intensification of fractional crystallization cascades?

Freeze distillation or fractional crystallization is normally a slow process. But they still work even if the crystals are very small, so there's no need for them to be slow. You could carry them out at frequencies in the neighborhood of 1 Hz using something like a phase-change regenerator. The "coolant" of the "regenerator" is probably something innocuous like brine, while the phase-change material in the "regenerator" is the material you're actually trying to separate by partial crystallization, and it isn't quite stationary: you pump the liquid phase in a direction parallel to the direction of the coolant, but 90° out of phase with the pumping of the coolant.

That is,

• First, you pump the coolant from the cold reservoir to the hot reservoir, freezing some of the phase-change material. Then,
• you pump the liquid part of the phase-change material (the mother liquor) toward the cold reservoir (that is, in the same direction, but in a separate isolated circuit). Then,
• you pump the coolant from the hot reservoir back to the cold reservoir, melting some of the phase-change material. Then,
• you pump the mother liquor toward the hot reservoir. Then you start again.

This should result in concentrating the lowest-melting solution of the phase-change mixture toward the cold reservoir, and the higher-melting parts toward the warm reservoir, while more or less maintaining the temperature gradient constant. The temperature swing may be more than you would expect, because metastable zone width increases with stirring and cooling rate, and our stirring and cooling rate here is yuuge.

If at some point the phase-change material passages are completely blocked, you can pump warm coolant past it until that's no longer the case.

Separated phase-change material can be removed at the extremes of the apparatus, and unseparated material can be added to replace it in the middle, providing a quasi-continuous process.

This process should be sensitive enough to separate substances by even very slight differences in solubility, including difficult cases like separating erbium bromate from holmium bromate or separating heavy from normal water. It might even be capable of competing with ion-exchange chromatography. The regenerator-like configuration eliminates nearly all of the energy waste associated with traditional fractional crystallization cascades.

It's important for the piping to be narrow enough to prevent diffusion of the liquid phase-change mixture against the concentration gradient from becoming turbulent rather than viscous, and also to prevent the diffusion of heat against the temperature gradient, since narrower passages are longer for constant volume; additionally, narrower passages mean that heat diffuses between the

coolant and the phase-change material more rapidly, allowing higher frequencies. However, narrower passages require more energy applied both to pump the fluids and to restore the temperature difference between the reservoirs.

If both fluids are liquids, it may be desirable to carry out the entire process under high pressure or even to alternate between pressures (in addition to or instead of pumping coolant) to alter the equilibrium phases of the phase-change material. This may allow an escape from pernicious eutectics. Doing this with a gaseous coolant might be feasible but seems like it would be very difficult due to adiabatic heating and possible deformation of the apparatus.

Here are some possible materials, depending on the temperature range in which the material to be separated solidifies:

temperature range	coolant	piping
<-200°	LN_2	copper
		brass
		cryogenic stainless
-200°--100°	ethane (to -182°)	cryogenic stainless
	R-32 (to -136°)	brass
	R-22 (to -175°)	copper
	propane (to -187°)	
-100°--20°	ethanol (to -120°)	silicone
	propylene glycol	copper
	(to -59°)	brass
	R-134a	low-temperature stainless
	SF_6 (to -50°)	
	R-22 (below -40°)	
-20°-0°	brine	polyethylene
	ethanol	polyethylene terephthalate
	propylene glycol	silicone
		copper
		stainless
		steel
		brass
		glass
		aluminum
		PTFE
0°-200°	water	polyethylene
	mineral oil	PET
	propylene glycol	glass
	(to 188°)	silicone
	glycerol	polyimide
	ethanol	copper
	silicone oil	stainless
		steel
		brass
		bronze
		aluminum

		PTFE
200°-500°	molten nitrate salts	borosilicate glass
	fluorocarbons	stainless
	lead-tin eutectic	polyimide
	type metal (Sn/Pb/Sb)	copper
	FLiNaK	brass
	FLiBe	bronze
	NaK, Na, PbSb	
	tin	aluminum
	air	steel
	CO_2	
	glycerol (to 290°)	
	steam	
	silicone oil	
500°-1000°	molten nitrate salts	fused quartz
	Sn/Pb, Sn/Pb/Sb, Sn	stainless
	FLiNaK, FLiBe	superalloys
	air	fluorination may be desirable
	noble gases	noble metals
	CO_2	
	nitrogen	
1000°-1200°	Al, Pb, Li	stainless
	CO_2	superalloys
	nitrogen	noble metals
	noble gases	fused quartz

(All of the above is kind of a guess, not deep materials knowledge.)

Presumably the only temperature limit on the applicability of the process is being able to find piping materials that melt hotter than the materials you're trying to separate and that won't significantly dissolve in or react with the materials you're separating at their melting point. (You don't want total nonreactivity, though, because you need the crystals to nucleate, ideally on the walls.) I just don't know what to propose above 1200°.

Laser ablation of zinc or pewter for printed circuit boards

Kragen Javier Sitaker, 2016-09-19 (4 minutes)

The typical way to make printed circuit boards is by buying copper-clad glass-reinforced epoxy circuit boards and etching away part of the copper — either with ferric chloride, with air-regenerated cupric chloride, or with electrolytic etching. Occasionally people will instead use end-mills in milling machines instead, which inevitably cuts into the highly-abrasive GRP board and spreads glass dust. Typically the copper is around 25 microns thick. But what if we could laser-cut the metal instead?

Well, copper is hard to laser-cut. It heats at 24.4 J/mol/°, boils at 2562°, sucks up 300kJ/mol, and from yellow well into the infrared, it reflects more than 90% of incoming light. (It only reflects about 60% of blue light, giving it its characteristic red or orange color.) But all the kinds of blue and ultraviolet lasers I know about are a real pain in the ass. So you're just about stuck with an extra factor of ten or so in the already-gigantic energy. (Maybe you could avoid the extra factor of ten by pre-oxidizing the surface.)

(Calculating: 2540° · 24.4 J/mol/° + 300kJ/mol ≈ 360kJ/mol; multiply by another factor of ten or so and you need 3.6MJ/mol for copper. At an atomic weight of 63.5 that's 5.7kJ/g; at a density of 9.0g/cc it's 51.3 J/cc. I'm leaving out heat of fusion because it's quite small.)

Zinc might seem like a more reasonable metal to laser-cut. It weighs 65.4 g/mol, boils at 907°, heats at 25.5 J/mol/°, weighs 7.1 g/cc, and sucks up 115 kJ/mol to boil, and typically has about 80% reflectance across the VNIR spectrum, with an inconvenient peak in the red, but a very convenient dip well below 70% in the 1μ range. Its conductivity is about a fourth of copper's, at 59 nΩm to copper's 17 nΩm, which you'd have to compensate for by making it four times as thick. So you need 885° · 25.5 J/mol/° + 115 kJ/mol ≈ 138 kJ/mol to ablate it, and if you get ⅓ laser efficiency, you need 0.4MJ/mol, an order of magnitude less ablation energy than copper. But then you lose most of that again with the factor of four increased thickness, making laser energy ablate only about two or three times as much circuit board area per joule.

(Or, if your laser pulses are longer time scales, maybe more, because copper conducts heat at 400 W/m/° while zinc only conducts it at 120 W/m/°. But I'm assuming the laser pulses are short enough that this isn't a consideration.)

Zinc has a major disadvantage for circuit boards: it tends to form zinc whiskers. It may be possible to fix this by alloying it with some other metal, such as copper (forming brass) or tin (forming a sort of pewter).

I don't know if it's possible to reduce the boiling point of metals by forming positive-azeotrope alloys from them.

Other candidate metals might include magnesium (1090°), bismuth (1560°), manganese (1962°), indium (2000°), and tin (2270°). Ytterbium (1466°) and thallium (1473°) are too unstable and toxic,

thulium is too expensive, and aluminum doesn't boil until 2470° and is particularly highly reflective.

Other candidate methods for thermal ablation of metal coatings include arc heating, electron-beam heating, and ion-beam heating.

Topics

Affine arithmetic optimization

Kragen Javier Sitaker, 2017-07-19 (updated 2019-09-15) (3 minutes)

Reduced affine arithmetic is an extension of interval arithmetic; it is a nonstandard semantics method for evaluating a computable function in the form $f(x_0, x_1, x_2 \ldots x_n)$ over some multidimensional interval $x_0 \in (x_{00}, x_{01})$, $x_1 \in (x_{10}, x_{11})$, … $x_n \in (x_{n0}, x_{n1})$ to get a conservative affine approximation $k_0x_0 + k_1x_1 + \ldots k_nx_n \pm k_{n+1}$ within which f is guaranteed to be contained; for arithmetic expressions, it normally takes a factor of n longer than simply evaluating the expression at a point, and for regular functions, in the limit, the error term k_{n+1} diminishes quadratically with the interval size.

(Can we apply RAA recursively once to get a reduced affine approximation of this error term, thus telling us which independent variables are not contributing any significant approximation error, and perhaps also getting a cheaper second-order approximation than the full $O(N^2)$ representation?)

Mathematical optimization is the problem of finding the minimum of a "cost function" of some "design variables" within some given "feasible region". Usually this can be restricted to the problem of finding the function's global minimum, because we can modify the function to guarantee its value outside the feasible region will be very large.

For perfectly linear functions, reduced affine arithmetic computes a perfect approximation; it is only nonlinear operations such as multiplication, division, or conditionals that contribute error.

(Can you apply RAA in other fields, such as $GF(2)^n$ with XOR, NOT, and either AND or OR? XXX $GF(2)^n$ isn't a field, dude)

Here is an algorithm for using reduced affine arithmetic to find the minimum of a function over some domain.

Begin with a single interval covering the entire feasible region, perhaps $(-\infty, +\infty)$ on every independent variable. Compute the function using reduced affine arithmetic over that interval. Store it in a min-heap of (interval, result) pairs indexed by least lower bound (i.e. the lowest value the function can possibly achieve on that interval).

At each step, select the interval with the smallest least lower bound. Remove it from the min-heap and subdivide it in some way, for example into three subintervals along a randomly selected axis. Compute the function for each subinterval, and insert the new subintervals into the min-heap.

At any step, (one end of) the best interval on the heap is in some sense our best guess at the true global minimum of the function, but any other interval whose least lower bound overlaps its least upper bound may actually be better. However, once the difference between the upper and lower bounds is within our desired tolerance, any one of those intervals is an acceptable answer.

Note that, although it is not a gradient-descent optimization algorithm, it is still an anytime algorithm.

Internal determinism

Kragen Javier Sitaker, 2016-08-17 (2 minutes)

Guy Blelloch and others wrote a paper in 2012, "Internally Deterministic Parallel Algorithms Can Be Fast".

Their basic theory is that fork-join nested parallelism with no communication between concurrently running threads allows you to program efficient parallel algorithms relatively easily without introducing nondeterminism.

Or wait, maybe their threads have "shared state" and consequently depend on "non-trivial commutative operations". If that's true I don't see how the stated properties of the dependency graph can be correct. I guess those commutative operations on shared state don't enter into the dependency graph except as a set.

So for example they have an AtomicAdd operation to add a value to a shared variable, but it can't return a value without violating internal determinism.

They support four different kinds of memory objects supporting commuting operations:

• memory cells, supporting the "priority write" operation x.pwrite(v), which updates x to have the maximum of its old value and v, and a read operation that returns its current value.
• reservables, supporting the operations x.reserve(p), x.check(p), and x.checkR(p) check-and-release. Check and check-and-release commute, I think? Not entirely sure. checkR sets the priority of the reservable back to ⊥ and returns TRUE if it was currently reserved with the specified priority. None of the checks commute with reserve(), but I think reserve() commutes with itself.
• dicts, supporting d.insert(x) and d.elements(), which returns an element for each key that has been inserted, eliminating duplicate keys. Both reads and writes commute among themselves but not with each other. Elements contain their keys within themselves. A user-specified priority resolves duplicates, and linear probing evicts elements with lower-priority keys and moves them further down to ensure that the final iteration order is not dependent on insertion order.
• disjoint sets, for spanning forests; f.find(x) returns the set identifier containing x, and f.link(s, x) merges the sets of s and x. The criteria for commutativity are somewhat tricky.

Thermodynamic systems in housing

Kragen Javier Sitaker, 2016-06-28 (24 minutes)

Much of the business of a house comes down to controlling the flow of a few crucial commodities:

- Heat;
- Light;
- Air;
- Water, whether as humidity or liquid;
- Noise.

(This is also true, incidentally, of gardening, of which more later.)

This is a Fullerian view of a house as a dwelling-machine, rather than a structural engineering effort to resist its own weight. It's also a sort of instrumentalist worldview: the house is designed for CONTROL, so that its owners can use that control to experience comfort.

In its crudest form, a house is just an enclosure to restrict the flow of all four of these commodities. The roof and walls stop the rain from soaking the space beneath, the sunlight from heating it, the wind from casting it into disarray, the cold night from chilling it, and the inhabitants from scaring the animals with their gasps and ululations. In nature, all five of these elements generally arrive together and depart together, and to exclude one is to exclude another.

But too much restriction is usually bad, even fatal. If heat cannot escape, an inhabited dwelling will eventually cook its inhabitants until they cease to heat it with their body heat; if light cannot enter, the inhabitants are blinded; if air cannot enter, they suffocate; if water cannot exit, everything becomes waterlogged with their breath; and if noise cannot enter, well, perhaps nothing bad happens.

More elaborate contrivances allow us to separate these five elements to some extent, reducing the necessity to compromise our needs between them:

- Solid windows, whether of mica, of glass, or of polyethylene film, damp noise but permit light to pass without bringing along air and water, or letting quite so much heat pass out the other way when it's cold out.
- Shutters allow us to further restrict the air, light, and noise that pass through windows.
- Curtains, too, are mostly used to stop the flow of light through windows; they can also be used for privacy, to stop the flow of heat through walls, and to absorb noise.
- Thermal mass, like adobe walls, damps thermal fluctuations like the big capacitors in your power supply. That same mass often serves to absorb noise and damp fluctuations in humidity.
- Furnaces, heaters, stoves, and microwaves produce heat with little light, but the flame-powered kinds require access to vent their exhaust.
- Luminaires provide a small amount of light upon demand, even at

night, along with correspondingly little heat.
• Air conditioners and other kinds of heat pumps move heat in the direction of our choosing without bringing air and light along for the ride, though often at the cost of noise.
• Plumbing provides water on demand, often leavened with a precise degree of heat for luxury; like heat pumps, it, too, can be used to control the flow of heat, which will probably be its primary function within a few decades, as machines' energy usage explodes.
• Rugs, historically, served largely to insulate us from chilly floors and absorb sound. (Since the 1930s, they have a secondary use of reducing the cost of housing by hiding plywood flooring which would otherwise have to be covered with more expensive hardwood.)
• Construction materials are often chosen to be porous to prevent condensation inside walls: if humidity can get into the wall from the warm side, the thermal gradient through the wall must be matched by a humidity gradient, or when it's cold outside, the thermal gradient will cross the dewpoint.
• Insulation in walls stops heat transfer without affecting airflow significantly.
• Weatherstripping around doors and windows stops heat transfer, noise, and airflow.

But there are a variety of other techniques, less widely used, some even entirely speculative, which promise to offer better tradeoffs. Some of these are proven but not widely known.

• Solar overhangs over windows permit sunlight to enter the windows during the winter but not the summer, passively reducing the temperature variation throughout the year.
• Electrically controlled shutters or mirrors could provide the same service, but controlled by a PID or better negative feedback system, rather than crudely by the season.
• Countercurrent air heat exchangers allow air to enter and leave a house without taking heat and humidity with it. These are necessary for Passivhaus structures, which are designed to limit heat flow to a much lower level than traditional, in the interest of reducing marketed energy consumption.
• Speculatively, regenerative heat exchangers are another way to achieve the same goal in less space, and possibly with less expensive materials. While a countercurrent heat exchanger runs currents in both directions at once, separated by a high-thermal-conductivity barrier (for example, warm air exiting the house in winter might be used to thus warm up cool air being brought into the house at the same time, by passing the air currents through parallel pipes separated by an aluminum wall with lots of fins), a regenerator instead alternates between the two directions. So a regenerator could consist of, for example, an insulated tube full of sand, gravel, or a microencapsulated phase-change material (see below). This, however, requires the air volume inside the house to vary, which is potentially difficult to achieve. With a little water, it's possible that the regenerator could simultaneously function as a filter, although of course water evaporation would also humidify and cool the air.
• Geomembranes could permit subterranean construction with much less compromise. One great difficulty of subterranean construction is that all traditional construction materials are porous, so below the

water table, a constant trickle of water enters in unpredictable places. It must be pumped out to avoid flooding, but it still compromises humidity control; I have known subterranean offices with deadly Stachybotrys infestations. Geomembranes are sheets of tough plastic welded together, developed for keeping landfills from leaking; they could conceivably solve this problem, although I'm not familiar with examples of their use in building construction.

• Speculatively, halite (sodium chloride, table salt) is a mineral that flows under pressure that is relatively light in geological terms. Perhaps halite could serve as a sort of self-healing geomembrane to seal out water, although over long periods of time it will eventually diffuse away in the groundwater, and it would rule out the use of steel-reinforced concrete construction.

• Light pipes (or "light tubes") are waveguides for transporting light long distances, up to tens of meters, through small apertures into a building. In essence, they are fat fiber optics. They can exclude the infrared wavelengths that carry a substantial fraction of sunlight's heat, and they can relieve the murky dimness that often plagues subterranean construction.

• Subterranean construction is superb for noise control, thermal mass, insulation, and security; military buildings have often been constructed underground for centuries for these reasons.

• Alkali scrubbers, like those used in submarines and space stations, remove carbon dioxide from air, reducing the amount of airflow needed to keep it breathable. (When you suffocate, the level of carbon dioxide reaches fatal levels long before the level of oxygen falls dangerously.) In their simplest form, these are just curtains impregnated with lithium hydroxide or a similar alkali, which convert to carbonates upon absorbing carbon dioxide. Lithium hydroxide, though preferred in submarines and space applications for its light weight, requires heating the carbonate to 1300° to regenerate the hydroxide; the carbonates of sodium, calcium, and magnesium are more manageable, at 851°, 550° to 825°, and 350°, respectively, and they are much less caustic as well.

• Phase-change materials like ice, Glauber's salt, or paraffin, provide effective thermal masses that are many times larger than their physical mass. A single ton of ice, with its enthalpy of fusion of 333 kJ/kg, can absorb the same amount of heat in its melting as 44 tons of feldspar rock, with its specific heat of 0.75 kJ/kg/K, over the range 20° to 30°; ice has an inconveniently low melting point, but you can use ice, rather than air, as a reservoir for a heat pump, getting a major efficiency boost, and other phase-change materials are capable of honorable performance at higher temperatures. Paraffins can be fractionated to have precisely calibrated melting points at any desired temperature, and Glauber's salt melts at 32°, just slightly too warm for comfort, absorbing 252 kJ/kg; at 1.46 g/cc, that's 368 kJ/ℓ. Wikipedia says, "For cooling applications, a mixture with common sodium chloride salt (NaCl) lowers the melting point to 18°C (64°F). The heat of fusion of NaCl·Na2SO4·10H2O, is actually increased slightly to 286 kJ/kg." As a useful ballpark, a square meter of sunlight inside your house during 12 hours deposits about 43 MJ of heat, enough to melt about 130 kg of ice or 151 kg (103 liters) of the Glauber's salt mix; a person during 24 hours burns perhaps 2500 kcal, enough to melt 31 kg of ice or 37 kg of the Glauber's salt mix (25

liters). (Other low-melting-point materials exist, but most are not affordable at the kilogram scale; eutectic sodium/potassium nitrate is, but melts at 260°; hydrated sodium silicate melts at 72°. A variety of other phase-change materials are commercially available.)

• Seasonal thermal energy storage are large thermal masses (whether phase-change or otherwise) intended to store enough heat to keep you warm all winter or cool all summer. Ballparking, a kilowatt per person over six months is 15.8 GJ per person, which is 47 tons of ice or 55 tons of the Glauber's salt per person, about 38 cubic meters (38000 liters); or 2100 tonnes of feldspar (820 m^3 at 2.56 g/cc) with a 10° temperature swing. This may sound like an impractically large amount of material, especially the feldspar, but even in that case it fits into a 12-meter-diameter sphere; it's house-sized, not city-sized. You don't have to move all that material, but you do have to somehow control fluid flow through or near it, with a typical technique being to perforate a field with boreholes 3–8 meters apart.

• Double- and triple-paned windows are hermetically sealed, typically with argon in between the panes, which dramatically drops heat loss and noise transmission through the window without noticeably affecting light transmission.

• Vacuum-insulated glazing is a more advanced version of double-paned windows with vacuum between the panes, reaching R-values as high as 12.5 K m^2/W.

• Evaporative coolers come in many forms, such as spray mist nozzles, box swamp coolers with coarse vegetable fiber such as wood wool, and open water pools; it trades an increase in humidity (and a loss of water) for a decrease in temperature, and in some cases the downdraft of the cooler air can also be harnessed. If you can arrange for the water to evaporate outside your house rather than inside, you avoid the humidity increase, but you also lose most of the cool.

• Flat-plate solar thermal collectors are very-low-cost ways of harvesting the sun's heat; they can be a simple aluminum sheet painted black with a thin Styrofoam backing with water pipes welded to it, or even black-painted plastic with channels running through it. (In cold climates, you need some antifreeze in the water, too.) Typical efficiencies are in the 40% – 60% range, several times higher than photovoltaic. With transparent plastic or glass over the top, the water can heat up efficiently to over 50° — not enough to drive a heat engine efficiently, but plenty for climate control or a hot tub, at a very low equipment cost per watt. The Drake Landing Solar Community, at the chilly latitudes outside Calgary, gets 97% of the energy it uses for climate control with this technique, storing it in a borehole field as described above.

• More elaborate kinds of solar thermal collectors, capable of higher temperatures and higher efficiencies, include evacuated-tube types, concentrating types, and types with wavelength-selective paints. Higher-temperature collectors may have to be made of more expensive materials (copper rather than plastic) and use more exotic fluids (oils or molten salts rather than water).

• Thermosiphons are an arrangement of the elements of a solar thermal collecting system such that no extra pump is needed: the heat sink or heat store is placed at a higher elevation than the solar thermal collectors, so that the warmer water from the collectors will rise into the sink or store, replaced by denser cool water. Often a backflow

prevention check valve prevents backward flow at night.
• Thermal radiators are simply solar thermal collectors used at night to radiate unwanted heat as infrared light into space. Wavelength-selective paint is counterproductive for this use. In some systems, the radiator is simply an open pan or floor flooded with water, which is free to shed heat both by radiating and by evaporating. Without the evaporation, the cooling rate is about 75 W/m² at normal temperatures.
• Short-term thermal storage tanks can store heat or cool (thermal absorption capacity) in thermal mass (probably of water) or a phase-change substance. In extreme cases, this could be done in a stainless steel Dewar flask, but less extreme temperatures permit the use of inexpensive plastics with no insulation or inexpensive insulation.
• Solar air heaters are solar thermal collectors that heat air directly rather than water. This reduces the need for waterproof materials, but because of air's much lower specific heat, requires larger systems and more flow. The Trombe wall is one well-known version of this system.
• Venturis and other fluidic pumps permit the use of one fluid flow to produce another, without any moving parts. This could be useful to drive ventilation air currents from convection currents produced by a solar air heater.
• Heat pipes are a lighter, faster way of moving heat than water-filled plumbing, and they also don't break if they freeze. They're sealed and filled with low-pressure water vapor, which rapidly flows to cool parts of the pipe and condenses, then flows along the inner walls until they reach a warm part, where it evaporates again.
• Non-imaging optics permit concentrating sunlight to a very high brightness in a compact space without having to track the sun (much); this is useful for feeding light to light pipes and also for heating fluids.
• Desiccant dehumidifiers are an alternative to refrigerative (or "compressor") dehumidification when humidity is too high. Instead of chilling the air to condense the humidity, the air is run through a desiccant (silica gel or synthetic zeolite) at ambient temperature, and the desiccant, usually mounted in a rotor, is then heated to release the humidity and recycle it for further dehumidification. These have several advantages over refrigerative dehumidifiers: they operate from readily available heat rather than expensive mechanical energy; they can typically dehumidify down to lower temperatures and lower humidities; the extracted humidity is in a more manageable form of vapor rather than liquid; the machinery is much simpler. They also cool the dehumidified air, so they are an alternative to absorption chillers (see below) for solar air conditioning.
• Hypocausts, or underfloor heating, are a great seven-thousand-year-old luxury, universal in Korea, in which the house is heated through its floor rather than by directly heating its air; https://www.youtube.com/watch?v=P73REgj-3UE shows the construction of one from stone and mud. This is more comfortable than the air-heating approach, because people are more comfortable when the radiant-heat temperature is higher than the air temperature. If energy is abundant, it may actually be worthwhile to use it to cool the air while heating the floor. The heat can be carried through the floor in channels for air or water or provided by electric heating

elements; the standard approach currently is to use cross-linked polyethylene (PEX) pipe (good up to 85°) with water.
• Heated counters and heated toilet seats are other similar luxuries that can be provided in like manner. Defrosting plates made of thick aluminum could be useful for many purposes.
• In snowy climates, such a heat reservoir could be used to melt snow covering driveways or roads. Experiments have been done of collecting heat using cross-linked polyethylene (PEX) pipes embedded in asphalt.
• Chilled slabs are the same system, but used to provide radiant cooling rather than radiant heating. I haven't had the opportunity to experience these, but they are in use in places.
• Absorption chillers are refrigeration systems which can be operated entirely from heat, even including low-temperature heat such as that provided by flat-plate solar collectors. They are in common use in camping refrigerators powered by propane flames, and in large-scale commercial use, but they could be used as heat pumps in a variety of climate-control uses, pumping massive amounts of heat entirely by solar thermal power. "Solair" was a 2009 EU research project aimed at commercializing small-scale air conditioning by this technique, achieving a coefficient of performance of 0.7 powered by a 65° heat source. The application to camping refrigerators requires ammonia, which is dangerous (corrosive, volatile, and inflammable, producing toxic fumes), but much safer aqueous lithium bromide is adequate at air-conditioning temperatures. This refrigerant appears to require some moving parts, even though the ammonia version does not.
• Reflective-wall booths, like those used for indoor marijuana growing, and directional LED task lighting can improve light usage efficiency. This should allow people to achieve greater well-being with relatively small amounts of light. Full daylight is on the order of 50 kilolux, which is to say 50 kilolumens per square meter. If you are sitting in a reflective-wall booth where your skin and some reading materials absorb the majority of the light, you might have 4 m² of absorbing area, thus needing 200 kilolumens. A normal GE Polylux 70-watt T8 fluorescent tube produces 6.3 kilolumens, so you would need 32 of them, a total of 2200 watts. Even at an eighth of that, though — 4 tubes, 6.3 kilolux, and 200 watts — you're still twelve times brighter than a normal office. The GE high-efficiency electronic ballast for this setup costs US$21 at retail.
• High-efficiency lighting systems such as sodium vapor high-intensity discharge lighting (favored by marijuana growers) have even higher luminous efficiency than fluorescent lights. While a candle is has a luminous efficiency of 0.04%, quartz halogen bulbs are around 3%, and the fluorescent tube is 12–15%, high-pressure sodium lamps can reach 22%.
• Speculatively, instant hot-water heating can be carried out by running the water through a heat exchanger with a much hotter substance; for example, a small amount of molten salts could be kept around 300°, or a larger amount of oil at above 100°, and water circulated through a heat exchanger with it would flash into steam. This is primarily useful for direct steam applications like foaming milk for cappuccinos or melting cheese, since simply keeping the heat in a larger quantity of water at a lower temperature would avoid any explosion dangers and would have lower heat losses.

• Speculatively, you could heat air for cooking a convection oven in the same way. Perhaps a gravel bed or large rock riddled with air channels would be a better heat reservoir for this than liquids.
• Dehydration of food, damp laundry, and similar things can be carried out with solar-heated air, either inside or outside the house.
• Speculatively, you could use a wet scrubber to remove particulate matter from the house air. This could be helpful if you live in an area with significant particulate pollution, both for health and for keeping the house clean. Dust particles larger than smoke, which are less of a health problem but necessitate cleaning, are probably better removed with a cyclonic separator, electrostatic separator, or paper or fabric filter. A house of 100m² with 4 m ceilings contains 400m³ of air; removing 90 to 99% of the particulates from that air with a venturi scrubber or indoor spray tower, at 0.5–3 ℓ/m³, would require some 200 to 1200 ℓ of water, which is a thing you would might want to do for all the air your bring in from outside. At 1500 kPa of water pressure in the nozzles of a spray tower, cleaning the whole house's air with 800 ℓ of water would use 1200 kJ (⅓ kWh).

Ideally, many or all of these systems would be available to the house-dweller to deploy as they saw fit, rather than hooked up in a fixed topology at build time; heat and cold reservoirs at various temperatures would be continuously replenished when possible, thermostats and humidistats would be programmed to provide a healthy diurnal variation in the living space, and when excess energy was available, it could be spent on greater illumination or radiant heating.

While such control of the indoor climate is pleasant for humans, we can after all put on a coat or take a cool bath if we're uncomfortable. For gardening, however, the differences in productivity from even small changes in temperature can be immense. More factors begin to matter — you care not only about the soil's temperature and humidity, but also its pH and its contents of nitrogen, phosphorus, potassium, and sulfur; and the carbon dioxide content of the air has a significant effect on plant growth. (You could obtain carbon dioxide by calcining calcium or magnesium carbonate, which you then deploy again as air scrubbers.)

In most climates, this level of climate control ought to enable immense gains in agricultural productivity: you should be able to grow sugarcane, bamboo, corn, squash, or rice even at periarctic latitudes, and with CO_2 supplementation, they should grow even faster than in their naturally optimal environments.

Plumbing with crossbars

Passing air through pipes or ducts is an efficient way to move two or three of our five crucial commodities: heat, air, and water in the form of humidity. Even if we want to heat or cool liquid water, for example for washing dishes or laundry or for a shower, it's probably a good idea to use air to transfer the heat or cool from the relevant reservoir to a heat exchanger for the water.

If we have the desire to

Computation with strain

Kragen Javier Sitaker, 2019-06-13 (17 minutes)

Traditional mechanical analog "computers" represented quantities only as displacements (sometimes linear, sometimes angular), but perhaps by using other quantities such as strain (tensile and shear) and velocity, we could construct simpler flexure computing devices that compute faster.

Needless to say, such devices ought to be as small as possible given the precision that is required; no advantage accrues to a calculating device from requiring lots of power and weighing a lot.

It's unfortunate that we're stuck with the misleading term "computer" for such analog devices, because in the digital realm, we do not call an adder, multiplier, or decoder a "computer"; we reserve that term for essentially Turing-complete digital systems. But it is not even clear what the analog equivalent of Turing-completeness would even be; an "analog computer" is a set of building blocks that can be reconfigured and connected together in different ways to perform different calculations.

Linear and nonlinear springs

The equilibrium or steady-state configuration of a damped sprung mass with a given force applied is a displacement that depends on the force, but not the mass. In some nonlinear cases, like Euler columns, there may be more than one possible equilibrium configuration, even without inelastic deformation. (Merkle's buckling-spring logic depends on this for its memory; see mechanical computation: with Merkle gates, height fields, and thread (p. 2494) for depth on such systems, and Elastic metamaterials (p. 719) and Snap logic (p. 2580) for some more related stuff.)

Hookean springs make this equilibrium displacement a linear function of the applied force, or to look at it the other way, they make the force a linear function of the displacement. This means that if you have a few different linear springs pushing on a single lumped mass, its equilibrium displacement is going to be a weighted sum of the displacements of the other ends of those springs.

Once any nonlinearity enters the picture, which can happen through rotation (as in Euler columns), contact (as a plucked ruler hanging off the edge of a table rattles against the tabletop), or maybe even fluid dynamics, the equilibrium displacement–force relation becomes not only nonlinear, but also potentially nonmonotonic, discontinuous, and multivalued (i.e., not a function).

Considering continuous cases, though, let's think about a cantilevered beam of constant width tangent to a cylinder. If you press it toward the cylinder, it starts to wrap around the cylinder, shortening the lever arm and increasing its Hooke constant. By using a varying curve, the increase of the Hooke constant can be tailored to the integral of some arbitrary nonegative function. You can thus get a nearly arbitrary continuous displacement difference between two parallel rulers wrapping around different-shaped curves under the influence of two parallel coil springs from some remote source.

Additionally, Euler-column-style rotations can provide

nonmonotonic force–displacement relationships, though even without stiction, this can result in memory.

Linearly converting a force to a displacement or vice versa can be done with linear springs; computing an arbitrary nonlinear function of a force as a displacement, or vice versa, can be done by the methods described above. Adding forces can be done by connecting multiple springs to the same object. In particular, it should be possible to use two cylinder-wrapped rulers to compute the logarithms of two input forces as positions, convert these positions back to forces through much lighter linear springs which push on another object, and convert its position to an exponentially increasing force by attaching it to a third even lighter cylinder-wrapped ruler, which thus at equilibrium computes the product of the input forces.

This suggests the ability to compute arbitrarily complex continuous numerical functions, although clearly some kind of energy amplification is necessary to prevent output "circuits" from unduly loading the inputs and to permit chains of more than three or four levels of depth.

These spring systems, like flexures in general (see Flexures (p. 2211)), have no backlash as long as the material is perfectly elastic, eliminating one of the major sources of error in mechanical analog computation.

Integrators and non-equilibrium systems

In general, though, sprung-mass behavior does in fact depend on the mass. The net force on the mass, due to the curves of the various springs acting on it and its current displacement with respect to those springs, produces an acceleration inversely proportional to the mass; the mass's displacement is the integral of its velocity from its initial position, and its velocity is the integral of its acceleration from its initial velocity.

This suggests a much more appealing way of building a time-domain integrator than the disc-on-plate and ball-on-plate devices used by Bush's differential analyzer: represent the time-domain quantity you want to integrate as a force, and then the velocity of some mass gives you its integral!

This has a couple of major disadvantages, though. How do you convert the velocity back into a force? The usual mechanisms for this involve either viscous fluid friction (which is notoriously tricky due to the laminar–turbulent transition), or electrical generation, like old car speedometers or eddy-current magnet braking. And how do you exert a controllable force on an object whose position is not an input to your computation?

I propose that we represent the integral not merely as a velocity but as a *harmonic oscillation amplitude*. A tapered, cantilevered bar will vibrate at some natural frequency, and its current oscillation amplitude is roughly the integral of the oscillatory forces that have been applied to it in the past. The oscillations decay over time in accordance with its Q factor, but Q>100 routinely happens by accident in oscillatory mechanical systems; I suspect this may provide sufficient time to perform a useful calculation to the precision afforded by the rest of the system.

If the cantilever is vibrating only in a single dimension, there are times during its motion that all of its energy is elastic, and other times

when it's all kinetic. This seems like it could complicate the process of continuously feeding energy into it from the quantity you want to integrate; you need to feed in that energy in different frms at different times.

A possible solution to this is to make it vibrate circularly in two dimensions around its natural position. With this approach, you can always apply a displacement or force to it to add or subtract energy; only the necessary direction of the displacement or force varies. (And if you're adding force, you need to add it in a direction that is 90° from the direction you'd need to add a displacement in.)

This has the possibility that you'll end up with a non-circular oscillation, because the signal you were adding had a periodic or near-periodic component at or near the frequency you chose for the oscillation. To remove that effect, you can add the squares of the X and Y component amplitudes.

To convert this oscillating integral value to a single-ended displacement, you probably need to rectify it, ideally a tiny fraction of it so as not to spoil the Q too much. Rectification can be achieved by the earlier-described kinds of nonlinear elastic systems or more simply by banging shit together or trying to push on a rope.

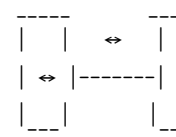
Speaking of pushing on ropes, that may be a way to get the necessary amplification.

Amplification through Euler columns and loose string

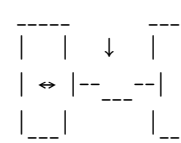
The crucial invention of Bush that made the differential analyzer practical was not the integrator itself — that dated back decades — but the "torque amplifier", a negative-feedback friction device that strongly drove an output shaft to the same position as a weakly-driven input shaft. How can we do something similar without friction, backlash, wear, lubrication, and the other headaches of sliding-contact machinery?

Euler columns

If you have a power-supply block that is being driven back and forth, by your power supply, with some fixed displacement, and it is connected to another block through a straight slender rod, it will tend to drive that other block back and forth, unless the force needed to drive the other block is so large that the rod approaches Euler-column instability:



However, a relatively small force pushing on the side of the rod can get it to buckle when it otherwise wouldn't, greatly reducing the force transmitted to the driven block:



The transverse displacement is relatively large (much larger than the displacement that would have been transmitted to the driven block) and oscillating, but the transverse force need do no net work over time. Consequently you want to apply this displacement through a spring with high compliance.

The column is shortened by this process, so I think the driven block must also have relatively large compliance, at least at DC; if it's stiffly, I think it won't work.

This provides a locally-continuous mechanism both for controlling a large force with a small force and for controlling an arbitrarily large amount of power with an arbitrarily small amount, like a MOSFET.

Making straight string crooked and thus "loose"

Possibly this can be generalized to adding slack to string by pulling it sideways. While the vertical "control string" is slack, as long as the "drive string" is under some DC tension, it faithfully transmits AC movements with high stiffness:

But if a little DC tension is applied to the control string, adding some slack to the drive string, the effective stiffness of the string drops greatly, and much less of the AC signal is transmitted:

(For frequencies sufficiently high to require a transmission-line model of acoustic propagation in the string, you also have to account for reflection from the knot and the conversion of longitudinal waves in the drive string into transverse waves in the control string.)

I think this may be the thread-based amplification construct I was looking for when I wrote about computing with thread in mechanical computation: with Merkle gates, height fields, and thread (p. 2494). What I had come up with at the time was the idea of frictionally clamping a thread running lengthwise down a dowel by tightening another thread that ran around the dowel several times, but I'm not totally convinced that's a workable mechanism. I'm more optimistic about this new design.

I've rigged this up on the back of a chair with a couple of meters of my knitting yarn, and pulling the control string certainly does dramatically attenuate the AC *displacement* that gets transmitted down the yarn. However, it also adds tension to the yarn, so it's hard to tell whether it results in less energy being transmitted than before; I don't have a quantitative measurement of the force. It also has the effect of making my bedroom look slightly more like *A Beautiful Mind*, and not the positive achievement parts.

Since this really only allows a DC signal to control an AC signal, you need a rectification step to produce a fully composable analog computation system made out of thread. Thread is fantastic at rectifying signals — as I said above, it's a cliché that you can't push on

a rope — but it's even worse than electricity at having memory, so you're going to have a lot of ripple in your rectification output. For digital computation, you can probably deal with ripple in a brute-force way if it comes to that — for example, separately switch two phases of a quadrature signal and full-wave rectify both of them into a single junction — but for analog "computation" it seems like a big problem.

Making loose string tight

Much larger and clearer amplification is available easily with string, though. Although the above contrivance can possibly be made to work, it has the major difficulty that it is trying to "loosen" string by adding tension to it, so as to make it no longer straight and thus less "stiff" to a power supply that's trying to drive it. Going at the problem backwards, there's a much simpler solution: try transmitting a displacement signal by moving one end of a loose string, and you will find that it doesn't reach the other end, unless the signal is so large as to pull all of the slack out; here # is used to indicate fixed, solid material:

```
#######
 |   |
_|   |_
↔|\ /|
 | v |
 |   |
#######
```

The slack string can attenuate an "ac power supply" by at least several orders of magnitude. (Here the vertical strings are "leaf springs" whose tension provides a restoring force for the two knots implicit in the diagram.)

But if something takes up the slack in the string, for example by pulling it at right angles, the string suddenly begins to transmit movement, although imperfectly:

```
#######
 |   |
_|   |_
↔|\ /|↔
 | v |
 | |↓|
###|###
```

Some of the energy from the power supply is also transmitted to the "gate string", but I think it is possible to choose the angles and compliances involved such that that energy is very small. In particular, if the slack "channel" string is nearly straight in its slack state, the force applied to the "gate" string will be much smaller than the force transmitted from the "drain" to the "source" through the channel — say, ten times less — so if the gate and source are of similar compliance, the interference energy backfed to the gate could be around 1% of the energy successfully transmitted to the source. I am not sure about the energy needed to pull on the gate string.

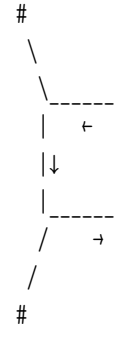
An even simpler nonlinear string mechanism is an "OR gate"

consisting of two input strings that can pull on a common knot, pulling an output string if either of the two input strings is pulled:

Direction change for a limited range of displacements is easily achieved with a knot that can swing in a circular arc because it is anchored to a fixed point:

Different parts of the arc provide different mechanical advantages between the string chosen as input and that chosen as output; if the arc is large compared to the expected displacements, this mechanical advantage will be relatively constant.

"Negation" of displacements, when necessary, is available through a sort of pulley mechanism made from two or three such direction-change arrangements:



But I think that, although these "OR" and "NOT" arrangements might seem logically universal, they might lack some necessary kind of amplification for full combinational logic, petering out somehow after a few stages. I think the right-angled-slack-string approach described above, coupled with a power supply, should provide all the amplification you could need.

Stick-slip violin amplification

Bowing a violin string tends to amplify existing vibrations in it; when a transverse wave movement reaches the bow, it rips the string free of the bow hair, causing it to slip, and when a peak or valley of the transverse wave is at the bow, the string can stick to the hair, which pulls it along and stretches it, adding energy that will be released at the next slip. This form of amplification is extremely nonlinear, but might work.

Amplification through multipliers

As described above, a force multiplier flexure — where the output force is proportional to the product of the input forces — is fairly easy to rig up, although to avoid enormous imprecision, the vast majority

of the input energy remains as elastic energy within the device, with only a tiny fraction reaching the output. But that might be okay if you're multiplying a weak input *signal* by a high-power power supply; it's not really a problem if most of the energy in the amplifier is resonating back and forth between the multiplier and the power supply, or even just being burned up as heat, as long as the output signal is stronger than the input signal.

I'm not sure if this will work.

Japan can achieve energy autarky via solar energy, but not much before 2027

Kragen Javier Sitaker, 2017-07-12 (4 minutes)

Ian Welsh tweeted, "Japan HAS to import energy."

Is he right? It turns out that photovoltaic changes things; Japan can sustain its current energy consumption on about 5% of its land area, using plain cheap photovoltaic panels. It will probably get the majority of its energy from photovoltaic panels starting in the mid-2020s, based on current growth rates.

Wikipedia says Japan used 477.6 Mtoe in 2011, which is 19.996 exajoules, a number suspiciously close to 20, or 630 GW average. The accompanying chart shows that the number is closer to 21 EJ, or 670 GW, roughly level since 1995. Solargis's solar resource chart gives numbers of global horizontal irradiance (GHI) from 1200 to 1600 kWh/m²/year; a rough average might be 1400, although Wikipedia gives somewhat higher numbers of 4.3 to 4.8 kWh/(m·day), which works out to 1600–1800 kWh/m²/year. Solargis also offer a "potential PV electricity generation" map for optimally-tilted free-standing crystalline silicon modules, ranging from some 900 to some 1600 kWh/kWp, with most of the land around 1200.

Japan's area is 378000 km², which gives us a total GHI of about 500 PWh/year, or 60 TW. With 16%-efficient (polycrystalline Si) horizontal solar cells, this gives us 10 TW, which is about 15 times Japan's total national marketed energy consumption.

That is, Japan could satisfy its current energy demands with about a fifteenth of its total solar resource, occupying perhaps 5% or 10% of its land area. To supply these 670 GW with an unremarkable solar photovoltaic capacity factor of 20% would require 3.3 TW of solar panel nameplate capacity (TWp); currently installed at the end of 2016 is 42.75 GW, about 78 times smaller. Installed PV capacity rose from 3.618 MW at the end of 2010 to 42.75 GW at the end of 2016, a factor of 11.82, an exponential growth rate of 51% per year. At this exponential rate, Japan would need another 10.6 years (mid-2027) to reach 100% of energy from domestic solar photovoltaic. Presumably the growth rate will slow earlier than that, perhaps around 2023.

At current photovoltaic prices of €0.53/Wp (May 2017, Japan/Korea market), 3.3 TWp is 1.7 trillion euros. Japan's nominal GDP is currently US$4.73 trillion per year, although only has US$697 billion in exports (€608 billion at US$1.146/€). So this represents an investment of about 2.8 years of Japan's exports or about 0.41 years (5 months) of Japan's GDP. Currently Japan pays a very high tariff of ¥42/kWh for solar, which, at ¥114/US$, is US$0.37/kWh or €0.32/kWh. So the full €1.7T investment will be paid for by the next 5.3 trillion kWh (19 EJ) of solar energy consumed in Japan.

That's only the cost of the panels, but at this point the levelized cost of new PV plants is under US$1 per peak watt, even including the

uncertainty premium to investors. That is, the cost of the whole plant is less than twice that of the panels. We can expect that cost to continue coming down.

There are some other obstacles to going majority-solar, such as utility-scale energy storage for baseload power (photovoltaic panels produce no significant power at night) and producing liquid fuels for transport. I expect them to be solved once the incentive of abundant but intermittent and stationary solar energy is there, which will probably require reducing the high solar tariff.

So, although Japan can definitely afford to switch to mostly photovoltaic, it can't do it much sooner than 2027, because it doesn't have enough exports.

utility-scale

How can we build an efficient microcontroller-based amplifier?

Kragen Javier Sitaker, 2016-07-13 (5 minutes)

Some folks at the Fabricicleta were asking me a few years back about making high-efficiency amplifiers for audio from bicycles, so that you can really blast music driven by a five-watt hub generator I guess.

Suppose you use, say, a 180MHz Cortex M3 LPC1830 as your processor, and suppose that you can only output one bit every two CPU cycles, or 90MHz. A simple pulse-density modulation scheme that swings from 100010001000... to 111011101110... should limit the artifactual waveform from the PDM modulation to one fourth of the bit rate, or 22½MHz; it can approximate waveforms of up to -6dB. Then you can feed this bitstream into a Darlington or a power FET or whatever, then filter its output reactively to avoid power dissipation.

(There may actually some lower frequencies that show up from dithering: 10101101010110..., for example, has an oscillation whose period is seven bit times.)

This 22½MHz is three decades or ten octaves above anything we need to reproduce for audio purposes. Even with just a single-pole 6dB/octave LR or LC filter, you get 60dB of attenuation as long as the cutoff frequency is at or below 20kHz; I think that with two stages of LC filter, you'll get 24dB/octave, which would give you 240dB of attenuation. You should be able to use fairly small-value inductors and capacitors for this, because the total amount of energy stored for half a cycle of a 22MHz wave is very small.

Supposing we're driving an 8Ω speaker, we'd probably like the output impedance of the final-stage filter to be a lot smaller than that at 20kHz. This actually means that the entire signal path from the amplifier through the two inductors to the speaker needs to have a lot less than 8Ω impedance, say, 0.8Ω.

Capacitive reactance is $1/\omega C$, while inductive reactance is ωL. This suggests that our maximum total inductance is when $\omega L = 0.8\Omega$, which happens when the inductors total 6.4μH. And we'd like the second one to have most of that, so, say, 0.6μH in the first inductor, and 5.8μH in the second one, thus 75 milliohms of reactance in the first and 730 in the second.

Now we want our capacitors to ground to have the same reactance as the inductors at our 20kHz cutoff frequency. So, for the first one, $75\ m\Omega = 1/(2\pi\ 20kHz)C$, $\therefore 2\pi\ 20kHz\ C = 1/75m\Omega$, $\therefore C = 1/(2\pi\ 20kHz\ 75m\Omega) = 106\ \mu F$. That's a reasonably attainable value, though it has to be electrolytic. The second one need only be 11μF.

Digi-Key's most popular inductor, with 1,077,238 in stock at the moment, is a 10¢ TDK 82nH 150mA inductor, the MLK1005S82NJT000. Sadly, its DC resistance is 1.8Ω, because it's in an 0402 package (1mm × 0.5mm), so it can't serve as a high-efficiency reactive filter for an 8Ω speaker unless we put a bunch of them together. Which is actually a reasonable thing to do.

Digi-Key's most popular inductor in the right range of inductance and DC resistance is Murata's LQM2HPN1R0MG0L, a 34¢ 1μH

(±20%) 1.6 amp 55mΩ ferrite-core inductor in a 2520 (2.5mm × 2.0mm) package. Its minimum self-resonant frequency is 60MHz, which suggests that it may actually not be a great choice here; it might capacitively couple through the exact high-frequency energy we want to stop.

If I restrict to only inductors with a self-resonant frequency over 180MHz, the most popular is the TDK MLZ1005MR47WT000, a 28¢ 470nH 500mA 200mΩ multilayer ferrite-core inductor with a 260MHz self-resonant frequency, in the same 0402 package as the most popular one. It's marketed as an "inductor for decoupling circuits". Its saturation current is 120mA, which I guess means that above 120mA it doesn't induct any more. 120mA on an 8Ω load would be 115 milliwatts, but I guess you could use several of these inductors.

I don't know, I guess I have a lot more to learn about reactive filters.

Could you just wind the inductor yourself?

$L = \mu n^2 A / l$, where μ is the permeability, n is the number of turns, A is the cross-sectional area, and l is the length. So if I want an inductor of 6 μH or so, 12 turns with a radius of 1 cm and a length of 1 cm and no core would be about right; or 39 turns with a radius of 1 cm and a length of 10 cm and no core. I feel like you could probably keep the parasitic capacitance and resistance down to trivial levels with that approach.

Git data

Kragen Javier Sitaker, 2007 to 2009 (5 minutes)

I looked at checking all the almost 400MB of crawl data into Git. Here's what I learned:

• nobody on #git had experience doing anything like this, so it's not terribly well-traveled ground.
• git's compressed index file format crunches the 389MB down to 110MB.
• despite this, doing a git clone on the same machine is more than twice as slow as cp -a, despite occasional claims to the contrary for other data sets.
• currently checkouts take less than a second, on the same machine. This would make them take a couple of minutes.
• downloading the data over my Argentine cable modem connection takes almost 45 minutes, as opposed to 13 seconds now. git is about 10% slower than rsync for the initial download. rsync transfers only about 101MB. I suspect that git is slower primarily because my laptop's disk is encrypted and painfully slow as a result.
• git is a lot quicker at subsequent small data updates than rsync, but neither one is slow enough to make much of a difference.
• git is better at dealing with subsequent updates in the sense that it can propagate them in either direction.

Here's what I concluded:

• checking the data into the main dev repository, which was my initial thought, is probably a bad idea, because it makes initial checkouts on a new machine take at least a couple of minutes, and maybe more than an hour, if your connection is slower than mine.
• checking the data into a git repository, rather than syncing it around using rsync, is probably a good idea. (But probably not for really large single files like the Freebase dump.)

Creating and doing initial checkouts:

```
kragen@watchdog:~$ time cp -a /home/watchdog/web/data web-data-copy

real    0m50.081s
...
kragen@watchdog:~$ cd web-data-copy/

Calculations about desalination in Israel

Kragen Javier Sitaker, 2016-08-11 (3 minutes)

(A comment I made on an article on the orange website.)

There are some crucial details here I'm not understanding.

The article says Israel needs (or needed?) 1.9Gm³/year (60 kiloliters per second, 60kℓ/s) of water, of which it got 1.5Gm³/year (48kℓ/s) from natural sources; but now (or when the plants opened?) it gets 127Mm³/year from the 2005 Ashkelon desal plant, 140Mm³/year from the 2009 Hadera desal plant, and 150Mm³/year from the new Sorek plant. These total 417Mm³/year (13kℓ/s), but the article says Israel's current total is 600Mm³/year (19kℓ/s) from desalination plants, which is more than 417. Also, it says, Israel now gets 55% of its domestic water from desalination. But 55% of 60kℓ/s is 33kℓ/s, which is 14kℓ/s more than the 19kℓ/s it says Israel gets from desalination. I suspect there's some confusing mixing of categories here leading to these numbers not adding up properly.

The other really crucial questions are about capex and opex. How much do these plants cost to build, and how much do they cost to run? How much of that is the energy cost?

They give the figure that the Sorek plant's reverse osmosis runs at 70 atmospheres (7.1 MPa; fucking Christ on a stick, why do people keep inventing new non-SI units?) which means that each liter of output water requires 7.1kJ of mechanical energy to force it through the membrane. There are presumably some other energy costs, but that may be the bulk of it. At US$100/MWh (US$28/GJ; fucking non-SI units again), which is a reasonable ballpark for the levelized cost of electrical energy, that's about 200 μUS$/ℓ or 200 US$/Mℓ. Irrigation water is commonly quoted in US$ per acre foot in the US; this is US$240 per acre foot, which would be a very competitive cost.

But it says the cost is US$0.58/kℓ, which is 580 US$/Mℓ or US$715/acre foot, about three times the cost of the mechanical energy and high enough that many crops are uneconomical. It is crucial to understand where that extra cost is coming from.

One of the comments on the Ensia version of the story claims that the new Carlsbad desal plant is selling its water for US$2000/acre foot. I don't know if that's true, but it's about 150% higher than the projected costs.

Derivative based control

Kragen Javier Sitaker, 2019-11-12 (6 minutes)

In cybernetics, hierarchical control systems have a "higher-level" control system which provides set points to (possibly multiple) "lower-level" control systems, which the lower-level systems then seek. For example, a reaction-wheel-robot attitude-control system might plan a maneuver and then command reaction-wheel control systems to seek particular velocities for their respective reaction wheels.

It occurs to me that under some circumstances it makes sense to send more than just a set point. For example, if the central control system for a robot arm commands the servo in each of its joints to a particular position, the force the servo applies to reach that position will depend on the difficulty of the movement — the mechanical impedance, as they say, and may reach a very high level if unexpected impedance is encountered, perhaps because a research assistant's head is unexpectedly in the way of the arm. It is possible for the central control system to pay attention to these error signals and send new commands under those circumstances, but this puts stringent demands on the response time of the central control system.

It might make more sense to command the lower-level control with not just a set point but also a gradient, including a derivative with respective to any of a variety of variables — in the above case, it might be the force. In particular, the derivative of position with respect to force is simply the mechanical compliance, so this amounts to commanding not just a position but also a compliance.

Under some circumstances the commanded compliance (or other analogous gradient) would be achieved by electronic or other active feedback control — position sensors feeding back to motor-control systems, for example — but in other cases it could be achieved wholly or partly through passive means.

For example, a "brushless DC motor" or a stepper motor has a variable stationary holding torque determined by the armature current when the motor is stopped; moreover, an analogous kind of control is possible when the motor is moving as well by controlling what percentage of the time the windings are carrying current that tends to slow down the rotation rather than no current; and a tendon-actuated system, such as parts of the humans' bodies, will be stiffer when both the extensor and retractor tendons are under tension ("muscle tone") than when both of them are relaxed.

In other cases, mechanical compliance can be usefully altered by taking advantage of redundant degrees of control. Holding chopsticks close to the base rather than close to the tip, for example, is a technique for increasing mechanical compliance and thus making it easier to pick up food.

In an electronic context, this "variable compliance" might amount to things like a varying gain on an amplifier, a variable DC bias on a varactor, or a bias current on a secondary winding that varies the permeability of a magnetic core, as in a magamp.

The variables whose values the lower-level control uses to perturb the set point are not necessarily directly related to the control

mechanism. For example, it sometimes makes sense for a hand computer display to brighten when the hand computer senses increased ambient light, even if the human using it doesn't command it to brighten; a quadcopter rotor might reduce the setpoint of its speed if a local accelerometer indicates that it's accelerating upwards; and so on. In general, the idea is for the lower-level control loop to have a set point that is a locally-linear approximation to the potentially more complex and time-varying function used by the higher-level loop to figure out what set point to send to the lower-level loop.

It is observable that the humans use mechanisms such as these at several levels in their motor control; this is demonstrated, for example, by attempting to use a mouse rotated 180° or to write legibly in a mirror.

Controlling the gradients of such "reflexive" low-level control loops can dramatically reduce the demands on the high-level control, in particular often permitting much higher communication and processing latency before the whole system begins to unintentionally oscillate. Also, it can allow the high-level control loop to send commands that suppress, excite, or control oscillations in the lower-level control loop (such as human voices producing higher pitches and the humans doing that freaky thing where they vibrate their eye irises sideways), also reducing the demands on the stability of that lower-level control loop.

Beyond just the gradient of the set point, it might make sense for the high-level control loop to alter other parameters of the low-level control loop; for example, if it's a PID controller, it might make sense to alter the gains of the P, I, and D components depending on circumstances. With modern electronics it is possible to get subnanosecond response times from analog electronic control loops and trivial to get submicrosecond response times.

Note that a PD controller (a PID controller with no I term) will also perturb its operating point according to the plant's response — linearly so if the plant is linear — and this can limit the force the robot arm exerts on the research assistant's head. So in a sense this is a special case of the more general concept I'm describing; but it is missing the crucial ability for the higher-level control loop to set the compliance separately from the set point, and it can only work at all in that context if the robot actuator is working against a spring or something.

It isn't necessary for the lower-level setpoint perturbation to be linear. It might be whatever nonlinear function is most convenient to compute (for example, using the exponential Ebers–Moll response of BJTs) or it might be a precision higher-degree approximation, as in mechanical naval fire control computers.

What would a better Unix shell look like?

Kragen Javier Sitaker, 2018-11-27 (1 minute)

A better shell might have some or all of the following properties:

• Opens a new pty for each command and allows you to either include the whole command output or a scrollable window on it in the overall scroll. Clearing the screen should, by default, fullscreen the command output.
• Displays which commands failed and which relied on now-changed inputs. (This requires tracking the inputs of every command.)
• Optionally re-executes selected commands periodically
• Displays per-command resource usage, such as CPU time and RAM usage. By default runs commands with limits to prevent horking the whole machine.
• Provides notifications of finished, idle, and newly non-idle commands in a way that doesn't interfere with foreground tasks. This requires at least some minimum UI for configuring it.
• Copes with voluminous command output gracefully, at least up to gigabytes. Should have options to FIFO-discard, block (like ^S), and increase the scrollback-retention limit.
• Supports distributed operation, including running commands on remote hosts, inside of Docker containers, and across multiple remote hosts, as well as session recovery from network disconnection and even machine restart.
• Options for fancifying command output; for example, hyperlinking `ls` and `ps` output, or colorizing and relayouting other commands' output.
• Programmable autocomplete, of course.

C bad

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

The other day I was helping a friend of mine with a bug in his C program. It turned out that he hadn't initialized a variable that was used as an in-out parameter, carrying a buffer length on the way into a Win32 API function, and the length of the data in the buffer on the way out; and consequently the function was failing with an error, which he didn't check for. This took me about 45 minutes to figure out, talking with him, partly because my Win32 is pretty rusty. It would have taken a much longer time if he hadn't been fairly competent himself, having very nearly figured out the problem before we talked.

I asked why he was writing the program in C, where both of the two bugs that combined to create this problem were possible, instead of, Python, Java, OCaml, C#, Haskell, or really any high-level programming language. His answer surprised me:

we do everything at my work in C or C++
I'm sure that almost makes you puke

I said that was stupid. C is a beautiful language, but that doesn't make it the best tool to use for everything. Quartz crystals are beautiful too, but if you build a bridge by gluing quartz crystals together, it's going to take a lot of work, and when you're done, your bridge is still likely to be fragile. (Although, if you do it right, it will be beautiful.) Much better to build your bridge by welding steel I-beams together, maybe using some cables to bear its weight.

Descending from analogy to reality, working large programs are built by incrementally improving working small programs. There are four major reasons that each incremental improvement to a C program takes longer than the corresponding improvement to a program in a higher-level language:

• The C program contains a lot more code than the corresponding higher-level program, which makes it harder to find the parts you need to change, and harder to understand them well enough to change them when you find them.
• The new code you add is several times as large, with the consequence that it contains several times as many opportunities for bugs, and therefore probably several times as many bugs.
• In C, cause and effect are not localized. If any part of the program invokes some kinds of undefined behavior (uninitialized data, out-of-bounds pointers, double-frees, and so on), then it can interact with any other part of the program at all. This kind of spooky action-at-a-distance makes debugging difficult --- a newly manifesting bug may be caused by an error introduced in any part at all of the code. The traditional Unix solution to this problem is to *not write large programs*: instead, write small programs that do one thing only ("and do it well"), and then connect them together with a scripting language.
• The first three points are, in part, related to the absence of garbage collection in C; but garbage collection not only reduces the amount of code in your program and helps to keep cause and effect localized,

it also has other benefits. For example, it reduces coupling between modules, since the interfaces don't have to specify who owns memory allocations when. It improves performance, usually (although it reduces the predictability of performance).
• The C toolchains are suboptimal; you often have to futz with Makefiles and compiler options, compilation has to be manually invoked and takes long enough that you have to wait for it, and when you make a mistake in your Makefile, you often end up with a program that crashes or otherwise mysteriously misbehaves until you `make clean; make`.

Randomizing delta-sigma conversion to eliminate aliasing

Kragen Javier Sitaker, 2014-04-24 (7 minutes)

Straightforward PDM (Pulse Density Modulation) is basically the Bresenham line drawing algorithm --- you bump up an error counter by the desired slope every iteration, and when that error counter hits a threshold, you move to the next discrete row of pixels on the display, and subtract from the error counter. Like this:

```
error_counter += desired_slope * 2 * threshold;
output_value = (error_counter > threshold);
if (output_value) error_counter -= 2 * threshold;
```

As `desired_slope` increases from 0 to 1, the duty cycle of `output_value` (which is always either exactly 0 or 1) likewise increases from 0 to 1. (And of course in practice you probably want to store `desired_slope * 2 * threshold` in a variable, i.e. prescaling `desired_slope`.) To draw a line, you add or subtract `output_value` to your X or Y coordinate, and always increment or decrement the other coordinate, according to which octant the line is in.

One potential problem with this for, say, audio applications, is that it adds an artifact: a high-power pulse train at a single high frequency, and that frequency can potentially be fairly low; it's highest when you're using PDM to produce a 50% duty cycle, at which point you have a square wave at a frequency of half the "sampling" frequency. At 25% or 75% duty cycle, the fundamental frequency dips to a fourth of the sampling frequency, which is to say two octaves lower; at more extreme duty cycles, the frequency drops reciprocally. At a 1% or 99% duty cycle, your artifact frequency is 100 times lower than your sampling frequency, more than six octaves lower.

In an environment that can produce subharmonics, for example due to aliasing, even artifacts too high in frequency to perceive can become disturbing by producing strong perceptible subharmonics. Pixel line-drawing is actually just such an environment: lines that cross one another interact nonlinearly, and it's easy for the high-frequency jaggies of Bresenham line-drawing to alias down into large-scale moiré patterns.

But, ideally, in the PDM case, you keep this artifact frequency high enough that you can filter it out easily, restricting the available duty cycles if necessary, in the analog domain if that's where you're ultimately sending the pulse train. But you may not be able to achieve that. Alternatively, you could *spread* the artifact out so that it's less problematic, making it more closely resemble white noise:

```
error_counter += desired_slope * 2 * threshold;
output_value = (error_counter > threshold + r * drand());
if (output_value) error_counter -= 2 * threshold;
```

Here `r` is a parameter that controls how much bandwidth the artifact noise is spread over. At `r == 0` you have exactly Bresenham

line-drawing, and as `r` grows to `threshold` the artifact noise gets spread over, I think, an entire octave, and I think grows slightly. If `r` grows further, it will *increase* the total artifact noise, but it might still become less obtrusive up to some point, by virtue of having lower spectral density.

I suspect that you could probably produce nearly-telephone-quality audio this way with a "sample frequency" of only about 30kHz and an `r` of about `threshold`, giving you a sort of "shaped dither" spreading the 1-bit quantization noise over the upper octave or so of human hearing, where we're relatively insensitive. A 100Hz wave would have 150 cycles positive and 150 cycles negative, so you'd have only at best an ENOB of about 8, and less for higher frequencies; but as long as the quantization noise stuck strictly to an annoying high-frequency hiss, that might not be so bad. By comparison, a 25%-to-75%-duty-cycle pure-PDM at the same sample rate would on occasions produce a high-power frequency-modulated whistle as low as 7.5kHz, which would be extremely noticeable; and an equivalent 7-bit PWM would use a fundamental frequency of 30kHz/128 = 234Hz, right in the heart of the sounds you're trying to reproduce, making it almost completely unusable.

If you're doing this on a microcontroller, such as an Arduino, you might be extremely interested in how many clock cycles the above code needs, since if the timer ISR you're running it in takes too long, you have to lower the sample rate further in order to have time to run other code. The basic 8-bit Bresenham PDM code is something like

```
   r1 := ram[error_counter]
   r2 := ram[scaled_desired_slope]
   r1 += r2
   ram[error_counter] := r1
   jump_if_overflow 1f
   io[output_pin] := 0
   reti
1: io[output_pin] := 1
   reti
```

using the wraparound carry to implicitly subtract `2 * threshold`. The overflow bit (assuming you have an overflow bit) gets set when the byte overflows from positive to negative. If you only have a carry bit (are there CPUs with only a carry bit?), you can use that instead by initializing `error_counter` to the most negative number (e.g. -128) instead of zero.

(As a side note, I don't know why this logic isn't embedded as a PDM-generation circuit in microcontrollers.)

I think that's about 8–16 clock cycles on a RISC machine, so on an Arduino you could probably up to do 1MHz or 2MHz, or more if you can reserve a couple of registers for the ISR so it doesn't have to access RAM. Another three cycles would give you 16-bit `error_counter` and `scaled_desired_slope` values, and maybe something approaching CD-quality audio:

```
   r1 := ram[error_counter]
   r2 := ram[error_counter+1]
   r3 := ram[scaled_desired_slope]
```

```
   r4 := ram[scaled_desired_slope+1]
   r2 += r4
   r1 += r3 + carry_bit
   ram[error_counter] := r1
   ram[error_counter+1] := r2
   jump_if_overflow 1f
   io[output_pin] := 0
   reti
1: io[output_pin] := 1
   reti
```

Adding the random diffusion is probably best done on the Arduino, which has a two-cycle hardware multiplier, with a linear congruential generator whose results are right-shifted to the proper scale. The LCG probably needs at least 16 bits, so you need at least four 8-bit multiplies and four 8-bit additions, an additional 12 cycles. However, this is not the end of it; the comparison complicates things somewhat, because we can no longer depend on a single test of a carry bit. Probably it's best to restrict the `error_counter` range to a subset of its possible values, requiring an actual conditional subtraction, and use an actual subtraction for the threshold test.

If you're thus limited to, say, 300kHz, then at 30kHz you'll be using 10% of the microcontroller's compute cycles for the audio PDM.

(Hmm, I should probably try this out with Python programs generating WAV files before I worry too much more about its efficiency...)

Prolog table outlining

Kragen Javier Sitaker, 2019-07-05 (11 minutes)

I've been thinking again about Darius Bacon's Sniki and the space of CRUD webapp development, which people still seem to be mostly doing using Django, Rails, and similar 2005-vintage designs, despite the popularity of schemaless and schema-lite database systems like MongoDB and Redis.

"Sniki"?

A few years back, Darius Bacon wrote an interesting "Semantic Network Wiki" supporting RDF-like triples, called Sniki. It explained:

> This is basically like a wiki only with typed links. Any page can serve as a link type. Each page lists all the links it's involved in, as source, type, or target. You edit the links in a separate text area.

It was really a free-form database. On any page, you could include a set of property-value pairs, using square brackets to enclose multi-word items:

```
written 2019-03-11
updated 2019-07-05
concerns politics
supersedes [Taxation without representation]
```

Each of these property-value pairs becomes a triple describing the page; for example, if that page were called "Declaration of Independence", we would have triples such as ([Declaration of Independence] concerns politics) and ([Declaration of Independence] supersedes [Taxation without representation]) in the semantic network.

Such a database is only interesting insofar as you can query it, and Sniki had a very easy and powerful way to query:

> [Y]ou can produce tables from database-style queries like this:
> [tabulate recipes recipe ID, ID title Title, ID description Description, ID date Date]
> … In general a query looks like [tabulate clause1, clause2, ...] where each clause is a triple denoting a typed link, with variables capitalized. The table then shows one row for each way of filling in all the variables.

So the query is Prolog-like, and the results of matching the query against the database of triples is displayed as a table. The "recipes" page I wrote on it when Darius had it running read:

> These came from an introduction to Ruby on Rails. I wondered how easy we could make the same sort of thing without 'programming' or a relational database. That example app also had forms for update and templates for the different pages, though.
> [tabulate recipes recipe ID,
> ID title Title,
> ID description Description,
> ID date Date]
> Here's just desserts:
> [tabulate recipes recipe ID,
> ID title Dessert,
> ID is-dessert true]
> Just recipes Beatrice likes:
> [tabulate recipes recipe ID,
> ID title Title,

ID description Description,
ID date Date,
ID beatrice-likes yes]

This rendered as three tables: one with ID, Title, Description, and Date columns, another with ID and Dessert columns, and a third with the same columns as the first but fewer rows.

This page had the following property-value pairs:

```
recipe recipe1
recipe recipe2
recipe new-recipe-for-rohit
```

The page new-recipe-for-rohit had the following property-value pairs:

```
title [hot cocoa]
description [Everyone's favorite]
date [20 April 2005]
is-dessert true
[see also] sniki
beatrice-likes yes
author [Kragen]
```

Being linked from the "recipes" page with a "recipe" property marked it as being a recipe, although an [is recipe] property like the is-dessert property would have worked too. Because it's a dessert and Beatrice likes it, it shows up in all three tables.

Another page explained:

Experiments with Oval from 1994 partly inspired this. It's a hypertext system built around Objects, Views, Agents, and Links, to make it possible for ordinary people to create collaborative apps without 'real' programming. The current to-do list comes partly out of this paper.

Sadly I still haven't read the Oval paper.

Providing an editable spreadsheet view of a query result

A feature of Sniki that was at times annoying was the fact that every variable in the query was visible in the table; the above queries, for example, include an ID column that says meaningless things like "recipe2". However, by the same token, if you added an "add row" button, it would be straightforward to insert the necessary triples into the database, or "assert" them, in Prolog terminology.

This is fairly asymmetric with deletion, since the absence of any one of the triples necessary for a table row would result in deleting the table row; in my recipe example above, deleting either the title, the description, or the date property — as well as the recipe link — would remove the row from the table. In cases like these, you'd probably want deletion to delete the entity and all the links to and from it, as well as perhaps the links that use it as a link type.

This suggests that in some cases you'd want to use a nested query, like a Prolog `findall`, for entities you want to appear in the table even if they lack a certain property — which probably suggests you'd like them to occur only once even if they have more than one value for

the property. Perhaps you could use nested [] for this if you want a lightweight textual syntax:

```
[Invoice for Customer, Invoice date Date, Customer name Name,
    [Invoice line-item Item,
    Item qty Quantity,
    Item price Price,
    Item sku SKU,
    SKU description Description],
    [Invoice payment Payment, Payment amount Amount, Payment date Date],
]
```

These nested queries would appear as nested tables in the table view, optionally with the ability to add, copy, update, and delete rows, or collapse the nested table.

An alternative, nesting-free way to handle nested queries is with a sort of outline view using something very vaguely like Prolog's ! cut operator:

```
[Invoice for Customer, Invoice date Date, Customer name Name
| Invoice line-item Item,
  Item qty Quantity,
  Item price Price,
  Item sku SKU,
  SKU description Description]
```

The idea here is that, interactively, you can navigate around a three-column table with Invoice, Customer, Date, and Name columns, and whatever row you have highlighted in that table, a detail table appears to the right with the Item, Quantity, Price, SKU, and Description columns for all the line items for that invoice. It's like Prolog's "cut" in the limited sense that once you succeed in getting to the right of it (in this case, because the user has selected the row) and exhaust the possibilities there, you don't cross to the right of it again. Unlike Prolog's cut, though, you do keep examining possibilities to the left of it in order to fill up the rest of the table there.

Here's a crude mockup with example data mostly from exampledb.py:

Invoice	Customer	Date	Name
i8032	c8021	2018-02-01	Edward Brooks, Morris Petroleum Enterprises
i8033	c8021	2018-06-07	Edward Brooks, Morris Petroleum Enterprises
i8034	c79474	2018-04-01	Anthony Hill, LHHB Engineering
i8035	c15376	2018-08-08	Janet Parker, Gray–Wright LLC

+

Item	Quantity	Price	SKU	Description
li181312	5	$300.50	sku901	Gray daily glass toaster oven ×
li181313	1	$21.00	sku353	Gray polyester ultrasonic sweater ×
li181314	1		sku759	Gold spandex surgical dress, size L ×
li181315	2	$20.00	sku751	Black spandex electronic boxers, size M

×
+

Ideally you could tag the generated ID columns so they don't display by default and so that an "add" command generates them automatically from some kind of id-generating function, even if Joe Celko *does* think this is a bad way to make a database:

Date Name
2018-02-01 Edward Brooks, Morris Petroleum Enterprises
2018-06-07 Edward Brooks, Morris Petroleum Enterprises
2018-04-01 Anthony Hill, LHHB Engineering
2018-08-08 Janet Parker, Gray–Wright LLC
+
Quantity Price Description
5 $300.50 Gray daily glass toaster oven ×
1 $21.00 Gray polyester ultrasonic sweater ×
1 Gold spandex surgical dress, size L ×
2 $20.00 Black spandex electronic boxers, size M ×
+

Field editing

I've said that record *creation* is straightforward with such a system, but *update* is surprisingly rather complicated. In a database viewer that displays a single SQL table as a table, it's straightforward to know which record to update: you update the database record that corresponds to the table row on the screen. Here, editing fields is a bit trickier.

In the above example query, the Description field in the line-item table came from the SKU entity, that is, the description of the product. In a case like this, it might not be ideal to automatically propagate edits to the SKU (and thus to all the other invoices and perhaps the web page for the product as well); conceivably you'd want the field to display read-only or to be a link to a detail page for the SKU entity itself, so that you could see the scope of the change you were making.

How about the SKU field itself, which links the line-item entity with the SKU entity? Suppose you choose to display the field and then edit it, changing "sku759" to "sku751". There are at least two reasonable candidate results of such an action:

- You could update both the triple (li181314 sku sku759) and the triple (sku759 description [Gold spandex surgical dress, size L]) to use "sku751" instead of "sku759". This would probably need to propagate to all the other occurrences of "sku759" in the system, as well. And, in this case, this would amount to merging two SKUs, since "sku751" already exists (it's the black spandex electronic boxers, size M), which is perhaps a situation the user should be warned about.

- You could update just the triple (li181314 sku sku759), where we originally got "sku759", to point to some other SKU that has a description; this will change the value displayed in the column to the right. Displaying this description during the selection process is probably necessary, too.

Recursion

If you name queries, you could very reasonably refer to a query within itself:

```
explore(Dir) :- Dir contains-file File, File file-size Size | explore(File).
```

With the columnar presentation described above, this is a Miller-columns filesystem explorer like the one in MacOS X, while with a collapsible tree view, it would be a tree-style filesystem explorer.

Self replication changes

Kragen Javier Sitaker, 2017-01-16 (5 minutes)

Efficient programmable self-replicating machinery does not need nanotechnology, and it will change economics and human life in many ways that are currently inconceivable.

The first and most obvious change is that it will change the nature of factors of production in a major way. If we analyze factors of production into land, labor, capital goods, information, and energy, it will provide abundant capital goods for any conceivable production process. This will increase the value of land, labor, information, and energy, but of these, information and energy are likely to be abundant.

Because capital goods will be abundant, we will stop counting them as a significant part of our assets. A brewery does not measure its wealth by how much yeast it has on hand, or a farmer measure his wealth by the amount of seed corn he has available to plant. Similarly, we will no longer consider machinery to be a form of wealth — perhaps architecture, either. We will instantiate them when we want them, then recycle them when we no longer do.

For the last three million years or so, accumulating capital goods — whether hand axes, bottle gourds, or Ferraris — has been a defining aspect of human culture. It is part of what it has meant to be human. And now that is going away.

Recycling capacity is becoming a new factor of production. So far our conversion of material into moop has been modest, despite occasional incidents like the New York garbage barges and the EU's e-waste directives. So far, our garbage production — ultimately the same as our production of goods — has been limited to a few tons per year per person. You could dry it out and store it in your basement if you had to. This will no longer be the case; we will have to recycle our moop into something else, something like Earthships or fresh metals.

Our concepts of quality will change. Historically, high-quality capital goods were those that were durable, pleasant to use, easy and inexpensive to repair, broadly applicable rather than overly specific, and augmented our economic productivity by a large factor. Once self-replicating machinery is in play, durability becomes a secondary concern that we can easily trade off against other kinds of merit. Traditionally, a bicycle chain breaker that breaks on the fourth use would be considered crap, but if you have it fabricated on the spot when you need to change the length of a bicycle chain and recycle it when you're done, you don't need much durability, and you don't need it to fit different kinds of chains. Instead you will care about how quickly it can be fabricated and how much energy it costs to fabricate and recycle it; perhaps you will also prefer it to last dozens of uses if you are in a bicycle shop, but you will be willing to trade that off against ease of fabrication.

Many repairs will likely be replaced by recycling, as they are in biological systems like our bones, or often in computer filesystems.

Two particular figures of merit are the exponential growth rate of the machines and the amount of life-cycle cost per machine (or unit

of productivity) measured in factors of production other than capital goods. The exponential growth rate is determined by the replication time — the time for one machine to construct another, replicating itself — and by the durability of the machines. If a machine's MTBF is lower than its self-replication time, the exponential growth rate will be negative; if the MTBF is equal, the growth rate will be zero. But once the MTBF is a few times greater than the self-replication time, further improvements in reliability and durability will have little effect on the population growth rate.

I think a good and plausible target is a 24-hour self-replication time and an 8-replication MTBF.

Once self-replicating machines are capable of producing solar cells with a reasonable EROEI, energy will also cease to be a significant limitation on their growth, leaving only labor, land, and knowledge.

Many jobs that can be done by self-replicating machines can be done at very small scales, perhaps even submicron scales, even if they do not amount to molecular nanotechnology in themselves. This reduces the material resources needed for replication proportionally. For things that can be reduced in this way, land for resource extraction will be a minimal, even negligible, cost; only labor and knowledge will add significant costs.

We should strive to ensure that everyone has access to knowledge and self-replicating machines, so that they will not be reliant on owners of capital goods for jobs, as they have been since the Industrial Revolution.

Quintic upsampling of time-series with 1½ multiplies per sample

Kragen Javier Sitaker, 2018-10-28 (2 minutes)

If f is a cubic $k_0x^3 + k_1x^2 + k_2x + k_3$, then $f(0) = k_3$ is a linear function of f(-3), f(-1), f(1), and f(3). Furthermore, the coefficients for f(-3) and f(3) are equal, as are the coefficients for f(-1) and f(1). This means that we can cubic-spline interpolate the samples at the midpoints of existing sample intervals using only two multiplications per sample, plus some additions and subtractions.

More specifically, $f(1) = k_0 + k_1 + k_2 + k_3$, and $f(3) = 27k_0 + 9k_1 + 3k_2 + k_3$, and f(-1) and f(-3) are the same but with alternating signs. This gives us this matrix equation:

```
[-27 9 -3 1]       [f(-3)]
[ -1 1 -1 1] k⃗ = [f(-1)]
[  1 1  1 1]       [ f(1)]
[ 27 9  3 1]       [ f(3)]
```

Inverting that matrix with `sympy.Matrix(...).inv()` gives us:

```
[-1/48  1/16 -1/16  1/48]
[ 1/16 -1/16 -1/16  1/16]
[ 1/48 -9/16  9/16 -1/48]
[-1/16  9/16  9/16 -1/16]
```

Of that, the last row is the one we want, which gives us $k_3 = f(0) = (-f(-3) + 9f(-1) + 9f(1) - f(3))/16$.

This means that in fact you don't need much in the way of multiplication: you only ever need to multiply samples by 9 when you're interpolating between them, which amounts to adding x_i<<3 to x_i. And if you're doing multiple iterations of interpolation, you only need to do the multiplication by 9 for the new samples on each iteration; you don't need it for the ones you already multiplied by 9 in the previous pass.

Doing the same exercise for quintics, we get:

```
[-3125 625 -125 25 -5 1]
[ -243  81  -27  9 -3 1]
[   -1   1   -1  1 -1 1]
[    1   1    1  1  1 1]
[  243  81   27  9  3 1]
[ 3125 625  125 25  5 1]

[-1/3840   1/768  -1/384   1/384  -1/768 1/3840]
[  1/768  -1/256   1/384   1/384  -1/256  1/768]
[  1/384 -13/384  17/192 -17/192  13/384 -1/384]
[ -5/384  13/128 -17/192 -17/192  13/128 -5/384]
[-3/1280  25/768 -75/128  75/128 -25/768 3/1280]
[  3/256 -25/256  75/128  75/128 -25/256  3/256]
```

So we get [3 -25 75 75 -25 3]/256, which requires 3 multiplications

per input sample for a single pass, or 1½ in the limit for many passes.

In two dimensions the situation is hairier.

Lithium battery welder

Kragen Javier Sitaker, 2018-06-21 (updated 2019-01-22) (2 minutes)

810 amps at 3.7 volts is 3000 watts, which is 150 amps at 20 volts, plenty for arc-welding; different 18650 lithium-ion (Li-ion) cells are rated at 10–35 amps, with most being 20 or 30 amps in theory; being cautious and only expecting 5–10 amps out of each cell, you'd need 80–160 cells, quite a reasonable quantity really. I mean a 9×9 array of cells would be 81 cells.

Charge and discharge rates are rated in "C"; 1C is a current that would yield the battery's rated capacity over one hour. 2C and 3C are typical charge rates, but discharge rates range from 2C to 15C, depending on application. Typical capacities range from 1000 to 3000 milliamp hours.

Dimensions are 18.5 mm diameter, 65 mm length, 47 g, so an 11×11 array of 2000 mAh 15C 3.7V cells would weigh 5687 g and deliver 3.6 kA. So uh I guess you could probably go with a quarter of that: a 6×6 array of 2000 mAh 15C 3.7V cells, or using a hexagonal array[0], 37 cells in a 7-across-the-corners hexagon (130 mm). This weighs 1700 g and can deliver 1100 amps at 3.7 volts, 4100 watts. An appropriate output circuit could convert this to 70 amps at striking voltage of 60 volts, then 200 amps at arc-sustaining voltage of 20 volts.

[0] N.concatenate(([1,], 6 * N.arange(1, 10))).cumsum() # [1, 7, 19, 37, 61, 91, 127, 169, 217, 271]

These cells cost about US$10 each, so the whole battery pack would cost about US$370.

Topics

bytecode interpreters for tiny computers

Kragen Javier Sitaker, 2007-09 (61 minutes)

Introduction: Density Is King (With a Tiny VM)

I've previously come to the conclusion that there's little reason for using bytecode in the modern world, except in order to get more compact code, for which it can be very effective. So, what kind of a bytecode engine will give you more compact code?

Suppose I want a bytecode interpreter for a very small programming environment, specifically to minimize the memory needed for a program; say, on a 32-bit microcontroller with 40KiB of program flash, where the program flash size is very often the limiting factor on what the machine can do.

My dumb fib microbenchmark looks like this in Smalltalk:

```
fib: n
        n < 2 ifTrue: [^1]
              ifFalse: [^(self fib: n - 1) + (self fib: n - 2)]
```

And in Squeak bytecode:

```
9 <10> pushTemp: 0
10 <77> pushConstant: 2
11 <B2> send: <
12 <99> jumpFalse: 15
13 <76> pushConstant: 1
14 <7C> returnTop
15 <70> self
16 <10> pushTemp: 0
17 <76> pushConstant: 1
18 <B1> send: -
19 <E0> send: fib:
20 <70> self
21 <10> pushTemp: 0
22 <77> pushConstant: 2
23 <B1> send: -
24 <E0> send: fib:
25 <B0> send: +
26 <7C> returnTop
```

Or, as I translated to pseudo-FORTH, "n 2 < if 1 return then self n 1 - recurse self n 2 - recurse + return".

The metric of goodness for a CPU instruction set is a little different from that for a bytecode interpreter. Bytecode interpreters don't have to worry about clock rate (and therefore combinational logic path length) or, so far, parallelism; they can use arbitrary amounts of storage on their own behalf; they're easier to modify; their fundamental operations can take advantage of more indirection.

Here are some examples of things a bytecode interpreter can do that a hardware CPU might have more trouble with:

• you can have a very large register set (which is more or less what Squeak's VM does, treating local variables as registers) without incurring slow procedure call and return; MMIX suggests how this could be done in hardware as well.
• you could imagine that every procedure could have its own register set (as, perhaps, on the SPARC), and a few of the instructions could access the contents of these registers; again, Squeak's VM does this
• you could have an instruction to create a new preemptively-scheduled thread, perhaps switching between threads every instruction, as in Core Wars or the Tera MTA;
• if the language is object-oriented, you could have a few instructions for calling certain distinguished methods of self, or the first argument, as in the Squeak VM;
• or, as a more general form of the same thing, entering some context might reprogram certain instructions to do some arbitrary thing;
• you can do all kinds of tag tests and dynamic dispatch on fundamental CPU operations, as in the Squeak VM, the LispMs, or Python's bytecode;
• you can support associative array lookups, appending to unbounded-size arrays, and the like, as fundamental machine operations.

Indirect Threaded 16-bit FORTH: Not Great For Density

I don't have a FORTH handy, but I think the definition looks something like this in FORTH:

```
: FIB DUP 2 <  IF DROP 1
  ELSE DUP 1- RECURSE  SWAP 2 - RECURSE + THEN ;
```

which I think, in an indirect-threaded FORTH, compiles to a dictionary entry containing something like this:

```
DUP (2) < (IF) #3 DROP (1) (ELSE) #8 DUP 1- FIB SWAP (2) - FIB + ;
```

That's 18 threading slots, so 36 bytes, plus the overhead of the dictionary structure, which I think is typically 2 bytes for a dictionary that has forgotten the word names. Better than PowerPC assembly (at 96 bytes) but not great, noticeably worse than Squeak.

Naive Lisp: Terrible for Density

What if we interpret fib with a simple Lisp interpreter that walks tree structures? We could define it as follows:

```
(labels fib (n) (if (< 2 n) 1 (+ (fib (- n 1)) (fib (- n 2)))))
```

That's 17 non-parenthesis tokens and 9 right parentheses, for a total of 28 leaf-nodes on the cons tree. That means the tree contains 27 conses, for 54 memory-address-containing cells in interior nodes, probably a minimum of 108 bytes. I conclude that while this program-representation approach is very simple, it takes up a lot of

space. I don't think cdr-coding would help enough, since none of the lists are very long; if you had 9 lists containing 25 pointers and 9 one-byte lengths or one-byte terminators, you still have 59 bytes.

Lua's VM: Four-Byte Register-Based Instructions

According to "The Implementation of Lua 5.0", Lua's virtual machine has been register-based since 2003. They claim that their four-byte register instructions aren't really much more voluminous than stack-based instructions, perhaps in part because they're comparing to stack-based instructions for a single-stack machine that has local variable storage in addition to its stack.

Lua's register-based virtual machine is fairly small: "[O]n Linux its stand-alone interpreter, complete with all standard libraries, takes less than 150 Kbytes; the core is less than 100 Kbytes." They've previously said that the compiler is about 30% of the size of the core, which suggests that the rest of the core, including the bytecode interpreter, is about 70KB.

They mention that it has 35 instructions, which would almost fit in 5 bits of opcode: MOVE, LOADK, LOADBOOL (converts to boolean and conditionally skips an instruction), LOADNIL (clears a bunch of registers), GETUPVAL, GETGLOBAL, GETTABLE, GETGLOBAL, SETUPVAL, SETTABLE, NEWTABLE, SELF, ADD, SUB, MUL, DIV, POW, UNM (unary minus), NOT, CONCAT (string concatenation of a bunch of registers), JMP, EQ, LT, LE, TEST, CALL, TAILCALL, RETURN, FORLOOP, TFORLOOP, TFORPREP, SETLIST, SETLISTO, CLOSE, and CLOSURE.

CALL passes a range of registers to a function and stores its result in a range of registers; this implies that the virtual machine handles saving and restoring of the stack frame. The paper uses the term "register window" to compare it to what the SPARC does.

The comparison instructions skip the next instruction on success.

Here's their example code to show how much better the register machine is:

```
local a, t, i   LOADNIL 0 2 0
a = a + i       ADD     0 0 2
a = a + 1       ADD     0 0 250
a = t[i]        GETTABLE 0 1 2
```

The old stack machine compiled this as follows:

```
PUSHNIL 3
GETLOCAL 0
GETLOCAL 2
ADD
SETLOCAL 0
GETLOCAL 0
ADDI 1
SETLOCAL 0
GETINDEXED 2
SETLOCAL 0
```

It seems that you should be able to compile this on a two-stack machine as NIL NIL DUP >R + 1+ R> NIL GETTABLE, which is 9 instructions instead of 11, and also clearly stupid, since nil is neither a table nor a number. If you could really fit that into 6 bytes, it might be an improvement over the 12 bytes of their current scheme or the 11 bytes of their previous one. It might be better to try more realistic code fragments.

The paper also discusses an interesting implementation of closures, in which captured variables migrate into heap-allocated structures upon function return.

The MuP21 and F21 instruction sets

The MuP21 was implemented in 6000 transistors, including an NTSC signal generator and a controller for external DRAM, so it ought to be possible to emulate its behavior with a fairly small amount of software. Here's the instruction set:

Transfer Instructions: JUMP, CALL, RET, JZ, JCZ Memory Instructions: LOAD, STORE, LOADP, STOREP, LIT ALU Instructions: COM, XOR, AND, ADD, SHL, SHR, ADDNZ Register Instructions: LOADA, STOREA, DUP, DROP, OVER, NOP

COM is complement. The CPU has an A register, accessed with LOADA and STOREA, that supplies the address for LOAD and STORE; I think LOADP and STOREP increment it as well. I think JCZ jumps if the carry bit is zero. (Each register on the stack has its own carry bit; the "21" refers to the 20-bit memory word size, plus the extra bit.)

The F21 had 27 instructions to the MuP21's 24. (Only 23 are listed above, hmm.) They were renamed:

Code	Name	Description	Forth (with a variable named A)
00	else	unconditional jump	ELSE
01	T0	jump if T0-19 is false w/ no drop	DUP IF
02	call	push PC+1 to R, jump	:
03	C0	jump if T20 is false	CARRY? IF
06	RET	pop PC from R (subroutine return)	;
08	@R+	fetch from address in R, increment	R R@ @ R> 1+ >R
09	@A+	fetch from address in A, increment	A A @ @ 1 A +!
0A	#	fetch from PC+1, increment PC	LIT
0B	@A	fetch from address in A	A @ @
0C	!R+	store to address in R, increment R	R@ ! R> 1+ >R
0D	!A+	store to address in A, increment A	A @ ! 1 A +!
0F	!A	store to address in A	A @ !
10	com	complement T	-1 XOR
11	2*	left shift T, 0 to T0	2*
12	2/	right shift T, T20 to T19	2/
13	+*	add S to T if T0 is true	DUP 1 AND IF OVER + THEN
14	-or	exclusive-or S to T	XOR
15	and	and S to T	AND
17	+	add S to T	+
18	pop	pop R, push to T	R>
19	A	push A to T	A @
1A	dup	push T to T	DUP
1B	over	push S to T	OVER

```
 1C push  pop T, push to R                >R
 1D A!    pop T to A                      A  !
 1E nop   delay 2ns                       NOP
 1F drop  pop T                           DROP
```

T is top-of-stack; R is top-of-return-stack; S is the element right under the top of stack. I think @R+ and !R+ are two of the three new instructions; push and pop are probably the other one, since they don't seem to be listed in the MuP21 list.

I'm not sure what +* is for, but I'm guessing it was ADDNZ.

I'm not sure where the else, T0, and C0 instructions jump to; maybe the next address on the operand stack.

Interestingly, there doesn't seem to be a straightforward way to get a "1" onto the stack without using the # instruction, which is annoying because that takes 25 bits of instructions. dup dup -or A! @A+ drop A is another approach at 30 bits, but it clobbers the A register and issues a useless memory reference. dup dup -or com 2* com is another 25-bit approach.

So here's my dumb fib benchmark expressed in F21 code, according to my limited understanding, and without trying to be very clever:

```
fib: dup #-2 + #returnone swap c0 dup #-1 + #fib call
                                swap #-2 + #fib call + ;
returnone: drop drop #1 ;
```

That loses pretty badly on literals; if we assume that # pushes its value immediately and doesn't require any NOPs (e.g. to avoid having multiple # instructions per word) then we have 22 instructions and 7 literals --- 6 words of instructions and 7 of literals, for a total of 32.5 bytes. Not the code density direction I was hoping this would take me!

But it's possible to avoid the redundant literals:

```
fib: dup #-2 dup push + #returnone swap c0 dup #-1 + #fib dup push call
                                        swap pop swap pop + swap call + ;
returnone: pop drop drop drop #1 ;
```

And actually #1 is somewhat redundant with #-2, being its bitwise complement:

```
fib: dup #-2 dup push + #returnone swap c0 dup #-1 + #fib dup push call
                                        swap pop swap pop + swap call + ;
returnone: drop drop pop com ;
```

That makes it 29 instructions but only 4 literals --- 8 words of instructions, 4 of literals, for a total of 12 20-bit words, or 30 bytes. Still worse than the Squeak version on size --- and quite hard to read! And some of the literals are still probably too close together to work on a real machine.

If we were instead using three-instruction 16-bit words with a high bit used to tag literals, we could maybe win a little more.

```
fib: #-2  dup push over  + nop nop  #returnone  swap c0
     dup  #-1  + nop nop  #fib  dup push call
     swap pop swap  pop + swap  call + ;
```

```
returnone: drop drop pop  com ;
```

That's 33 instructions, but the four literals don't count, so 29 instructions or 10 16-bit instruction words, plus four 16-bit literal words. That's 28 bytes, almost the same as the Squeak version, but still worse! And that's with me trying to get clever with the instruction reordering, too.

Now I begin to understand why Chuck Moore was getting to the point where he would repeat FOO twenty times by doing : FOO5 FOO FOO FOO FOO FOO ; FOO5 FOO5 FOO5 FOO5 instead of using a DO loop. Numbers are a real pain on the F21! (But perhaps that's as it should be; programming isn't about numbers, anyway.)

Local Variables: Registers Or Stacks?

Having two stacks removes the need for local argument vectors; you can always shift the variables left and right between the call and return stack, possibly swapping as you go, to get to the values you want. (This could be shortened if there was a "repeat next instruction four times" instruction: >R, >R >R, 4x >R R>, 4x >R, 4x >R >R, 4x >R 4x >R R> R>, 4x >R 4x >R R>, 4x >R 4x >R, and so on; and similar in the other direction.) It wasn't apparent to me which approach would use less code, or whether it would depend on the number of arguments and local variables.

I thought I'd see what the distribution is like in a body of real code, so I ran the following code in Squeak 3.8-6665. (No doubt any Smalltalk programmer could improve it.)

```
gatherMethodStats
        "How common are methods with lots of temps?"
        | totaldict tempdict argsdict update |
        tempdict := Dictionary new.  "Maybe not the best container."
        argsdict := Dictionary new.
        totaldict := Dictionary new.
        update := [:dict :key | dict at: key put: (1 +
            (dict at: key ifAbsent: [0]))].
        Smalltalk allClassesDo: [:class |
            (Array with: class with: class class) do: [:cl |
                cl selectorsAndMethodsDo: [:sel :meth |
                    update value: tempdict value: meth numTemps.
                    update value: argsdict value: meth numArgs.
                    update value: totaldict
                            value: meth numTemps + meth numArgs.
                ]
            ]
        ].
        ^ {'temps' -> tempdict. 'args' -> argsdict. 'total' -> totaldict.}
```

In a fraction of a second, this returned the following (reformatted):

```
#('temps' -> a Dictionary(
    0->18952 1->13665  2->6366   3->3697  4->2301
    5->1492   6->939    7->676    8->426   9->346
    10->196  11->193   12->139    13->99   14->60
    15->47    16->46    17->30    18->15   19->20
```

```
    20->12    21->11    22->15     23->6     24->3
    25->5      26->4     27->3     28->5     32->1
    33->2      37->1     39->1               50->1)
'args' -> a Dictionary(
    0->26114  1->15903  2->4717  3->1712  4->756
      5->309    6->138    7->64    8->37   9->13
       10->8     11->2    12->1    13->1 )
'total' -> a Dictionary(
    0->18952  1->3240   2->11976  3->3128  4->4290
     5->1760  6->1947     7->999   8->983   9->558
     10->521  11->293    12->276  13->155  14->196
     15->115   16->81     17->57   18->52   19->31
      20->43   21->24     22->20   23->11   24->17
       25->9    26->6      27->9    28->7    29->5
       30->6    33->1      35->1    36->1    38->1
       42->1    44->1      46->1    62->1 )
)
```

That's out of 49775 methods; so roughly 95% of these methods have 8 or fewer arguments and temporaries, 90% have 6 or fewer, 75% have 3 or fewer, and 69% have 2 or fewer. That suggests that in a codebase like Smalltalk, it would probably be a marginal cost to use two stacks in the bytecode instead of a local-argument vector.

But probably the methods that have a lot of local variables and arguments are longer, so inefficiency in implementing those methods might cause inefficiency out of proportion to their number. How much does that skew the results? The CompiledMethod class has initialPC and endPC methods which return the bounds of its bytecode, so I changed the code to count bytecodes rather than methods:

```
gatherMethodStats
    "How common are methods with lots of temps?"
    | totaldict tempdict argsdict update |
    tempdict := Dictionary new.
    argsdict := Dictionary new.
    totaldict := Dictionary new.  "Maybe not the best container."
    update := [:dict :key :incr |
        dict at: key put: (incr + (dict at: key ifAbsent: [0]))].
    Smalltalk allClassesDo: [:class |
      (Array with: class with: class class) do:
        [:cl | cl selectorsAndMethodsDo: [:sel :meth || methbytes |
            methbytes := meth endPC - meth initialPC + 1.
            update value: tempdict value: meth numTemps value: methbytes.
            update value: argsdict value: meth numArgs value: methbytes.
            update value: totaldict value: meth numTemps + meth numArgs
                                    value: methbytes.
        ]
      ]
    ].
    ^ {'temps' -> tempdict. 'args' -> argsdict. 'total' -> totaldict.}
```

This counted 1 334 542 bytecodes:

```
'total' -> a Dictionary(
```

```
 0->171811  1->95663  2->182923  3->117718  4->125591
 5->92320   6->92671   7->72908   8->61526   9->49807
10->46568  11->36943  12->27096  13->21759  14->27821
15->17379  16->13309  17->10390  18->9528   19->7659
20->10162  21->5969   22->5238   23->3087   24->5804
25->5229   26->2915   27->3747   28->2551   29->2217
30->3014   33->12     35->405    36->505    38->341
42->357    44->235    46->336    62->1028 )
```

50% of them are defined in a context with 4 or fewer locals and args; 60% with 6 or fewer; 70% with 7 or fewer; 80% with 10 or fewer; 90% with 14 or fewer; 95% with 27 or fewer. That's not quite as encouraging as the raw method counts, but it still suggests that the approach is viable and probably does not need the "4x" instruction I suggested earlier. (Even in a method with 14 local variables, all of which are simultaneously live, with really random access, I think the average distance from the variable you're currently at to the variable you want is only a third of 14, or 4.7.)

Adapting the MuP21 Instruction Set to a Smalltalk-Like System

Maybe I could follow the MuP21's lead and use five-bit zero-operand instructions for a two-stack abstract machine. Probably I should pack them five to a 32-bit word, or three to a 16-bit word; the left-over bits can be used for tagging immediate data in the instruction stream, as in Leong, Tsang, and Lee's MSL16 FPGA-based FORTH CPU.

The appeal of the 5-bit instructions is that, say, my sample fib program could perhaps be expressed in less than 26 bytes, or 13 16-bit words: 39 instructions or 16-bit literals. Can we do that? Clearly it depends on the instruction set. An ideal FORTHish instruction set for the sample dumb fibonacci program would make it simply

```
dup 2 return-1-if-less-than dup 1- recurse swap 2- recurse + ;
```

which is 11 instructions in length, 8 bytes, with 9 distinct instructions. Some of these instructions --- dup, swap, +, and ; --- would clearly be included in any FORTH-like CPU; others --- 1-, return-1-if-less-than, 2, 2-, and recurse --- are less likely. Here's a version with a more likely instruction set:

```
dup 1 swap 2 - negative? conditional-return pop
dup 1- literal(fib) call swap 1- 1- literal(fib) call + ;
```

call, literal, and pop are also almost certain to exist; this version uses additionally only 1, 2, -, negative?, conditional-return, and 1-. It contains 17 non-literal instructions and two literals, so it would be 16 bytes if literals were two bytes.

For this function, we don't really need 2 or - as instructions; "2 -" can be rewritten just as easily as "1- 1-". That brings the required instruction repertoire down to 9 regular instructions, plus literal.

The only dubious instruction in the remaining repertoire is negative?, and it's only dubious because the MuP21 doesn't know about negativity. I think it amounts to testing the carry bit, which is

actually probably a pretty reasonable thing to either have an operation to test or to have conditional-return test.

Following the MuP21/F21 model, maybe we could improve on Squeak's bytecode by avoiding the use of a special space and special instructions for local variables, by avoiding the need for message argument counts (and by supporting multiple return values), and probably by putting references to message selectors inline in the bytecode rather than in a separate literal table. My instance of Squeak currently only has 30474 different message selectors, so 16 bits for the selector identifier would probably accommodate many more years of evolution.

These erasures would not be at the cost of safety --- in Smalltalk, the argument signature of a method is implicit in the selector, and as long as the bytecode compiler was bug-free, whatever bogus method got called would pop the right number of arguments and push a single return value.

Probably the stack manipulation instructions (# dup over push pop nop drop) and the control-flow instructions (call else To Co ret) would stay the same, with the addition of a "send" instruction; it would probably also be good to keep the A register around in some form, as the destination for messages, which implies keeping the A and A! instructions as well, for a total of 14 fixed instructions. The "send" instruction could simply leave the object reference in A during the call, and expect it to be preserved --- an "A push" sequence before clobbering it and a "pop A!" sequence before returning is probably not too much to ask.

Smalltalk's blocks might have a little difficulty in this environment --- to access method-local variables, to answer from their containing method, and to call methods on self; none of these are difficulties in the cases where the compiler inlines the control structure, of course. It is, of course, possible to make them into full-fledged objects, as the abstract semantic models of Smalltalk and Scheme do.

As an alternative to the complete omission of a literal table, a literal table could override on a per-element basis the elements of a default literal table that defined the meanings of most of the instructions; the most common instruction meanings would be at one end of the table, while the literals would override meanings (with messages) starting from the other end. Probably messages to call and constants to push have roughly equal frequencies, in which case we could use the low bit of the instruction to distinguish them. If the stack-manipulation and control-flow instructions are non-overridable at 11 instructions, that gives us a maximum literal-table size of 18 redefinable instructions, which would default to a statically-determined set of the most common constants and messages in the system.

Literals that overflowed the literal table could still be used inline with the # instruction, possibly followed by call or send. If, as previously suggested, the # instruction were merely a high bit in a 16-bit word, the disadvantage relative to a literal-table entry would be fairly small --- more a 15-bit size limitation than anything else. If we trust our byte-compiler (or some Java-like type-inferencing stack-effect verifier), we can probably do type erasure and avoid the overhead of tag bits here, at least for message selectors.

Larger constants can be constructed fairly easily with a sequence of multiple literal words and some combining operation such as (\x y ->

x * 8192 + y).

I said the control-flow operators should stay the same, but probably the To and Co conditional branches aren't quite the right thing for Smalltalk; maybe ifFalse and ifNotNil instead.

Speculative Case Study: An F21-like Squeak

It might be worthwhile to profile the selector and constant usage of, say, Squeak, to see what the 18 default literals would be, how many literals are used more than once in a method (and therefore might benefit from being put into a literal table). From that perhaps I could estimate the literal table size of each method in the new regime, and then I could hand-translate a few methods to see if they were smaller.

For now I am going to look at a sort of worst-case: suppose we only had dup, over, push, pop, nop, drop, and literals for stack manipulation; send, jump/else, ifTrue, ifNotNil, ifFalse, and ret for control flow; A and A! for changing the destination of messages; and everything else were done by message sends getting their messages from inline literals (rather than a literal table), with the literals distinguished from instructions by a high bit in a 16-bit word. From results with this worst-case, we can estimate how much better some piece of code would be if all its selectors and constants had bytecodes assigned to them.

That gives us 14 opcodes, so we can stuff them four to a 16-bit word normally, let the high bit be 0 for literals, and make sure that "nop" has its high bit be zero so we can insert it in the instruction stream where necessary.

Furthermore, let's assume that we have to handle all blocks, other than those for ifTrue, ifNotNil, and simple loops, by lambda-lifting. Lambda-lifting means that we turn each block into, effectively, an object class; when we instantiate that class, we send it the variables over which the block is closed, and it stores them in instance variables.

If the block modifies the variables, we will have to extract their current values from the block thenceforth, since without further control-flow analysis there's no way to tell when the block might be invoked by some apparently unrelated message send.

Here's a method chosen at pseudorandom, CompiledMethod>>copyWithTrailerBytes: bytes.

```
| copy end start |
start := self initialPC.
end := self endPC.
copy := CompiledMethod newMethod: end - start + 1 + bytes size
            header: self header.
1 to: self numLiterals do: [:i |
    copy literalAt: i put: (self literalAt: i)].
start to: end do: [:i | copy at: i put: (self at: i)].
1 to: bytes size do: [:i | copy at: end + i put: (bytes at: i)].
^ copy
```

In Squeak's bytecode, with suggested bytecode translations

interspersed, and a display of the two stacks separated by a : after a .

```
    37 <70> self
    38 <D0> send: initialPC

#initialPC send  \ bytes start : retaddr

    39 <6B> popIntoTemp: 3
    40 <70> self
    41 <D1> send: endPC

#endPC send  \ bytes start end : retaddr

    42 <6A> popIntoTemp: 2
    43 <43> pushLit: CompiledMethod

#CompiledMethod push  \ bytes start end : CompiledMethod retaddr

    44 <12> pushTemp: 2
    45 <13> pushTemp: 3
    46 <B1> send: -

A push  \ bytes start end : self CompiledMethod retaddr
A! \ bytes start : self CompiledMethod retaddr
dup push \ bytes start : start self CompiledMethod retaddr
#- send  \ bytes end-start : start self CompiledMethod retaddr

    47 <76> pushConstant: 1
    48 <B0> send: +

A push \ bytes end-start : end start self CompiledMethod retaddr
A! #1 #+ send \ bytes end-start+1 : end start self CompiledMethod retaddr

    49 <10> pushTemp: 0

    56 <70> self
    57 <D5> send: numLiterals

pop A! #numLiterals send  \ A=self; end start bytes copy numlits : retaddr
```

So far, we're at 46 pseudo-FORTH operations and 11 literals (10 distinct), or about 46 bytes of this "worst-case" code, nearly half of which is literals. That compares poorly to Squeak's 21 bytes up to this point; even if all the literals in our pseudo-FORTH were instructions, Squeak's bytecodes would still be slightly smaller up to this point! (Not counting the Squeak method's 32-byte literal table, most of which is for the part of the method we haven't gotten to yet.)

Squeak doesn't seem to be getting a big space advantage from its literals table, since none of the literals have been repeated yet (except for #+, which would probably be an opcode in either case).

If I could evaluate subexpressions of a method call in an arbitrary order, the above might be smaller (I could avoid "push push push push push"), but I wouldn't count on it.

This method is at the median of about four parameters and named temporaries, but it also has to deal with unnamed temporaries.

Now we're about to start a loop, from 1 to numlits. The last method send in the loop is to "copy", so we're going to arrange to have it in the A register when we enter the loop as well.

```
    58 <6D> popIntoTemp: 5
    59 <76> pushConstant: 1
    60 <6C> popIntoTemp: 4

\ A=self; end start bytes copy numlits : retaddr

push #1  \ A=self; end start bytes copy : 1 numlits retaddr
A push A! \ A=copy; end start bytes : self 1 numlits retaddr
pop \ A=copy; end start bytes self : 1 numlits retaddr

    61 <14> pushTemp: 4 ; loop starts here

\ A=copy; end start bytes self : i numlits retaddr

    62 <15> pushTemp: 5
    63 <B4> send: <=

A pop dup A! \ A=i; end start bytes self copy i : numlits retaddr
pop dup #<= send \ A=i; end start bytes self copy i numlits stillgoing : retaddr

    64 <AC 0D> jumpFalse: 79

#79 ifTrue  \ A=i; end start bytes self copy i numlits : retaddr

    66 <11> pushTemp: 1
    67 <14> pushTemp: 4
    68 <70> self
```

```
    69 <14> pushTemp: 4
    70 <E7> send: literalAt:

push push push A! \ A=self; end start bytes : copy i numlits retaddr
pop pop dup \ A=self; end start bytes copy i i : numlits retaddr
#literalAt: send \ A=self; end start bytes copy i selfati : numlits retaddr

    71 <F6> send: literalAt:put:

A push push push A! \ A=copy; end start bytes : i selfati self numlits retaddr
pop dup pop #literalAt:put: send \ A = copy; end start bytes i trash : self nu..

    72 <87> pop

drop

    73 <14> pushTemp: 4
    74 <76> pushConstant: 1
    75 <B0> send: +
    76 <6C> popIntoTemp: 4

#1 #+ send  \ A=copy; end start bytes i+1 : self numlits retaddr
```

Now we have to get the stack back to the state for starting the loop, which turns out to be more work than I'd like:

```
A push A!  \ A=i+1; end start bytes copy : self numlits retaddr
pop A  \ end start bytes copy self i+1 : numlits retaddr
push push A! \ A=copy; end start bytes : self i+1 numlits retaddr
pop  \ A=copy; end start bytes self : i+1 numlits retaddr

    77 <A3 EE> jumpTo: 61

#61 else
```

So here we are at the end of the first loop. 44 more ordinary instructions (22 bytes), plus 8 literals. Squeak, by contrast, did the whole loop in just 21 bytes. Again, even if all the literals went away, Squeak's bytecode design would still be tighter.

It might be possible to do a better job of arranging things on the stack so that the computation feels less like programming a Turing machine --- run over here to fetch that, run back there to put it down --- and it seems like there's probably an initial state for the loop that doesn't require 9 instructions to re-establish it at the end.

Still, if there were any code where we'd expect the two-stack machine to shine, it would be stuff like this --- where we only have three variables (and a loop limit) accessed inside the loop.

I also made a bunch of mistakes, but I don't think they undermine my basic conclusion: the two-stack machine design is not density-competitive with a design with a local-variable vector.

Here's the rest of the Squeak bytecode, which I haven't bothered to translate:

```
79 <13> pushTemp: 3
80 <6C> popIntoTemp: 4
```

```
81 <14> pushTemp: 4
82 <12> pushTemp: 2
83 <B4> send: <=
84 <AC 0D> jumpFalse: 99
86 <11> pushTemp: 1
87 <14> pushTemp: 4
88 <70> self
89 <14> pushTemp: 4
90 <C0> send: at:
91 <C1> send: at:put:
92 <87> pop
93 <14> pushTemp: 4
94 <76> pushConstant: 1
95 <B0> send: +
96 <6C> popIntoTemp: 4
97 <A3 EE> jumpTo: 81
99 <10> pushTemp: 0
100 <C2> send: size
101 <6D> popIntoTemp: 5
102 <76> pushConstant: 1
103 <6C> popIntoTemp: 4
104 <14> pushTemp: 4
105 <15> pushTemp: 5
106 <B4> send: <=
107 <AC 0F> jumpFalse: 124

113 <10> pushTemp: 0
114 <14> pushTemp: 4
115 <C0> send: at:
116 <C1> send: at:put:
117 <87> pop
118 <14> pushTemp: 4
119 <76> pushConstant: 1
120 <B0> send: +
121 <6C> popIntoTemp: 4
122 <A3 EC> jumpTo: 104
124 <11> pushTemp: 1
125 <7C> returnTop
```

You could make the argument that the abstract machine Smalltalk presents to the user is more like a register machine than a stack machine, and that this may account for the code being awkward when you translate it to a stack machine. If I were programming this originally in a Forth dialect, I probably would structure the code a little differently, but I doubt it would make that much of an improvement in the code size, unless we used some kind of auxiliary non-stack storage for local variables --- at which point we're pretty much back to Squeak bytecode.

Steve Wozniak's SWEET 16 Dream Machine

Steve Wozniak's SWEET16 16-bit virtual machine, included as part of Integer BASIC, supposedly doubled the code density of the 6502. The virtual machine itself was 300 bytes of 6502 assembly, implementing these instructions; here "#" means "[0-F]".

```
0x1# SET: load immediate                0x2# LD: copy register to accumulator
0x3# ST: copy accumulator to register   0x4# LD: load byte indirect w/ increment
0x5# ST: store byte indirect w/incr     0x6# LDD: load two bytes ind w/incr
0x7# STD: store two bytes ind w/incr    0x8# POP: load byte indirect w/predecr
0x9# STP: store byte ind w/predecr      0xA# ADD: add register to accum
0xB# SUB: subtract register from acc    0xC# POPD: load 2 bytes ind w/predecr
0xD# CPR: compare register w/acc        0xE# INR: increment register
0xF# DCR: decrement register            0x00 RTN to 6502 mode
0x01 BR unconditional branch            0x02 BNC branch if no carry
0x03 BC branch if carry                 0x04 BP branch if positive
0x05 BM branch if minus                 0x06 BZ branch if zero
0x07 BNZ branch if nonzero              0x08 BM1 branch if -1
0x09 BNM1 branch if not -1              0x0A BK break (software interrupt)
0x0B RS return from sub (R12 is SP)     0x0C BS branch to sub (R12 is SP)
```

0x01–0x09 and 0x0C have a second byte which is a signed 8-bit displacement. If you want a 16-bit jump, you can push it on the stack and RS.

That's it, 28 instructions, 300 bytes of machine code to implement them. And I thought the 6502 was already reasonable on code density, so this was apparently quite a win.

It's pretty terrible compared to Squeak's bytecode, though. I think our fib microbenchmark should do fine, since it's all arithmetic and local jumps. Let's assume a calling convention that puts the first argument in R0 and returns the return value in R0. (I don't care where other arguments go; they can go hang, because this function only has one.) Here's my first attempt, which may be buggy:

```
FIB   DCR R0    ; subtract 2 by decrementing twice
      DCR R0
      BM BASE   ; if it was <2, go to the base case
      INR R0    ; re-increment, so R0=n-1
      STD @R12  ; save a copy of n-1 on the stack
      BS FIB    ; recurse; now R0=fib(n-1)
      ST R4     ; save fib(n-1) so we can retrieve n-1
      POPD @R12 ; now we have n-1 in R0
      ST R3     ; stick n-1 in R3 so we can use R0 to save fib(n-1) on stack
      LD R4     ; now R0=fib(n-1) again
      STD @R12  ; and we push fib(n-1) on the stack
      LD R3     ; now R0=n-1
      DCR R0    ; now R0=n-2
      BS FIB    ; now R0=fib(n-2)
      ST R3     ; we have to get it out of the way so we can pop fib(n-1)
      POPD @R12 ; great, R0=fib(n-1) and R3=fib(n-2)
      ADD R3    ; now R0 = fib(n)
      RS        ; return
BASE  SUB R0    ; base case: R0=R0-R0=0
      INR R0    ; increment
      RS        ; return
```

That's 21 instructions, three of which have parameter bytes, so 24 bytes. It may be possible to cut this by a couple of bytes, but not more, so it's not really a win over Squeak's system. But it's not a huge loss. (As I said, the code may be buggy, but it's probably good enough for size estimation.)

Suppose we were trying to translate CompiledMethod>>copyWithTrailerBytes: bytes from earlier. You could imagine starting like this, with self in R1 and bytes in R2, and a calling convention that requires us to preserve all registers, including arguments (but, naturally, lets us use the stack), except for R0.

```
CWTB  LD R3          ; We don't have to save anything to preserve it
      STD @R12       ; from the call, because of the calling
                     ; convention, but we do need a place to keep the
                     ; return value.
      BS *+1         ; These four instructions, 7 bytes, are a far call.
      SET INITIALPC
      STD @R12
      RS
      ST R3          ; store return value in R3 (start)

      LD R4          ; now clear out R4 to receive "end"
      STD @R12
      BS *+1
      SET ENDPC
      STD @R12
      RS
      ...
      POPD @R12
      ST R4
      POPD @R12
      ST R3
      RS
```

We're only two lines of code into the method, and we're already at 24 bytes, where the Smalltalk had used six bytecodes and two literals for a total of 14 bytes; and that's glossing over the issue of polymorphic sends for now, assuming that you could compile each "virtual function" into a real function that you could far-call. "end - start + 1 + bytes size", if we write it monomorphically for 16-bit integers, looks something like this:

```
  LD R7       ; clearing out another reg
  STD @R12
  LD R4       ; end
  SUB R3      ; - start
  INR R0      ; + 1
  ST R7
  LD R8       ; a temp slot for expression result
  STD @R12
  LD R1       ; also we have to change "self"
  STD @R12
  LD R2       ; bytes
  ST R1       ; self <- bytes
  BS *+1
```

```
SET SIZE
STD @R12
RS
ADD R7      ; pedantically, this is "bytes size + (end - start + 1)"
ST R8
```

That's 18 instructions plus three parameter bytes, for 21 bytes. Squeak's version was from byte 44 to byte 51, 8 bytecodes, referring to no literals. Unsurprisingly, I guess, SWEET 16 was roughly equivalent on "fib", but much worse on more realistic code.

NanoVM: Java Bytecodes on the AVR

NanoVM is an AVR implementation of Java bytecode; it is about 7100 bytes of AVR machine code and includes garbage collection, arithmetic, inheritance, presumably polymorphism, and needs about 400 clock cycles per Java bytecode, plus 256 bytes of RAM for the VM. However, it only supports "a small subset of the Java language", without "exceptions, threads, floating point arithmetic and various other things like e.g. inheritance from native classes."

As I posted previously, the Java bytecode instruction format looks like it's in the same ballpark with Squeak's, but the bytecode file format may have some hefty overhead; adding a second copy of the "fib" method to Fib.java, under a different name, inflated the .class file by 82 bytes, from 577 bytes to 659, even though javap -c only shows 15 bytecode instructions occupying 21 bytecode slots in the method.

So it's probably possible to fit a bytecode engine similar to Squeak's into 8 kilobytes of ROM, but 4 kilobytes may be pushing it. Two orders of magnitude performance loss is heavy but may be acceptable.

Code-Compact Data Structures

If you want a flexible but painfully slow language to run on a machine without much code space, you probably need some built-in way to represent common data structures so that you don't have to implement them yourself in your user-level code. The usual set present in modern high-level languages (JavaScript, Python, Lua, Perl) includes numbers, (generally immutable) strings, dictionaries, and mutable, growable lists or arrays.

Symbols, as in Lisp or Smalltalk, are probably a very useful optimization in this setting; they allow you to throw away the keys to your dictionaries if you never print them out.

You may be able to save code space by implementing strings as arrays or lists of character or integer objects, but the run-time space cost is terrible; this may be OK if you never or rarely have strings.

Lua's dictionary ("table") implementation uses some hashing technique I don't understand to be able to operate with a load factor of 100%; I don't know how much code it needs. FORTH's dictionary structure is probably the simplest efficient growable dictionary structure: an eight-entry hash table with separate chaining. If you have space-efficient resizable arrays, you could perhaps store each chain in one of those instead.

Here's a working implementation in my pidgin OCaml of these growable arrays and hash tables. I wrote it in OCaml because I don't have an assembler handy, that's the only language implementation I

have handy that produces reasonably compact assembly code, and I haven't written enough code in any assembly language to be able to write this in assembly from memory. It's 42 lines of OCaml code and comes out to 477 instructions, and it omits only two necessarily polymorphic sends: one for hashing in get_table, and one for equality testing in hsearch. I'm pretty dissatisfied with the number of instructions there --- I feel like I could do better, by a factor of 2 or 3 --- but the example at least provides an upper bound that doesn't look insane.

```
(* code-compact data structures. *)

(* The point of this file is not to provide data structures you'd want
   to use in OCaml (OCaml provides other data structures) but to see
   how much assembly code they compile to. *)

(* growable array *)
type 'a ary = { mutable a: 'a array; mutable n: int;
                mutable allocated: int } ;;

```

This puts all the code for the class (except its instance variable list) in 161 bytes, including ten four-byte literals, so we'd be down 20 bytes if the literals were 16-bit instead. This is noticeably less than the probably 1008 bytes OCaml wanted for essentially the same code. The corresponding Tinyhash is 301 bytes of methods, including 65 (20%!) for the 'keys' method I left off of the OCaml version and 100 bytes of literal pointers. As variants, I did a version using no hashing at all, just Associations in a Tinyarray, which was 199 bytes, a version that used parallel arrays instead of Associations, which was 329 bytes (9.3% larger). A minimal variant of the Association class is 31 bytes (of methods) so I suspect that including Associations is probably a win --- they don't have to save much code anywhere else to be an absolute win.

(I also wrote a version that was just an alist, without Associations or hashing, which was 131 bytes, and a hash table wrapped around that, which was 154 bytes plus a 27-byte Tinyarray>>#do: method, which all adds up to be 312 bytes, slightly larger than the non-alist-based hash-table version; but Tinyarray>>#do: is likely to be useful in other contexts as well.)

(All of this code depends on very little from Array --- it doesn't fall back on its bounds-checking at all, doesn't query it for its size, just

uses #at: and #at:put: and allocates new arrays of fixed size --- so it should be able to run atop a very primitive Array implementation.)

Library Design

Historically people have often made the mistake of thinking that computers were for computing --- that is, arithmetic, with numbers. But the number-handling in many programs is confined the lower levels.

Consider these numbers, again from Squeak:

method name	calling methods
sinh	0
ln	13
tan	15
squared	40
raisedTo: (a power)	55
signal: (raising an error)	78
sin	78
-> (creating a pair)	114
signal (raising an error)	119
on:send:to: (metaprograms)	117
\\ (integer modulo)	263
addMorph: (GUI design)	333
next (stream input)	493
bitAnd: (bit twiddling)	609
value (invoking a thunk)	674
notNil (testing for nil)	702
collect: (mapcar)	862
// (integer divide)	912
nextPut: (stream output)	968
add: (incremental constr)	1055
* (multiply)	1919
at:put:	1990
<= (numeric comparison)	2186
@ (creating a pair)	2372
, (sequence concatenation)	2399
do: (sequence iteration)	2508
at: (collection indexing)	3290
- (arithmetic)	3684
new (instantiating class)	5150
+	5186
= (comparison)	5342

This is out of about 50 000 methods.

Transcendental functions are really unpopular. Most of the math isn't all that popular, in fact, compared to things like operations on sequences. #+ is an exception, but it's used for several things besides arithmetic on numbers: sound mixing, pointer arithmetic, color mixing, date/time manipulation (which is arguably numerical), animation compositing, and voice composition. I suspect that the surprising popularity of #- is due to Smalltalk's unfortunate decision to index its collections from 1 and use closed intervals everywhere, resulting in lots if "-1" in otherwise clean, arithmetic-free code.

The methods for things like iteration and conditional testing are probably more widely used than any of the above, but the compiler

inlines them, so I can't get statistics easily.

In general, a system that provided no arithmetic *at all* would be of limited use, but it's possible to get surprisingly far without floating-point or transcendental functions, let alone complex numbers; you probably get +, -, and < almost for free. It's likely that you'd be better off devoting precious ROM space to some kind of flexible collection classes than to transcendental functions, rational numbers, or possibly even division.

Other Existing Small Interpreters

• S21

Jeff Fox's S21 simulator for the MuP21 microprocessor (1995-1998) is a 187KB MS-DOS EXE file. It includes the simulator for the processor, a a single-stepping debugger with an MS-DOS console user interface, and it itself is running inside the FPC FORTH virtual machine, which also includes an interactive development environment with a program editor, a virtual memory system, and cooperative multitasking.

• Squeak?

On this Intel Mac, the Squeak virtual machine binary is 967868 bytes. I don't understand how that's possible, since I thought it was built from just the Interpreter and ObjectMemory classes, which are only 10 000 lines of code in total, about the same as the Lua interpreter.

• pepsi/Albert/the golden box

Ian Piumarta's "pepsi" system, the lowest-level substrate for which Alan Kay's NSF-funded reinvention-of-programming system, is 144 lines of C code and compiles to 1451 bytes, or 1602 bytes with inline caches enabled. It provides very efficient, very dynamic method dispatch, and a minimal object system, but no bytecode interpreter.

• The Basic STAMP

The Basic STAMP uses a sort of bytecode for executing BASIC on a PIC; most of the variable-length instructions are less than a byte long. Chuck McManis's 1994 article "Decoding the BASIC Stamp" describes them. They're really little more than a tokenized BASIC. I have no idea how big the STAMP ROM is.

• UCSD P-System

The UCSD P-System, a stack-based bytecode interpreter with compilers from Fortran and Pascal, ran on a lot of small microcomputers back in the day. Z8080:INTERP.TEXT, the UCSD Pascal Interpreter for the Z-80 and Intel 8080A by Peter A. Lawrence and Joel J. McCormack, is about 6100 lines of 8080 assembly when you include all the things it .INCLUDEs. (I found this in a file called I5Z80Interp.TXT.) This includes floating-point math, set arithmetic, transcendental functions, booting from disk, character terminal addressing, single-stepping, virtual memory, a tokenizer for Pascal, binary search trees, I/O interfaces for CP/M, and all kinds of such nonsense. However, I don't have an 8080 assembler handy on this Mac, and there are a fair number of macros (on one hand) and conditional compilation (on the other), so I'm not sure how big that actually ends up being. It's 5000 non-comment non-blank lines.

The PDP-11 interpreter ("mainop.mac" or "I.5-PDP-Interp.TXT")

seems to be just the bytecode interpreter itself, and it's only around a thousand lines of PDP-11 assembly.

The virtual machine instructions listed in the assembly are quite similar to the set of P-Code instructions in Steven Pemberton and Martin Daniels's book, "The P-Code Machine" and also Jensen and Wirth's 1973 "ASSEMBLER AND INTERPRETER OF PASCAL CODE", (PROGRAM PCODE(INPUT,OUTPUT,PRD,PRR)). Said Jensen and Wirth code is 775 non-comment non-blank lines of Pascal, which suggests very roughly about 4000 assembly instructions.

• PICBIT

PICBIT is Feeley and Dubé's bytecoded Scheme implementation for PIC microcontrollers. It uses a register-based virtual machine with six registers for object references, plus PC and number-of-args registers; it has 17 instructions, which are inadequately explained in their paper, "PICBIT: A Scheme System for the PIC Microcontroller," but which reflect a very Schemey view of the world, with a "continuation" register, a CALL instruction that's really JMP-and-adjust-nbargs, and so on. One of their example programs was 38 lines of Scheme (about 1000 bytes), which compiled to 2150 bytes of bytecode. Larger programs were inflated by less than half as much, but they were still much larger than I would expect with other bytecode systems.

I venture to guess that this suggests that their register-based virtual machine bytecode was a memory hog. Dubé's earlier BIT bytecode system, after which they modeled their system, used stack-based bytecode, which was less than half as big on their five example programs.

However, the entire R4RS Scheme library only took 11248 bytes of bytecode, so it seems likely that you can get a relatively powerful set of primitives into not very much space with the general approach of using bytecode. With BIT, it was under 8000 bytes.

They report 37000 bytecodes per second, but it's not clear whether they mean on a 10MHz PIC microcontroller or extrapolated to a 40MHz microcontroller.

• F-83

F-83 was an indirect-threaded FORTH programming system available on most microcomputers in 1983, at a time when many of them had 64kiB of total address space. I have the F-83 books somewhere, but I don't have a copy of the sources here, and I don't know how big the whole system was, but I think it was normally all in memory at once --- the assembler, the FORTH compiler, the indirect-threaded-code interpreter, the interactive interpreter, the full-screen editor, the decompiler, and the virtual-memory system (which couldn't be effectively used for code).

• Various combinator-graph-reduction machines

I haven't looked very much at these, but I suspect that laziness may reduce program size. (Perhaps the same thing could be said of backtracking and concurrency.)

Conclusions: Squeak Rules, We Should Be Able To Do Python In A Few K

Most of the approaches I looked at are considerably more compact

than PowerPC machine code on the toy "fib" problem, by a factor of 2–4, with Squeak among the best; this includes Java (?), Squeak, indirect-threaded 16-bit FORTH, SWEET 16, and the F21 CPU. A couple (OCaml bytecode, PICBIT) sound much worse on density. Beating a factor of 4 (25 bytes for the "fib" program) looks difficult. The factor-of-4 improvement in code density looks realistic from the Tinyhash and Tinyarray examples, and based on previous work, I think a virtual machine for some Squeak-like bytecode can be contained in 4000–8000 bytes of machine code, with a rich library requiring a few thousand more bytes.

Probably Squeak's approach, using a stack for expression intermediate results (to keep instruction size down), a local-variable vector for slightly-longer-term usage (to cut down on stack-manipulation noise words), and a local-literal vector for constants and linkage, with nearly all instructions contained in a single byte, is the best one known for tight bytecode. I suspect that conditional return may be a more compact control-flow primitive than conditional jump, but it could make compiler implementation more challenging.

I'm going to assert that polymorphism, even (especially!) on "fundamental" operations that have machine instructions assigned to them, increases code density. In the case that you don't have any polymorphism in your program, it costs you very little code density (none in bodies, maybe a couple of bytes each in definitions), and in the case where you do, it saves you conditionals. This should hold a fortiori for multiple dispatch.

If we are going for absolute minimum run-time code size, it's perhaps best to have a small kernel written in machine code (probably in a stack-oriented fashion, such that you can put CALL instructions one after the other with no intervening setup) that implements a fairly primitive stack-based virtual machine, atop which a more Squeak-like virtual machine is implemented. (They need not be separate abstract machines --- perhaps unimplemented bytecodes will trap into a user-defined instruction handler.) For example, the hash tables and growable arrays mentioned previously should probably be mostly implemented in this level; in Squeak bytecode, they need around 500 bytes.

Library design probably makes a big difference in how few literals you have to use --- if most of the messages in your system belong to a few small interfaces like #at: and #at:put: or arithmetic, you'll have a much easier time with the bytecode.

With this approach, it should be possible to get a very slow language, with flexibility something like Python's, into maybe 2000–6000 bytes of a microcontroller's ROM. This should allow you to interactively get out-of-memory errors with great convenience and flexibility.

Topics

Notations for defining dynamical systems

Kragen Javier Sitaker, 2016-10-03 (updated 2016-10-06) (6 minutes)

Playing with this scientific calculator and thinking about the Mill CPU and write-once memory (such as, roughly, NOR flash), and then spending some quality time with Gnumeric and watching Joel Spolsky and Martin Shkreli coax magic from Microsoft Excel, it occurred to me that there was maybe an interesting and expressive programming model that captures pointwise calculations on vectors as well as generalized prefix sums over them.

The programming model is as follows. You specify a sequence of updates to apparently scalar variables, such as

```
x := y + 1
z := z + x
```

These updates are run, in sequence, repeatedly.

As syntactic sugar, we use → for assignment, put the variable on the right side, make the assignment an expression and return its value from the assignment expression (as in Lisp or C), and support augmented assignment operators as in C, but spelled +→, -→, ·→, and so on. This allows us to abbreviate the above example as follows:

```
y + 1 → x +↦ z
```

By itself, this is just a formalism for deterministic dynamical system evolution rules. But you might want to visualize a trajectory or the trajectories of a dynamical system, such as the famous Minsky circle:

```
x · k +↦ y · k -→ x
```

This allows us to consider the dynamical system as a function from initial values to trajectories, which we could conceptualize as vectors of successive values taken by the different variables. From that point of view, we are no longer overwriting the previous value; we are merely appending to a vector of values.

Note that in particular this expression has a somewhat APLish meaning in this interpretation:

```
x + y → z
```

If x and y are vectors that something else is building at the same time, corresponding items in them will be added and the sums appended to z; if one of them is a scalar (i.e. a value that doesn't change during the loop), then it will be added to each value of the other and the sums appended to z; if they are both scalars, then some undetermined number of copies of the sum will be appended to z.

From this point of view, it is natural to add an operator to look back in history, like Git's ~ operator; `HEAD` is the current value of `HEAD`, while `HEAD~1` is its previous value, and `HEAD~2` is the value before that (equivalent to `HEAD~1~1`). For example, if we initially have two values

in x, we could write linear extrapolation to the next value as follows:

```
2 · x - x~1 → x
```

As a more complex example, we can write the Goertzel algorithm as

```
x + b · s - s~1 → s - c · s~1 → y
```

where b is 2 cos ω_0 and c is exp(-i ω_0). Note that this is potentially confusing in that the expressions s and s~1 occur twice in the same formula with different meanings. It might be less confusing to write this as follows:

```
x + b · s - s~1 → s
s - c · s~1 → y
```

Now, in this form, this is sort of incomplete; if x decays to the latest value added to x, it only implements the Goertzel algorithm if stuff is getting added to x while the above code is running.

There are a couple of different ways we could handle that. One is that we could package the above code into a function, and define a function composition operation that implicitly gloms together the various state transition functions into a single evolution rule. A more conventional alternative would be to provide a while or foreach construct. In this case, due to the one-dimensionality of the temporal constructs described thus far, a foreach construct could pun the sequence with its iterator. If we use @, we get:

```
x @ x + b · s - s~1 → s - c · s~1 → y
```

This in some sense creates a new local variable x inside the scope of the loop (the right side of the operator) that is an alias for the nonempty prefixes of the original x on sequential iterations of the loop.

Augmenting this with a : sequence-construction operator like Octave's (but zero-based), we now have a way to control the number of iterations of something like Minsky's circle algorithm; we can write, for example:

```
1→x→y
:1000@x·k+→y·k-→x
```

However, I think it's useful to consider evolution rules like x·k+→y·k-→x as entities in themselves rather than incomplete code snippets. It may be useful to compose them, perhaps with β-reduction and α-renaming, as part of a larger evolution rule involving more variables, or to attempt to differentiate them with respect to their inputs, or to attempt to find inverses for them, in general or from a particular point.

You could iterate over multiple sequences in parallel; vector dot product can be expressed as follows:

```
0 → t
u, v @ u · v +→ t
```

Nested loops make sense in only a few circumstances without adding a way to store arrays with more dimensions, but for example, here's a time-domain FIR filter convolving `x` with kernel `k`, storing intermediate sums in a variable `t`:

```
:#k → n
x[#k:] @ 0 → t
        k, n @ x~n · k +↦ t
        t → y
```

In an environment with very limited screen space, such as a scientific calculator or an Excel formula, you could write that without indentation, whitespace, or newlines:

```
:#k→n;x[#k:]@0→t;(k,n@x~n·k+↦t);t→y
```

That's 36 characters, which should fit on the screen even on a fairly low-end scientific calculator.

This data model is more convenient in many cases than Excel's, but somewhat less powerful, because it doesn't natively support two-dimensional arrays. But maybe the right thing is actually to have this kind of merged native support for one-dimensional arrays and scalars, but require some kind of extra operation for two-dimensional arrays, the way C and Perl5 require an extra operation to dereference pointers.

Microfinance

Kragen Javier Sitaker, 2007 to 2009 (6 minutes)

James Surowiecki criticizes nanocorps, in "What Microloans Miss":

This vogue has translated into a flood of real dollars: institutional and individual investments in microfinance more than doubled between 2004 and 2006, to $4.4 billion, and the total volume of loans made has risen to $25 billion, according to Deutsche Bank. Unfortunately, it has also translated into a flood of hype. There's no doubt that microfinance does a tremendous amount of good, yet there are also real limits to what it can accomplish. Microloans make poor borrowers better off. But, on their own, they often don't do much to make poor countries richer.

This isn't because microloans don't work; it's because of how they work. The idealized view of microfinance is that budding entrepreneurs use the loans to start and grow businesses—expanding operations, boosting inventory, and so on. The reality is more complicated. Microloans are often used to "smooth consumption"—tiding a borrower over in times of crisis. They're also, as Karol Boudreaux and Tyler Cowen point out in a recent paper, often used for non-business expenses, such as a child's education. It' s less common to find them used to fund major business expansions or to hire new employees. In part, this is because the loans can be very small—frequently as little as fifty or a hundred dollars—and generally come with very high interest rates, often above thirty or forty per cent. But it's also because most microbusinesses aren't looking to take on more workers. The vast majority have only one paid employee: the owner. As the economist Jonathan Morduch has put it, microfinance "rarely generates new jobs for others."

This matters, because businesses that can generate jobs for others are the best hope of any country trying to put a serious dent in its poverty rate. Sustained economic growth requires companies that can make big investments—building a factory, say—and that can exploit the economies of scale that make workers more productive and, ultimately, richer. Microfinance evangelists sometimes make it sound as if, in an ideal world, everyone would own his own business. "All people are entrepreneurs," Muhammad Yunus has said. But in any successful economy most people aren't entrepreneurs—they make a living by working for someone else. Just fourteen per cent of Americans, for instance, are running (or trying to run) their own business. That percentage is much higher in developing countries—in Peru, it's almost forty per cent. That' s not because Peruvians are more entrepreneurial. It's because they don't have other options.

Surowiecki's argument seems to have two parts: first, that the only way to create jobs is to hire people, and second, that small investments have a lower internal rate of return than larger investments --- that is, they are more efficient uses of capital.

I think neither of these arguments is correct.

As Coase pointed out decades ago, there isn't a large distinction between a service supplier and an employee; in either case, you pay money and receive services. If there are two people engaged in making nails and five more engaged in carpentry using those nails, then if five more people take up the trade of carpentry, there is work available for two more nail-makers. It doesn't matter whether these seven people work for the same firm, or whether they buy the nails on the open market; the number of jobs created is just the same. Similarly, economies of scale do not necessarily depend on all the workers working for the same firm.

To put it another way, traditional companies create jobs by hiring people; nanocorps create jobs by buying goods and services.

Coase also pointed out that there is some distinction; one arrangement or the other might be more efficient, depending on the costs of transacting in the market and the inefficiencies of large firms.

Perhaps the Peruvians are entrepreneurial because they have particularly harsh pressures against large firms, for example due to government corruption or organized crime.

On to the issue of "big investments".

The number of jobs created is largely a function of the amount of value produced by the capital investments in question, and so the number of jobs created per dollar of credit is largely a function of the IRR of those investments, modulo the effects of inequality in distribution. If US$1000 of investment increases workers' productivity by US$1000 per year, it creates some number of jobs; but that number is likely to be more or less the same whether it is increasing 20 entrepreneurs' income by US$50 per year each (some of which they can spend on inputs such as cellphone minutes, electricity, wool, or wood, creating jobs in those industries) or whether it is increasing a factory's income by US$1000 per year (in which case it might do the same, or it might hire another worker or three).

The high (not to say usurious) interest rates of the microcredit loans in question, coupled with their low default rates, are strong evidence that the internal rate of return on these small investments is fairly high. Most of those loans are probably good choices for the people who receive them, I believe, or microcredit would have a serious image problem. (Journalists love nothing more than unmasking hypocrisy.)

There is no principled reason to think that in general, large capital investments will have high IRRs that are systematically unavailable to small capital investments. This kind of thing depends greatly on the technology available.

There are probably some big investments that are worthwhile.

Hybrid RAM

Kragen Javier Sitaker, 2016-09-24 (5 minutes)

There were a couple of papers published in the 2000s about "hybrid memory" systems with SRAM and phase-change memory (PRAM or PCM-RAM).

Here's the deal. The standard memory hierarchy for the last 35 years has been SRAM → DRAM → spinning rust, and now that's diversifying a bit, with SRAM → DRAM → NAND Flash → spinning rust, sometimes missing the spinning-rust part. Each item in this hierarchy is much more costly per bit than the next one, but also much faster. On each of these, the time to write one byte at a random location, the retail cost of that location, and the amount of such storage on a typical small netbook or cellphone, might be, very approximately:

- SRAM: 0.2 ns, 20 000 nanodollars, 1 MiB
- DRAM: 100 ns, 3.5 nanodollars, 4 GiB
- NAND Flash: 10 µs (10 000 ns), 0.26 nanodollars, 64 GiB
- spinning rust: 8 ms (8 000 000 ns), 0.03 nanodollars, 1000 GB (or 0!)

You'll note that the cost of each of these levels of the memory hierarchy is on the order of US$20.

From this you might think it was some kind of a natural law that faster memory costs more to make, but the truth is that there's plenty of memory that's both more costly to make and slower than something in that list. It's just that people stopped making it. Bubble memory, core memory, TTL SRAM, acoustic delay lines, punched paper tape, Williams tubes, magneto-optical disks, even magnetic tape and most photo and movie film have fallen to this economic logic.

I think this kind of thing is called the "efficient frontier" or "Pareto frontier", and it's a pretty general economic phenomenon: possible technologies are scattered around some cost/benefit plot space at random, but the ones that are economically viable are the ones that have more benefit than everything that's less costly, dramatically reducing the diversity of technologies. When there are more different benefits to trade off among, more diversity can survive.

A weird thing about this is that the time to read a byte is the same in all cases except for NAND Flash, because the process of erasing a block of NAND is slow, but reading it is potentially quite fast. In fact, reading it can be as fast as reading SRAM or DRAM, depending on how the Flash is designed. (A friend of mine went off to found a CDN startup based on this observation a couple of years ago; it's called Fastly and now powers a substantial fraction of the internet, disrupting the business of some internet giants.)

This is not as visible as it could be, because Flash has been slotted into the existing computing ecosystem as a disk replacement, so to some extent it's been limited by the I/O hardware and software built to support spinning-rust disks. Also, I think NAND Flash typically doesn't support byte reads, just reads of 256-byte blocks. I have to

investigate further.

This suggests that below a certain ratio of writes to reads, Flash (and similar technologies like PRAM, FeRAM, CBRAM, and MRAM) can displace not only some spinning rust but also many applications of DRAM and SRAM. This is especially interesting to me because of a different benefit of nonvolatile technologies like Flash: they use much, much less power than DRAM.

This is especially important because refreshing DRAM is actually a major user of computer energy nowadays, especially in mobile devices where power is so crucial. If it's possible to replace a large amount of DRAM with a larger amount of nonvolatile RAM and a much smaller amount of SRAM, it would be a huge win. This is what inspired all that "Hybrid RAM" research.

Of these alternatives to Flash, PRAM was the first to hit the market, and so it's the one that inspired the papers on hybrid RAM; it was only made by Micron, but only from 2012 to 2014. Intel is trying to commercialize crosspoint PRAM it developed with Micron under the name "3D XPoint". CBRAM, FeRAM, and MRAM are still available and mainstream.

A typical PRAM part might have been the Micron NP8P128A13TSM60E, 128 megabits (16 megabytes) of PRAM in a 56-pin package with 115-ns random reads (using a 25 MHz clock) and 50-ns random writes (using a 50 MHz clock), which is read performance slightly better than DRAM. (This was through an SPI interface.) It was rated for a million write cycles, and although its write speed was not as fast as DRAM, it didn't require a separate slow erase step. It supported writing or "programming" (ANDing) at 64-bit granularity.

US$10M for a new, much better McMurdo Base, or less

Kragen Javier Sitaker, 2016-05-18 (updated 2016-05-19) (7 minutes) (on http://idlewords.com/2016/05/shuffleboard_at_mcmurdo.htm)

Reading this article (highly entertaining, as always, Maciej; thanks for brightening my day with your cynicism) led me to reflect on architecture. It seems pointlessly wasteful to have built a bunch of Quonset huts and trailers that people have to walk between, and also to have built the buildings above ground in the first place. I suppose digging in permafrost is difficult, and bringing in machinery so that you can have economies of scale is difficult, even if we no longer have the problems of cold steel embrittlement and tin pest that bedeviled the old polar explorers.

A little quick calculation, since calculation is always what I end up doing when confronting stories of human folly and suffering.

If you need to house, say, 1024 people, with 128 m² of floor area for each one (home plus office plus bar, etc.), with a mean ceiling height of 4 m, that's 524 288 m³. If you want to enclose that volume inside a hemispherical dome, the radius (and thus the height) of the dome is about 64 m, or 16 floors. The skin of the dome — the part that insulates the people from the cold wind — is about 26000 square meters, 25 square meters per person. The cross-sectional area that the dim sun illuminates during the summer is about 6400 m², so if we assume a bit less than 1000 W/m², you receive about 6 megawatts of solar energy during the summer, and about 3 megawatts year-round (3 kW per person).

How much insulation do you need? If the inside-outside temperature difference is 40° C, and you need to maintain that on 1500 W per person (maybe your thermal solar collection is only 50% efficient and you don't have significant other sources of heat) then you need insulation with an average R-value of about 3.8. 1-inch polyisocyanurate foam panels have an R-value of about 6, and they only cost US$19 for a 4'×8' panel (US$6.40/m²; this is the Home Depot retail price and includes aluminum facers) which works out to about US$160 000 to cover the whole dome. Unfortunately they aren't transparent, so you can't get solar radiation through them; you kind of need some kind of non-imaging optics heliostat if you want to gather the solar heat to illuminate and keep warm with. As far as I know, these don't exist yet.

At this point, and certainly when McMurdo was built, it would make more sense to use heavier insulation, and do your climate control by dissipating energy that you generate by some other means, such as with the nuclear reactor or by burning fuel oil. If you're dissipating 500 watts per person, you need three times the R-value (11.4, a bit under two inches of foam insulation, or US$320 000 of insulation). You need to use countercurrent heat exchangers to keep the air from going stale.

16 stories is small enough that people can avoid using elevators most of the time, at least if the common areas they usually travel to are

intelligently located; 128 meters diameter is small enough that you can walk anywhere (in about two minutes), but large enough that bicycles or skateboards would occasionally be convenient.

If each floor is concrete 250mm thick (suitable for essentially any purpose that doesn't involve armored vehicles), we need 32768m³ of concrete, or about 65536 tonnes, if we use somewhat lightweight concrete. Concrete typically costs about US$120/m³, so that's about US$4 million of concrete, plus probably a similar cost in rebar. This cost isn't particularly sensitive to whether you build a bunch of separated buildings or a single giant arcology like I'm suggesting above, as long as the buildings are more than two or three stories tall. It is sensitive to things like whether each person gets 128m² or 32m² and to the flooring material.

If you could somehow get by with more inexpensive floor materials like expanded steel sheet with drywall under it, you could reduce the cost dramatically — the 250mm reinforced concrete I suggested above costs about US$60/m², while 9-gauge expanded steel sheet might cost US$24/m² (according to MetalsDepot.com). I feel like that kind of thing might be acceptable for a lot of floors that don't separate unrelated strangers.

This is important not so much for the cost of the materials (although that is kind of important) but more because you don't have a cement plant or even a quarry onsite there in McMurdo; all your manufactured materials have to be shipped in, as if you were in Alaska or something. A heavy-tested TEU only holds 28 tonnes; the amount of concrete suggested above is 2340 TEUs' worth of mostly sand and rocks. That's because the concrete weighs a ton per square meter, while the expanded sheet metal weighs 8.8 kg per square meter. That way, you might only need 25 or 30 TEUs instead of 2300 of them.

(The above conveniently omits the sheetrock...)

What about trash? Is it really necessary to haul it away from Antarctica? Let's make some pessimistic assumptions: suppose we need to plan to store 64 years' worth of garbage — ideally, frozen — and that the McMurdo Base residents and visitors produce the same amount of garbage per capita as New Yorkers, who are twice as productive of waste as any other major metropolis, at 7.8 million tons per year (220 kg/s) out of 8.6 million people (26 mg/s per person). Over 64 years and 1024 people, this is 54 000 tonnes of garbage, or about 54 000 m³.

This is about an order of magnitude smaller than the size of the people dome. If we just build a garbage dome near the people dome and put garbage in it every day and let it freeze, the garbage dome will only be five stories tall if it's built for 64 years' worth of garbage.

Presumably it will take less than 64 years for it to become economic to mine the rich deposits of refined mineral resources (indium, gallium, gold, copper, maybe even aluminum if energy prices don't fall dramatically) in the garbage pile.

Hopefully, the McMurdo residents will demolish less buildings, buy less new clothes, junk less taxis, and compost more of their food than New Yorkers do, so hopefully their garbage volume will be even smaller.

So you could probably build a new, much better McMurdo Base for under ten million dollars.

Alphanumerenglish

Kragen Javier Sitaker, 2015-04-06 (updated 2016-07-27) (6 minutes)

Arabic has some phonemes that don't have a reasonable corresponding phoneme in Latin languages. A common approach when writing Arabic with Latin letters is to use European digits for the missing phonemes, as in "3arabawy". This has the great advantage over X-SAMPA that it doesn't deprive you of the uppercase/lowercase distinction entirely — although the digits themselves, in ASCII, don't show the distinction visibly, you can still distinguish between "3arabawy" and "3ARABAWY", or between "a7a", "A7a", and "A7A". The European digits are assigned to sounds represented by Arabic letters that physically resemble them.

This seems like a great idea for English, too! English has a few more phonemes than the Latin alphabet, and consequently has to force some letters to represent multiple different phonemes, but its traditional orthography worsens the problem by wasting some of the Latin letters (c, q, and x) on redundant assignments. A rough phonological inventory of English follows, with a corresponding set of alphanumeric codes.

Latin	IPA	Alphanumerenglish
a	æ a ɑ eɪ ə	4 a 2 8 e
b	b	b
c	k ʃ tʃ	k c tc
d	d ɾ	d d
e	ɛ i	3 i
f	f	f
g	g dʒ ʒ	g dj j
h	h	h
i	aɪ ɪ i	ai 1 i
j	dʒ ʒ	dj j
k	k	k
l	l	l
m	m	m
n	n ŋ	n 6
o	u ʊ ɑ ɔ oʊ æʊ	u 5 2 0 o au
p	p f	p f
q	k	k
r	ɹ ɚ	r er
s	s ʃ z	s c z
t	t θ ð d ɾ	t x q d d
u	u ʌ ju	u 7 yu
v	v	v
w	w hw	w hw
x	ks	ks
y	j i ɪ aɪ	y i 1 ai
z	z ʒ	z j

In a few cases, I've taken the liberty of giving a diphthong a spelling that isn't quite what you'd deduce logically, in the interest of making it easier to write: /oʊ/ is "o" rather than "o5" or "ou", because I think /o/ doesn't occur in outside of that diphthong in

English, and likewise /eɪ/ is assigned a single digit "8"; /æʊ/ is "au" rather than "4u" or "45", because although [au] is not the central instance of the /æʊ/ class, it's certainly a valid pronunciation of it; and /aɪ/ is "ai" rather than "a1" for the same reason.

The mnemonics for the digits and other nonstandard pronunciations are as follows:

0	ɔ	looks like an 0
1	ɪ	looks like an I
2	ɑ	no clue, sorry
3	ɛ	looks like an ɛ, backwards
4	æ	looks like an A
5	ʊ	no clue, sorry
6	ŋ	looks like the G in NG
7	ʌ	looks like ʌ tilted a bit
8	eɪ	8 is pronounced /eɪt/ in English
c	tʃ	"c" is pronounced like standard "ch"
e	ə	looks like ə; also, the most common vowel
q	ð	no clue, and this one is super weird, sorry
x	θ	no fucking clue, sorry

In the interest of ease of typing and reading, I've tried to assign the less common sounds to digits, and especially digits that don't look like anything. You might be able to get some benefit from swizzling around the assignment of 2 and 5, and maybe x and q too.

You might also get a readability improvement out of reassigning /ə/ to "a" rather than "e", which would leave "e" free for /ɛ/, but would require reassigning /a/ to something else, such as "9" or "3". /a/ alone is relatively rare in English, but "ai" and "au" are relatively common.

I've written a short Python hack to use eSpeak to convert traditional English orthography to Alphanumerenglish, not perfectly but with a tolerably low error rate. It turns out Alphanumerenglish is about 10% shorter.

Dercuano plotting

Kragen Javier Sitaker, 2019-09-03 (updated 2019-09-05) (34 minutes)

Related to Dercuano rendering (p. 2300), Dercuano formula display (p. 495), Dercuano calculation (p. 3135), and Dercuano drawings (p. 64), but not the same — I want some kind of equation-and-data-plotting thing in Dercuano, with some kind of Jupyter-like rapid feedback. I think I can make it simpler and less fiddly than Numpy or Pandas, using the ideas in APL with typed indices (p. 3264), A principled rethinking of array languages like APL (p. 1995), Relational modeling and APL (p. 1217), and First impressions on using the µMath+ calculator program for Android (p. 195), plus some I got from Darius Bacon, and get some formula display out of it into the bargain.

As discussed in those notes, prerendering images to PNG or JPEG files like the humans normally do is not really an option for Dercuano because of its 5MB total download size budget.

A concrete example

In Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) I wrote 4800 words about an algorithm; the resulting HTML compresses to 11kB. I tried it in an IPython notebook which contains 511kB of text, mostly compressed images, so I'm not including it as part of Dercuano (that, and because it's in a file format that browsers don't recognize). The actual Python code in the notebook is 2.3kB and compresses to 0.7kB. With reasonable JS signal processing and plotting libraries, this implementation could be part of the text, also costing only about 0.7kB, the plots would be viewable alongside the text, and they could be an "explorable explanation" in the sense that you could interactively vary the parameters and observe how this affects the plots.

Rapid feedback HCI

In 2015 I wrote an RPN editor with numbers and 1-D arrays that generates simple plots and formula renderings as you calculate, a followon to an older JS calculator I wrote in 2005; in 2016 I did a similar hack where instead of calculating on *arrays* the elements you calculate on are *functions*, starting from the identity function $f(x) = x$ and constant functions $f_k(x) = k$, then combining them pointwise. These are all fairly keyboard-driven (Interactive calculator (p. 2771) explores how to do a multitouch UI) and prototype-quality.

One of the interesting things about the 2015 RPN editor above is that it uses the URL #fragment identifier to store the entire application state, much like erlehmann's `glitch:` URLs for bytebeat, so that you can bookmark the calculation state or pass it to someone else in a link. In some sense, it's an interactive *viewer and editor* for a calculation *text*, with some linguistic representation — in this case, RPN, since nothing more complex is needed.

The 2015 RPN editor also allows you to highlight subexpressions (with the ←→ keys) to see their values, and to structure-edit it (with ^←/^→), although that is confusing.

Another thing about all three of these prototypes is that you don't have to request for a result to be plotted — as soon as it exists, it gets plotted. But they need more flexibility in *how* to plot things. (The 2005 one gives you the option of resizing a plot with the mouse, while the others don't even do that much.) Every value has an infinity of possible visible presentations; peremptorily displaying two of them is not enough.

These all feel much more immediate than the experience with IPython/Jupyter, where you are constantly faced with the alternative between *using* a value you have calculated:

```
t = dt * arange(20e-3 / dt)
```

and *seeing* it:

```
dt * arange(20e-3 / dt)
```

and plotting a function so you can see *both its domain and range* and have it *labeled* and have *more than one plot* requires bending over backwards:

```
subplot(211)
plot(t, VR, label='$V_R$')
plot(t, VL, label='$V_L$')
plot(t, VC, label='$V_C$')
legend()
subplot(212)
plot(t, I, label='$I$')
legend();
```

Consider, instead, being able to say:

```
(VR over VL over VC) atop I
```

or the equivalent with keystroke or touch commands? I mean `VR` isn't dependent *just* on `t` — in this notebook it also depends on `C`, `L`, `R`, and `dt` — but `t` is the axis I've been thinking of it as varying with here, while I've been treating those other variables as constants. So is it too much to ask that my calculating and plotting system would be able to infer that, at least unless I override it? Especially when I'm plotting `VL` *on the same axis where I already plotted `VR` against `t`*? Sheesh!

Another thing is that, if you're evaluating a function of more than one variable at many points so you can plot it, Numpy (like APL, Octave, and R) can't keep straight which variations belong to the X-axis and which belong to the Y-axis. It chokes on this:

```
R = array([1000, 2200, 4700, 10e3, 22e3, 47e3])
C = array([100e-9, 220e-9, 470e-9])
matshow(R * C)
```

It complains, "ValueError: operands could not be broadcast together with shapes (6,) (3,)", which is to say that it was trying to multiply corresponding elements of `R` and `C` to get time constants. If we want the two to vary independently, `R.T * C` doesn't work as you might expect, but we can say

```
matshow(multiply.outer(R, C))
```

or

```
matshow(R.reshape((6, 1)) * C)
```

But then the next time you do a calculation involving both `R` and `C`, you have to tell Numpy *again* that you want them to vary independently. And this is what A principled rethinking of array languages like APL (p. 1995) is about. (Also, don't forget `colorbar()`, which is not the same as `legend()`.) This is actually the same problem as getting the X-axis labels right by default: for Numpy, `R` is just a vector of six numbers, just as earlier `VR` was an array of 100'000 numbers. It doesn't have any idea why there are six.

The only software I've seen that does get this right is μMath+; see First impressions on using the μMath+ calculator program for Android (p. 195) for details.

Of course, I keep using Jupyter, despite the above, and even though I can't incorporate the plots into Dercuano. That's because in my 2015 prototype calculator I haven't even implemented typing in negative numbers or decimals, much less multidimensional arrays, the Fast Fourier Transform, or singular value decomposition; moreover, I can probably expect a 10× slowdown just from switching the inner loops of these numerical algorithms to JS from Fortran in LAPACK.

Integration with my current workflow

This AJAXy thing I described above has a difficulty: I'm mostly writing Dercuano in Emacs, not in some kind of browser-based IDE. I could reasonably pop out of writing to the browser to do some graphing (I could even add a keybinding in Emacs), but ultimately whatever I put together in the browser needs to be something I can paste into a text editor, and ideally something that will diff reasonably well.

Probably the best I can hope for there is to pop open a textarea that says something like

```
<script>
calc(`jasiodj jiaji aoj ioaj iojgosjo
jaiogjaoj
aijgwj jaiojgioawj owj oiajio jaweoj jaiojo
jaiogjwojao ioj ioaj oij ioawj oaj aj iawjiawejisjga0 auj
ajigwaj jawjiawjipwuj0aweuj890ejgp aji
ajiajijwijapgjawpj`)
</script>
```

where the text inside the `` encodes the calculations and plotting options. Then I can copy and paste this into the text editor, hopefully remembering to delete the previous version. A hassle, but manageable. (Maybe a keybinding can find the surrounding `<script>` tag, paste in whatever is on the clipboard, and if it looks like a new `<script>` tag, delete the old one.)

The `` syntax is new in recent versions of JS.

Even the hairiest plots I've been doing so far should be encodable in a kilobyte or two of text, and maybe different plots in the same

document could talk to each other.

Why I don't want to try an embedded DSL in JS

Numpy is an embedded DSL in Python, rather than a separate language implemented in Python, much less a funky keystroke-driven RPN UI. So why not do the same thing in JS?

First, JS doesn't support operator overloading, which is a bigger deal for readability than it sounds like. (a + b + c + d)/e.sum() becomes a.plus(b.plus(c.plus(d))).divide(e.sum()). It's already hard enough to tell if the computation you specified was really the computation you wanted; this makes it much harder still.

Second, I prefer the RPN UI because it's a lot more fluid than typing in strings of Python or JS. See the above complaints about Numpy for some of the reasons.

Third, I want to be able to define functions in a somewhat abstract, static way so that replotting them over different regions is a reasonable thing to do. I even want to be able to do this for Runge–Kutta integration and things like that, although I don't know how successful I'll be. Embedding your DSL means that the host-language facilities are always ready-to-hand, but they would frustrate this ambition.

Rendering improvement

As explained in Antialiased line drawing (p. 1803), we could go a long way to improve the readability of graphs by using LCD subpixel antialiasing and a bit of signal-processing theory, instead of drawing PostScript-style convolutions of the graph line with a one-dimensional boxcar kernel at right angles to it.

Ideally, the line plotted on a plot is infinitely thin, a line-shaped Dirac delta, but rendering it that way requires not only infinite resolution but also infinite dynamic range. (The infinite dynamic range is particularly a problem for dark lines, since it would require either emitting negative amounts of light (at infinite concentration) from the line itself, or drawing on an infinitely bright background.) Bandlimiting the Dirac delta to a sinc that won't alias at the screen resolution and maybe inverse-filtering a bit to compensate for the rectangularity of LCD pixels (which amounts to a low-pass filter through convolution with a rectangle) should give a high-quality rendering; windowing the sinc should make it more computationally tractable, but of course requires a little more frequency headroom. Reducing the height of the peak in the center of the filter kernel should help at reducing the demands on the dynamic range of screen pixels, but maintaining the sharpness of the peak there should help with visibility. High-pass filtering the filter kernel a bit, maybe without terribly strong stopband attenuation, should also improve the precision/visibility/dynamic-range tradeoff.

Attenuating the lowest- and highest-frequency components this way has the effect of spreading the line's brightness over more pixels, which means that it can vary more within the same dynamic range; this is important when lines cross or pass very nearby. However, I don't know whether the dynamic range increases proportional to the number of pixels or to their square root.

Any opacity, even if it merely results from saturation, is nonlinear and tends to generate alias frequencies. (It might be possible to avoid the generation of alias frequencies through some kind of very careful balancing, but if you don't manage to do that, they will be present, and for the right pattern of lines they will be overwhelmingly strong.)

Windytan's oscilloscope-emulation algorithms demonstrate what can be achieved with closer-to-ideal plot rendering — aside from the issues of correct interpolation close to the Nyquist frequency, there's lots of detail that is lost to the nonlinearities of the standard approach to waveform plotting but visible on an analog oscilloscope.

It might be possible to get such effects purely in SVG — SVG 1.1 in 2003 already defined the `filter` element and the `filter` property, which supports an `feConvolveMatrix` filtering primitive that I think could in theory handle this. I've rarely or never seen this element in the wild, making me think its implementation is probably not well tested, and so might have performance or even correctness issues. The spec page is well worth reading as an overview of what 2-D graphical primitives the experts at Adobe thought were important in 2003; they go well beyond what PostScript can do.

To get deep-subpixel line positioning, a brute-force approach is to render with minimal antialiasing at a much higher resolution, then convolve with an antialiasing filter kernel at the high resolution before decimating to screen resolution. This is probably not very computationally efficient. More efficient approaches might include precomputed fractional-delay filters to shift patterns by fractions of a pixel and texture-mapping with a 1-D texture representing the pattern produced by the integrated filter kernel along a line perpendicular to the line being drawn, plus some kind of linear or quadratic adjustment to account for sharp angles or sudden ends.

It's often observed that bright lines on a dark screen background are more visible to the humans than dark lines on a bright screen background; this is particularly a problem for things like visualizing two-dimensional scalar fields such as the signed response of a filter kernel. I don't have a good understanding of why this is; I wonder if it has something to do with the humans' logarithmic brightness perception, where a bit of blurriness diminishes the white around a black line by an imperceptibly tiny amount, while the same blurriness will convert the black around a white line into a slightly dimmer white.

If this is the reason, it means there's an unavoidable compromise between correct in-focus appearance (where the logarithmic perception law means we should do our convolutions in logarithmic color space) and correct out-of-focus appearance (where the defocus inside the human's eye mixes the light linearly, so we should do our convolutions in linear color space). Using strong contrast sparingly should reduce the costs of this compromise.

With these tricks, it should be feasible to get lines that are an order of magnitude more visible than the traditional 250-micron-wide 125-micron-quantization-noise Bresenham lines that Gnuplot will give you by default, while at the same time being more than an order of magnitude more precisely positioned in the X dimension (say, 10 μm), on a traditional 100-dpi, 250-micron-resolution LCD screen with vertical RGB subpixels, and nearly a factor of magnitude more

precisely positioned in the Y dimension (say, 30 μm).

On the high-dpi screens now common on hand computers — 200 dpi, or 127-micron pitch with 42-micron pitch if it has RGB subpixels, is a typical resolution nowadays — it should be possible to get positioning errors on the order of 5 μm in X and 15 μm in Y.

Still, none of this is needed for an "MVP", which can be done straightforwardly with <canvas> or SVG (possibly using d3).

What I use most in Numpy, SciPy, and matplotlib

Maybe if my calculating/plotting thing can do most of the things I can do in IPython/Jupyter, it'll be comfortable to use for a variety of things.

I looked through 16 of my recent IPython notebooks and came up with this top-64 list by frequency of use (in source code, not execution):

```
105 plot
 68 subplot
 55 *
 41 **
 40 len
 40 []
 39 [:]
 35 -
 27 xlim
 27 abs
 26 copy
 19 @
 18 matshow
 17 contour
 17 [:,:]
 16 sum
 16 '.'
 15 set_*scale('log')
 15 resize
 15 print
 15 arange
 15 /
 14 linspace
 14 legend
 14 -=
 13 max
 13 fft.fft
 13 +=
 13 [:,]
 12 stem
 12 colorbar
 12 array([])
 11 zeros
 11 ylim
 10 pi
 10 [,:]=
  9 exp
```

```
9 +
9 [,:]
9 >
8 inv
8 concatenate
8 [:]=
7 []=
7 [:,:]=
6 .T
6 cumsum(axis=)
6 '.-'
5 sin
5 shape
5 reshape
5 min
5 max(axis=)
5 gca().set_aspect('equal')
5 cumsum
5 cond
5 [:,]=
4 xticks
4 where
4 svd
4 plot(linewidth=)
4 [,]
3 sum(axis=)
3 round
```

This is from a bit over 1000 invocations of Numpy array operations and matplotlib operations. `plot` is super popular, and so is damned `subplot`, but `stem`, `matshow`, and `contour` also appear a lot. Arithmetic `*`, `**`, `-`, `@` (matrix multiply), `/`, `-=`, and `+=` are very popular; `+` is less so. Popular aggregate operations are `len`, `sum`, `max`, and to a lesser extent `min`. And `abs`, `exp`, and `sin` are surprisingly popular.

Then there are indexing and slicing operations. A *lot* of indexing and slicing operations. Like, just scalar index reads are #6, more popular than *subtraction*. It might have been worthwhile to break down the kinds of slicing a bit more: sometimes it's between two constant indices like `x[200:400]`, sometimes it's dropping some elements from the beginning `x[3:]` or the end `x[:-3]`, and sometimes it's some other calculated index like `x[pos:pos+size]`. Sometimes it's a coordinate shift, sometimes I intended to select a subset (often for plotting), etc.

Popular plotting options include `xlim`, `'.'`, `'.-'`, `yscale('log')` (and occasionally `xscale` too), `legend`, `colorbar`, `ylim`, `gca().set_aspect('equal')` (which doesn't have a convenient function in pyplot the way `set_yscale('log')` does), and `xticks`.

Popular heavy-duty algorithms are `fft.fft`, `inv`, `cond`, and `svd`. Maybe matrix multiply `@`/`dot` should be included there too.

Popular ways of generating arrays, other than arithmetic, include `copy`, `resize` (which in Numpy repeats an array, like `tile`), `arange`, `linspace`, `array([])` (converting a literal list to an array), `zeros` (typically followed by assignments), and `concatenate`, which puts the elements of one after the elements of the other.

Other miscellaneous facilities I apparently use a lot include `pi`, `cumsum`

, `.T`, `reshape` (a generalization of `.T`), and `where` (conditional: `where(a, b, c)` is `b` where `a` is true, `c` where `a` is false).

Not all of these operations would map over to other environments in exactly the same way. In particular, a lot of the plotting options are maybe things to set with the mouse.

Attaching aesthetics to data

The Grammar of Graphics refers to the visual appearances we attach to data to make it visible as "aesthetics" — as in:

> Aesthetic attribute functions are used in two ways. Most commonly, we specify a variable or blend of variables that constitutes a dimension, such as *size*(**population**) or *color*(**trial1+trial2**). Or we may assign a constant, such as *size*(3) or *color*("red").

They specifically disclaim "the derivative modern meanings [of "aesthetics"] of beauty, taste, and artistic criteria".

In GG, as in most graphics systems, data do not have aesthetics. Instead, aesthetics have data. This is also how matplotlib, d3, and Gnuplot do things. The data are floating around in vectors or whatever, and at some point they collide with a plotting command or a plot-update command, and at that point they get used, perhaps ephemerally, to generate a graphic; but subsequently they lose their connection to the graphic.

I think this is probably not the best approach for an interactive calculator with instant feedback. Instead, aesthetics and indeed a whole presentation should be attached to the data, so that the data can always be plotted in a sensible way at any point in the calculation. (Bret Victor has demonstrated some visualizations of Dan Amelang's Nile which probably inspired this thought.)

I don't know how exactly this should work. Probably if you plot two different voltages in different colors or different linewidths, they should retain those aesthetics whether you're plotting them against time or against their common current — but what if you are plotting them against each other, with one on X and the other on Y? What if the current has its own color? What color should the sum of the voltages be, or the square of one of them? I probably need to try stuff to see what feels least frustrating.

For short discrete signals, `stem` is probably the correct presentation under most circumstances, and plenty of operations on discrete signals are closed; so probably if you add two stem-displayed signals, or multiply one by a constant, you should get another one. But `stem` becomes unwieldy for sufficiently many samples. Do I need conditional formatting?

(One potential benefit of the more symbolic way I'm thinking about doing things is that discrete and continuous signals are not the same.)

Square aspect ratios — a common tweak — are nearly always appropriate when the axes are in the same dimension. But tagging every variable with units of measurement might be unwieldy. (On the other hand, it might help to associate some aesthetics with units of measurement rather than values. And `units.dat`, now `definitions.units`, gzips to 78 kilobytes.)

The implicit, conditional associations in A principled rethinking of array languages like APL (p. 1995) should help somewhat with the problem of associating varying quantities with an aesthetic — it should be just as easy to set the voltage's linewidth to be the current as to set

it to 3. (You might need some kind of scale mapping from amperes to pixels, though.)

A possible alternative is, as in the 2016 prototype, to do computation by *changing* a *variable* — for example, adding a constant to it, or multiplying it by a time-lagged version of itself — and update a pre-existing display accordingly.

Another approach, explored in Relational modeling and APL (p. 1217), is for these quantities to exist as named attributes of a model, which then has one or more visual presentations. A cylinder, for example, has a volume, a cross-sectional area, a lateral area, a total surface area, a radius, a diameter, and a length. But I'm not sure how this would work with plotting a series of different cylinder volumes against some independent variable.

Abstract model/language semantics

There are two pieces here: one is the semantic model of the *plotting*, and the other is the semantic model of the *calculation*.

I anticipate that the model of the calculation is going to be a longish document, so I'm preemptively splitting it out into A formal language for defining implicitly parameterized functions (p. 144).

Performance

JS is not going to be as fast as Fortran, as evidenced by things like PDF.js, modern JS interpreters can be coaxed to be fast enough to do some substantial computation.

Firefox takes about 3.6 seconds to run this JS on my laptop:

```
function tri(n) {
  let t = 0
  for (let i = 0; i < n; i++) t += i;
  return t;
}

tri(1000000000)
```

It also gets the wrong answer, because of 64-bit floating-point roundoff error, but that's not the point. The point is that it was able to chew through 280 million loop iterations per second. Given a 32-millisecond budget to render a graphic, it can do 9 million simple arithmetic operations like the above.

I tried it in C:

```
#include <stdio.h>
#include <stdlib.h>

long long tri(long long n)
{
  long long t = 0;
  for (long long i = 0; i < n; i++) t += i;
  return t;
}

int main(int argc, char **argv)
{
```

```
  printf("%lld\n", tri(strtoll(argv[1], 0, 10)));
  return 0;
}
```

Without optimization, it was the same speed as Firefox; with optimization, I had to make the number a command-line parameter to keep GCC from evaluating the loop at compile time, and it takes 900 ms, four times as fast. (Also, it gets the right answer, unlike JS.)

So the cost of JS for this simple integer numerical code is about a factor of 4. So JS on my laptop or my phone is faster than C on my netbook. And my rule of thumb is that code in Numpy takes 5× longer to run than reasonably written C, so JS might actually be faster than Numpy. We just need to compile the dataflow graph into nested loops in JS before evaluating it in order to get that delicious JITty goodness!

I tried to test array indexing speed but all I found out was that integer division is super slow and now I need to redo everything below

But JS array indexing is bounds-checked, so it might be a lot slower than C. So I wrote these quick functions in Firefox's inspector console to see:

```
function leap(a, n) { let m = a.length, j = 0; for (let i = 0; i < n; i++) { a[j]
 += i; j = (a[j] + j) % m; } }

function time(t) { let a = new Date(); let b = t(); let c = new Date(); return [c
-a, b]; }
function repeat(x, n) { return new Array(n).fill(x); }
```

Thus `time(() => leap(repeat(0, 8), 5000000))` gives 1.49–1.51 seconds (in another run, mentioned below, after a reboot, 1.23–1.28 seconds instead); at 10 million it gives 3.09–3.11 seconds. *Enlarging* the array to 8192 *speeds up* both of these, 5 million to 1.09–1.12 seconds; enlarging it further to 65536 speeds up 5 million to 9.91–1.02 seconds; at 16777216, 2.3–2.6 seconds; at 1048576, 1.46–1.52 seconds; at 2097152, 1.32–1.37 seconds; at 33554432, 3.9–4.6 seconds. Moreover, at 33554432, doubling the loop count to 10 million only extends the time to 5.5–6.9 seconds. It doesn't start to get linear again until 20 million, at 8.5–9.6 seconds.

(I did three trials of each one to get some idea of the variability, but probably the JIT is too unpredictable for just three trials to be decent.)

I don't know what to make of this precisely, but it seems like for small arrays, it can do 3 to 5 million of those Array inner loops per second, which is enormously less than the 280 million it was getting for just adding the loop counter, and then starts to get slower presumably due to cache effects for indexing arrays over 32 mebi-items.

To see if the optimizer is replacing the % with a &, I tried reducing the array size to 33554431, which didn't make any difference. This suggests that maybe I should try explicitly using & to see if the 97% of the work this program is doing has a lot of division in it.

At 10 seconds, Firefox shows its warning that "a web page is slowing down your computer", offering the option to kill the computation; this is a thing to beware of.

Typed arrays

To compare, I tried `time(() => leap(new Float32Array(8192), 5000000))` and got 0.964–0.969 seconds; Int32Array gave 0.924–0.935 seconds; Uint8Array gave 0.50–0.53 seconds; Uint16Array gave 0.74–0.76 seconds; Uint32Array gave 1.170–1.172 seconds; and Float64Array gave 1.21–1.23 seconds. Both of these last two are slower than just using `Array`. This is well below the size where cache effects came into play, and the `leap()` loop is specifically designed to not be vectorizable, so I don't know why the smaller data types give a performance boost (up to 10 million iterations per second!).

To see if we get big caching effects, I tried `time(() => leap(new Float64Array(33554432), 20000000))` and got 8.35–8.41 seconds; with Float32Array I got 5.9–6.2 seconds; and, astonishingly, with Int16Array — which I expected to be *faster* — I got 14.6–15.3 seconds.

I don't think these results are predictable enough to draw very precise conclusions about whether, or even when, typed arrays help or hurt performance. They seem to help performance by a factor of 2 in some cases and hurt it by a factor of 1.5 in others. Maybe a better benchmark function would help.

Adding methods to arrays makes no difference

After the reboot mentioned below, I thought I would try `time(() => { let a = repeat(0, 8); a.method = function(x) { return "hi, " + x; }; leap(a, 5000000)})` to see if the extra method on the array frustrated Firefox's optimizer. (This is a thing I'd done in 81hacks and always wondered if it was the reason for what seemed to me to be relatively poor performance.) It didn't make any difference: it took 1.262–1.265 seconds, within the 1.23–1.28 range observed immediately previously.

However, it's certainly possible that the bottleneck in `leap()` isn't actually the array indexing! (It turns out to be true, so I need to redo this test.)

Memory use

I tried running `x = repeat(0, 1024*1024*64)` and had to reboot after Firefox allocated a few gigabytes of virtual memory.

After rebooting, it was hard to tell which of the many Firefox processes to watch in htop. `x = repeat(0, 16777216)` did not make it apparent. It turned out to be pid 4172, as revealed by `f = n => (n < 2 ? 1 : f(n-1) + f(n-2)); f(36)`, using 1839MB VSZ, 336MB RSS. Rerunning the `repeat` boosted that to 2366MB VSZ, 858MB RSS, a difference of 527 and 522 megabytes respectively. That suggests that each array item is occupying a bit over 32 bytes, which is four times what I expected. `delete x` returned the process to 1976MB/465MB.

Presumably typed arrays should reduce this substantially, and indeed, after `x = new Uint8Array(16777216)`, we see 1972MB/479MB, a 14MB jump in RSS, close to the expected 16MB. `delete x` has no effect (481MB remained constant before and after) but `x = new Float64Array(16777216)` boosts memory use to 2257MB/606MB, 285MB and 127MB respectively; the latter is very close to the 128MB you'd expect at 64 bits (8 bytes) per array item.

So native JS arrays are four times more expensive on memory use

than you'd naively expect, while typed arrays have exactly the memory price they say on the tag, which can be more than an order of magnitude better. Given that there's no consistent runtime cost for using typed arrays, though also no consistent benefit, it is probably better to use typed arrays by default for numeric data arrays. (Presumably using typed arrays will make *other* code run faster by reducing the load on the garbage collector.)

How I found out the speed tests above were totally wrong

This took 1.0–1.4 seconds: `time(() => { const a = repeat(3, 16777216); let t = 0; for (let i = 0; i < a.length; i++) t += a[i]; return t })`. That's, like, 10 or 20 million array indexing operations per second. However, this still took 0.9 seconds: `time(() => { const a = repeat(3, 16777216); let t = 0; for (let i = 0; i < a.length; i++) t += i; return t })`. So it wasn't really the array indexing in the loop; it was the `repeat` function above. Changing to `time(() => { const a = new Array(16777216); let t = 0; for (let i = 0; i < a.length; i++) t += i; return t })` gives 61 milliseconds instead, 15 times faster — so it was the `.fill()` call.

It only takes 73–75 ms to run `time(() => { const a = new Float64Array(16777216); let t = 0; for (let i = 0; i < a.length; i++) t += a[i]; return t })`, which just totals up all the zeros. But I'm not sure how far I can trust Firefox's optimizer here.

This version takes wildly varying times from 168 ms to 639 ms: `time(() => { const a = new Float64Array(16777216); for (let i = 0; i < a.length; i++) a[i] = 3; let t = 0; for (let i = 0; i < a.length; i++) t += a[i]; return t })`. Using `Array` instead slows it to 0.9–1.5 seconds, which is probably slower than calling `.fill()` inside `repeat`.

So, I don't know. Loop analysis and bounds-checking hoisting is easier with loop counters, and maybe that's what accounts for the difference. Certainly my earlier typed-array tests weren't calling `.fill()`; they just relied on the implicit zero-filling provided by these constructors (even the float ones), which, as we see above, is much faster than what I was doing. So maybe it really was the inner-loop division.

Here's a division-free version specialized for power-of-two arrays:

```
function laap(a, n) { let m = a.length-1, j = 0; for (let i = 0; i < n; i++) { a[o
oj] += i; j = (a[j] + j) & m; } }
```

And, with that, `time(() => laap(repeat(0, 8), 5000000))` takes 50–80 ms. On my netbook, it takes 270–310 ms, or 370–420 ms on the netbook in Chromium. I totally fucked up by using division! `time(() => laap(repeat(0, 8), 500000000))` takes 5.36–5.37 seconds, so 93 million loop iterations per second.

I was going to say, "This explains why there was no difference (usually) between JS arrays and typed arrays," but it turns out `time(() => laap(new Float64Array(8), 500000000))` is still three times as slow as the plain-Array version above. Still, the better benchmark function probably will make it easier to understand what differences do exist.

Argentine electric bill

Kragen Javier Sitaker, 2019-12-18 (3 minutes)

Now that I've been living here for a year and a half, the electric utility finally got around to installing an electric meter. My bill for the first 31 days, from 2019-10-28 to 2019-11-28, is 68 kWh, and it works out to AR$497.98. Most of this, AR$278.94, is the installation of the meter, although supposedly we'd already paid AR$2000 for that; the remainder is divided into a "fixed charge", AR$21.37, and a "variable charge", AR$90.62. This adds up to AR$390.93, to which are added a "municipal contribution" of 6.383% or AR$24.95 and the value-added tax of 21% or AR$82.10, for the total of AR$497.98.

However, they explain they're actually only charging 15 of the 31 days, perhaps because that's when they installed the meter. The "fixed charge" is AR$43.46 per 31 days (presumably this has to do with maintaining the electrical connection?) while the "variable charge" is given as a "unit price" of 2.832, which is multiplied by 32 kWh (apparently 68 multiplied by 15/31 and rounded down, although this calculation makes no sense) to get AR$90.62.

So, in effect, I'm being charged AR$2.832 per kilowatt hour, plus 27.383% of taxes, for a total of AR$3.60748656 per kilowatt hour. At the AR$64.50 per US$ rate that was current last weekend when I checked the prices in Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196), this rounds to US$0.056/kWh, rounding. In diagonally printed letters that make it difficult to read several of the numbers, the bill helpfully explains, "CONSUMO CON SUBSIDIO DEL ESTADIO NACIONAL", consumption subsidized by the national government, even though I'm being charged AR$82.10 of VAT on it.

The new president has just announced a 180-day freeze in electricity and gas prices, which presumably means that this already relatively low energy cost will drop by another 15% or so as our currency inflates --- though whether the drop is 10% or 40% is really anybody's guess at this point.

68 kWh in 15 days is 190 watts, which is a surprisingly low consumption level given how much of the time I've had the air conditioner running, as well as cooking on an electric stove. Presumably this would be doubled if I had a refrigerator. The apartment is wired for 66 amps at 240 V, of which 20 goes to the stove. 66 amps would be 15.8 kW, which would be US$21.24 per day or US$646 per month at this price. Such great consumption might, however, change the category of service and cause variability in the fixed charge.

This at last tells me the cost of the energy to run the air conditioner. If I can trust the label, it sucks 4.5 amps and delivers 2700 kcal/hour (= 3100 W) of cooling. 4.5 amps at 240 V is 1080 W, so that's AR$3.90 per hour or, at the moment, US$0.06 per hour. In all likelihood, the depreciation on the air conditioner is greater than that; various similar portable air conditioners cost AR$25000, which is about 6000 hours of operation.

Flexible text query

Kragen Javier Sitaker, 2018-07-14 (4 minutes)

Here's an example of the problem I want to solve. I have a crontab which records my battery capacity estimates from the OS once a minute; here's a sanitized transcript:

```
$ crontab -l
# m h  dom mon dow   command

*  *  *  *  *  (date; date +date=\%s; cat /sys/class/power_supply/BAT0/ueven
ot) >> .battery-samples
$ tail ~/.battery-samples
POWER_SUPPLY_CAPACITY_LEVEL=Normal
POWER_SUPPLY_SERIAL_NUMBER=
Sat Jul 14 16:40:01 -03 2018
date=1531597201
POWER_SUPPLY_NAME=BAT0
POWER_SUPPLY_STATUS=Discharging
POWER_SUPPLY_PRESENT=1
POWER_SUPPLY_TECHNOLOGY=Li-ion
POWER_SUPPLY_CYCLE_COUNT=0
POWER_SUPPLY_VOLTAGE_NOW=11400000
POWER_SUPPLY_POWER_NOW=20508000
POWER_SUPPLY_ENERGY_FULL=45828000
POWER_SUPPLY_ENERGY_NOW=24886000
POWER_SUPPLY_CAPACITY=54
POWER_SUPPLY_CAPACITY_LEVEL=Normal
POWER_SUPPLY_SERIAL_NUMBER=
Sat Jul 14 16:41:01 -03 2018
date=1531597261
POWER_SUPPLY_NAME=BAT0
POWER_SUPPLY_STATUS=Discharging
POWER_SUPPLY_PRESENT=1
POWER_SUPPLY_TECHNOLOGY=Li-ion
POWER_SUPPLY_CYCLE_COUNT=0
POWER_SUPPLY_VOLTAGE_NOW=11400000
POWER_SUPPLY_POWER_NOW=20565000
POWER_SUPPLY_ENERGY_FULL=45828000
POWER_SUPPLY_ENERGY_NOW=25216000
POWER_SUPPLY_CAPACITY=55
POWER_SUPPLY_CAPACITY_LEVEL=Normal
POWER_SUPPLY_SERIAL_NUMBER=
```

Now suppose I want to plot battery capacity over time. Getting the capacity itself is easy enough:

```
$ grep -a _FULL= ~/.battery-samples
...(29000 lines omitted)...
POWER_SUPPLY_ENERGY_FULL=45828000
POWER_SUPPLY_ENERGY_FULL=45828000
POWER_SUPPLY_ENERGY_FULL=45828000
$
```

(The -a is necessary because there's a block of 541 NULs that got in there last Wednesday, presumably due to some kind of filesystem corruption on power loss.)

But this only gives me the Y-coordinate. The X-coordinate of time is missing.

Now, I could write it this way:

```
$ perl -lne '$date = $1 if /date=(.*)/;
             print "$date $1" if defined $date
                              and /_FULL=(.*)/' ~/.battery-samples
```

And I can plot that with gnuplot, and it looks right:

```
$ perl -lne '$date = $1 if /date=(.*)/;
             print "$date $1" if defined $date
                              and /_FULL=(.*)/' ~/.battery-samples |
  gnuplot -p -e "plot '-' with linespoints"
```

And that works. But it's a relatively large amount of hacking for a fairly simple task. If we want to include both POWER_SUPPLY_ENERGY_NOW and POWER_SUPPLY_ENERGY_FULL, it's going to start to be complicated.

What I really want here is an interaction like:

- Show me the lines that say date=.
- Okay, now infer POWER_SUPPLY_ENERGY_FULL from the next line that says POWER_SUPPLY_ENERGY_FULL=
- Okay, now infer POWER_SUPPLY_ENERGY_NOW from the next line that says POWER_SUPPLY_ENERGY_NOW=.
- Okay, now display just date, POWER_SUPPLY_ENERGY_FULL, and POWER_SUPPLY_ENERGY_NOW as columns.

At the command line, this could be something like:

- q2 date=
- q2 date= +_FULL=
- q2 date= +_FULL= +_NOW=
- q2 'date=(.*)' '+_FULL=(.*)' '+_NOW=(.*)'

For logfile processing, it's common to want to limit matches to a particular request ID and to exclude "noise" events based on some other kind of pattern. So it's useful to conceptualize this process as the repeated execution of some possibly nondeterministic program:

- First, find date=, and save what comes after it; discard upon fail.
- Then, search forward for _FULL=, and save what comes after it, discarding upon fail; then return to the position from step 1.
- Then, search forward for _NOW= and save what comes after it, discarding upon fail; then return to the position from step 1.
- Then, display the three saved strings.

You could imagine, for example, running one of these subordinate steps on the set of lines that contain "id=$1 ", where $1 is a previously captured id. You don't want to necessarily constrain the entire rest of the query to do that. And you might want to be able to emit nested structures here, and exclude domains in a known spammer list, and whatnot.

This is pretty similar to what I need for my mailreader qyap: I have a nested structure of mail message threads to extract from a possibly out-of-order mailbox (or more than one), and I might want to hide particular threads or subthreads.

(I've done something like this previously with batchagenda.py.)

The Z-machine memory model

Kragen Javier Sitaker, 2017-07-19 (4 minutes)

I was reading about the Z-machine and playing around with "Lists and Lists", which is a Lisp tutorial interactive-fiction game running on the Z-machine, playable online in Parchment at http://eblong.com/zarf/zweb/lists/.

I was struck by the fact that the basic Z-machine memory model has a combination of two properties very rarely found together: it has no dynamic allocation (and thus no possibility of out-of-memory errors and no need for a garbage collector), but it supports flexible collections and relationships of objects, like Lisp. Also, the basic operations on its memory model are constant-time.

The basic memory model of the Z-machine is a fixed set of objects ("Things", originally) which are referenceable by integer IDs, arranged into an ordered tree. (Or, really, a forest, since there can be any number of separate roots.)

Mutating the tree structure is normally done with this single Z-machine opcode (from http://inform-fiction.org/zmachine/standards/z1point1/sect15.html):

insert_obj: Moves object O to become the first child of the destination object D. (Thus, after the operation the child of D is O, and the sibling of O is whatever was previously the child of D.) All children of O move with it. (Initially O can be at any point in the object tree; it may legally have parent zero.)

Navigating the tree structure is done with three opcodes:

get_child: Get first object contained in given object, branching if this exists, i.e. is not nothing (i.e., is not 0).
get_parent: Get parent object (note that this has no "branch if exists" clause).
get_sibling: Get next object in tree, branching if this exists, i.e. is not 0.

(In addition to the tree structure, the objects have arbitrary mutable fields ("properties") drawn from a small set of 64 field IDs, with values containing a variable amount of data up to 64 bytes, but usually 1 or 2 bytes; they also have 48 boolean "attributes". And they have a "short name" too. Each of the 64 possible properties has defined a "default value" in a "property defaults table" which is returned when you try to read that property from an object that doesn't have it. These aspects of the object memory are somewhat incidental, but without some way of associating other data with the objects, the whole tree thing would be almost pointless. Also, you can access memory as an array of bytes.)

In order to make get_parent and insert_obj constant-time and fast, each object has a redundant parent pointer.

The typical kinds of interactions in text adventure games involve doing things like listing the objects in a room, or searching through the objects in a room to see which one the player is referring to, and whether that might be ambiguous; they aren't sensitive to the ordering of the objects in the room.

So I was wondering what kind of Lispy generic functions you could write on top of this ruthlessly-side-effect-filled structure. Clearly you can write a constant-space function that visits every object in a subtree, for example, or moves all the objects in a subtree, or all the children, to a given other object. But can you write

general-purpose utilities to raise the level of abstraction at which you program? It seems like CLU-style coroutine iterators might be the best you can do in many cases.

Fukushima leak

Kragen Javier Sitaker, 2014-04-24 (6 minutes)

The recently-revealed continuing leaks of radioactive contaminants from Fukushima, although they are 500 times smaller than the initial release and 100 million times smaller than the natural radioactivity of the Pacific Ocean, could still be dangerous to local ecology and human health, but does not represent a global catastrophe.

This is my conclusion as a non-expert in the field summarizing the publicly available information. It could be wrong.

Details follow.

Different accounts give different amounts of radioactive water leaked into the Pacific from the Fukushima nuclear plant via continuing leaks. Some of them give the amount, rather uselessly, in tons, but the better accounts give the amount of radioactive material in the water in becquerels. One TV report says it's a PBq, but that sounds like it's probably referring to part of the initial, much larger release; other reports give the amount as 10 to 50 TBq: More Fukushima Fallout and a Japan Times article say 30 TBq, Asahi Shimbun's article says 24 TBq, while National Geographic's article gives the groundwater concentration of radioactive cesium in places as around 1kBq/kg, gives the total release as 0.3 TBq/month, describes the immediate aftermath of the disaster as a release of around 10PBq, and contextualizes it by comparing to the 89 TBq release of cesium-137 from the Hiroshima bombing.

The raw becquerel numbers are sort of meaningless without context on how big a becquerel is. Mijlkovic's 2012 article says:

> 9.3 percent of the catches exceeded Japan's official ceiling for cesium, which is 100 becquerels per kilogram (Bq/kg). ... Canada's much higher ceiling, which is 1,000 Bq/kg

Comparing to natural radioactivity, typical rocks and dirt have hundreds of Bq/kg, mostly due to potassium, but with significant amounts due to uranium, thorium, and radium. Seawater has on the order of 10 Bq/kg, almost all due to potassium. A human body contains on the order of 10 kBq, mostly due to potassium and carbon-14. The Pacific Ocean naturally contains about 7000 EBq, because it contains about 700 million km³ of water.

That means that, purely in terms of increased radioactivity, the leak is so small as to be insignificant. A 70 TBq leak of radioactivity would be 100 000 000 times smaller than the natural radioactivity of the Pacific Ocean. Increasing the radioactivity by one part in a hundred million is not dangerous; if all radioactivity were equivalent, it wouldn't even be detectable. Even the initial 10PBq release was only enough to increase total Pacific Ocean radiation by about one part per million.

The fatal dose of cesium-137 is on the order of 100MBq/kg for dogs. So a 70TBq leak, if not sufficiently diluted, is enough to kill about 700 000 kilograms of dogs or other similar animals, such as people — about ten thousand people.

However, it's sensible to have different safety limits for different radioactive elements, because some of them, like potassium, are biologically regulated at a constant level — so eating more radioactive

potassium probably doesn't increase your exposure to radiation at all — while others bioaccumulate, like strontium-90, which replaces calcium in your bones and can therefore continue irradiating you for the rest of your life. Cesium bioaccumulates to some extent, so it becomes more concentrated in animals than in plants, more concentrated in predators than in herbivores, and more concentrated still in secondary predators like tuna. Tritium, a third radioactive contaminant in this case, is not known to bioaccumulate, but it also isn't homeostatically bioregulated like potassium; chemically, it's almost identical to hydrogen.

Also, the radioactive material is not evenly distributed. Ocean-caught fish from near the Fukushima reactor had levels up to tens of kBq/kg in 2012, hundreds of times higher than normal fish, and we can reasonably expect that fish that feed in areas where the water has been released will continue to be contaminated to much higher than normal levels, perhaps 100 times higher than normal. However, it's believed that the water that has leaked has already had most of its radioactive cesium removed, unlike the water that leaked early on; strontium-90 may be a bigger concern now.

So there are real health concerns, but they are not very large with the current size of the leak.

The National Geographic article says that the total amount of contaminated water stored, now and in the future, is on the order of a million tons; only a third of that is there now. Unfortunately, I don't have a good handle on how many becquerels that water contains. It appears that the total water loss was 300 tons, mixing into 400 tons per day of groundwater; that gives us roughly 30 TBq/300 tons or 11 MBq/kg, about a million times more radioactive than natural seawater. A million tons of 11MBq/kg water would add up to 10PBq, roughly the same size as the initial Fukushima disaster. So, in a worst-case scenario where all the tanks vented into the ocean, it would be roughly comparable to the initial incident, and despite bioaccumulation of strontium, probably would not be enough to cause more than local ecological damage.

Topics

Transactional screen updates

Kragen Javier Sitaker, 2015-04-01 (10 minutes)

So I was thinking about one of my usual hobbyhorses: how to design an entire usably efficient interactive computing system as a pure function of some mutable, but in some way orderly, state.

History

The basic idea goes back to McCarthy's "Elephant 2000" proposal, where you define a data processing system in terms of keeping commitments based on its past history, and then the compiler figures out what information the data processing system needs to store about that past history to comply with its commitments. That is, the entire data structure of the system is purely the result of compiler optimization. You just make assertions about the relationships between past events and the system's outputs, and the compiler produces a running system that satisfies those requirements.

I explored it a bit in "rumor-oriented programming", where the idea was that you accumulate an ever-growing history of "rumors" that get automatically synchronized between your devices (because you only ever add new ones, synchronization is trivial and guaranteed to be convergent, though potentially expensive) and the actual screen you see is the output of a query over that rumor history, using a query language that doesn't expose the order in which the rumors arrived on the current device; then you have buttons and shit that add new rumors and possibly cause like a recomputation of the query result you see on the screen.

I also explored it a bit in "dependency-driven composition, or make for websites", where the idea is that you use a `make`-like build process over a dependency graph of resources. Some resources are human-produced and editable, while others are produced on demand from other resources, and then cached.

This is all closely related to functional reactive programming, which is perhaps unsurprisingly (at long last!) getting a lot of attention in the last couple of years in the JavaScript world, with React, Angular, and Meteor all becoming suddenly popular.

Automatic dependency detection

A simpler model than `make` for dependency-driven recomputation in the world of building software projects is `redo`, which was designed by Daniel Bernstein and later implemented by Avery Pennarun. The idea of `redo`, as I understand it, is that the script to build a file `foo` is contained in the file `foo.do`, which is a shell script which recursively invokes `redo` to ensure that each of the things `foo` depends on is up to date, and then does whatever it needs to do to build `foo`. Because `redo` knows that it was trying to build `foo`, it can tell that each of those recursive calls represents an edge in the dependency graph.

This is closely reminiscent of how optimistic STMs (software transactional memories) detect transaction conflicts and automatically retry the transactions. Within a transaction, you read some set of STM variables and write some other set of them, and the STM records each of those sets; when the transaction goes to commit, it

atomically publishes your set of writes, but only if no transaction has written to some variable that you read since the time that you read it. If so, your results are discarded and automatically retried. (This is also, I think, closely related to how speculative instruction execution works in CPUs, although I don't know the details.)

In a sense, the STM has concluded that since it's possible all of the writes could have a dependency on any of the reads, so it needs to discard them and rerun the transaction if any of those variables that have been read has changed.

This is very similar to how Meteor detects dependencies in its dependency graph: if a Meteor-controlled reactive computation reads from a reactive variable, that variable records a dependency, which it can then choose to invalidate later. Unlike `redo`, and similar to optimistic STMs, this causes that reactive computation to be eagerly rerun, a policy choice which I suspect can lead to exponential-time execution from diamonds in the dataflow graph.

The delightful thing about this kind of tracking, taken advantage of by all of Meteor, optimistic STMs, and `redo`, is that it doesn't depend at all on the internal functioning of the computation that it's re-executing; it only has to be able to re-execute it on demand and intercept its I/O, and trust that it is deterministic. You could even imagine an "STM server" which provides these services over the network, although it has to trust its clients to retry when they get a commit rejected.

(I confess I haven't actually used Meteor or `redo`, so I could be totally confused about them.)

The other interesting thing about it is that, usually at least, you can do a simple version of it with very little actual dependency tracking. You can just re-execute stuff blindly. This is how Pennarun bootstraps `redo`.

Dependency-driven and immediate-mode GUIs

So, what if we try to take this kind of thing all the way to pixels on the screen? Like, it would be super cool if I could write some kind of straightforward computation over, I don't know, an editor buffer of text in some form, some kind of specification of where I'm scrolled to in that text, and a font, that results in setting some pixels on the screen, and results in smallish recomputations. It would be even better if I could, like, write a thing that parses HTML and CSS and lays out boxes on the screen and draws glyphs into them, and have that be able to automatically detect changes in the CSS and figure out which parts of the screen they affected.

A crucial part of this is that if you want the dependency-tracking overhead to be small, the dataflow graph probably has to be relatively small, which means the nodes in it have to be fairly large; and if you want a recomputation to be small, the nodes in it have to be relatively small. To be concrete, in the editor example, if there's a change to a part of the text that isn't displayed on the screen, you'd probably prefer to not have to recompute the entire screen contents from scratch; and maybe if there's a change on one line of the screen, it would be nice to redisplay just that line.

There's a somewhat relevant field of work called

"immediate-mode GUIs", popular in videogames, where you don't try to avoid redrawing the screen, part of the reason being that in a videogame you typically redraw the screen 60 or 120 times a second anyway. Immediate-mode GUIs don't have data objects that stick around in memory in some kind of nested window tree structure, the way regular ("retained-mode") GUIs do; instead you do things like this:

```
set_drawing_background(start_button_background);
if (button(120, 200, 600, start_button_height, "Start!")) start_game();
```

which redraws the button in the specified position, with its possibly updated height, and then checks to see if the user has just clicked their mouse in it. The button has no persistent existence in memory, other than as pixels in the framebuffer that have changed color, but while control flow is down inside of it, it exists on the stack and can react to the mouse click.

I feel that immediate-mode GUIs are a lot easier to program — for example, the above example doesn't have to add an event listener to redraw when `start_button_background` or `start_button_height` change, nor does it have to worry about when to destroy the button object — and they use less RAM.

The analogy here is between immediate-mode and retained-mode graphics systems. `<canvas>` is immediate-mode; SVG is retained-mode. Both have their performance advantages. One of the potential disadvantages of immediate-mode drawing is that you have to draw all the pixels on the screen every frame, even when they haven't changed.

So, suppose you execute some series of transactions to draw your immediate-mode GUI on the screen. Each transaction updates some region of pixels on the screen, having read some set of reactive variables (the window size, the text buffer contents, the clock, etc.) and executed some deterministic computation driven by them.

Can we use this to improve the efficiency of immediate-mode GUIs in the case where the entire screen is not actually changing? It's not super straightforward, but I think so. If your `start_button_height` is tracked by something like Meteor, you can automatically rerun the draw-button transaction; and if it fails to overwrite pixels that it was previously overwriting, you can rerun the transactions that generated those pixels in order to get them back. (Or maybe you could retain the pixels in a backing store.)

If you're doing alpha compositing, of course, you may have to redraw the background pixels you're blending the button with first.

¿Se puede armar un colector solar de agua caliente que anda en invierno acá en Buenos Aires?

Kragen Javier Sitaker, 2017-04-17 (2 minutes)

Depende. Hice algunos cálculos que sugieren que sí. Si tenés 40m² de techo, estamos a casi 35° de latitud, y en el solsticio el sol llega a casi 24° de latitud de norte, tenés una elevación de 90°-59° = 31°, y sen 31° = 51.5%, así que tu techo de 40m² cuenta con solo 20.6 m² de sol; el constante solar es alrededor de 1kW/m², así que tenés tipo 21 kWt disponible al mediodía solar. Si supongamos que tenemos tipo un tercio de eso en promedio en el recorrido del día, tenés un promedio de 7kWt; si su colector es de una eficiencia de 50%, cosa fácilmente alcanzable, será de 3.5kWt. Si lo estás usando para calentar agua de 10°C a 40°C para tu casa, lo cual necesita (40-10)·4.2 kJ/kg ≈ 126 kJ/kg, podés calentar tan solo 2400 kg de agua por día. Pero probablemente necesitás menos de 100 para ducharte y lavar los platos y la ropa. Así que un día de sol te da lo suficiente de calor para aguantar 23 días de nubes sin calentar tu agua con gas.

Hay otros usos de calor en la casa, tales como calentar el aire, cocinar, secar ropa, y deshidratar frutas, pero son tan pequeños al lado del costo de calentar el agua que podemos considerarlos errores de redondeo.

Así que, para mí, es fácilmente alcanzable con la cantidad de sol que nos alcanza hasta en el medio del invierno. La cuestión es construir la cantidad de colector solar y que puede bancar una diferencia de temperatura de más de 30°C.

Rubber wheel pinch drive

Kragen Javier Sitaker, 2019-08-16 (updated 2019-08-18) (8 minutes)

I ran across some discarded stroller wheels on the way home, which I resisted the temptation to bring home. They had hard rubber around the outer rim (of about 200-mm diameter and 20-mm thickness), and it occurred to me that a motor shaft pressed directly against that outer rim would be an effective way to drive it with a fairly large mechanical advantage for mobile robotics.

Pressing the motor shaft against the wheel

Suppose we mount a motor above the wheel with its axis parallel to the wheel and its 10-mm-diameter shaft running across the top, held in one bearing on each side of the wheel, each of which is pressed toward the wheel axis by some kind of mounting preload, thus pressing the shaft into the rubber. Steel on rubber has a frictional coefficient around 1, so the bearing radial load needs to be a bit larger than the maximum drive force we need to be able to apply to the wheel. And we have about a 20:1 mechanical advantage in the torque sense (but 1:1 in the sense of linear motion).

Let's say the robot weighs 10 kg and thus 98 N, so we want at least 30 N of force to be able to handle reasonable slopes with some reasonable acceleration and deceleration. With the 5-mm radius of the shaft, we need 0.15 N m of torque from the motor, or 0.11 foot-pounds in medieval units. This is a reasonably large amount of torque; many small electric motors cannot provide it. Ten watts at 30 N is 330 mm per second, a very slow walking sort of speed, at which speed the wheel would be turning 1.9 revolutions per second (113 rpm), and our hypothetical 10-mm-diameter shaft 38 revolutions per second (2300 rpm), which is not an outrageously low speed for a modern small motor, but somewhat lower than optimal. Also, the 10-mm shaft is enormously larger than most small motors have.

So it would be nice to be able to use a smaller shaft in this way, thus getting more mechanical advantage and not needing to attach a thicker shaft to the motor. But if we take a shaft that's much thinner than 10 mm, mount it through bearings on both sides of the wheel 20 mm apart, and press down on the bearings with, say, 50 N or 100 N of force, the shaft will probably bend in the middle, yielding, and be ruined.

A 10-watt NMB motor

I don't know what a typical motor in this power range is like these days, but on the strength of Digi-Key having 221 of them in stock, I'll consider the Minebea DIA42B 10W 31A as a representative. Digi-Key charges US$33 for it, which seems high.

The DIA42B 10W is a ten-watt 24-volt BLDC motor optimized for 500–3500 rpm (running up to 4000 rpm with no load at 300 mA), and although it's only rated for ten watts, it's also rated for ten amps. It weighs 150 grams and it's 42×42 mm with a 6-mm-diameter shaft. It has a 100-pulse-per-revolution rotary encoder. The torque curve on p. 13 of the datasheet shows it at almost 6000 rpm at no load, 60 mN m of torque at 3500 rpm, 90 mN m of torque at 2000 rpm,

100 mN m of torque at 1000 rpm, and about 105 mN m at its 500-rpm minimum speed. At these high torques it's sucking up to 2 amps of current, so if you keep it up it'll burn up; what I think is its top sustainable current of about 400 mA would give you about 20% to 40% of those torques, about 20 mN m.

At the surface of its 6-mm-diameter shaft, 20 mN m works out to 6.7 N, which is significantly lower than 30 N but would still permit significant robot movement, especially if the robot ends up lighter than suggested above. Clearly gearing it up further by using a thicker shaft would be bad!

Rollers

So, how could we press this 6-mm shaft against the wheel, other than running it between bearings 20 mm apart on opposite sides of the wheel? We could press it onto the wheel by backing it with two rollers, not themselves in contact, which trap it in a triangle of compression between the wheel and the rollers.

But the rollers can't be very large. If they're 6 mm in diameter themselves, then they could be as far as 180° apart viewed from the motor shaft before they hit the wheel, but then we haven't really solved the problem, just reduced it by a factor of 2 or 3. If we make them larger, we can improve that situation, but soon they hit the wheel.

However, if we make the rollers out of stacks of parallel discs with spacers between them on a shaft, like hard disk platters, we can *overlap* them, though not arbitrarily far. If the shaft diameter approaches zero, each disc of roller A can extend to the center of roller B, and vice versa; with a physically plausible shaft diameter, they need to be somewhat further out. The discs could be, for example, 1.4 mm in thickness with a 1.6 mm space between them, with somewhat rounded edges, so that the 6-mm shaft only needs to span spans of about 2 mm unsupported from one direction.

For example, you could imagine 16-mm-diameter discs on 9-mm shafts (including the spacers), yielding 11 mm distance from roller center to motor-shaft center and 13 mm distance between roller centers (including ½ mm of clearance). This means that the motor shaft center will be sqrt($11^2 - 6½^2$) mm or about 8.87 mm away from the roller-center-to-roller-center axis. This means that the bottom of the motor shaft will be 11.87 mm from the roller-center-to-roller-center axis, while the roller edges are only 8 mm from it, so they won't touch the wheel. They could even be a little bigger than that.

Bigger rollers would mean not only more stiffness but also improved leverage to overcome the friction in the rollers' bearings, and thus less friction loss.

A quadcopter motor

Consider a higher-powered modern BLDC motor, the Turnigy BC2836-8 quadcopter motor I used as my example in Drone cutting (p. 1106). It has a 4-millimeter shaft and delivers 336 watts at 15000 rpm on 14 volts; this suggests an output force of almost 100 newtons at the surface of the 4-mm shaft --- ample to drive the wheel in this way, but definitely needing something like this roller system.

If you try using the same two rollers, the motor shaft center will be

sqrt(10² - 6½²) mm or about 7.6 mm from the roller-center-to-roller-center axis, and the shaft edge 9.6 mm from it, slightly over the 8 mm of the rollers themselves.

Multiple motors

You could reasonably easily connect multiple motors to the same wheel in this fashion, just clamping them on around its upper rim.

Varying wheel sizes

The wheel in this system is only being used to transfer linear motion from the surface of some motor shaft to the road or floor, so the calculations here are entirely insensitive to the wheel size --- it would work in precisely the same way with rollerblade-sized wheels as stroller-sized wheels, applying the same amount of force to the road at the same speeds. The only relevant difference would be that, driving a smaller wheel, the rollers would have a bit more clearance to avoid contacting the wheel.

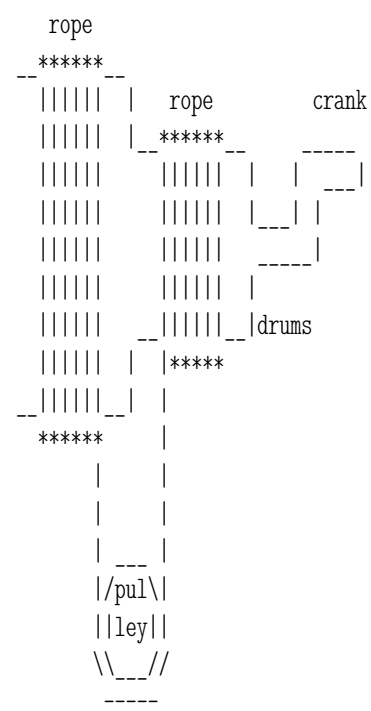
Spiral chinese windlass

Kragen Javier Sitaker, 2019-07-23 (updated 2019-07-24) (7 minutes)

(Related to Differential spiral cam (p. 512), which describes a way to use a similar mechanism to get a complex programmed sequence of motions from a simple mechanism.)

The standard Chinese windlass mechanism

The standard Chinese windlass mechanism gets a very large mechanical advantage from a simple mechanism by using a pulley as a differential:



Rope is wound in the same direction around two drums of different sizes which rotate together, typically turned by a hand crank, or by another wheel with an endless chain or rope or belt around it; rotating the drums will always pay out rope from one and take up rope from the other. The rope runs down from one drum, around a free-hanging pulley, and back up to the other drum. So the pulley moves up or down by half the difference in the rope paid out from one drum and taken up by the other.

Through the magic of the differential mechanism, this very simple mechanism provides an arbitrarily large mechanical advantage, inversely proportional to the absolute difference in diameter of the two drums. If the two drums are equal in size, the mechanical advantage is infinite.

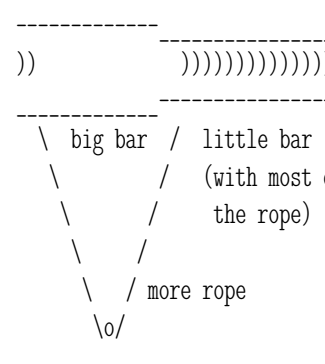
To take a more practical example, if you want to lift two tonnes (20 kN) by exerting 100 N on a 200-mm-radius crank, you need a mechanical advantage of 200: a 2-mm difference between the two drums will provide you with this. (That's in radius; it's a 4 mm difference in diameter.) Perhaps one drum is 50 mm in diameter, while the other is 54 mm in diameter, or perhaps one is 400 mm in diameter, while the other is 404 mm in diameter (although it may be

difficult to find such a drum); the mechanical advantage is the same either way.

Let us suppose that we use a 50-mm and a 54-mm drum, or rather bar. Each lifting revolution lifts the pulley by 2πmm ≈ 6.3 mm, paying out π50mm ≈ 157 mm of rope from one bar and taking up π54mm ≈ 170 mm of rope on the other bar. Lifting the two-tonne weight by 2000 mm requires some 320 turns of the crank, paying out 50.24 meters of rope from one bar and taking up 54.4 meters of rope wrapped onto the other.

Some difficulties with it

This has the somewhat annoying result that you will need 55 meters of one-tonne rope or webbing wrapped around your windlass to lift the two tonnes by only two meters. This rope might average 3 mm thick, and if we want predictable mechanical advantage, it cannot freely wrap in multiple layers — that would increase the effective diameter of the windlass by 6 mm. And we need about a meter of length of each drum, since we need 320 turns of 3-mm rope, one right next to the other. This has the rather dismaying result that our pulley hangs *down* by two meters but *across* by half a meter relative to its attachment point on each bar:



This is going to put rather significant side forces on the rope that will attempt to slide it along the length of the bar, add extra tension to the rope that isn't part of the load it's bearing, and change the mechanical advantage.

The helical-grooved cone pulley

So, the alternative I was thinking about is that, instead of two drums, you can use a *single* tapered conical pulley with a single spiral groove on it, and run the pulley between two near-adjacent turns of the groove, one with a radius 2 mm greater than the other.

For example, suppose the groove is 3 mm wide, and there is a 16.5-turn blank spot with no rope on it in between the takeup part and the payout part. This makes the blank spot 49.5 mm long and means that the pulley tapers by 2 mm of radius every 49.5 mm of its length, an included angle of 4.6°. Because you still need 320 turns of rope, you still need a meter-long tapered cone, but now it's only one meter long instead of two, or 1.01 m to be more exact. Its radius at the wide end is 40.8 mm greater than at the narrow end, and the pulley hangs from two points that are only separated by 49.5 mm of length and, say, 40 to 80 mm of width.

(You might be able to squish adjacent turns of rope together a bit if you skimp on making a full half-circle profile for the groove, or make

it a bit elliptical in cross-section, deeper than a perfect torus, I don't know. Maybe you could shorten the apparatus by a third that way.)

High-precision movement

There are three different reasons for wanting very large mechanical advantages like the one provided by this mechanism. The first, discussed above, is to develop very large forces. (Tapered thread (p. 363) discusses another very simple mechanism that does this using a tapered helix.) A second is precisely the reverse — achieving very high *speeds* but low forces by applying force to backdrive the mechanism through its stiffer part. In this case this is not applicable because the frictional losses are too large, and this self-locking behavior is considered a feature in the original use of the Chinese windlass to lower buckets down wells. The third is to achieve very high *precision* by precisely translating a reasonable-sized movement, such as moving the crank by a millimeter, into a much smaller movement, such as moving the pulley by ten microns. Differential screws are an analogous mechanism commonly used for such high-precision movements.

With high-rigidity materials like UHMWPE, this mechanism may be applicable to such uses, in particular in parallel kinematics; the groove guiding the cable should reduce uncertainty about where the cable is anchored to, and hexapod-crane-type mechanisms can be considerably more rigid for a given total mass than mechanisms that rely on resisting bending moments over long distances. Particularly with UHMWPE's high lubricity on steel, it may be possible to dispense with the movable pulley and its bearings and simply run the cable through a metal eye, but the bearings of the conical drum will still be a source of error.

I worry, though, about the unknown and presumably load-dependent amount of squish in the transverse dimension of the cable as it wraps around the drum.

Transistors vs. Microcontrollers

Kragen Javier Sitaker, 2018-06-17 (updated 2018-07-05) (8 minutes)

I was just looking at the ATTiny13A on Digi-Key, the one in an 8-pin SOIC. It costs 33–40¢, depending on quantity, has six GPIO pins, runs at anything up to 20 MHz (or 0.128, 4.8, or 9.6 MHz on the internal RC oscillator), and can source or sink 20 mA per output pin, up to a max of 60 mA across all the pins. Its input pin bias current is 1 µA. It has the usual assortment of AVR peripherals, cut down a bit: one 8-bit timer/counter with two PWM channels, a separate watchdog, a 10-bit ADC with an internal voltage reference (same speed as the one on ATMega328, 15ksps at max resolution), and a comparator. It only has a kilobyte of Flash and 64 bytes of RAM. It's 5.4 mm × 5.35 mm × 2.2 mm in the SOIC version.

So far this sounds like a pretty wimpy microcontroller, even if it is an AVR. But I think maybe instead of comparing it to microcontrollers I should compare it to transistors.

(Incidentally, the same chip also comes in a much smaller MLF package with 20 pins, which gives you 18 GPIOs instead of 6. And the ATTiny5 costs 17¢ now, but is limited to half the memory, 12MHz, and 8 bits of ADC resolution, but has a 16-bit timer — in 2 mm × 2 mm.)

(And the STM32F031x4/6 comes in a WLCSP25 package that is 2.5 mm × 2.4 mm and has 20 GPIOs, or 18 GPIOs and an I²C interface, or 16 GPIOs and an SPI interface. It can handle somewhat less current or voltage than the AVRs but is not at all wimpy, rather the opposite. I think it costs 56¢ but I may have it confused with a larger package of the same chip.)

For example, a 2N7002T-2 MOSFET costs US$0.51 (or down to 9.4¢ in quantity 1000), about 30% more than the microcontroller (again, in quantity 1). It can switch 115 mA at up to 60 volts, a much higher voltage than the microcontroller but less than twice the current, and its input bias current is 0.1 µA, ten times higher. It can do analog things the AVR can't. But you need 10 volts to turn it all the way on, it can only reasonably be used up to a few megahertz, and its biggest disadvantage is that it has only one input and one output.

Depending on the circumstances, you could replace as many as six 2N7002s (US$3) with a single ATTiny13A (US$0.40). That's nearly an order of magnitude cheaper, and it's smaller too.

But maybe it's unfair to compare the microcontroller to power MOSFETs, even lightweight ones like the 2N7002. Maybe you should be comparing it to small-signal transistors, like a 300MHz MMBT3904, which only costs 10¢ and can handle 200 mA at up to 40 V, or a 12¢ BC849, which is 30V and 100mA, which is good to 100MHz. But those still cost more per output pin than the microcontroller. And typically they come in a SOT-23 package, which is 2.9 mm × 1.3 mm × 1 mm, larger than many of the microcontroller packages mentioned above.

It seems like if you just want to turn things on and off, even very fast, the microcontroller is best up to 60 mA at 5 volts — 300 milliwatts — and perhaps 5 megahertz out, 7 kilohertz analog in. If you need higher voltage, higher current, analog output, or higher

frequency, then maybe you should go with discrete transistors or perhaps other ICs.

This suggests a real potential niche for microcontrollers with open-drain GPIO outputs, which could potentially directly switch much higher-power loads — I suspect 60 V at 20 mA wouldn't be unreasonable, and would be over a watt without dissipating any more power in the μC itself than an ATTiny does. Hmm, and any I²C/TWI interface already has open-drain hardware… I wonder if it's possible to take advantage of this?

The STM32 line of microcontrollers has 5V-tolerant GPIO pins that can be configured as open-drain, but the datasheet warns not to try to run them over 5.5V, and gives Vdd+4V as the "absolute maximum". So 60 V is probably unwise.

An interesting question is how you design things to make this potential advantage real. What kind of software do you run on the microcontroller? How much autonomy do you give it? How do you divide up the functionality of a complex device among different microcontrollers?

A difficulty with these super tiny devices with 4 or 6 GPIOs is that you don't have much left over for communication. An ATtiny48, by contrast, has 24 or 28 GPIOs (depending on the package), and three of them suffice for SPI at 3 Mbps. In between 21 remaining GPIOs, you could plausibly charlieplex 441 LEDs, which would be a pretty decent chunk of transistors, or run 10 tiny DC motors in an H-bridge configuration. These packages, not counting the DIP, range from 7 mm square to 4 mm square.

Other possible chips are reasonable alternatives to microcontrollers. There are I²C GPIO extenders, for example, and there are op-amp chips, and there are shift registers, and maybe you could use JTAG. The LM7321 op-amp comes in a SOT-23 (1.75 mm wide, 3.05 mm long, not counting the pins) or dual in a 8-pin VSSOP (3 mm square) or SOIC.

An amusing possible alternative is to use some kind of voltage regulator — Horowitz & Hill suggest treating an LM317 as a cheaper alternative to the LM395 "protected transistor", with "~1.2 V base-to-emitter voltage and 50 μA pullup base current," and mention using 7805s in a similar way despite their annoyingly large base-to-emitter voltage. But you should also be able to use a buck or boost converter in this way, generating a sort of class-D amplifier.

GPIO extenders include the Microchip MCP23008, which Digi-Key classifies as "Interface — I/O Expanders", a category with 1643 chips in it. These are mostly SPI and I²C with 8 or 16 pins and can sink or source a few tens of mA. They tend to cost about 50–100¢. Examples include the 129¢ TI TCA9534APWR, a 400kHz I²C 16-TSSOP (4.4mm square) with 8 push-pull GPIOs that runs anywhere from 1.65–5 V; the 144¢ Semtech SX1502I087TRT, a 400kHz I²C 20QFN (3mm square) with 8 push-pull GPIOs of 8mA source, 24mA sink capacity at anywhere from 1.2 to 5.5 V; and the 150¢ TI TCA9535PWR, a 400kHz I²C 24TSSOP (4.4mm) with 16 push-pull GPIOs of 10 mA source, 25 mA sink at anywhere from 1.65 to 5.5 V; the MCP23008-E/ML, a 113¢ I²C 20QFN (4 mm square) with 8 push-pull GPIOs of 25 mA source or sink at anywhere from 1.8V to 5.5V; and the obsolete 5MHz SPI NXP PCA9701D,112, with 16 input-only pins, in a 7.5mm 24-SOIC. (All prices from Digi-Key

in quantity 1.)

The thing to notice here is that the price per GPIO here is 16¢, 18¢, 9.4¢, 14¢, and ∞¢, respectively. While this is reasonable compared to the price of a whole discrete transistor, it compares unfavorably with the price of GPIOs on a full-fledged microcontroller. And the size, too, compares unfavorably.

Sous vide

Kragen Javier Sitaker, 2019-04-02 (2 minutes)

I want a temperature-controlled water tank for food preparation, including things like sous-vide cooking. In particular, it would be very valuable to me to be able to do the following:

• Cook eggs in the shell without risk of overcooking them, boiling away all the water, exploding the eggs.
• Heat water for mate to the appropriate mate temperature and maintain it there, rather than boiling water and then mixing it with an unknown amount of water.
• Controlling the temperature of yogurt so that variations between different batches of yogurt, and different jars in the same batch, are not due to variations in the temperature curve. This way I can experiment with different temperature curves. It would be nice if, as a bonus, I can make larger batches of yogurt.
• Cook plastic-wrap-wrapped vegetarian sausages at a known temperature without risk of burning the plastic (e.g., when steaming them in a pot there is the risk that the plastic comes in contact with the pot, which is at a higher temperature than the water, or that the water all boils away).
• Rapidly defrost hermetically-sealed frozen food with a rapid flow of warm water.

There are also fun tricks like cooking part of an egg, or normal sous-vide cooking of meat for long periods of time at low temperatures, but I think of these as much less valuable.

I think this device needs one or more thermometers, a heating element (maybe one of the cheap immersion heaters they sell at truck stops), a relay (or SSR) to control the heating element, a microcontroller, and some kind of water-circulating pump that can handle water at temperature. And, of course, a microcontroller with a well-tuned thermal control system to prevent overshoot.

This is somewhat related to my desire for a dehydrator (see files Notes on circuitry for the Nutra seed activator (p. 3099) and Home dehumidifier (p. 3131)) for food preparation and food waste handling, the main difference being the heat transport medium — water in the case of the sous-vide cooker, air in the case of the dehydrator. The dehydrator would also probably need to measure humidity.

Assembler bootstrapping

Kragen Javier Sitaker, 2019-07-18 (updated 2019-12-08) (16 minutes)

I've explored the question of bootstrapping computer systems from scratch in some detail, but one of the things I haven't touched on much is the design of the assembler — that is, the compiler from assembly language into machine code. This is somewhat curious, because assemblers have been quite critical in the bootstrapping process of actual computers, historically speaking, and often they have been highly extensible.

Suppose you had a minimal assembler that you could gradually extend into a reasonable high-level-language programming environment, starting with some tiny minimal core and gradually adding functionality. What would it look like?

(See Forth assembling (p. 940) for another take on this.)

Maybe we should start by looking at the history of assemblers.

History

Early computers were divided into the "first generation" of vacuum-tube computers (arguably starting with EDVAC and EDSAC in 1949), the "second generation" of transistorized computers (for example, the popular IBM 7090, first shipped in 1959), and the "third generation" of integrated-circuit computers (such as the System/360 model 85, 1969). Similarly, there were three "generations" of programming languages around the same time — the "first-generation programming languages" were binary or decimal machine code, the "second-generation programming languages" were assembly languages (originating on the EDSAC in 1948, before it actually operated, but becoming popular around 1955 with SOAP for the IBM 650), and the "third-generation programming languages" were high-level languages like COBOL, ALGOL, and FORTRAN, arguably starting in 1951 with Grace Hopper's A-0 compiler or in 1955 with her FLOW-MATIC, but not becoming popular until the 1960s.

Assemblers were adopted more rapidly on drum machines like the IBM 650 because the placement of the instructions was not sequential, and due to the nonuniform access time of the drum, even choosing the addresses for a straight-line sequence of instructions was a difficult optimization problem.

(Many subsequent "generations" have been touted by one or another person, most famously Moore's 1970s language FORTH, the fad for marketing new languages as "4GLs" in the 1990s, and the Japanese Fifth Generation Computing Project; their implicit promises of revolutionary improvement have not been fulfilled.)

From their initial popularity around 1960 until C finally made assemblers obsolete except for niche tasks around 1988, most computer systems software (including the assemblers themselves) was written in assembly language, and during much of this time, even much application software was written in assembly language. Among other very influential software, I believe that all of OS/360, MACLISP, TECO, BASIC-80, GW-BASIC, AppleSoft BASIC, TOPS-10, TENEX, TOPS-20, MS-DOS, SNOBOL4,

SKETCHPAD, WordStar, VisiCalc, Lotus 1-2-3, QuickDraw, nearly all NES games, and early versions of Turbo Pascal were all written in assembly language. Unix was very unusual in being an operating system *not* written in assembly starting around 1972 (although the early versions of Unix, before 1972, were indeed in assembly).

Well into the 1990s, computers were slow enough (and compilers bad enough) that programming in assembly language was occasionally necessary for any "serious" programmer — nearly all software ran into performance bottlenecks that could only be overcome with assembly language or custom hardware. So video game engines and transaction-processing software were routinely written in assembly. Nowadays, this is much less often the case, and a much smaller fraction of modern software is written in assembly, particularly since the bulk of computing power in modern personal computers has shifted to their Tera-like GPUs — now if you want more computing power, you reach for the GPU, not assembly language for the CPU.

Knuth (who wrote the software for his landmark book series The Art Of Computer Programming entirely in assembly language) has suggested that it's reasonable to write an assembler in an afternoon, for a computer that's not overly complicated, anyway. Modern binary executable formats add a certain amount of overhead to this, as do modern complicated addressing modes.

Macros

Serious assembly programming makes use of assembly-language macros, which are considerably more powerful than the macros we're used to in other programming languages. In httpdito, I defined some gas macros that use conditionals to do a little bit of size optimization, providing special shortcuts to set registers to 0, 1, 2, or themselves:

```
### Set dest = src.  Usually just `mov src, dest`, but sometimes
### there's a shorter way.
.macro be src, dest
        .ifnc \src,\dest
        .ifc \src,$0
        xor \dest,\dest
        .else
        .ifc \src,$1
        xor \dest,\dest
        inc \dest
        .else
        .ifc \src,$2
        xor \dest,\dest
        inc \dest
        inc \dest
        .else
        mov \src, \dest
        .endif
        .endif
        .endif
        .endif
.endm
```

This is used in macros like these:

```
.macro sys1 call_no, a
        be \a, %ebx
        sys0 \call_no
.endm

.macro sys0 call_no
        be \call_no, %eax
        ## There's a new, faster instruction for system calls, but I
        ## don't know how to use it yet.
        int $0x80
.endm
```

In tokthr, I used gas assembler macros to define bytecode including relative jumps:

```
2:      .byte b_c_at_inc, b_rot, b_c_at_inc, b_rot
        .byte b_sub, b_dup # - dup if
        fif 1f
        .byte b_unrot, b_twodrop, b_unloop, b_exit
1:      .byte b_drop, b_swap
        floop 2b
```

Here `b_sub`, `b_dup`, etc., are bytecodes, and `fif` and `floop` are macros that insert jump bytecodes with relative jump offsets encoded in the format tokthr's bytecode interpreter wants:

```
        .macro fif, target      # if, or end of while loop
        .byte b_branch_on_0, \target - . - 1
        .endm
        .macro floop, target    # do loop
        .byte b__loop, \target - . - 1
        .endm
        .macro felse, target    # else, unconditional jump
        .byte b_branch, \target - . - 1
        .endm
```

Unfortunately, gas assembly macros aren't quite powerful enough to define things like nested conditional control structures. The above code uses the "local" numeric labels `1f` and `2b`, an invention of Knuth's adopted by gas.

The `b_branch_on_0` bytecode is itself defined by a macro, in this case `defasm`:

```
        defasm branch_on_0, "(if)"
        pop %eax
        and %eax, %eax
        jz branch
        inc %esi                # skip 1-byte jump offset
        jmp next
```

`defasm` is defined as follows in terms of a more basic `define_bytecode` macro, which uses the process of adding data to a given section and subsection as a sort of counter variable: each newly defined bytecode

is assigned a unique address, and if the 256-entry table overflows, you get a compile-time error:

```
        .macro define_bytecode name, realname, origin
        .pushsection .data      # save current position, go to data section
        .subsection 1           # and subsection 1, where we put the addrs
        b_\name = (. - token_table) / 2 # define b_foo as the index of this ptr
        .ifeq b_\name - 256
        .error "\name got bytecode 256"
        .endif
        .short \name - \origin # insert offset which will be resolved next
        .popsection             # return to where we were, and
        .pushsection .dictionary
        countedstring "\realname"
        .popsection
\name:                          # define the name
        .endm
        .macro defasm name, realname
        define_bytecode \name, "\realname", machine_code_primitives
        .endm
```

But gas also has a `.set` pseudo-op that gives you variables that can be mutated arbitrarily during the process of assembly.

To generate unique labels, you can declare them as local to a particular macro (in gas with the `.altmacro` pseudo-op, for example), you can generate unique labels from a parameter (as above in `define_bytecode`), you can use local numeric labels, or you can generate unique labels in some other way, such as the following:

```
        .macro countedstring name
        .byte stringlength\@
1:      .ascii "\name"
        ## Here we count the length of the string --- computers
        ## are for counting bytes so people don't have to!
        stringlength\@ = . - 1b
        .endm
```

Here `\@` is a magic counter that gas increments for each macro expansion, providing enough randomness for the macros to generate unique symbols.

I also defined a `def` macro which takes an arbitrary number of arguments, in order to define bytecode subroutines that fit on a single line with straight-line control flow:

```
    def neg1, "-1", b_dolit_s8, -1   # ( -- -1 )
    def add, "+", b_umplus, b_drop  # ( a b -- a+b ) drop the carry
    def sub1, "1-", b_neg1, b_add    # ( n -- n-1 )
```

This uses the `vararg` feature of gas's macro system:

```
    .macro def name, realname, bytes:vararg
    defbytes \name, "\realname"
    .byte \bytes
    .byte b_exit
    .endm
```

In many assemblers, even the native machine instructions are defined as macros, rather than being built in to the assembler. Here's an excerpt from a disk image of the RDOS operating system for the Data General Nova (see Nova RDOS (p. 1724)):

```
; COPYRIGHT (C) DATA GENERAL CORPORATION 1977, 1978, 1979, 1980, 1981, 1982
; 1983, 1984
...
;INSTRUCTION DEFINITON FILE
...
;DEFINE MEMORY REFERENCE INSTRUCTIONS THAT DON'T REQUIRE AC'S
.DMR JMP=      000000
.DMR JSR=       004000
.DMR ISZ=       010000
.DMR DSZ=       014000

;DEFINE MEMORY REFERENCE INSTRUCTIONS THAT REQUIRE AC'S
.DMRA LDA=   020000
.DMRA STA=      040000

;DEFINE THE ALC INSTRUCTIONS
.DALC COM=      100000
.DALC NEG=      100400
.DALC MOV=      101000
```

However, I think `.DMR`, `.DMRA`, and `.DALC` are in fact built into the DG assembler.

Nowadays NASM is a more popular assembler than gas, in large part because its macro system is more capable; NASM's macro system , though it's still ad-hoc, has not only conditionals and macro-local labels but also a "context stack" mechanism that enables you to define macros for nesting control structures and the like by providing labels that are local to a "context" rather than a single macro expansion.

Stacks and expressions

A major weakness of assembly languages is that they don't have expressions, except for expressions evaluated at compile-time. In effect, you must name all your temporary variables. This makes assembly language verbosity and bug-prone, though it's not the only factor. Consider these two lines of C from dietlibc's `strtod` function; here `value` is a floating-point number:

```
while ( (unsigned int)(*p - '0') < 10u )
    value = value*10 + (*p++ - '0');
```

These get compiled to the following assembly and machine code, somewhat abbreviated and commented:

```
 74 0046 EB0C       jmp .L7
 76                .L8:
 78 0048 D80D0000   fmuls .LC2       ; multiply value by floating-point 10
 78      0000
 80 004e 47         incl %edi        ; p++
 82 004f 51         pushl %ecx       ; copy binary number to memory address
```

```
 83 0050 DA0424     fiaddl (%esp)    ; add in-memory binary number to float
 84 0053 5B         popl %ebx        ; fix the stack
 86                .L7:
 88 0054 8A07       movb (%edi),%al  ; *p
 89 0056 0FBEC8     movsbl %al,%ecx  ; sign-extend into %ecx
 90 0059 83E930     subl $48,%ecx    ; - '0' to convert from ASCII to bin
 91 005c 83F909     cmpl $9,%ecx     ; < 10?  i.e., <= 9?
 92 005f 76E7       jbe .L8          ; if so then loop!
255                .section .rodata.cst4,"aM",@progbits,4
256                .align 4
257                .LC2:
258 0000 00002041   .long 1092616192 ; floating-point 10, poorly represented
```

The particular thing I want to call attention to here is that the C code refers to only two variables, `p` and `value`, which are assigned to the assembly-level registers %edi and st(0), which is the top of the 8087 register stack that `fmuls` and `fiaddl` implicitly act on. The assembly code, however, additionally refers to "variables" %ecx, %esp, %ebx, %al, and .LC2, although .LC2 is just the literal constant 10. Of these, %al, %ecx, and (%esp) are used to hold temporary results that in the C code are left nameless, while %esp is used as a pointer to (%esp), and %ebx is used as a bit bucket.

You could write the code in a pretty closely analogous way in C, though I've taken the liberty of reordering the basic blocks so that we have an exit from the middle of the loop instead of an entry into it, and there's no C equivalent for squirrelling a value away in memory so the 8087 can see it:

```
for (;;) {
    char a = *p;
    unsigned c = a;
    c -= '0';
if (c > 9) break;
    const static float t = 10.0;
    value *= t;
    p++;
    value += c;
}
```

To my eye, at least, this is not an improvement; the indirection of dataflow through explicit variables, which are mutated, makes that dataflow (which is mostly tree-like) much harder to understand. If we call out the one place where the dataflow goes to more than one place by using a variable, it gets better, and I think a bit better even than the C original:

```
unsigned c;
while ((c = (unsigned)*p - '0') < 10) {
    value = value*10 + c;
    p++;
}
```

I think that, in some sense, this is the essence of stack-machine instruction set designs like the GreenArrays F18A core in the GA4 and GA144, and of FORTH: by adding an operand stack to assembly

language, they eliminate the need to assign temporary variables explicitly to intermediate nodes of tree-shaped rootwards dataflow. In FORTH the code precisely analogous to the above looks something like this:

```
variable c
...
begin  p @ c@  [char] 0 -  dup c !  10 u< while
    value f@ 10. d>f f*  c @ 0 d>f f+  value f!
    1 p +!
repeat
```

This is 27 run-time operations ([char] and begin are purely compile-time) which is just over twice the 11 instructions in the i386 code above. Such a 2:1 ratio is typical for stack-machine code and register-machine code.

It happens, though, that there's no need for the separate variable c; we can store it on the operand stack:

```
begin  p @ c@  [char] 0 -  dup  10 u< while
    d>f  value f@ 10. d>f f*  f+  value f!
    1 p +!
repeat drop
```

Or the return stack:

```
begin  p @ c@  [char] 0 -  dup >r  10 u< while
    value f@ 10. d>f f*  r> 0 d>f f+  value f!
    1 p +!
repeat rdrop
```

Nor do we need an explicit fvariable value; as the i386 code does, we can use the top item on the floating-point stack, which ANS FORTH allows to be the operand stack or not:

```
begin  p @ c@  [char] 0 -  dup >r  10 u< while
    10. d>f f*  r> 0 d>f  f+
    1 p +!
repeat rdrop
```

Forth also has compile-time evaluation, which we can use to avoid reconverting 10 to floating-point every time through the loop:

```
begin  p @ c@  [char] 0 -  dup >r  10 u< while
    [ 10. d>f ] fliteral f*  r> 0 d>f  f+
    1 p +!
repeat rdrop
```

That's only 21 operations, just under 2:1. However, perhaps more to the point, it's *dramatically* less code than the assembly version; it's close to the C version in verbosity. (On the other hand, I feel that I have more bugs writing stack code than register code; I succumb too easily to the temptation to keep lots of things on the stack, and then I lose track of where things are.)

The upshot of this is that if you have an operand stack sitting

around somewhere, then it becomes feasible to compose "expressions" by concatenating bits of executable code that communicate implicitly through that operand stack. This more or less gives you Forth.

Topics

Convolution applications

Kragen Javier Sitaker, 2015-09-07 (updated 2019-08-14) (9 minutes)

I think convolution, even the ordinary linear kind, is potentially an underappreciated abstraction for computer systems architecture. A well-chosen abstraction is a sort of "bowtie knot" in the dependency graph: the services it provides can, on one hand, be implemented in many different ways, and on the other, can be used for many different applications. This allows the indiscriminate and highly productive combination of any of *N* different implementations with any of *M* different applications. Successful large-scale examples include the Internet Protocol, the C programming language, the SQL query language, the i386 instruction set, the POSIX API, and more narrowly the filesystem interface.

This note focuses on underappreciated *applications* of convolution, but there are also underappreciated *implementations* of convolution. It doesn't touch on generalizations of convolution such as morphological operations or convolutional neural networks.

(See also the convolution section of More thoughts on powerful primitives for simplified computer systems architecture (p. 1895), the notes about mathematical morphology in Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm (p. 216), and notes on efficient algorithms in Real-time bokeh algorithms, and other convolution tricks (p. 2661) and file `mcgraw-convolution`.)

Music

Convolution is of course widely used in computer music for things like reverb and frequency selection, but even broader applications are imaginable, especially once we consider time–frequency representations.

Consider synthesizing a xylophone melody. The score is a time-frequency representation of the music: at certain moments, there begins a note of a certain pitch with a certain amplitude. This is a scalar function of two independent variables, time and pitch. An instrument patch representing the xylophone can also be thought of as a scalar function of the same two independent variables, with the time in this case being the time since the beginning of the note and the independent variable being the PCM sample — say, the instantaneous air pressure. And if we reverse the instrument patch in time and frequency, its convolution with the score produces a new function from time and pitch to PCM samples. A timewise slice through that result at pitch=0 gives us the synthesized melody; timewise slices at other pitches, if we use equal temperament and the typical logarithmic scale measured in semitones, give us the melody synthesized in other keys.

There are some other dimensions to consider. If the notes in the "score" are not perfect impulses, but rather have some variation in their frequency content, they will simulate striking the xylophone keys differently; for example, impulses bandlimited to low frequencies will simulate striking them with a softer hammer; using a sharpening kernel instead of an impulse will drop out the lower

frequencies from that note. Of course, you can consider convolving the one-dimensional output slice with a reverberation, but this convolution can also be applied to individual notes in the "score" to add reverberation or softness (or especial sharpness) to particular notes.

But suppose we add a third dimension to the score, such as the note's position in its measure. Then we can convolve the score with a function that applies such color systematically to notes in particular positions in their measures before summing along the measure axis.

Consider also the problem of synthesizing a string sound, such as a violin. Karplus-Strong string synthesis traditionally works by feeding white noise into a digital delay line, which is an all-pole IIR filter with high-Q resonances, which amounts to convolving the (potentially very long) impulse response of the delay line with the input noise. If the noise is continuous and low-amplitude, this sounds a lot like a violin; the process of stimulating the violin string with the random roughness on the bow is somewhat similar, although there's some nonlinear amplification involved. But of course, modulo nonlinear effects like dispersion (e.g. from piano string stiffness), this is just convolving the input noise with the impulse response of the IIR filter.

If you take a "mother wavelet" that is a windowed sample of a continuous sound and convolve it with white noise in this way, the result will have the frequency content of the original continuous sound, frequency-broadened by the time restriction of the window, multiplied by white noise, which has little effect. This should allow you to provide arbitrary amplitude envelopes to an arbitrary continuous sound, within the limits set by the bandwidth-responsiveness tradeoff. Variations of this effect are widely used in music under the name of "vocoders", though usually they don't literally use a windowed sample of a continuous sound. (If your window is about 64 ms, your frequencies will be uncertain by around 15 Hz, and the sharpness of time-domain variation in the "carrier" sound will be diminished by about 64 ms.)

Graphics

Convolution is also widely used in graphics, but largely to apply visual effects like blurring and sharpening.

Text rendering

Consider rendering text on a screen. You can treat this as the convolution of a "window codepoints signal" and a "font signal", each three-dimensional. The "window codepoints signal" has an impulse at (x, y, c) precisely when the character with codepoint c should appear at (x, y); the "font signal" has the color at $(x, y, -c)$ of pixel (x, y) for the glyph of codepoint c. Convolving these two signals produces a three-dimensional signal whose $(x, y, 0)$ plane is the desired text display.

If the signal representing the original font is instead two-dimensional, you can merely space the glyphs farther apart than the width of the window; the convolution output is then a very large two-dimensional surface containing the text of the window and also a large number of scrambled copies of the text of the window. The original window codepoints signal is then a very sparse signal that is

almost equally large, with an impulse at each coordinate where it is desired to select a character.

Putting the glyph index instead into a third dimension avoids the need for the font encoding to depend on a maximum window size and instead produces the desired window as one spacewise slice across a glyph-index axis, with scrambled versions of the window in other spacewise slices.

You could imagine adding a fourth dimension of font style, which could be continuous.

This convolution approach to font glyph rendering can handle overstrikes, hinted glyph rendering, accents, blurring, and even coloring, but it falls down on rotation, multiple font sizes (including zooming), and even, surprisingly, text drop shadows. The drop-shadow problem is that where the solid letter is present, you would like it to opaquely obscure the shadow, not linearly add to it. You need some kind of opacity.

So suppose that, instead of directly producing the two-dimensional image, the convolution generates a three-dimensional opacity field, and we use perspective volume rendering techniques to render it into a 2-D image. Drop shadows can be physically *behind* the glyphs, and larger letters can simply be closer to the camera (with their X and Y coordinates scaled accordingly, of course).

With the addition of this final nonlinear stage of opacity and perspective, convolution becomes much more powerful: not only can it produce drop shadows and multiple font sizes, but it can also take over much of the work of rendering the glyph outlines. You can convolve stroke fonts such as Hershey fonts with a sphere or circle, for example, or more interestingly, with an ellipse at the traditional calligraphic 45° angle, or even a spiky ball to produce a shape with surface striations following the pen. You can represent a serif-font letterform as a sparse three-dimensional signal in (x, y, feature) space, then convolve it with a library of features such as serifs, stems, and bowls in order to generate overlapping three-dimensional forms that comprise the glyph; and you can modify this library to modify the font. Cursive pen-strokes might be signals in an (x, y, pressure) space, allowing you to vary the stroke width, opacity, or ink color by convolving with the appropriate pen. (And of course you can convolve with a small sphere or horizontal ellipsoid to thicken the outlines of outline fonts.)

3-D modeling

There's an existing body of knowledge in rendering convolutional surfaces, that is, implicit surfaces defined by level sets of the convolution of some fixed "kernel function" with a skeleton of a 3-D model. This involves an additional level of nonlinearity between the convolutional operation and the image you see: rather than smoothly varying between opaque and transparent, with the nonlinearity imposed by the tendency of nearby objects to nonlinearly obscure faraway ones.

This can perhaps be applied to the text-rendering problem.

The problem is not that people are not turning to real journalism anymore

Kragen Javier Sitaker, 2016-11-15 (8 minutes)

A dear, admirable friend of mine recently wrote:

> Well, [I agree that Facebook doesn't want to fix their fake news problem]. But the real problem [with the virality fake news] is people not turning to real journalism anymore.

There are several assumptions that I think underlie this statement, all of which are incorrect:

- Real journalism exists, or used to exist, as a thing that provides reliable information.
- Reliable information can make a person adequately informed about the world.
- Humans who are adequately informed about the world will make good political decisions.
- Good political decisions by voters will result in good government.

I may, of course, be misunderstanding his point of view; but, absent a better alternative for now, I will proceed to rebut my interpretation above.

If any one of these four is false, then the link from "people not turning to real journalism anymore" to good government is a false trail. Here I explain why all four of them are false, but if you find my arguments on one of these four points unconvincing, please have the patience to consider whether at least one of them receives its quietus here.

Journalism has never provided reliable information

Journalism, since its 17th-century inception, is done by people who are ignorant about the topic they are writing about; they learn enough about the topic to be able to explain it authoritatively to others, but their explanations are nearly always ridiculous to anyone knowledgeable about the topic. Worse, journalists are only allowed to explain things that are timely — which is the time when the least is known about them.

This has resulted in journalists clothing all manner of ridiculous lies in the solemn garments of Received Wisdom, with the lightest dusting of background information generally cribbed from some other recent article on the subject.

(Maybe you remember the period when dozens of articles mentioning the World Wide Web described it as "the graphical section of the Internet", when of course the internet does not and did not possess sections; the World Wide Web was not and is not graphical but primarily textual; and many graphical applications that are not Web browsers also ran on and run on the internet. The only way such nonsense could propagate is if each ignorant journalist

copied it from an earlier one.)

Journalism's standard of exceptionality as a factor of newsworthiness also undercuts its reliability, as is widely observed; famously, it has led many people to imagine that commercial airline flight in the US in the 1970s and later was much more dangerous than driving, because plane crashes are exceptional, while car crashes are not.

This makes journalism, even when it achieves its highest standards, as in Consumer Reports, extremely poor as a source for information. But journalism has never frequently achieved its highest standards. Most journalism has always been schlock. The Pulitzer Prize is named after a yellow journalist noted for his sensationalism and unconcern for veracity.

Furthermore, even when reliable information is available, reading it has never been very popular; novels have always been much more popular. This seriously limits the possible readership of a would-be provider of reliable information — the kind of people who think a 5,000-word article is a "long read" are never going to obtain much information about anything outside their direct personal experience.

This has gotten worse in recent years as newsrooms have cut their budgets, but it was always thus: in the 17th century when journalism began, when Hearst arguably launched the Spanish-American War, when reporters interviewed me in my childhood, when Crichton formulated his famous Gell-Mann Amnesia effect in 2002, when the New York Times shrank from calling torture "torture" for a decade, and today.

Reliable information is not enough to adequately inform you about the world

But suppose that the information you get is reliably correct. Instead of reading conceited ignorants parroting the misunderstood words of whatever expert they were able to talk to, you can instead read the brilliantly expressed, deeply knowledgeable analysis of the world's leading experts on a topic, which furthermore is carefully contextualized and prioritized so that you aren't left with big holes in your knowledge. This would be like reading a good textbook on a subject, instead of the low bar journalism aspires to reach and almost invariably fails at, because of the structural problems I described above.

And let's suppose, improbably for nearly all humans, that you actually do read the whole thing. Is this enough to make you informed?

No. If you read a textbook and do not do the exercises, you still do not gain the understanding that the textbook author attempted to convey to you. You cannot become informed about a topic merely by reading about it. You must practice it.

Adequately informed humans still often make terrible decisions, even in politics

The catalogue of human folly is limitless. Many humans smoke several cigarettes per day, thus making a decision several times a day that they know will likely cause them to die in agony while those

they love most watch helplessly. We have all seen humans neglect important parts of their lives until they fell apart — a marriage, a diabetic condition, a leaking roof, their own illiteracy. We all waste our money sometimes, from the poorest to the richest. Procrastination is a universal experience, though some are harder hit than others.

Humans do not decide their actions intellectually. They decide emotionally. Their thoughts affect their emotions, and vice versa. But their thought and beliefs do not determine their actions. Much of the time they invent justifications for their actions after the fact. Salesmen and other negotiators spend enormous attention on modeling the emotional reactions of their prey, even more than they spend on modeling their prey's incentive structures.

All of this applies to politics as well. Informing humans — even when it is possible to do so — often merely provides them with further justifications for their existing belief systems, which (especially for allistic humans) are determined mostly by their social milieu, not by their own attempts to think based on the information they have access to.

Good political decisions by voters are not adequate for good government

If the candidates are corrupt, the government will be corrupt, regardless of which one the voters choose. If the officials, once in office, are confronted by perverse incentive structures in their institutions, even good officials will produce bad government. And Arrow's Impossibility Theorem places strong limits on how good a voting system can be.

Institutions matter. Voting is not enough. Consultation matters. Expertise matters. Low-quality elites don't become high-quality elites by competing for votes.

None of this means voting and journalism are useless

The popular vote is still the most important safeguard against the kinds of disastrous policies that led India to famine after famine under colonial administration, that led the US to commit genocide against the Native Americans, and that kept a substantial fraction of the US's population in chattel slavery for generations. If Indians, Native Americans, and African Americans, respectively, had had the vote, these things would not have happened, as clearly shown by the end of slavery.

And even the very rotten kind of information that journalism provides at its best can still be valuable when it's about current events, where no better information is available.

But let's not mythologize "real journalism" or create unachievable expectations for it.

Toward a lightweight, high-performance software prototyping environment

Kragen Javier Sitaker, 2018-12-10 (15 minutes)

I was thinking that it might be worthwhile to prototype a client project, but I don't have a reasonable environment to do it in. The easiest way is to use a high-level language to write the high-level app logic, while using existing libraries for storage, cryptography, and networking; the necessary user interface can be provided portably by an embedded HTTP server.

I'm going to talk a lot about performance in here, along three axes: speed, memory usage, and package size. If you can do something ten times as fast, often that means you can do ten times as much of it, and in many contexts if you can do it in a tenth of the memory, you can also do ten times as much of it. A lot of computing resources are available in the form of fungible megabyte-seconds. Package size is probably less important, except as a proxy for implementation complexity, but there are cases where it matters because of either limited storage or limited network bandwidth. For example, if you're embedding an interpreter compiled with Emscripten or wasm in a web page, it's okay if it's 1 MB but probably not if it's 100 MB.

It turns out that software has advanced significantly, and there are several pieces of software out there that offer one to three orders of magnitude performance improvements over commonly-used alternatives.

High-level language: Lua

Lua is a safe, simple, easy-to-embed scripting language, with semantics similar to JS — but its whole grammar fits on one page of the 79-page reference manual. Its interpreter performance is better than that of other languages at a similar level, such as Python, Perl, Tcl, and even most implementations of Scheme, and there's a tracing JIT implementation called LuaJIT whose performance exceeds even that of best-in-class JS JIT implementations like V8 and even, on some scientific benchmarks, C.

More specifically, Lua is a dynamically-typed Algol-like lexically-scoped statement-oriented imperative language with a mark-and-sweep GC (incremental since version 5.1), closures, dynamically-growing hash tables, eval (but no apply), tail-call elimination, a reified global environment, exception handling (with stack traces by default), a metaobject protocol, dynamic method dispatch, reflection, lightweight cooperative threads, a generic iterator protocol, finalizers, weak references, operator overloading, multiple-value returns, multiline strings, goto, variadic functions, and an immutable 8-bit-clean encoding-agnostic string type.

Lua **does not have** classes, ML-style pattern-matching, inheritance (though you can implement it), integers (until 5.3), complex numbers, first-class continuations, built-in serialization, first-class tuples, function overloading, named or default arguments (though there is

syntactic sugar that comes close), preemptive threading, Prolog-style backtracking, lazy evaluation, sequence slicing, unwind-protect, UCS Unicode strings, macros, or much of a standard library.

Like PHP, Lua uses the same mutable type for sequences and finite maps, and a single value can have properties of both. Despite guaranteeing tail-call elimination, Lua's closure syntax is heavyweight enough to preclude using it to define custom control structures as in Smalltalk or Ruby, and it has no macro facility.

The standard Lua 5.1 interpreter is only 171 KiB on my machine, and LuaJIT 2.0.4 is only 443 KiB. The documentation says, "The virtual machine (VM) is API- and ABI-compatible to the standard Lua [5.1] interpreter and can be deployed as a drop-in replacement." LuaJIT is, unfortunately, orphaned, as is Lua 5.1, but its FFI is to die for (it includes a runtime parser for C) and its performance is seriously impressive. The current version of Lua is 5.3; its stock interpreter is 215KiB.

I'm not quite as comfortable in Lua as I am in Python, and I find that Lua is a bit more bug-prone and a bit more verbose. However, modern Python is now also extremely bug-prone due to serious mistakes in how Unicode support was added, and Python is becoming quite unwieldy; /usr/lib/python3.5 on my laptop contains 183,000 SLOC of Python code, and the interpreter itself is another roughly half-million lines of C, half of which is in extension modules. This is roughly 30× the size of the Lua 5.3 codebase. A Python installation is 100 MB; a Lua installation is 171 KiB, or 443 KiB if you use LuaJIT.

Lua is particularly appealing for high-concurrency applications like network servers because it supports "coroutines", which are really cooperative threads rather than coroutines; this is similar to Python's "generator" construct used in the asyncio library, though it differs in some significant details. Even more closely, it resembles the "greenlet" construct used in the now-orphaned Stackless Python EVE Online is written in. Coroutines allow programming of network protocols in a much more structured fashion than that permitted by promises in JS.

Lua is somewhat easier to extend with modules in C than Python or even Tcl, although its style is not to everyone's liking.

A freshly started Lua 5.1 virtual machine on my laptop has a resident set size of 2.7 MB. In modern terms this is exceedingly lightweight, some 300 times smaller than a browser tab with Slack open, but it's still large enough that this environment is not going to be usable for deeply-embedded processing (though NodeMCU provides a Lua 5.1 environment on an ESP8266, which has 96KiB of RAM — as of September 2018 it supports XIP for Lua code, so you can have 256KiB of Lua code and constants). LuaJIT is even smaller, at 908 KiB resident set size.

Software embedding Lua includes Grim Fandango, Escape from Monkey Island, Vim, awesome, Elinks, VLC, World of Warcraft, nmap, Wireshark, haproxy, Haka, sigrok, MediaWiki, LuaTeX, the Battle for Wesnoth, LÖVE2D, OpenResty, and Adobe Lightroom.

Bug-proneness

Above I said Lua was pretty bug-prone; I will elaborate on that here, because I think it's the main disadvantage of Lua, though one that's worth accepting in order to get the rather awesome features

described above. Eventually this bug-proneness seems likely to limit the fraction of your code that's worth writing in Lua.

Of course, Lua is dynamically typed, which isn't really a problem in itself, but does slightly exacerbate the other problems.

In several cases, it attempts to DWIM in ways that can cover up bugs; Lua does not believe that "errors should never pass silently", as the Zen of Python says. Specifically:

• Reads of nonexistent variables and table entries simply returns `nil` rather than raising an error;
• I/O errors do not raise errors by default when using the more general I/O library;
• worse, writing to nonexistent variables creates new global (!) variables;
• function argument list and return value adjustment similarly introduces nils, and also silently discards extra values.
• In Lua 5.3, which adds integers, implicit numeric coercion (int to float, and vice versa) is the rule, and integer math can produce different results from floating-point math;
• concatenating numbers to strings implicitly converts them to strings; and
• as in JS, writing to nonexistent sequence indices extends the length of the sequence.

In a few cases, the special nature of `nil` can create bugs analogous to SQL injection and blueboxing — `a[b] = c` will delete the table entry `a[b]` if `c` is unexpectedly nil; worse, if `b` was a number, that may unexpectedly change the length of the sequence `a`. Similarly, unintentionally returning a `nil` value will terminate an iterator early.

Lua's choice of indices for sequences — 1, 2, … n rather than the now-conventional 0, 1, … n-1 — is slightly more bug-prone, for precisely the reasons described by Dijkstra.

As in multitasking Forth systems, but unlike Python generators (or for that matter JS promise callbacks), any function invoked by a Lua coroutine has the possibility of yielding control. But because coroutines are resumed explicitly, rather than using an implicit global run queue, there is no locking mechanism that could block potentially interfering concurrent executions. Ierusalimschy claims this makes the coroutine mechanism "more powerful", which is certainly true, and precisely the problem. It's precisely analogous to unchecked exceptions, aspect-oriented programming, or dynamic method dispatch: by allowing a local change to have an effect that would have otherwise required a global change, this power means that to determine a certain property of the program that would have been local, instead a global search is needed.

Storage: LevelDB

LevelDB is a high-performance persistent bytestring key-value store by Jeff Dean and Sanjay Ghemawat, supporting ordered traversal and a limited form of transactions; on my laptop, it can handle about 300,000 key-value-pair insertions per second, about 10 to 100 times faster than Postgres and 2 to 20 times faster than SQLite. Unlike Berkeley DB, LevelDB remains fast when inserting many widely scattered keys into a large existing data store, even on high-capacity spinning-rust disks rather than lower-capacity SSDs,

using a data structure sometimes known as the "LSM-tree" or "log-structured merge tree".

The library itself is 359 KiB, but it depends on libsnappy, the high-speed compression library previously known as Zippy, which is another 30 KiB.

Other popular alternatives for this kind of thing include Berkeley DB, Redis, MongoDB, SQLite, or using some kind of serialization library (such as a JSON implementation, FlatBuffers, Protocol Buffers, or Thrift) to generate bytes that your code then manually writes to a file; and then there's RocksDB, which is a fork of LevelDB. Most of these are very large, very featureful, and very slow.

Redis and MongoDB involve running separate processes, and their authors are playing dishonest games to confuse people about free software.

Berkeley DB is 1.7 MiB and many times slower at bulk insertions; also, it's controlled by Oracle.

SQLite is 922 KiB and many times slower at everything except inserting large blobs and reading.

RocksDB was written as a fork of LevelDB with improved performance, but it's 3.1 MiB.

LevelDB is used by the official Ethereum client, formerly the official Bitcoin client, the high-performance distributed filesystem Ceph, Chrome, PouchDB, and Riak; Parse was built on RocksDB.

Cryptography and networking: libsodium

Libsodium is a better-packaged version of the highly-regarded NaCl networking and cryptography library, with some extra functionality added. Unlike other popular libraries such as OpenSSL, libsodium doesn't expose a wide variety of cryptographic primitives; instead, it provides a small number of functions that are easy to use securely, based on a small and conservatively chosen set of cryptographic primitives, including Salsa20, AES-256-GCM, SHA-256, SHA-512, ChaCha20, Poly1305, and Ed25519. In many cases, it includes the fastest available implementations of these primitives for many platforms.

The only plausible alternatives here are NaCl itself and monocypher, a fork of libsodium.

Compression: Snappy and zlib

LevelDB optionally compresses the data it writes using Snappy, since Snappy compression and especially decompression is significantly faster than spinning-rust disks (250MB/s per core for compression, twice that for decompression). Since the platform embeds LevelDB, it necessarily includes Snappy, so we might as well expose it at the Lua level.

However, zlib — the universally-used implementation of LZ77 compression — compresses sufficiently better than Snappy that it's worth including it as well. In particular, for compressing library code which is loaded at startup, zlib is a big win; it also permits implementing compressed HTTP and accessing zipfiles. zlib is only about 100 KiB, and the lua-zlib binding is 9 KiB.

As a quick test, I compressed a Lua source file I wrote a few years ago with Snappy and zlib. It compressed to 0.50 times its original size

with Snappy and 0.34 times its original size with zlib.

HTTP server

You can hack together an adequate HTTP/1.0 server in about 300 machine instructions on top of Linux sockets, or a similar or smaller number of lines of code in higher-level languages. (Often the worse performance of higher-level languages requires a bit more complexity to compensate, but even the fairly rich implementation in Python's `BaseHTTPServer`, `SimpleHTTPServer`, `urllib`, `urlparse`, and `cgi` modules only works out to about 2600 lines of code.)

There exists a fairly full-featured webserver in Lua called Xavante (142K, plus dependencies on coxpcall (46K), copas (99K), and luafilesystem (82K), for a total of 369K).

Embedding an HTTP server is by far the easiest way to provide a modern user interface, even on the local machine.

Miscellaneous libraries

The Lua standard library contains very little; even sockets are provided by the external "luasocket" package (563K, including implementations of HTTP, SMTP, and FTP), and although the built-in filesystem interface allows you to read and write files, it doesn't support directory creation or listing; until Lua 5.3, the language doesn't natively include an integer type or bitwise operations. The "luaposix" library is a smaller alternative (204K, plus bitop, a 75K dependency) to the luasocket and luafileystem libraries, providing the full POSIX API.

Total weight

The total virtual machine should be 0.45 MB of LuaJIT + 0.37 MB of LevelDB + 0.38 MB of libsodium + 0.03 MB of Snappy + 0.10 MB of zlib + 0.10 MB of other library code (mostly Lua), for a total of 1.43 MB, a floppy disk's worth.

However, *those are the uncompressed sizes*. The zlib-compressed sizes of the various pieces are as follows:

	KiB	KiB (gz)
LuaJIT	443	227
/usr/lib/x86_64-linux-gnu/libleveldb.so.1.18	359	151
/usr/lib/x86_64-linux-gnu/libsodium.so.18.0.1	376	165
/usr/lib/x86_64-linux-gnu/libsnappy.so.1.3.0	30	13
/lib/x86_64-linux-gnu/libz.so.1.2.8	102	55
misc		100

If we figure we need an uncompressed zlib to bootstrap uncompressing the rest of the platform, then the total is 758 KiB.

Other candidates for inclusion

I'd really like to include support for high-performance numerical computation, machine learning, windowing user interfaces, GPGPU, audio, ØMQ or similar, and FlatBuffers (or Cap'n Proto or SBE). Torch 7 has numerical array support for Lua; it's billed as "a scientific computing framework [for LuaJIT] with wide support for machine learning algorithms that puts GPUs first," and it also supports non-LuaJIT Lua 5.2; unfortunately it's orphaned in favor of a C++

replacement called “ATen”.

Differentiable neighborhood regression

Kragen Javier Sitaker, 2019-08-31 (15 minutes)

Neighbor predictors are a family of predictors in machine learning; they work by predicting, from a probe point, some kind of average of the points nearest to it. K-nearest-neighbors, or K-nn, with a constant number of nearest points, uniform weights, and the mode as the kind of average, is the most common, but there are also R-neighborhood algorithms which use all the points within some radius R.

When the variable being predicted is continuous, it's called *regression*, and it's common to use a weighting function or kernel so that points very near the probe point weigh more heavily in the average.

Commonly neighbor regression has discontinuities in their predictions as the probe point moves around, and this represents suboptimal performance, and makes them unusable for some purposes. For example, in Multitouch and accelerometer puppeteering (p. 1785) and $1 recognizer diagrams (p. 1264) I was looking for a way to morph smoothly between "keyframes" placed at arbitrary points in a two-dimensional state space. So I was looking for a way to fix discontinuity in neighbor regression, and one occurred to me. Maybe it's known.

Continuous neighbor regression

So, consider specifically the case where we're using a weighted mean: $\sum_i w(r, x, x(i))\ y(i)$, where $x(i)$ is the position of previously observed point i, x is the position of the newly observed point we're trying to predict, $w(r, a, b)$ is a weighting function which tells you how relevant a point at b is for predicting a point at a with a neighborhood of radius r, and $y(i)$ are the observations at the points $x(i)$ of the variable to be predicted. Commonly we normalize by dividing by $\sum_i w(r, x, x(i))$, particularly when the number of points in the neighborhood may vary, and usually the weighting function is a shift-invariant kernel of the form $w(r, a, b) = v(r, b - a)$.

Now, in this formulation, you could get discontinuities in three ways. First, the radius r could change discontinuously as you move continuously around the space. Second, the function v might have discontinuities, so that either a continuous change in $b - a$ or a continuous change in r might give rise to a discontinuity in v. Third, if a point has nonzero weight when it enters or exits the neighborhood, that will also give rise to a discontinuity, unless another point simultaneously exits or enters in a way that compensates for the discontinuity.

So the simplest way to get neighbor regression to be continuous is to use a constant r and the kernel function

$$v(r, c) = 1 - |c|/r$$

so that when points enter or exit the neighborhood window, they do so with zero weight, thus producing no discontinuity.

You can use a more elaborate kernel function; the only thing that's

important is that it be continuous and reach 0 when $r = |c|$. Usually you want it to be nonnegative, too, and rapid to compute.

Similarly, you can use a varying radius, as long as it varies continuously. The appeal of K-nearest-neighbors (as opposed to R-neighbors) is that it becomes more detailed without becoming less efficient in areas where you have more data; in Knn, the radius *also* varies continuously, as there is never a discontinuity in the distance to the Kth-nearest point.

Differentiable neighbor regression

The above cone kernel gives a continuous regression function, but its derivative has discontinuities when points enter and exit the kernel and when they cross its center.

If, additionally, the radius changes *differentiably* with your position in the space, the kernel function $v(r, c)$ is differentiable as r and c change differentiably; points enter and leave the window with not only zero weight but also zero weight *derivative* (with respect to differentiable movement of the probe point), then the resulting predictor is also differentiable.

If v is purely a function of $|c|$, making it rotationally symmetric, it needs to have zero gradient when $|c| = 0$; otherwise it will fail to be differentiable at that point.

The simplest way to satisfy this is to use a fixed r and a function such as the "zero-phase Hanning window"

$$v(r, c) = 0.5(1 + \cos(\pi r/|c|))$$

which is differentiable and nonnegative, and has zero derivative at $|c| = 0$ and $|c| = r$, value 1 at $c = 0$, and value 0 at $|c| = r$.

However, the Hanning window is a bit heavyweight, requiring as it does a transcendental function. A low-degree polynomial function would be more desirable; for example

$$v(r, c) = 1 - 3d^2 + 2d^3 \text{ (where } d = |c|/r)$$

This can be computed as $(2d - 3)d^2 + 1$, requiring a doubling, a subtraction, a squaring, a multiplication, and an increment. Like the Hanning window, it is differentiable and nonnegative, and has zero derivative at $|c| = 0$ and $|c| = r$, value 1 at $|c| = 0$, and value 0 at $|c| = r$. Visually it is almost impossible to tell the two windows apart; they differ by about 0.01 at maximum. (This function is in fact the unique degree-3 Hermite interpolation of the "Hanning window" at those two endpoints.)

This computational cost estimate is leaving something out, though: the cost of computing $|c|$, which requires a square root!

$$|c| = [\sum_i (x_i(j)) - x_i)^2]^{0.5}$$

So let's consider instead the following much cheaper kernel function, which has the same desirable properties but without requiring any irrational functions:

$$v(r, c) = 1 - 2R + R^2 \text{ (where } R = |c|^2/r)$$

This function, too, looks visually close to the Hanning window (though it differs from it by up to about 0.065), is differentiable and nonnegative, and has zero derivative at $|c| = 0$ and $|c| = r$, value 1 at $c = 0$, and value 0 at $c = r$. But it can be evaluated by just a doubling, a squaring, a subtraction, and an increment, once you have $|c|^2 = \sum_i (x_i(j)) - x_i)^2$. Not only does it avoid the square root, it doesn't even require a multiplier! (Except for the pesky r scale factor, that is.)

An alternative way to avoid square roots is to use a different Minkowski p-norm of c rather than the Euclidean L_2 norm used above, sacrificing pure rotational symmetry but avoiding the squaring operations necessary to calculate $|c|$ or even $|c|^2$. The L_1 norm and the L_∞ norm are both easier to compute, and in 1-D and 2-D they are equally good approximations; in higher dimensionalities the L_∞-norm ball touches the L_2-norm ball in more places than the L_1-norm ball does, which perhaps makes it a better approximation.

You can get a reasonably good approximation of the L_2 norm in a variety of cheaper ways. Taking the maximum of the L_∞ norm multiplied by $\sqrt{d}$ (where d is the number of dimensions) and the L_1 norm gives you a somewhat better approximation, as does the sum of the L_∞ and L_1 norms, scaled appropriately. At least in two dimensions, the sum of these two approximations, again scaled appropriately, is a better approximation still. (All of these approximations are also norms, as is easily verified.)

The level set of the L_∞ norm is a hypercube, while the level set of the L_1 norm is its dual, a "cross-polytope" or "orthoplex" such as an octahedron or 16-cell. The level sets of the other combinations described above are progressively rounder polytopes with their vertices all equidistant from the origin.

Most of the above discussion of efficiency concerns minimizing the bit operations necessary, as if you were designing circuitry. If you're using a modern CPU or GPU, the computation needed to dispatch an instruction absolutely dwarfs the computation needed to multiply two numbers or take a square root, so you should just use whatever takes the fewest instructions.

Differentiably variable neighborhood radii

The above is perfectly fine for a fixed radius, but at times a variable radius might be better, both to avoid deserts with no samples to work from (or one sample, resulting in a flat plateau) and to avoid well-covered regions where the kernel function blurs out almost all of the local detail and additionally demands a lot of work. But if we just use a radius for K nearest neighbors, we inevitably run into points where differentiability fails, as our expanding moving circle bumps into a new Kth point and starts to contract, leaving an old point behind.

So we need some way to compute a differentiably-changing radius that still includes about the same number of points.

One way to handle this is to use a fixed-radius kernel to find nearby points and see how many there are, or more precisely, what their $w(r, a, b)$ adds up to. This is a differentiable quantity, and except at zero, so are its reciprocal and the reciprocal of its square root. If it covers a region where the points are distributed more or less evenly, we can use that reciprocal square root as a kernel radius, and it will tend to cover a more or less consistent number of points.

It might be worthwhile to iterate this some fixed number of times, such as two: use the sample of points captured by kernel i to calculate a smaller radius at which to run kernel $i+1$, to calculate a smaller radius at which to run kernel $i+2$.

Division by 0 is a constant risk here. Perhaps for a given set of points you could calculate a minimum radius needed to always avoid it.

This approach is commonly called a "balloon estimator".

Interpolation versus regression

In machine learning it is typically assumed that the observed values are subject to some noise, so predicting them all precisely is symptomatic of overfitting and will lead to poor future results. But for some of the applications I have in mind, like animation keyframes in an abstract character state space, we really would like to exactly hit the given data point — we want to precisely interpolate a spline (in the sense of Levien, not de Boor) rather than fitting a curve to noisy data.

All the variants of neighbor regression described above, on a fixed set of probe locations and data points, is a sparse linear transformation of the data points it's regressing to — the weight values don't depend on the $y(i)$, just the $x(i)$. Moreover, I think it tends to be a reasonably-well-conditioned one, at least if your neighborhood widths are reasonable. So determining the set of ersatz observations $y(i)$ we would need for it to precisely predict the *actual* given observations $b(i)$ is simply a matter of solving the sparse linear system $\mathbf{A}y = b$, where the rows of the square matrix $\mathbf{A}$ are computed with w on the observation points $x(i)$. Interpolating between y and b allows you to choose the degree to which the surface has a little bit of freedom to suppress noisy points.

This turns neighbor-regression algorithms into N-dimensional surface-fitting algorithms, and they can be used thus as an alternative to NURBS.

It lacks some desirable properties for such surface-fitting algorithms; in particular, it lacks locality, in that a change to any input point will in general result in changes everywhere on the surface, not just near that point.

It should be mentioned that there's an existing standard way of doing this, used for example in the sklearn documentation, but it sucks. It is to use $r/|c|$ as the weight function, which diverges when $|c| = 0$, but in that case you're at a sample point and you can just use the value of that sample point. It's continuous close to the sample point, but it can have discontinuities when faraway points slip in and out of the window; also, it's far from differentiable, with sharp spikes at all the sample points.

Vector regression or interpolation

Above I've been speaking in terms of observations $y(i)$ and predicted values. It bears mentioning explicitly that these observations are not necessarily scalars such as the height of a surface; they might be, for example, vectors of 256 (x, y) pairs describing the path of a pen stroke, as in the application to $1 recognizer diagrams (p. 1264). All the math above works in the same way, since the only thing we're ever doing with the $y(i)$ is forming linear combinations of some of them weighted by the normalized weights from w — except for the linear-interpolation linear system to be solved in the interpolation-versus-regression section above, which should be solved separately for each component of the observation vector. For example, solve one $\mathbf{A}y = b$ problem for the x coordinate of the first point in each pen stroke, then a second $\mathbf{A}y = b$ for the y coordinate of the first point, then a third $\mathbf{A}y = b$ for the x coordinate of the second point, and so on.

A note on terminology

My terminology in the above has been fairly inconsistent, both with itself and with established terminology. Knn is normally called *k* -NN; the sample points are often called "training examples" rather than "samples" and the space they are located in (the independent variables) is called the "feature space" and sometimes the "search space" with its dimensions being "features"; the regression result is a "prediction" of a "property value" for the "object" or "query" or "query example" or "test point" (what I sometimes called the probe point above). I should probably go back and fix it.

Nonlinear differential amplification

Kragen Javier Sitaker, 2016-12-14 (2 minutes)

Transistors, especially FETs, are lovely little devices. They have very high energy gain — effectively infinite in the FET case. They respond very quickly, and aside from that finite response speed, their response is historyless, which makes the electronic design and test problems considerably more tractable. In particular, circuits that are linear, noninverting, or non-amplifying are not capable of universal computation, and the transistor immediately takes care of all three of those barriers at once. (I'm fairly sure it's possible to imagine nonlinear, inverting, amplifying circuit elements that are still incapable of universal computation, but I don't know what they'd look like.)

Transistors do have a few problems, though. One is that their response speed, while good, could still be better; it's in the picoseconds range for sizes that are practical to fabricate. Another is that the transistors that we know how to fabricate are still somewhat tricky to fabricate, requiring exotic materials, materials not found in nature and of very high purity.

Braess's Paradox gives us a way to convert some kinds of noninverting nonlinearities into inversion; the well-known construction with resistors and a Zener diode is an example. In general, the bridge topology (used in the Braess circuit) provides a way to materialize a *difference* in your circuit, which gives you a way to get inversion and amplification, in some sense anyway. A change of 1% in the voltage across one of the "shores" of the bridge can easily result in a change of 10,000% in the voltage across the bridging element.

Nonlinear circuit behavior and behavior with memory is actually fairly universal in real circuit elements; it's just that normally we consider it a problem to solve, because especially in analog circuits, the distortions introduced by nonlinearity are difficult to characterize and predict. But, for example, capacitor databooks are full of information about the capacitors' deviations from linearity, which often reach 20% or more despite their best engineering efforts to remove them. What if we could take advantage of such everyday nonlinearities to implement digital logic?

Bootstrapping rope bridges and other tensile structures with UHMWPE-bearing drones

Kragen Javier Sitaker, 2019-11-25 (5 minutes)

To build a suspension bridge across a river, you hang it from a heavy cable. To pull the heavy cable across, you use a rope. To pull the rope across, you use a thin cord. To pull the thin cord across, you use a fine thread. But how do you pull the fine thread across? Well, according to stories, you shoot an arrow. But nowadays maybe a small quadcopter would be better.

How fast can you do this kind of bootstrapping? To simplify the problem, consider the problem of running a heavy cable 100 meters straight up, looping it over something smoothish with no significant friction, and running it back down. Instead of using discrete sizes, let's suppose the cable tapers exponentially, and that it is made of UHMWPE with 2.4 GPa yield stress (see Dyneema (p. 123)) and 0.97 g/cc, and that our initial flight can lift 10 g.

But let's save the initial flight for later.

Once we're in steady state of cable embiggening, the weight of the 100 m of up-going hanging cable needs to be supportable by the thinner cable looped over the top, and (more demandingly) the *difference* in the weight of the up-going cable and the down-going cable needs to be supportable by the still thinner cable we're reeling in at ground level.

Before solving the problem exactly, let's consider a crude approximation: the cable reeling in at the ground needs to be able to support the 100 m of up-going cable, which is all the thickness of the cable leaving the ground, 200 m in the future. So, over 200 m, the cable can only get thicker by a factor such that the cable 200 m ago is still thick enough to support 100 m of it.

100 m of Dyneema weighs 97 g/cm², which is 97 tonnes/m², or 950 kPa. This is 2500 times less than the yield strength, so we're safe as long as the cross-sectional-area growth over 200 m is a factor of 2500 or less, or a factor of 50 or less in diameter. So, by pulling on a 100-micron-thick fiber, you can lift a 5-mm-thick cord on the other side, and by pulling on the 5-mm-thick cord when it gets to you, you can lift a 250-mm-thick cable on the other side.

But that's actually ridiculously conservative, because at cable position t you're not actually lifting 100m $f(t - 200\text{m})$, where $f(s)$ is the linear density of the cable at point s, but rather $\int_a^b f(u)\,du - \int_b^t f(u)\,du$, where $a = t - 200\text{m}$ and $b = t - 100\text{m}$, and the second integral is insignificantly small. Solving this exactly is pretty easy.

Even using the simple approximation, though, 10 g over 100 m at 0.97 g/cc is 0.103 square millimeters, so the initial thread you send up to loop over the top can be 0.103 square mm (320 microns in diameter) at the bottom of the tower. That, too, is ridiculously conservative if you taper it.

In practice it is probably difficult and inconvenient to handle fibers of less than 10 microns in diameter; even though UHMWPE is

highly biocompatible, inhaling tiny rigid fiber fragments may cause mechanical damage. (By comparison, spider silk fibers are 2.5 to 4 microns in diameter.) They're also likely to run into significant trouble with wind, especially given UHMWPE's brittle nature. 10-micron UHMWPE fibers can, if we extrapolate the mass yield stress downwards, withstand 0.19 N of force, the weight of 19 grams. 10-micron-diameter UHMWPE weighs 76 micrograms per meter, which is 76 mg per km.

Sending such tapered ultrastrong fibers around on microminiaturized drones or balloons may be a quick way to get hold of things that are far away, build enormous tensile structures between buildings and mountains, and snarl up rotating machinery, such as helicopter blades, although for such impact applications it might be useful to knit or zigzag the fibers in some way to reduce the acceleration shock, for example weaving them into a yielding net which, when hit, draws up heavier fibers from the ground.

Parallel register file

Kragen Javier Sitaker, 2018-11-27 (2 minutes)

A thought that occurred to me as I read about the LMI K-machine 's duplicated register file:

Suppose you are executing a 32-bit 3-address instruction with three 8-bit register fields. As a possible alternative to having 256 registers (or a smaller register field), you could have 8 registers, one bit in each register field identifying some subset of the registers to use. For example, you could specify 00001000_2 to indicate register 3, or 01000000_2 to indicate register 6. In the case where you specify more than one register to write to, the results are written to all specified registers; 11111111_2, for example, writes to all 8 registers, and 00000000_2 discards the result.

A perhaps more reasonable design here is to have an output register field that is twice the length of the input register fields, each of which can address only one half of the register space, thus eliminating the necessity for a multi-ported register file. For example, you could have 6 bits per input register field and 12 bits of output register field. If the two halves of the output register field were always identical, it would look like a machine with 6 registers and the usual dual-ported register file, just with an inefficient instruction encoding.

Presumably the results when you select more than one input register should be specified; for example, wired-AND or wired-OR would be reasonable. Wired-OR has the advantage that 000000_2 produces 0, which is more commonly useful than the -1 that would be produced in the wired-AND case. This also, of course, eliminates any necessity for an OR instruction.

12 registers in this form would probably be about as comfortable as 8 registers in the more usual form.

Distinguishing natural languages with 3-grams of characters

Kragen Javier Sitaker, 2013-05-17 (updated 2013-05-20) (7 minutes)

In outgoing-notes-mail-01.

I thought a fun tiny program would be something to identify languages from training data. Some few N-grams are highly distinctive of particular languages; it should be possible to use a table of a few such N-grams to distinguish. Stuffing an entire byte 3-gram into a machine register, a simple C program can tabulate about five megabytes of 3-grams per second on my netbook:

```
#include <stdio.h>
#include <ctype.h>

enum { n_threegrams = 256*256*256 };
int threegrams[n_threegrams];

static inline int
update(int threegram, char c)
{
  unsigned char uc = c;
  threegram <<= 8;
  threegram |= uc;
  threegram &= 0xffFFff;
  return threegram;
}

int main(int argc, char **argv)
{
  int threegram = 0;
  int out_of_word = 1;
  char cc;
  int ii;
  threegram = update(threegram, '-');
  threegram = update(threegram, '-');
  threegram = update(threegram, '-');
  while (fread(&cc, 1, 1, stdin)) {
    if (isalnum(cc) || cc == '\'') {
      out_of_word = 0;
      threegram = update(threegram, cc);
      threegrams[threegram]++;
    } else if (out_of_word) {
      /* nothing */
    } else {
      out_of_word = 1;
      threegram = update(threegram, ' ');
      threegrams[threegram]++;
    }
  }

  for (ii = 0; ii < n_threegrams; ii++) {
```

```
    if (!threegrams[ii]) continue;
    printf("%d %c%c%c\n", threegrams[ii],
           ii >> 16 & 0xff,
           ii >> 8 & 0xff,
           ii >> 0 & 0xff);
  }

  return 0;
}
```

The top 3-grams my program finds for Spanish in my Spanish dictionary file are:

```
4000 dor
4225  de
4336 a c
4609  n
4936 te
5006 nte
5537 ra
5710 ado
6742 ent
8842 ar
```

For English from the KJV bible:

```
22273 d t
24569 to
35631 of
36735  of
43476  an
45407 and
59014 nd
74898 he
96843 the
121874  th
```

In the KJV, 'ar ' was at 3638, some 40 times less common than ' th', while 'ado' was at 181, some 673 times less common; 'ra ' was less common still.

Running it against the 20MB spanishText_10000_15000 from the Spanish WikiCorpus v1.0 yields somewhat different results:

```
109439  co
112939 en
134011 el
136181 es
136930 la
138318 as
151942  la
195466 os
251117 de
319299  de
```

In the KJV results, I got ' de' 4575 times, 'de ' 2851 times, and 'os '

only 45 times. ' th' occurrs only 1354 times in the Spanish WikiCorpus text.

So in Spanish text, 'os ' is 195466/1354 = 144 times as common as ' th', while in English text, ' th' is 121874/45 = 2708 times as common as 'os '.

So it seems reasonable to guess that a text containing more 'os ' than ' th' is Spanish if it's one of Spanish and English, and vice versa; and both are sufficiently common in their respective languages that even a very short sample of one of these languages is likely to contain an instance. 'os ' occurred about once every 100 bytes in Spanish, while ' th' occurred about once every 40 bytes in English.

So you can probably do a reasonable job, on x86, of discriminating between these two languages as follows:

```
enum language { lang_en, lang_es };
enum { sp_th = ' ' | 't' << 8 | 'h' << 16,
       os_sp = 'o' | 's' << 8 | ' ' << 16 };
enum language __attribute__((regparm(2)))
lang_id(char *text, int len) {
  int englishness = 0;
  for (; len; text++, len--) {
    int threegram = *(int*)text & 0xffFFff;
    if (threegram == sp_th) englishness++;
    else if (threegram == os_sp) englishness--;
  }
  return englishness > 0 ? lang_en : lang_es;
}
```

This works well, and compiles (with -Os -fomit-frame-pointer) to 22 instructions, 53 bytes:

```
08048504 <lang_id>:
 8048504:       53                      push   %ebx
 8048505:       31 c9                   xor    %ecx,%ecx
 8048507:       eb 23                   jmp    804852c <lang_id+0x28>
 8048509:       8b 18                   mov    (%eax),%ebx
 804850b:       81 e3 ff ff ff 00       and    $0xffffff,%ebx
 8048511:       81 fb 20 74 68 00       cmp    $0x687420,%ebx
 8048517:       75 03                   jne    804851c <lang_id+0x18>
 8048519:       41                      inc    %ecx
 804851a:       eb 0e                   jmp    804852a <lang_id+0x26>
 804851c:       81 fb 6f 73 20 00       cmp    $0x20736f,%ebx
 8048522:       0f 94 c3                sete   %bl
 8048525:       0f b6 db                movzbl %bl,%ebx
 8048528:       29 d9                   sub    %ebx,%ecx
 804852a:       40                      inc    %eax
 804852b:       4a                      dec    %edx
 804852c:       85 d2                   test   %edx,%edx
 804852e:       75 d9                   jne    8048509 <lang_id+0x5>
 8048530:       31 c0                   xor    %eax,%eax
 8048532:       85 c9                   test   %ecx,%ecx
 8048534:       0f 9e c0                setle  %al
 8048537:       5b                      pop    %ebx
 8048538:       c3                      ret
```

You could squish this down quite a bit more; the eight-byte `sete;movzbl;sub` sequence is there to avoid a three-byte `jne;dec` sequence, if you swapped the functions of `%edx` and `%ecx`, you could use the two-byte x86 `loop` instruction instead of the five-byte `dec;test;jne` version; and you can probably skip the handling of the empty string with the unconditional jump to the end of the loop. The untested 45-byte result is:

```
        ## Distinguish English from Spanish in a text buffer.

        .globl langid
langid:
        push   %ebx
        mov    %edx, %ecx
        xor    %edx, %edx
loop:   mov    (%eax), %ebx
        and    $0xffffff, %ebx
        cmp    $(' ' | 't' << 8 | 'h' << 16), %ebx
        jne    test2
        inc    %edx
        jmp    incr
test2:  cmp    $('o' | 's' << 8 | ' ' << 16), %ebx
        jne    incr
        dec    %edx
incr:   inc    %eax
        loop   loop
        xor    %eax, %eax
        test   %edx, %edx
        setle  %al
        pop    %ebx
        ret
```

By factoring out the N-grams into a data structure (`for threegram, idx in features { if threegram == here { counts[idx]++ } }`) , you could probably extend this with another 4 bytes or so per language, up to a dozen or so languages, with reasonably good results, but you'd need to choose the N-grams with reference to all the languages; 'os ' and 'de ', for example, turn out to be common in a number of Romance languages, so you might end up using some other, less common N-gram; and as a result you might have to use more than one N-gram per language.

As an example, here are the top 3-grams from 12 megabytes of Catalan (also from WikiCorpus 1.0):

```
56343 que
58327 en
62273 ent
62702  el
67923  la
76707 el
80647 la
110601 de
126960 es
169507  de
```

Compared to Spanish:

```
109439  co
112939 en
134011 el
136181 es
136930 la
138318 as
151942  la
195466 os
251117 de
319299  de
```

In the Catalan corpus, 'os ' occurs 15674 times, about once every 800 bytes --- one-eighth as common as in Spanish, but common enough that you should probably pick a different 3-gram to distinguish between Spanish and Catalan. ' i ' occurs much more frequently in Catalan than in Spanish (and ' i ' occurs not at all in the KJV) but I'm not quite sure what occurs much more frequently in Spanish than in Catalan.

If you found a reasonable set of 3-grams (or even 2-grams or 4-grams) that distinguished the different languages in your set, you could perhaps search for a machine-code hash function that maps one or two of the desirable 3-grams into each of a few buckets. This might take less space than storing the 3-grams themselves, since you could choose a set of 3-grams that happened to have a compact machine-code representation.

Topics

Options for bootstrapping a compiler from a tiny compiler using Brainfuck

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

What's the simplest instruction set for a compiler that can compile itself? I think you probably need some kind of looping construct, some kind of way to read in bytes, some kind of way to output bytes, and probably sequencing of statements. You can probably avoid much parsing by making the input instructions be single bytes, but you probably still need some kind of arithmetic to calculate the jump offsets.

Mats Linander's Awib is a multi-target optimizing BF compiler written in BF, with six backends (it can output Linux i386 ELF executables, C, Tcl, Golang, Ruby, and Java), so BF is clearly a sufficiently powerful language to write a self-compiling compiler in. (It also contains an ASCII-art portrait of Meriday in the morning and can be compiled as Tcl, bash, or C, as well as BF. Truly impressive.) It's about 43 kilobytes, and it would presumably run under Urban Müller's original 240-byte AmigaOS BF compiler or Brian Raiter's 199-byte Linux version: http://www.muppetlabs.com/~breadbox/software/tiny/bf.asm.txt

Daniel B. Cristofani has written a much more minimal BF self-compiler, targeting C; I found a copy at http://esoteric.sange.fi/brainfuck/impl/compilers/dbf2c.b, and he has a copy on his own web site at http://www.hevanet.com/cristofd/brainfuck/dbf2c.b. It seems to work; anyway, I compiled it with itself, verified that it produced the same output when compiled with the self-compiled version of itself, compiled Linus Åkesson's Game of Life with it, and played Life successfully on the result. Cristofani's self-compiler for BF is 1183 bytes, but running Erik Bosman's bfstrip utility from http://esoteric.sange.fi/brainfuck/utils/bf-tools/bfstrip.c on it reduces it to 904 bytes.

So, one approach to bootstrapping things from BF would be to compile programs from other languages into BF, and then run them with one of these BF interpreters. But I think there's a much more interesting approach available, which is to add some instructions to a self-compiling BF implementation, recompile it with itself, and then update it to use the new instructions.

Topics

Solar-powered portable computers

Kragen Javier Sitaker, 2016-09-17 (updated 2018-10-28) (15 minutes)

Today, with off-the-shelf microcontrollers, you could build a computer, somewhat superior in speed and screen size to a Sun 4, that runs off a solar cell from a solar calculator. Memory is somewhat trickier. The hardware BOM cost is about US$30 or US$40.

Computational power would not be the power bottleneck, even with a fairly powerful CPU; rather, memory power (to erase Flash especially) and display power are likely to outweigh the CPU.

Suns

First, a word on the class of machine that desktop software was designed for.

The Unix workstation revolution was sparked by what Raj Reddy called the "3M computers": one MIPS, one megapixel, one megabyte of RAM, for under a megapenny. This was what you needed for a PARC-style GUI. The SUN (later called the Sun-1) was one of these, as were the NeXT, the Apollo, and the doomed PERQ. These machines all came with dozens of megabytes of disk.

The diskless Sun-3/60 I used to use as an X terminal is about 3 MIPS (InfoWorld, 1988-11-14, "Sun Shows Tempest Versions of Sun-3/4 Workstations", by Scott Mace) with an 1152×900 display (I think it has a bwtwo and a cgfour in it, but I think I was using a monochrome monitor). By the end of the 1980s, various Sun 4 models (based on the 1987 SPARC family) exceeded 10 MIPS; the contemporary DECStation 3100 was 20 MIPS, with DEC forcing its competitors down to a price of a thousand dollars per MIPS. Some DECStations at UNM provided internet access to 50 or 100 concurrent users when I started using them around 1994.

By that time, much more than a megabyte of RAM was commonplace on these workstations. There was a memory-price bubble from about 1992 to about 1996 during which a RAM cartel held prices steady at around US$40 per megabyte before finally collapsing to the Moore's-law trend line at about US$10 per megabyte; before that, memory was halving in price every couple of years, so, in 1990, it was around US$80 per megabyte. My Sun-3/60 from 1988 has, IIRC, a full complement of 48 megs of RAM, which at US$160 per megabyte would have cost Sun about US$8000, a bit out of line with the cost of the rest of the machine — but I suspect that RAM was added later.

But 16 megs would be an entirely reasonable amount.

So, our target is 10 MIPS, 1 megapixel, 16 megabytes of RAM, and let's say a gigabyte of disk.

Displays

An E-ink display needs about 1 mW on average to keep it updated for continuous comfortable reading. (This number comes from the Keyboard-powered computers (p. 2220), which says that a 6" E-Ink display needs about 750 mW during a 120 ms screen update, for 122×91 mm at 167 dpi, 190 nJ/pixel, 8100 nJ/mm²; 8 20-em lines of 7-point text work out to 49 mm × 20 mm, or 8 mJ per update, and

about 50 words, so about 0.16 mJ per word; at 350 words per minute that's almost a milliwatt. Larger text is more power-hungry.)

They can be a little hard to come by; the Seeed Studio one I found on DX is AR$390 (US$26) and only 200×96 pixels at 111 dpi (57 mm × 29 mm), enough for 12 lines of 40 characters. Old reflective passive-matrix feature phone replacement displays might be a viable alternative, and they are very cheap if you can find them (US$3, say). The Nokia 2730 display costs AR$78 (US$5) on MercadoLibre at the moment; it's QVGA resolution (which I guess is 320×240) and does 200 dpi 18-bit color. More recent smartphone displays are probably too power-hungry.

Microcontrollers

Various kinds of off-the-shelf low-power microcontrollers consume a bit less than a nanojoule per instruction, which has been stable for a decade or more and might finally start trending down again.

Processing power can scale down smoothly with available energy up to a point. Atmel picoPower ARMs, which go up to 48MHz (at 1 insn/cycle), do 1–10 µW in standby (and only 250 pJ/insn) but take 4–20 µs to wake up. Some MSP430s are below 0.3 µW idle, while others are in the same range as the Atmel chips, but wake up much faster. (These numbers come from file low-power-micros in this repo.)

ARMs are ubiquitous these days, and they're power-efficient and do a lot of work per clock cycle and per instruction. However, it might make bootstrapping quicker to use a different processor architecture, one that has existing self-hosted assemblers, compilers, and development environments available as relics from the homebrew personal computer era that have some chance of running in the very limited RAM on a microcontroller. That basically means 6502, 8080, or 8086, and nowadays that basically means 8080, specifically Z80.

Zilog — now a fabless semiconductor house — still makes Z80s (now the "eZ80" and "ZGATE" lines) for microcontroller applications. Toshiba has a Z80-compatible microcontroller line called the 870/C. Unfortunately all of these are fairly overpriced and underpowered. A typical part is the EZ80F93AZ020SG, which costs US$6.14, runs at 20MHz, and has 64K of Flash and 4K of on-chip RAM, but supports off-chip RAM too. It's not designed for low-power operation — it sucks 180 milliwatts when not sleeping, working out to a rather hefty 9 nanojoules per instruction, assuming one instruction per cycle. Even Zilog is switching to ARMs nowadays.

For a while, many MP3 players used Z80-derivative DSP chips like the ATJ2085; some of them were called "S1mp3", and an alternative firmware was developed for them. Digi-Key doesn't carry the ATJ2085.

Nowadays it probably makes more sense to try to run a Z80 emulator in software on an ARM core than to run an actual Z80. An LPC4310FET100.551 runs you US$7.74 from Digi-Key, has 168 kB of RAM, is ROMless (it has a bootloader in ROM that loads code from an external NOR Flash or other device at startup), runs its two ARM cores at 204MHz, and runs down to 2.2 volts, and even then it uses only 160 milliwatts, less than the EZ80F93AZ020SG.

Solar calculators

I walked by a cheap-shit electronics store today and saw a bunch of small solar calculators for AR$40 (US$2.60). It occurred to me to wonder how much computational power you could run off one of their solar cells.

I think they use inefficient amorphous silicon photovoltaic cells rather than the standard 16%-efficient polycrystalline silicon used for rooftop and utility-scale solar panels, and the cells look like they're about 9 mm × 36 mm. This means about 320 milliwatts of sunlight falls on them even in direct sun. If we suppose it's 9% efficient, as Wikipedia's "Thin-film cell" article says of production thin-film amorphous (silicon?) cells, then that's 29 mW, which at the 1.7-V a-Si bandgap voltage would be 17 mA.

At a nanojoule per instruction, 29 mW is 29 MIPS!

```
You have: 9 mm * 36 mm * 1000 W/m^2 * 9% / nanojoule
You want: MHz
        * 29.16
```

Energy storage in capacitors

Can you extend the usefulness of a wimpy solar cell with some solid-state energy storage?

Off-the-shelf ceramic capacitors can store in the range of 1–4 mJ; you can get a 1 mJ 6.3 V 47 µF ceramic capacitor, holding 1 mJ, for US$0.12. If you were to try to stuff the calculator with US$2.60 worth of these, you would have 21 mJ of storage, enough for about 21 million instructions (or 84 million on the picoPower chips). This is enough for a minute or so of CPU word processing, but it's not enough to update the display.

Garden lights and batteries

I bought some solar garden lights at the supermarket a few months ago for AR$40 (about US$2.90 I think; XXX check this). They have a 300 mAh 1.2 V NiCd AA cell inside powering a white LED and a polycrystalline solar cell on top that's about 40 mm × 40 mm; they claim it provides light for about 8 hours, although I haven't tested how much current it takes. It probably doesn't have a MPPT controller (the only component visible on the tiny PCB is a through-hole ⅛ W resistor, although there's a tiny blob of epoxy that might be hiding something). But it probably doesn't need one, in the sense that the cell should produce about a quarter watt in full sun, which would fully charge the cell in 1.4 hours:

```
You have: (300 milliamp hours 1.2 volts) / (40 mm * 40 mm * 1000 W/m^2 * 16%)
You want: hours
        * 1.40625
```

So it's probably limited by the battery, not the solar cell, so it probably fully charges the battery to its full charge of 1.3 kJ (!!), which is 1.3 trillion nanojoules and thus about 1.3 trillion instructions, which would be 1.3 million seconds (about two weeks) at 1 MIPS, or about two weeks of continuous E-ink reading. ¼ W at 1 nJ/insn is of course 250 MIPS.

Memory

Unfortunately, the microcontrollers I mentioned above are plenty fast, have very little memory. A typical example is the NXP MKW01Z128 mentioned in License-free femtowatt UHF radio transceiver ICs under a μJ per bit (p. 162): a 48 MHz 32-bit RISC in-order Cortex-M0 CPU with a built-in 600 kbps license-free RF transceiver, with 128 KiB of Flash and 16 KiB of RAM. (It uses about 1.2 nanojoules per instruction if it's receiving data at the same time.)

For many year, it has been normal for a desktop computer to have about as much RAM as it can access in a second, which works out to have been very roughly a megabyte per megahertz. You will note that this microcontroller is nowhere close to this balance, with 48 MHz (and about 48 MIPS) but 0.144 megabytes, a factor of some 300 away from the balance for a desktop computer. This is a very common problem with current microcontrollers.

At this point, old 36-pin and 72-pin SIMMs are e-waste that can be freely scavenged or bought for prices in the neighborhood of a dollar or less, typically ranging from 4 MB to 32 MB. But these run on 5 V and typically have standby currents of a few milliamps and operating currents of over an amp, which means they use on the order of 5000 mW running at full speed and tens of milliwatts just to retain data. So they aren't really an option.

Chips to look at:

https://www.pjrc.com/mp3/simm/simm.html

There are reasonably inexpensive SRAM chips out there that can provide a megabyte or two of RAM for a few dollars, but nothing bigger. DRAM is thousands of times cheaper (right now Pricewatch lists DDR3-1600 DIMMs at US$30 for 8 GiB, under US$4/GiB, which would be 6¼¢/16 MiB) but very power- hungry. Even just retaining data in DRAM uses a lot of power.

(You will note that US$4/GiB today in 2016 and US$40/MiB in 1992 is a factor of ten thousand in 24 years, which is a bit over 13 doublings — a doubling time of about 22 months, reasonably close to the Moore's trend line I mentioned.)

Flash memory, by contrast, can typically retain data for ten years while turned off and dissipating only tiny amounts of energy it had stored while turned on, and always at least a few months. And it's even cheaper than DRAM: Pricewatch lists 64GB SDHC cards at US$18, or US$0.28 per GB, almost 15 times cheaper than DRAM. It even uses a little less power to read than SRAM or DRAM do. But erasing Flash is enormously more power-hungry than erasing SRAM or DRAM.

(Other kinds of nonvolatile memory — FeRAM/FRAM, MRAM, CBRAM, PCM RAM — have broadly similar characteristics to Flash.)

It's tempting to think of Flash as having similar access characteristics to a hard disk, but that's only really true for erasing. Reading written data is very fast, and can typically be done a byte at a time only a few times slower than reading entire blocks. This means that with the appropriate data structures, Flash can replace much of the RAM in our 1990 workstation, as well as its disk.

Erasing and writing data to Flash is about a thousand times slower than reading it.

Writing to erased blocks is somewhat fast, Even when you have to write by pages, they're 256-byte or 264-byte pages, and writing them takes about 700 microseconds — you can do 1400 pages per second on a single cheap Flash chip, compared to the 50 random spinning-rust disk writes you could do in 1990, or the 120 you can do nowadays. Sequentially, you could write a megabyte per second (2048 pages) to pre-erased disk at the time, or a third of a megabyte per second (1400 pages) to pre-erased Flash now. And these Flash chips are so cheap that it makes sense to use several of them, multiplying your bandwidth and allowing block erases to be concurrent with reads and writes.

Many Flash chips have bit-serial interfaces, which makes them much easier to hook up to a microcontroller. None of the SRAM or DRAM chips I've been able to find on Digi-Key have bit-serial interfaces, which means that driving them from a cheap microcontroller is going to require hooking up some kind of shift register to control the address bus.

So maybe we can get by with only a megabyte of real RAM and, say, 32 gigabytes of Flash.

There's a distinction I'm ignoring here, which is that the Flash that's fast to read a byte from is NOR, and a megabyte of it costs about US$0.46. So 32 gigabytes of it would be about US$15000, which is significantly more than the US$9 of NAND Flash. In practice you probably want all three types: maybe a couple megabytes of real RAM (US$8), 16 megabytes of NOR Flash (US$7), and 32 gigabytes of NAND Flash (another US$7).

A brief note on autonomous cyclic fabrication systems from inorganic raw materials

Kragen Javier Sitaker, 2018-04-27 (1 minute)

"Cyclic fabrication system" is a term due to Moses, Yamaguchi, and Chirikjian for, roughly, a fabrication system that can reproduce itself — a self-replicating robot. Such systems, once they exist, will eliminate scarcity of many or most material goods, make interplanetary mining an annoyingly ubiquitous reality, and convert problems like global warming and asteroid strikes from existential risks into manageable problems.

So how do we build one? This depends in part on the environment (terrestrial, space?) and the available materials (iridium, platinum, water, aluminum oxide, carbon, iron, nickel, oxygen?).

I'm going to restrict my attention here to inorganic raw materials, even though this body is typing this in an environment with a locally high density of available organic materials with very nice engineering material properties.

Fired clay

Fired clay is the fundamental technology for human-driven (non-autonomous) terrestrial cyclic fabrication. Although tools of stone figure prominently in the human geological record, going back a hundred and fifty thousand generations, we developed pottery some fifteen hundred generations ago, and this is currently the basis for all of human industry.

Clay has

The Adafruit Feather

Kragen Javier Sitaker, 2018-06-30 (1 minute)

The Adafruit Feather 32U4 seems like the modern successor to the Arduino. It has a slightly smaller form factor (22.9 mm × 50.8 mm), comes with a LiPo battery-charging circuit, weighs 4.8 g, and it's based on the ATmega32U4 at 8 MHz at 3.3V. This is a step down in computational power, but also in power consumed. But it has 20 GPIOs, 7 PWM pins, 10 analog inputs, a prototyping area, and its pin spacing is breadboard- and perfboard-compatible; and it supports USB directly, so you can directly do things like keyboards.

And of course it's software-compatible with Arduino, although it's running at half the cock speed.

Instead of "shields", the Feather has "wings", which plug into optional female headers you can solder on. There are a few dozen wings available, including things like Wi-Fi, OLED displays, etc. I²C is the primary means of communication between the Feather and its Wings in order to get a limited amount of stackability.

There are also Feather base boards with other CPUs, apparently including a Cortex-M0 with Wi-Fi (an ATSAMD21 and ATWINC1500, US$35), a Cortex-M4, an ESP32 ("Huzzah32", US$20), an ESP8266 ("Huzzah", US$17), and an STM32F205 with Wi-Fi ("WICED", US$35).

Parallel NFA evaluation

Kragen Javier Sitaker, 2015-09-03 (updated 2015-10-01) (8 minutes)

How can you parallelize or incrementalize the evaluation of a finite state machine? Although this has been considered in the past in the context of parallelizing text search queries like WAIS across Thinking Machines, this is a particularly important problem right now, because tokenization is almost always the performance bottleneck of simple compilers and parsers, and parallelization is the key to performance on modern computers.

Background

All of this is well known; it's included in Blelloch's 1993 review of parallel prefix sum computation but was almost published by Ladner and Fischer in 1980, and then was published by Hillis and Steele in 1986.

Explanation

A simple and general approach which yields logarithmic running time for an NFA on a sufficiently large parallel machine is as follows. Assume WOLOG that the text length n is a power of 2. Begin with an ε-free NFA. For each character `c[i]` for `i` from 0 to n–1 of the input text, in parallel, compute a relation `t[i, i+1]` as the set of edges in the NFA that transition on `c[i]`. Then, in lg n parallel steps, coalesce adjacent intervals in `t` into larger intervals with this compose operation: compose(a, b), where a and b are relations, is the ordinary relational composition operation, which produces the relation (`s[j]`, `e[j]`) for the maximal set of `s[j]`, `e[j]` such that for each `j` there is at least one `m` such that (`s[j]`, `m`) is in a, and (`m`, `e[j]`) is in b. In each parallel step h, we are coalescing intervals of size 2^{h-1} with this composition operation.

That is, in step $h > 0$, for each `i` divisible by 2^h, we compute

`t[i, i+`2^h`] = compose(t[i, i+`2^{h-1}`], t[i+`2^{h-1}`, i+`2^h`])`

using the values we computed in step $h - 1$.

The size of the relation for any given interval of any size is capped at the square of the number of states in the NFA, so in the worst case, it does not increase with the length of the text, so for a given NFA, this takes Ω(lg n) runtime in the worst case. Average-case analysis is trickier, in part because it depends both on what an "average" NFA is and on what an "average" text is, but my intuition is that, in practical cases, the relation size for a text span of any length more than a few characters will be under, say, 10.

Sooner or later you need to constrain the leftmost state to be the NFA's initial state; it is probably best to do this by a special case in computing `t[0]`, since that will save work in all the nodes that include it.

Having done this, you can propagate the results back down the tree of intervals in another lg n steps, providing you with the exact reachable set of NFA states at each character boundary in the initial input.

This is the standard Blelloch prefix-sum algorithm, merely using

the relational composition operator as the reduction operation rather than numerical addition. (Apparently Kogge–Stone is more common in current codebases?)

In theory, you can get about a 5% improvement in total runtime by coalescing triples of adjacent intervals in each step rather than pairs. In practice, depending on the relative costs of communication and computation, the optimal branching factor may be something different from 2, 3, or 4. For example, if communication has high latency, it may be 32 or 1024. (This also depends on the characteristics of the NFA: a higher branching factor may reduce the size of the intermediate-result relations substantially.)

Reducing an NFA to a DFA is useful for many computational models, but in this case, the larger number of states in the DFA is likely to be a handicap. You probably want to be coalescing your intervals using the smallest alphabet of states you can get away with.

In practice, you probably want to do most of the computation serially; if you have 8192 cores, the best you can do is an 8192× speedup (ignoring superlinear speedups from caching and the like) so you might as well start out generating 8192 `t[i, i+m]` values on the 8192 cores by linearly running the finite automaton over each of 8192 chunks (probably as a lazily-materialized DFA rather than as an NFA), followed by, say, 13 steps of alternating communication and coalescence.

Applications

Using Bjoern Hoehrmann's new parsing algorithm "parselov", which conservatively approximates the language of a context-free grammar by compiling a stack-limited conservative approximation of its PDA into a finite automaton, it should be possible to perform nearly all of the work of parsing in parallel using this algorithm. However, I'm not entirely sure how big parselov's finite automaton is, and if it has a sufficiently large set of intermediate states, this might not work.

Google Code Search used to provide a public regular expression search over all public code. For normal kinds of regular expression searches, where you aren't interested in matches bigger than a few megabytes, parallelization on a cluster is probably not useful. If you do need larger matches, for example on genome or proteome searches, parallelism may be useful.

Using Levenshtein automata, you can generate reasonable-sized NFAs to find strings within a small Levenshtein distance of a given string. (Baeza-Yates and Gonnet, I think, came up with a different way to do this that takes advantage of bit-parallelism in modern CPUs and is therefore usually faster in the serial case.) However, if the text being searched is static enough to be indexed, it is probably faster to run Levenshtein automata on a suffix array of the text, especially now that we have compressed indexing and practical linear-time suffix-array construction algorithms.

You can use a variant of this algorithm to incrementally update finite-state-machine results — the construction is the usual construction of an incremental algorithm from a parallel algorithm, where the high concurrency of the dependency graph of the values computed during the execution of the algorithm translates into being able to change some of the input without invalidating much of the

total data flow graph. Concretely, if one of the input blocks at the leaves of the tree changes, you recompute its mapping of starting parse states to ending parse states, then propagate that change back up and down the tree, potentially affecting the parses of all subsequent blocks.

You can also use this approach to parse a *substring* of a sentence of a regular language, simply by starting the parse of the leftmost block with the "superposition" of all states, like the other blocks, rather than the usual initial state. This is potentially useful, for example, for syntax highlighting in a text editor (or in a code snippet in a web page) or for parse-error recovery in a compiler. Moreover, the substring parse can then be extended in either direction by inspecting a larger part of the sentence.

            resources: irq:17 memory:f3000000-f3003fff
```

This card is reputed to have 192 Kepler-architecture shader cores (plus another 192 that are locked), and its performance is similar to the GeForce 630M. It runs at 850 MHz and has 2GiB of RAM, "16 texture mapping units and 16 ROPs".

Pixel Rate: 3.400 GPixel/s
Texture Rate: 13.60 GTexel/s
FP32 (float) performance: 326.4 GFLOPS
FP64 (double) performance: 13.60 GFLOPS (1:24)
DirectXL: 12.0 (11_0)
OpenGL: 4.6
OpenCL: 1.2
Vulkan: 1.1.82
CUDA: 3.0
Shader Model: 5.1

326.4 gigaflops sounds like a lot. The Intel GPU in my ultrabook (see Notes on the Intel N3700 i915 GPU in this ASUS E403S laptop (p. 2033)) is 51.2 gigaflops, and its CPU is 25.6. So it's a bit more

than 4× the speed of the ultrabook.

It's from 2012 and still sold for US$60 in 2017.

The memory system is 900 MHz DDR3 and 128 bits wide, so it can do 1800 million 128-bit transactions per second, for a total bandwidth of 28.8 gigabytes per second.

The GeForce 600 series page on Wikipedia has further details. The GeForce 630 is listed as "Entry level".

By contrast, a current NVIDIA Volta card is the US$9000 Nvidia Quadro GV100, with 14800 gigaflops, plus tensor processing units that do 4×4 FP16 matrix multiply-accumulates.

Notes on QR code capabilities on typical Android hand computers

Kragen Javier Sitaker, 2018-09-10 (2 minutes)

Alejandra's cellphone automatically scans QR codes when they show up in the camera app, popping up a translucent notification. If they are a Mecard (or presumably a VCARD) it offers to add a contact, attaching the photo from which the QR code was snagged. If they are text, it displays about the first 27 characters of it, displaying newlines as spaces, and offers a chance to copy it to the clipboard. If they begin with "http:" (I guess?) it has a "chain link" button to follow the link. Gzipped data shows up as a question mark in a diamond, the "substitute" symbol.

Presumably it also supports vCalendar and Wi-Fi network codes.

Encoding life.py (1987 bytes) resulted in a QR code it failed to recognize. However, angleadd.py (1060 bytes) resulted in a scannable QR code, which resulted in text that could be pasted into a notepad, containing the full Python program; however, this doesn't work reliably. With -s 1 and the default PNG type in qrencode, I get a 117×117 barcode. fraktur.py (566 bytes, 89×89) worked somewhat more reliably, including at 2×2 pixels per module (which I guess means 50 modules per inch?); the UTF-8 decoded properly but most of the Fraktur glyphs are missing from the phone's fontset.

Alejandra installed an QR-code scanner from F-Droid, and it was able to scan the Mecard, but it didn't recognize it as a Mecard.

https://github.com/zxing/zxing/wiki/Barcode-Contents goes into some more details, though from a 2016 perspective.

https://qrworld.wordpress.com/2011/06/16/how-to-create-qr-codesoo-for-business-cards/ talks about Mecard vs. VCARD in 2011. Apparently by then Mecard was actually more widely supported than VCARD.

Aaron Toponce went hardcore for his business card: https://pthree.org/2010/01/07/qr-code-with-mecard-and-hcard/

State of the world 2016

Kragen Javier Sitaker, 2016-09-05 (10 minutes)

An apocalyptic religious cult has captured an area the size of Syria in an effort to bring about the end of the world. It conducts mass executions of "apostates" about once a month, and enslaves many of the people it conquers. This year, it says, the Mahdi will appear; he will lead them to victory against Rome's crusader armies in Dabiq.

The United States routinely uses tele-operated flying military robots to incinerate people suspected of opposing it in areas far from any battlefield. A repentant US robot operator has just gone public with his story after personally killing some 1600 people, many of them innocent. A repentant CIA agent has just been released from prison, where he was serving a sentence for blowing the whistle on the CIA's illegal torture program. No other participants in the torture program have yet been charged with crimes by a court.

A resurgent undemocratic Russia has just revealed that, for the last fourteen years, rogue intelligence agents in the United States has been inserting undetected spying software into computers around the globe, including reprogramming the controllers in their hard disk drives.

A year and a half ago, a soft-spoken ex-CIA employee fled the US, first to Hong Kong and then to Russia, having released a massive collection of classified documents showing the extent of the US's illegal spying programs at home and abroad. He is still in hiding in Russia. Among other things, he showed that US spies had broken into all of the data centers of many US technology companies and stolen their customers' information. Now, US tech companies are in open conflict with the intelligence agencies. Many of them are redesigning their products and systems to frustrate intelligence agencies.

At about the same time, the founder of Russia's biggest online social networking system, through which hundreds of millions of users maintain contact with their friends, fled to the US after legal harassment by the Russian government. Today he is working on an encrypted messaging system.

Meanwhile, in a room in the Ecuadorean embassy in London, there lives an Australian hacker and award-winning journalist whose hair went white in his thirties. He has not left the embassy for years. The Ecuadorean government granted him political asylum three years ago when the British government sought to extradite him to Sweden, from which he claims he would be extradited to the US. A secret US grand jury investigation of his journalism started years ago, after it published a large collection of classified US embassy cables which have been a crucial source for journalists and scholars of international relations ever since.

The political assassination of nearly the entire staff of a satirical weekly newspaper in France has resulted in a wave of anti-Muslim violence throughout the country and new restrictions on speech and freedom of association throughout the continent.

In Argentina, where the currency is collapsing, the president has just been indicted by a state's attorney for covering up an Iranian

terrorist attack on a Jewish building. The previous state's attorney was found dead in his apartment the day before he was to present the charges against her.

The Pope and the president of Russia both announced last year that the Third World War had begun.

A volatile, pseudonymous virtual currency built on cryptography, implemented by software written by a mysterious figure known only by the pseudonym Satoshi Nakamoto, has a US$3 billion market capitalization (down from US$17 billion) and half a billion dollars a month in trading volume. Many countries have outlawed it. Custom chips designed only to process this virtual currency now populate multi-megawatt data centers throughout the world.

Meanwhile, prominent technologists warn that artificial intelligence is likely to end the human race, and that automation will destroy most jobs even sooner.

US citizens seeking solace in traditional belief systems have begun to shun vaccination, and diseases such as measles that were eradicated generations ago have begun to return to the nation. Polio begins to spread internationally in areas afflicted by armed insurrection, especially Pakistan, where many polio vaccination workers have been killed since the US hunted down jihadist leader Osama bin Laden in 2011 using a fake vaccination program.

A US movie studio shut down a couple of months ago for a period of time and pulled a satirical movie about North Korea after all its internal emails were stolen and released. The US government blames the attack on North Korea, but an anonymous group of bored teenagers seems more likely.

A worldwide conspiracy of anonymous bored teenagers known as Anonymous has been temporarily politically neutralized by, primarily, US law enforcement, after they began to uncover and publish information about illegal conspiracies within large US companies. The US has one journalist imprisoned for attempting to report on the group. A splinter group numbering a few hundred thousand has been honing harassment tactics against US feminists, particularly those who criticize video games.

Uruguay, Colorado, Washington, Alaska, Oregon, and Washington, DC legalize recreational marijuana. Belgium legalizes euthanasia for the terminally ill, and the Queen of Belgium, who has been sick for years, dies.

A year ago, Ukraine exploded in protests that overthrow its pro-Russian government; Russia annexes part of Ukraine. US elites are debating the merits of arming Ukraine. Ukrainian nationalists are using hand-launched artisanal flying robots made in Dnepropetrovsk to surveil pro-Russian forces from the air, but not yet to kill them. Ukrainian children collect fresh remnants of artillery shells.

Switzerland unpegs the Swiss franc from the Euro, immediately bankrupting several major foreign-exchange brokerage firms who had offered their customers extreme leverage with which to speculate.

Greece, suffering a worse economic downturn than the Great Depression, elects a party that claims to be a coalition of the radical left, which immediately begins to reverse privatization and government downsizing, and plan to shut down the concentration camps into which the previous government had herded asylum seekers. The new government hires a video game company's

Economist-In-Residence as its finance minister, and the continent is full of speculation that Greece will withdraw from the Euro. Greek banks seem to be collapsing as a result.

Australia, by contrast, continues to herd asylum seekers into concentration camps, where they are imprisoned for the rest of their lives for the crime of not being Australian.

The US continues to lead the world in imprisoning its own citizens with 1% of its adults in prison, rivaling the Stalin-era USSR on a per-capita basis, and remains the only country in the Americas to execute them. Although it continues not to publish any official statistics on the matter, its police continue to extrajudicially execute several times as many US citizens (Wikipedia counts 593 cases in 2014) as are executed legally (Wikipedia counts 39 cases in 2013), a practice that has provoked widespread protests for the last several months, centering around the execution of an unarmed teenager in Ferguson, Missouri. China, however, leads the world in executions, executing thousands of people per year, more than the rest of the world combined.

Amidst all of this, the total installed volume of photovoltaic panels (almost entirely made in China, which is now the world's biggest economy) is increasing by 30% per year, and oil prices have fallen by more than half to their lowest price in years, plunging Venezuela into a serious economic crisis and putting economic pressure on Russia. After adopting controversial new mining techniques that cause frequent earthquakes in previously seismically stable areas, the US has returned its oil production to their peak levels in the 1970s, and now its oil production is exceeded only by Saudi Arabia and Russia.

Meanwhile, atmospheric CO_2 has shot past 400 ppm, higher than it has been in 4.5 million years, 120 ppm higher than before the Industrial Revolution, due to burning fossil fuels. As a consequence, 2014 was the hottest year in recorded history; NASA reports that the southwestern US is almost certain to face "megadroughts" lasting decades, droughts unmatched in a millennium.

This is the political landscape of the early 20th century.

A quarter of the world's population has Linux-based personal computers in their pockets, running at microwave frequencies and always wirelessly connected to the internet. This number doubles every year. These computers are not secure, and their users do not have root, so they can be used to spy on the users without their knowledge. The US commonly does this to target people for assassination by flying robot.

We have a free encyclopedia universally available to anyone on the internet, and that anyone can edit. It continues to grow linearly, reaching almost 5 billion articles, the equivalent of about 2000 volumes. Against all odds, it continues to remain more reliable than any previously written encyclopedia. Encyclopedia Britannica has ceased print publication. Many newspapers have also ceased publication.

All new luxury cars now come with onboard supercomputers that record GPS traces of their travels. This data is sent back to the manufacturer to analyze.

Vector instructions

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

Old Crays had vector instructions. These used a "vector length" register and a "vector mask" register to specify which items in the vector to process.

On the Cray Y-MP C90, there were eight vector registers, V0 to V7, each containing a 128-element vector of 64-bit values; a vector instruction would process corresponding elements of two of these registers, two at a time, and deposit the results in another vector register. But you didn't have to process all 128; the "vector length" register could terminate the process early if you didn't have that many.

These vector instructions could be pipelined in the sense that the result from one could be fed incrementally to another, as long as they used different functional units.

Vector registers were loaded from and stored to central memory using a "block transfer" with a first word address, an increment or decrement (stride), and a vector length; and this could participate in the pipelining. Thus a sequence of vector instructions could construct a flow graph that loaded some sequences of values from main memory, processed them, and wrote them back to main memory, all in a pipeline, but the viewpoint of the assembly program was that it was conducting a series of in-order operations on large vectors. As the manual says, "The CRAY Y-MP C90 computer system allows a vector register reserved for results to become the operand register of a succeeding instruction."

There were also scalar registers, which could be used with vector instructions as arithmetic operands.

The only vector integer operations provided were sum, difference, and, or, xor, and leading zero count. In floating-point, you had the usual operations, except that instead of division, you had only reciprocal.

The "vector mask" register could be used to select elements from one vector or another, or to replace selected elements with zero or a scalar register. (In related selection operations, you had a "register shift" group which I don't understand.) The vector mask could be set by numerical tests on a vector register: [<=>≤≥≠]0. There was also a variant of the VM-setting instruction that puts the indices of the matching elements into another vector register, although I don't think there was a way to use those indices except one at a time.

GPT-2 sets the scene

Kragen Javier Sitaker, 2019-11-22 (updated 2019-12-01) (22 minutes)

I thought I'd try out GPT-2's abilities at generating some adjective-heavy descriptive prose, using Talk To Transformer.

I think this kind of thing could be dangerous for humans with an inclination towards psychosis; they could easily start to think these texts were messages for them from God or demons or the CIA or something. Even humans not prone to psychosis are vulnerable to the Eliza Effect, where by pareidolia they read all kinds of meaning into any text with even the slightest semblance of coherence. And this text has more than the slightest semblance.

Yawning in the echoing forest

My prompt:

As the red sun rose over the mists of the echoing forest, I awoke to a spiderweb sparkling in the fog, yawned and stretched, and smelled the musty-sweet smell of the bog.

GPT-2 completions:

• I yawned again and stretched, and ate breakfast. I ate a little more, and yawned some more. I was very hungry, but I couldn't figure out what my new surroundings were, except that there were new memories that I didn't want to lose. After lunch I walked down into the bog, pulling my shoes onto my feet and shivering.
• It reminded me of hot stewed serpents and sweet jellies and it terrified me, like at any moment I might step onto wits one of those monsters of my dreams and get jolted like Milla Jovovich. I emerged from the forest, using a talisman to summon my trusty Glaive. The
• Like a cheap copy of Gray's Anatomy, a billowing furry body yawned "I love you", it said in my ear. I woke again, and gazed at the black waters of the Old River. "You're still here", I croaked, and let a limp hand break free of my splintered wrist. "Don
• I crawled to the wick of the bulbous flame, snuffed it out, and brought it to the campfire. [hippies including Wes Craven! Craven doesn't actually use the term "personas", the last thing I want to do is abuse a trend in film criticism that some people cherish. "Person
• When I remembered this I laughed, and took a moment to look around. Only one person on the park had been sleeping that night, a slim man with a thin mustache and a big purple head, who had not attended to his own business but was watching me with that perplexed look of his.

"I sleep

Well, that's interesting. Sleepy amnesiac exploring nature; terror fantasy; extreme furry S&M porn; film criticism, and some kind of creepy sci-fi.

Trumpet flower moths in the night

My prompt:

The trumpet flowers opened at dusk and released their intoxicating scent, drawing giant clearwing moths from near and far, who fluttered like doves as they came to sip the sweet nectar.

GPT-2 completions:

• A stormy sky blanketed the land, thick with thunder and lightning. A sea of rubble had amassed where the town of Mazarkis had nodded in unison. A massive oak tower had caught the lightning that struck the town and released sparks that cut the air like torches. "It is here," the rain outside his window
• Until the lights were gone, the guards seemed to sit there for hours
On the smooth-skating marble atrium, chattering idly in their
Pause one, out of sight, as if just as anxious to get back to their
Equipment as to allow happy times for themselves.
At noon, another guard came by with a bou
• They would land and start up the sky lane a few times in an hour, or perhaps take a nap. While women in my family were the avid bakers, the fondness of my father for stone roasted, braised and popcorn tofu grilled chicken barbecue johndoes not even begin to cover what a goddamn delight he found each of these
• The night continued to be dark and bright. About that time the sound of water from a well almost drowned us all. Ten feet down the cave was a basin, in which two men and two women were bathing.
But I wondered why they were there, and found it very puzzling. We were none of us dumb enough to
• The birds were gone by daybreak, and the scent they left was said to be iridescent in the cold morning air. When the night arrived, the blossoms burst out into the night sky, reaching skyward for a few moments before lowering on either side. By the time dawn emerged, most of the blossoms had withered into black globes

Again, a great variety: a suspenseful fantasy scene (what happened to the town of Mazarkis? Did the lightning reduce it to rubble?), poetry about guards on (?) an atrium, weird family cooking recollections, some kind of group adventure story, rapid cycling of dark and light with "iridescent scent". I love it! It's better than a cut-up!

Boca Juniors celebration

My prompt:

Safe within my massive artificial mountain of glued-together pebbles and sand, I listened to the wild festivities celebrating our victory over Boca Juniors without, as the revelers danced in the streets and beat their wild drums.

GPT-2 completions:

• But I was too saddened by our defeat for this. I too was beat down by feelings of regret and remorse that no-one, not even George Ross, could stop from allowing it to happen. Why? Because he knew, without a doubt, that there was always an impossible task
• Not to be outdone, the team took to the field to advance the story of the year by beating Santos on match day and earning the franchise's first win over the most hated team in Liga MX. After a rematch, Montagliani presented us with the trophy, giving his team the trophy

• So I lay back, relaxing and savoring the moment. The lovely Filipino lady came in behind me and as she rubbed my shoulders I began to lighten up a little.
She drew my hand towards her breasts and kissed me like I had

never been kissed before and she wanted
• My sun-kissed skin flowed in waves along my pebbled thighs as I
• What a war these factions have fought for a week. Boca Juniors, I fear not their armies, nor their luck, nor their rich coffers, but what would a victorious opponent for them? Would they tolerate our spirit, our style of play, and our joy of life? Surely no

This is hilarious! A tortured self-reflection, sports nonsense, regular porn, very weird but short porn, and some kind of political agitprop against a soccer team.

Swordfight scene

My prompt:

Gray struck him again, harder, with the edge of his shining scimitar, but the Mazarkin's armor held. With a great cry, he leapt into the air and kicked at Gray's head, but Gray had already ducked, and as the other landed on his feet, Gray whirled to face him, battered shield up.

GPT-2 completions:

• "Better protect my lord!" he shouted, "If you kill me, your queen dies!" To Gray's surprise, Brown's face went white, and his spear dropped. The elves
• Gray only had his blade at his side. "I'm through with you, Garro ! "

"No," says Garro, looking up at Gray with eyes hard as stones. "
• It took half a dozen blows before Gray was soundly knocked to the ground. Once on the ground, Gray saw that the Mazarkin had seemingly dodged everything he could think
• "You! A coward. You must have been blind, talking Your Grace. But not brave. A coward. You cannot give up so easily. This will make you strong."
• With one hand, he banged the edge of the shield upon Gray's head again, causing blood to come spilling from the wound. Then he lifted his great sword again and

So, pretty consistent in that they're all continuations of the fight scene, but several are dialogue, and one has elves. They're shorter than the earlier continuations and thus less interesting, which I think is a limitation of the Talk To Transformer site.

Vampire predation

My prompt:

As her hot blood filled my mouth, she trembled in helpless delight. I felt her fiery life filling my veins, dispelling for a little while my ghostly pallor, as I held her delicate form firmly

• in my arms. I swallowed my hard-earned seed. I was still feeling pretty drained when she finally came down from her thrilling, and very intense, release.

When I had finally finally calmed down, I sat back and looked at what I had just accomplished. Her delicate flesh was bulging from her shapeless suit. Even the crisp dressing on her soft flesh was
• by my dainty hands. I willed her to fall into deep sleep, and so drove her to all her. Lips, and to her great desires.

I willed all in me now to throw my strength into renewing this last struggle, even that I might not fail to make her submit to my

advances. Soon, the heavy suck
• in my arms.
"Haah, I'm getting too old for this now."
"Do not be, the life energy is a nourishment that is best given when married. However, because we married earlier, we would need to make it look like our love is growing as if it were a flower that you throw out into the wind. With this, we
• in my embrace. With a tongue as rough as the hungry pit on her throat, my lips caressed her beautiful jade-cut lips, and softly nibbled her hard tender nips. Turning her head to face me, she whispered: "You have captured my spirit, and I am yours forever."

• in my arms.
My hands had been in rough contact with her soft and delicate torso, and I could feel a pair of soft yet firm buttocks growing between my fingers. With no other thought than that she needed what I wanted, I guided my now numb
Okay, so, normal if somewhat surreal porn, incoherent vampire story, more coherent vampire story, romantic porn with links, and very weird porn that I actually cut off here because it got more sexually explicit than I want to include here. "Firm buttocks growing between my fingers" is a very surreal image.

An agony of grief

My prompt:

I crumpled to the ground in agony. "Why?" I asked. "Why him? Why now?" Suddenly knowing I would never again in my life see his dear, sweet face, never again touch his cheek, filled my chest with an unbearable tightness.

GPT-2 completions:

• "Why?" "What can it mean?" "Do you know how I hate you, O God?" "Then answer me. And she has been here, who knows not, never seen the place? "Oh, Christ
• I cried aloud, weeping with all my yet unearthly force, as though my heart had been broken, my blood were I heard some one moaning, muffled somewhere deep in the woods, the roar of an unknown beast. N
• I ran back to the big tree and tried to put out the fire. I had to wash my face before I could get a word out. Even the pebbles in my face and from the tree trail made my arm ac
• "Why this at last ?" I mumbled. "Why, what's the matter?" One minute. . . . . and then. "Shame on the hotel!" It was 9:30 P.M. Why? Why
• My palms had been moistened and my cheeks throbbed when I touched him, but this new feeling struck me too and all my physical and psychological strength fled. As he passed, I went to one corner of the room and sat quietly

This one is harder. Emotionally, I mean. The first is some kind of bargaining with a very interactive sort of God; the second continues in the theme of grief and weeping ("cried aloud" would have been better than "asked" in my prompt, I think); the third is some kind of emergency response; the fourth is incongruously pedestrian; and the fifth is about accompanying a loved one in their death.

FOREST NEEDS MOAR MODIFIERS

My prompt:

The ancient, verdant forest sighed sweetly and fragrantly in the warm, soft breeze. Excitable young bluebirds flitted brightly between the thick, secretly radioactive branches,

GPT-2 completions:

• happily humming their song and laughing as they threw confetti into the air. The hum was barely noticeable to her; her already radiant mood greatly improved. The towering cypress trees looked grand in the background of the sparkling white lakes and sparkling white waters.

'Beautiful, isn't it? Wonderful!'

'Oh, this is just like our precious home.'

'Our home

• poking and pecking each other, and eyeing the red-headed teacher intently. It was a moment of peace before all hell broke loose...

The Vermilion Girls: Softly Sharp Knives of Laughter

From the Sword Art Online anime is currently airing a one-shot manga, and by my count there is at least 6 different chapters in this series. In each volume,

• their vibrant, brilliant blue feathers just as bright as those of a current-day hummingbird. It was like one long day spent reading a long, windy passage of literature, or smelling a powerful perfume.

What-what-what-what? Sniffle.

'Waaaaaaaah'

As if somehow overcome by pleasure and a lingering sense of despair, Erin

• a new specimen emerging from the shadows and spying on me. I approached the bird and gave a quick squawk. "Hah, alert! You're too early. A feeder came by just before the first meal!" I was almost there. "Ugh, sorry." "You won't catch a feeder there." "Uh-huh. Not any time

• and those who weren't looking for secrets quickly went in to the forest in a hurry. After searching through dozens of trees and examining their contents, they finally realized something: it was a lockpick.

How to hide a lockpick? It was easy, the trees did not have to be smothered with soot and they did not need to be cut down to have easy access to the

This was an experiment in going overboard on adjectives and adverbs, and in some cases it was successfully transferred to the output, to the point of self-parody at times; "the sparkling white lakes and sparkling white waters," really?

The first is some kind of party-nostalgic scene (bluebirds throwing confetti!); the second one is some kind of blurb for a lesbian porn manga or something (whose awesome title is original); the third one is some kind of fiction but I don't know what; the fourth has anthropomorphic birds seeking "feeders"; and the fifth is some kind of demented adventure.

No modifiers, just a helicopter

My prompt:

Rayentray slid through the door half a second before it slammed, belting herself

into the helicopter's copilot seat. "Ready!" she grinned, as the blades deafened the neighborhood and they began to rise.

GPT-2 completions:

• Angie shuddered and slammed the door shut behind them, as the primary ignition roared to life. The helicopter's mated engines roared to life, as the aircraft soared above the rooftops. The two pilots, each carrying one M107 Thunderchief heavy machine gun, looked down
• "Well, I'm expecting lots of calling, but no need to hurry. It will be taken care of. I could be here any minute. Come on!" Right at the moment their throats were becoming over-taxed, Sabertooth I stepped into view through the door,
• "We're a military-transport aircraft, and I'll get into any a simulation where I can beat you any time!" she laughed. Soon, the aircraft had climbed so high in the sky, the top-shelf F-111s that were based at Roswell with their Predator-2s were unable
• she spoke into the radio. "Crew elevator deck 703, VCHADE 703, emergency closing."

She flipped the switch and as they hurtled upwards the top canopy opened, revealing a woman with pigtails and a headband.

"Shall we do this?" Judy smiled, gripping her pistol tighter
• "You want to stop? Here we come."

The exterior walls of the home were immaculately maintained. The interior might as well have been a spaceship. The home belonged to Georgette and her small brood, who lived out their afternoons in comfort, ignorance and opulence. It was

So, lots of military stuff; an interesting thing is that three other characters appear, and all three are also women, like Rayentray. Unless Sabertooth is a person.

The fake military terms are really impressive. The "M107 Thunderchief heavy machine gun" sounds so convincing you'd think it must have been lifted wholesale from somewhere, but in fact the M107 is a sniper rifle, one person can't carry a heavy machine gun, and the Thunderchief was a US fighter-bomber aircraft. Similarly, the F-111 was retired in 1998, before the Predator really entered use, and the Predator-2 is a handheld toy quadcopter; you wouldn't use either a Predator or a Predator 2 with an F-111 even if they were in service at the same time.

This was an experiment in going to the other extreme: *no* adjectives or adverbs (except, I guess, "copilot seat" uses "copilot" as an adjective). To compensate, I tried to channel my inner thesaurus, Tom-Swifting things a bit.

#2 is pretty incoherent.

Invented Wikipedia articles

The Arbëreshë are a real people, Albanians who settled in Italy several centuries ago, but essentially everything GPT-2 says about them is false. They generally belong to the Orthodox Christian Church.

My prompt:

[edit]
Religiously, most Arbëreshë belong to

GPT-2 completes:

• the Church of the 'Everlasting God' (Qanat, a god eternally active, and the offspring of all other gods). Indeed, they consider the Dark Lord of the universe to be a reincarnation of the god(s) originally at war with Elantris and are constantly warning others to stop him. Their dread of the Mortal World greatly offsets their obsession with magic, which often turns them astray and warps their thinking. They don't fear death, even at the hands of
• the Church of Sarben, which has its headquarters in Anarres. The belief in the omnipotence and total justice of the Gods and Goddesses is generally the basis of most Arbëreshë beliefs, which sometimes come to the fore in disputes or personal conflicts. Even if one does not follow any specific religion, Arbëreshë still consider themselves to be descendants of the gods and goddesses of their forefathers. For example, Velyar 'cause it is his beloved
• several different Indo-European groups (see Wikipedia:Indo-European), with Ashirasë, the highest, being associated with the Nordics (see Norse, Bulgars).

In their position of the highest divine state, the Shaidar-i-Asrar or Shaidar-i-Ištar were historically known as the primary divine of all the Arbëshes, and the more exalted of the divine-favored inhabitants of the world. Ashiras
• the Old Fëan religion. Most have strong ties to Athelâr, and it is through that religion that most Arbëreshë worship and take their oaths. There are some more distant Arbëreshë, especially those who worship other deities, who do not belong to a single religion. It is rare, however, for Arbëreshë to do so without also taking an oath from them.[1][2]

Some Arbëreshë form their
• a tradition that dates back to the founding of the city by Tulu (also called Tulu-túru) in the year 498 Eru. Since that time, it has flourished, but still today the chief religion is still that of Tulu-túru. During the present times it was preached, practiced, and followed by most people in the region, who consider the church to be the ancestor of the current Tulu-túru, and especially its priests and lector

I think the first of these is wonderfully creative: a god that is the *offspring* of all the other gods. The second refers to Anarres, the fictional impoverished anarchist moon in Le Guin's *The Dispossessed*.

Gauzy shit

Kragen Javier Sitaker, 2018-11-04 (4 minutes)

Trying to calculate caustics (see files Caustics (p. 1619) and Caustic simulation (p. 1454)) and "Windy" Oona Raisanen's oscilloscope traces and whatnot, it occurred to me that there's a very simple solution.

Let's think about caustics first. You have some uniform light density ρ on some original surface, you know, a caustic generator, and that density gets splayed across some other surface in some nonuniform but computable and continuous way. If you want to find the density at a pixel of the caustic, the simple solution is to take the *inverse* of that computable, continuous mapping, and map the pixel center point through it; it will give you zero or more points on the generator, since the inverse is not, in general, a function. You need to sum the density from those zero or more points.

The density from each point, however, depends on the "focusing" from that point on the generator (which may be infinite). Consider a small parcel of area ε around the point on the generator. This parcel, with total brightness ρε, gets spread over some area on the caustic, which is some function of the partial derivative matrix of location on the caustic according to location on the generator. I think maybe it's the determinant. Anyway, then you take the reciprocal of that, and you get the brightness contribution at that point. (You may want to add some small value to the absolute value of the reciprocal to prevent singularities, analogous to how the finite spatial coherency of light in space prevents singularities in the electromagnetic field.)

I think that you can do this more efficiently in the usual cases by computing not just this brightness but also its gradient in the neighborhood of the sample pixel. Then you can do the full calculation of the inverse and its gradient at some subset of points, like 1/16 or 1/64 or something, and just interpolate at other points.

If your sample points are evenly spaced, this is a lot like the algorithm for computing Perlin noise, except that not just the gradient but also the base brightness value is nonzero at the sampled point. And of course it's not random.

However, I think you can do better than this with an approach similar to raymarching with signed distance functions. You don't need very many samples in areas with very uniform gradients, and in areas where the gradients are changing rapidly, you need a lot of samples. You can try to approximate this by sampling the derivative matrix of the gradient (is that the Jacobian?) or you can compute the gradient over an area using interval arithmetic, rather than at a point using ordinary arithmetic.

(Yes, that's the Jacobian, and the Jacobian determinant gives you the brightness, or the reciprocal brightness, depending on which Jacobian you're considering.)

In the case of Raisanen's oscilloscope traces, we have to solve the same problem once for each column of oscilloscope pixels. Within that time interval, our brightness is spread out uniformly over a single dimension of time, but there may be very many points in time that map to the same vertical pixel. We can sum the reciprocals of the

(absolute plus epsilon) derivative of the waveform at these points to get the total brightness deposited at the pixel. And, as before, if the second derivative is very small, we don't need to sample very densely.

In both cases, of course, we could avoid the inverse problem and just iterate over parcels of the generator. But I think that's almost certain to lead to sampling some areas far too densely while sampling other areas far too sparsely.

Or will it? Approximating the inverse function, in the general case, seems like it'll mostly depend on that same kind of sampling, so it may not actually gain us anything to start from the pixels on the caustic rather than the generator.

A stack of coordinate contexts

Kragen Javier Sitaker, 2007 to 2009 (9 minutes)

I thought I had a novel way of thinking about automatic APL-style lifting of pointwise operators, and it yielded some interesting suggestions, but I think it turns out it kind of sucks as a generic way of thinking about APL operators. Here I document my blind alley in case other people find it interesting.

The Problem

In APL, you can write 4 + 5 and get 9, or 4 + 3 4 5 6 and get 7 8 9 10, or 4 5 6 + 2 3 8 and get 6 8 14. And you can similarly add a vector to a matrix, and each element of the vector will be added to an entire row (or column, depending on your point of view) of the matrix. And so on.

The Basic Approach

So here's a way to think about that.

Suppose we have a (possibly finite) stack of coordinate contexts, each of which contains one coordinate, and each of our values is a function of this stack. Scalars don't look at the stack at all. Vectors look at the top item on the stack to figure out which scalar to return. Matrices look at the top two. Now we consider our language's e.g. multiplication to be pointwise multiplication over these functions.

Suppose we use + to denote mathematical addition and +. to denote the addition operator of our language. Then we can say

```
x + y = \ C . x(C) +. y(C)  where C is a coordinate stack.
```

So if x and y are both scalars, then so is the result; if one is a vector and the other is a scalar, then the result will be a vector, in that it will depend on the top item of the coordinate stack for one side of the addition; and so on. This automatically provides the desired behavior for binary operators on vectors of different ranks.

Unintuitively, the indices that we normally think of as changing fastest are further down the stack.

Can we define other APL functions this way?

Transpose and Compose

If we want to define the transposition operator that transposes the first two indices, we can define it in terms of cons, car, and cdr functions on coordinate stacks. car returns the top index off the stack; cdr returns a coordinate stack missing that top index; and cons returns a coordinate stack with a new car pushed on top of what was previously there.

```
transpose x = \ C . x(cons (car (cdr C)) (cons (car C) (cdr (cdr C))))
```

That's just the Forth SWAP or the PostScript exch operator. It's probably clearer if I write it with Haskell's right-associative infix cons operator ':' and pattern-matching:

```
transpose x = \a:b:z . x (b:a:z)
```

If we define transpose this way, then we can apply it to a scalar --- but the resulting value will require at least two stack levels that it actually ignores, i.e. will be an infinite matrix. I could add error-checking cases to transpose to handle this.

(XXX this is wrong. What you want is something that transposes the two leftmost indices, the ones that change slowest, not the ones that chnage fastest.)

There's a useful operator that Numeric calls "take", and which APL implements by indexing one array with another (e.g. 4 5 6[1 2 1] yields 4 5 4, and 4 5 6[2 3 rho 1 2 2 1 3 1] yields 2 3 rho 4 5 5 4 6 4).

In its most basic form it only applies to a one-dimensional array as its first argument. I'll call it "compose". Can we define this "compose" operator?

```
compose(lookuptable, indices) = \C.lookuptable(cons(indices(C), nil))
```

That is, we create a new coordinate stack to use to index the lookuptable, consisting only of the values from indices. That's OK for one-dimensional lookuptables, but maybe we can generalize it so that it does the right thing if the elements of the lookuptable are vectors or more complicated things.

To do that, we need to provide the leftover elements of the coordinate stack --- the ones not needed to index into indices --- to lookuptable in place of the nil.

Taking Rank Into Account

So now we need to consider each array as more than just a function from coordinate stacks to scalars; now we also care about its rank (although that was obvious from the start, since without knowing its rank and also its size in each dimension, we can't do simple things like display it on the screen).

So now I am losing interest, because I think this way of thinking about it doesn't actually simplify things any over the traditional view (where an array consists of a vector of dimensions and a vector of contents). But I'll pursue it just a little bit longer. Let's call the contents function of x "x.f", and its rank function, which tells how many items it cares about on the coordinate stack, "x.r", and write { f = x.f, r = x.r } to express a new one identical to x. So we have

```
x + y = { f = \ C . x.f(C) +. y.f(C), r = max(x.r, y.r) }
transpose x = { f = \a:b:z . x.f(b:a:z), r = x.r }
compose(lookuptable, indices) = {
    f = \ C . lookuptable.f(cons(indices.f(C), dropn(C, indices.r))),
    r = indices.r + lookuptable.r - 1
} where dropn(X, 0) = X and dropn(X, N>0) = cdr dropn(X, N-1)
```

The more general form of the "+" case for scalar binary operations is

```
scalarop(op, x, y) = { f = \C . op(x.f(C), y.f(C)), r = max(x.r, y.r) }
```

You could treat arbitrary unary scalar operations as if they were

vectors, then apply them with compose:

```
opvalue(op) = { f = \C . op(car C), r = 1 }
```

Or you could have a scalarunop:

```
scalarunop(op, x) = { f = \C . op(x C), r = x.r }
```

(It seems like you ought to be able to derive the "r"s mechanically from the expressions for the stacks to which you're applying the "f"s. In the transpose case, the stack is still the same height, so the rank is the same; in the compose case, we drop indices.r items from the stack and then add one, so we need an extra indices.r - 1 items. But I'm not quite sure how to do that yet.)

The other basic Forth stack manipulation operators also have interesting functions. DUP, diminishing the rank by 1, takes the diagonal of a matrix; DROP, increasing the rank by 1, turns a vector into a matrix so that it can be applied column-wise. For now I'm not going to think about OVER (diagonal between first and third dimensions?), ROT (rearranging the order of the top three coordinates?), NIP, TUCK, 2DUP, and 2DROP.

Iota

One-dimensional monadic iota is fairly straightforward; its content function doesn't depend at all on its argument. (Only its size does, and we haven't talked about size yet.)

```
iota = { f = car, r = 1 }
```

APL's N-dimensional monadic iota is kind of stupid; it takes the values produced by the one-dimensional iota --- as many as needed --- and then reshapes them into the requested shape.

Numerical Python has a somewhat more general operation called "indices". Applied to a vector describing an N-dimensional shape, it returns N sets of indices, each of which has the shape requested, and contains the Nth index. For example:

```
>>> Numeric.indices((2, 3))
array([[[0, 0, 0],
        [1, 1, 1]],
       [[0, 1, 2],
        [0, 1, 2]]])
```

So the first top-level item has the first coordinate of each location, the second item has the second coordinate, etc. That is, Numeric.indices((a,b))[0][x][y] == x, and Numeric.indices((a,b))[1][x][y] == y. This sounds stupid but is very useful if you want to tabulate values of N-dimensional functions.

Unfortunately it's a little clumsy to work with in the one-dimensional case, because iota (which it calls "arange") is wrapped in another layer of nesting. It's a little clumsy to define in this system; although its pointwise value is, like iota, just one of the coordinates, the number that specifies which coordinate is hidden deep in the stack, and counts backward from there.

```
indices(dims) = {
    f(C) = C[length(dims) - C[length(dims)] - 1],
    r = length(dims) + 1
}
```

The "- 1" is there to make the coordinates zero-based.

Reshape

Reshape (dyadic rho) is extremely simple in the standard representation, and rather a dog's breakfast in this one.

Reduce

Reduce ought to work by default along the axis that changes slowest, and that's kind of ugly here.

Conclusions

It was a cute idea --- especially the Forth stack manipulations turning into operations --- but I think it makes things more complicated, not less.

Obscurity platform

Kragen Javier Sitaker, 2018-04-27 (1 minute)

One useful measure for security through obscurity might be running on a platform that doesn't have a lot of out-of-the-box exploits available for it. GEF supports x86, ARM, AARCH64, MIPS, PowerPC, and SPARC, but GDB also supports ARC, MicroBlaze, m68k, NDS32, Nios II, S/390, and TMS320C6x; of these, m68k is pretty comfortable and has a lot of tooling available, so might be a good choice.

The J1A or RISC-V might also be pretty reasonable platforms, but a bit bleeding-edge.

Linux on m68k seems to be pretty dead (web page not updated since 2000; last Debian release Etch) and FreeBSD is gone too, but NetBSD still supports m68k. Also HP-PA, SuperH, and VAX. These are "Tier II" ports. There are a number of JIT 68000 emulators for popular machines; Basilisk II (GPL) successfully runs old versions of MacOS, and there's a reasonable amount of interest in QEMU support for it; QEMU at one point in 2014 got to being able to boot Linux/m68k on an emulated Mac, barely. These unfortunately require Macintosh ROMs.

GCC also, crucially, supports m68k, up to at least GCC 4.9 and maybe GCC 5, I'm not sure.

(Unicorn also, unfortunately, supports m68k.)

Maybe Counting Characters in UTF-8 Strings Isn't Fast After All!

Kragen Javier Sitaker, 2007 to 2009 (15 minutes)

These are responses to Reddit comments on http://canonical.org/~kragen/strlen-utf8.html.

I Think I Was Wrong

From reading the Reddit comments, I now think that the results I got didn't justify the conclusion I drew, and the evidence now suggests that iterating over the code points in a UTF-8 string *is* significantly slower than iterating over the code points in an ASCII string. Thanks, guys! I should dig into it a bit more and see if I can learn more.

It looks like my results were really skewed by using `gcc -O` instead of pretty much any other level of optimization. By ill chance, I happened to test things on the single optimization level that would give the results I got.

"bonzinip" writes:

> crap. no one in their right mind would use lodsb on a modern processor. my results are

> ```
>
> more or less the same for all three benchmarks

Well, I pointed out in the page that `lodsb` was a bad idea, even on an old processor; on old processors, you should use `scasb` instead, as `gcc -O` does. XXX aristotle used lodsb

The really interesting thing about your results, though, is that `my_strlen` is more than *twice as fast* as any of the UTF-8 versions, and *four times as fast* as what the C compiler used in this case. If that's the best we can do for UTF-8, then counting characters in UTF-8 strings *isn't* fast. It's slow!

I'll try to reproduce your results; what processor are you using, what compiler and options, and what is the generated assembly code?

"Porges" writes:

3:             my_strlen_s(string) =   33554431: 0.120325
```

Edit: I should note this is -O2, not -O as in the post.
... I've posted a followup to this. http://reddit.com/info/6moej/comments/

As with bonzinip's results, the UTF-8 counters are half as fast as the C-coded byte counters, and about one fourth as fast as `strlen`. What processor is this, and what is the emitted assembly?

"splidge" comments on "Porges'" post:

Yes, for me running with -O gives results similar to the original post whereas -O3 gives results similar to yours.

In fact, running without -O gives pretty much the same results for the default strlen() as -O3, with -O coming out significantly slower. The other C implementations improve from no optimisation to -O to -O3 as you would expect.

(I don't have anything to say about this, except that it's kind of depressing, but I thought it was important to archive.)

"rolfr" writes:

This guy's using obsolete performance measurements. Number of instructions in the inner loop hasn't been important for ages; it's all about the pipeline characteristics of said instructions.

Yes, you are right. I'm pretty ignorant about assembly-language optimization on modern processors, or, for that matter, on non-modern processors. Knowing I was ignorant, I only used instruction counts as a heuristic and relied on observed runtime measurements for my actual conclusions.

"Wavicle" writes:

To be fair, he bases his final conclusions on the observed runtime over large strings *of the same value repeated*. Thus he trains the branch predictor to always make the same optimization each time.

That's a fair objection. I wonder if it makes a large difference.

The Point

I didn't write that page to prove some predetermined point. I wrote it to document my (our) exploration of a hypothesis of Aristotle's, namely that iterating over the code points in a UTF-8 string was approximately as fast as iterating over the code points of an ASCII string.

Then, at the end, I listed some things I thought I'd learned in the process, including this #3:

Aristotle was essentially correct: the penalty for counting UTF-8 characters, or indexing into or iterating over the characters of a UTF-8 string, is very small.

As a result of this structure, the Reddit comments contained a lot of speculation about what "the point" of the page was, and a bunch of people missing it.

"ochuuzu1" writes:

> Also, plus, WTF: no one in their right mind would use `strlen()` in a performance-critical inner loop of any real application.
>
> You can tweak `strlen()` to make it run as fast as you possibly can, but it will never be faster than not calling `strlen()` in the first place.

Of course you are right. `strlen` is just a proxy here for the speed of iterating over the characters in a string, which is indeed found in performance-critical inner loops of many real applications.

"cracki" writes:

> haha. nullterminated strings are stupid. **counting** characters is stupid. it costs you nothing to keep the length around.

Same comment.

UTF-8 as an Internal Representation

"GolemXIV" writes:

> I hope that I should not have to use UTF as in memory representation at all (with exceptions of course). It would be so nice if I could leave UTF* to places where characters are stored or streamed.
>
> UTF/UCS combining marks means that programs cannot treat one code point as being the same as one unit for editing even when you use UTF-4 (UTF-32). That sucks small planets when not streaming or storing strings.
>
> Is there string libraries on programming languages where character type refers to a base character together with all the combining characters that are attached to it? I would like to work with vectors of character objects, not with code points.

I agree that often it would be much better to have vectors, or at least sequences, of character objects rather than code points or bytes or UTF-16 bytepairs. I don't know of any string libraries that work this way, but I'm pretty ignorant about Unicode, so maybe there are some.

It's a good point that converting UTF-8 to UCS-4 still doesn't save you as much hassle as one might naively hope, because of things like combining characters.

Occasionally, though, I've heard assertions that UTF-8 is very inefficient, because finding the Nth code point of a UTF-8 string is O(N). The hypothesis I started with was that (a) iterating over the code points is more important than indexing them randomly and (b) iterating over them is as fast as iterating over ASCII bytes. If that's correct, then while you might decide that UTF-8 is a bad internal representation for some reason or other, it shouldn't be because you're afraid it's slow. And GolemXIV makes a good point that even in UCS-4, you can have arbitrarily many code points that display in a single spot on the display.

"cracki" writes:

> besides, it's an encoding. you're meant to decode it if you need to work with the contents. hardly anybody has any excuse for not expanding utf-8 to 32 bit characters in memory. then, even indexing is constant time.

Well, regardless of what you're *meant* to do, you should decode it if that leads to a system that makes people happier --- say, running acceptably fast while being simpler and overall easier to debug and modify. A lot of times, finding a simpler way involves exploring a lot of ideas that sound kind of crazy, like not decoding your UTF-8. And most of them *are* crazy, and this one probably is too, but you have to explore them in order to find out.

Miscellaneous

"silon" writes:

> Please do not call the function strlen

I didn't; I called it things like `my_strlen_utf8_s`.

"bonzinip" writes:

> because the string instructions are very slow and go through the microcode sequencer. i would just use normal `mov` and `inc` instructions.

You'll notice that that's what the C version of `strlen` compiled to, and that it was faster than my dumb `lodsb` version and GCC's dumb `rep scasb` version.

"bart2019" writes:

> The storage of an integer is ridiculously little compared to the storage of the string contents itself.

I suppose that depends on how many of your strings are less than 4 or 8 bytes, doesn't it? I've written a number of programs nearly all of whose strings were that short.

(That said, I basically agree that null-terminated strings are a bad idea.)

Carl Friedrich Bolz ("cfbolz") writes:

> Implementing ropes well is not trivial. A while ago I tried to to implement the Python string type in such a way as to internally use ropes [in] PyPy. I never managed to get ropes perform significantly better than array-based strings for real-life benchmarks (although I admit I didn't try anything extreme with 2GB of text or so).

It's true that ropes, like other clever data structures with beautiful big-O numbers, tend to have higher constant factors. But I don't think they're all that much higher. (I seem to recall that the SGI STL includes a C++ rope implementation called "cord", and the Boehm garbage collector includes a rope implementation called "rope"; I might have gotten the names backwards, though.)

One of the trouble with real-life benchmarks is that people write real-life code to perform acceptably on the implementations they have; so they tend to heavily lean towards the things that were very efficient on the old implementation, and away from the things that you hope you're improving. Dick Gabriel wrote about this back in the 1980s in p.3, section 1.1 of Performance and Evaluation of Lisp Systems:

> There is a range of methodologies for determining the speed of an implementation. The most basic methodology is to examine the machine instructions that are used to implement constructs in the language, to look up in the hardware manual the timings for these instructions, and then to add up the times needed. Another methodology is to propose a sequence of relatively small benchmarks and to time each one under the conditions that are important to the investigator (under typical load average, with expected working-set sizes, etc). Finally, real (naturally occurring) code can be used for the benchmarks.
>
> Unfortunately, each of these representative methodologies has problems. The simple instruction-counting methodology does not adequately take into account the effects of cache memories, system services (such as disk service), and other interactions within the machine and operating system. The middle, small-benchmark methodology is susceptible to 'edge' effects: that is, the small size of the benchmark may cause it to straddle a boundary of some sort and this leads to unrepresentative results. For instance, a small benchmark may be partly on one page and partly on another, which may cause many page faults. Finally, the real-code methodology, while accurately measuring a particular implementation (namely, the implementation on which the program was developed), is not necessarily accurate when comparing implementations. For example, programmers, knowing the performance profile of their machine and implementation, will typically bias their style of programming on that piece of

code. Hence, had an expert on another system attempted to program the same algorithms, a different program might have resulted.

He goes into more detail in section 1.4.3, p. 28:

One way to measure those characteristics relevant to a particular audience is to benchmark large programs that are of interest to that audience and that are large enough so that the combinational aspects of the problem domain are reasonably unified. For example, part of an algebra simplification or symbolic integration system might be an appropriate benchmark for a group of users implementing and using a MACSYMA-like system.

The problems with using a large system for benchmarking are that the same Lisp code may or may not run on the various Lisp systems or the obvious translation might not be the best implementation of the benchmark for a different Lisp system. For instance, a Lisp without multidimensional arrays might choose to implement them as arrays whose elements are other arrays, or it might use lists of lists if the only operations on the multidimensional array involve scanning through the elements in a predetermined order. A reasoning program that uses floating-point numbers 0--1 on one system might use fixed-point arithmetic with numbers 0--1000 on another.

Bolz makes the same point in his blog post on the PyPy ropes:

Using ropes to implement strings has some interesting effects. The most obvious one is that string concatenation, slicing and repetition is really fast (I suspect that it is amortized O(1), but haven't proved it). This is probably not helping most existing Python programs because people tend to code in such a way that these operations are not done too often.

More to take into account:

http://porg.es/blog/ridiculous-utf-8-character-counting George Pollard's comment on Colin Percival's approach
http://www.reddit.com/r/programming/info/6m5yg/ reddit comments on Colin Percival's approach, which includes the lovely comment:

What would be even more useful, would be if people attempted to make a "fastest" random-access indexed lookup of a full Unicode codepoint in a stream or buffer of UTF8. If that could be made speedy enough, then there would be less of a need to store 16 or 32 bit codepoints internally, and always need conversions.

XCHG: An Archival Swap Machine

Kragen Javier Sitaker, 2014-06-29 (7 minutes)

Move machines suffer one big problem as a replacement for Brainfuck: the register operands are necessarily in pairs, which halves code density in some sense and means that reading the code can easily suffer from framing errors. $&@ might mean write to $ and then transfer & to @, or transfer $ to & and then read from @, depending on where we are.

As a fix to this, I suggest a variant move machine with 26 directly nameable registers, one for each English letter, and two instructions for each one: a capital letter to read it into the accumulator, or perhaps subtract it, and a lowercase letter to write the accumulator to it. So Ab would copy A to B, and Abc would copy A to both B and C.

A further convenience for compiled code would be to define the digits such as 4 as "multiply accumulator by 10 and add 4". This allows constants to be provided in a reasonable way.

Subleq is a universal OISC. So we can get all arithmetic from just subtraction; a single subtracting accumulator is thus a sufficient interface for all arithmetic. You could memory-map it with a single location, which gives the current total when read or subtracts when written.

Subleq, however, also includes a signed comparison and conditional jump. And to program anything more than state machines on it, you need self-modifying code, unless you make its output and one of its inputs indirectly addressed.

To get around the state machine limitation, you can memory-map a pointer register and its pointee, like the PIC. And getting a jump requires memory-mapping the program counter. The combination almost gives you a conditional jump; all that's left is a way to get a Boolean to index with, like a < instruction that fills the accumulator with its sign bit. That way you can index to either the program counter or the word after it.

This memory-mapping the PC thing means that your memory cells need to be more than a byte, so figure 32 bits.

One final thing needed to make the machine reasonable: a subroutine return mechanism. Let's say that when writing to the program counter directly (not as a pointee) we swap the would-be new program counter value with the accumulator. Then the callee can save it upon entry for return later.

Could that work as a general mechanism? It would eliminate the read-write distinction, but you would need a memory-mapped copy/discard device in addition to the subtractor, the pointer, the pointee, and the program counter. But you would get 80-some printable registers instead of 26. As a special bonus, you could claim the machine was "linear" or "reversible".

You also need input and output devices. The traditional Brainfuck ., interface seems adequate, but should use the accumulator contents, and can reliably report end of file.

I recommend writing code for this machine on fixed-width lines of 100 characters in order to make subroutine calls work reasonably.

This seems like a machine that should be nearly as easy to implement on most machines as Brainfuck, but much easier to generate code for. Let's take the always-swap option:

; always reads as the last value written to :, discarding written data
, discards written data and reads as the next byte of input
. writes output and reads zero
0123456789 multiply accumulator by ten and add a digit
- reads the subtracted total and also subtracts the current accumulator from it
' is a register pointing to memory
" is an alias for the place ' points to
< sets the accumulator to -1 if it is negative, 0 otherwise
^ is the program counter

9 instructions and memory-mapped locations, not much worse than Brainfuck's 8 instructions. Alternatively, without the cutesy swap thing, except for jumps:

Aa read and write bytes of input and output
0123456789 multiply by ten and add a digit
B reads the subtracted total
b subtracts the accumulator from it
C reads the value at the address written to D (maybe use B instead?)
c writes the value at the address written to D
Dd read and write a register that is normal except for controlling C
E reads the address of the next instruction
e sets the address of the next instruction, causing a jump, and also sets the accumulator to what the next instruction would have been
< fills the accumulator with its sign bit
Other letters read and write general-purpose registers.

This is 7 to 10 instructions depending on how you analyze it. It seems to me that these two formulations are close to the same complexity to implement, but the first one is much more novel, and either might turn out to be easier to program with — by which I mostly mean write compiler backends targeting it. You have the capacity to do subroutines/functions, multiple threads, dynamic dispatch, array indexing, and so on.

x = y + z is, with the swap machine, y-z--:;-;--x, I think, starting with a zero subtractor. We subtract y and z from zero to get the negated sum. We store that in : to use it twice to make it positive, then read the sum and store it in x.

Zeroing the subtractor is a challenge, because zeroing is irreversible. We need to subtract not only the subtractor's original contents, but also the accumulator contents that we folded into it in the process. After the sequence --, the subtractor has had its previous contents canceled, but it still has the negated original accumulator contents in it. :;--; saves these original accumulator contents in :, then wipes out previous : contents with ;. After --; we have wiped out the old - contents too, leaving the original accumulator contents negated in - and unnegated in : and the accumulator. Another - gives us the negated original in - and twice the negated original in -; now if we save the negated original in :, we can subtract it twice: :;-;- or in full :;--;-:;-;-. There may be a simpler way to zero the subtractor, but I think that way works.

Interesting features of the GNU assembler Gas

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

Interesting features of gas:

• multiple subsections: `.data 0`, `.data 1`, etc. You can switch around between them during assembly, and then they get concatenated when assembly is done. There's some ambiguity in the manual about how this interacts with the "." symbol.
• The "." symbol, which is like Intel's $, and which can be reassigned to move around and assemble things in funny places. I haven't yet tried using it to assemble code someplace we've already been (e.g. for a counted string). The documentation for `.org` says this won't work.
• `.fill` would be useful for filling an area with a pattern (despite its bizarre semantics.)
• there is of course a full conditional compilation system.
• there is of course a full macro facility, with default arguments, named arguments, recursive macros, string interpolation, the ability to redefine existing symbols, and optionally local variables.
• `.incbin` lets you suck in an external file, or part of an external file, as data.
• It uses Knuth's `1f`, `1b`, `2f`, `2b` local labels. These work remarkably well for something so archaic-looking.
• The `-a` option generates an assembly listing. There's a bunch of formatting stuff for the listings: `.eject`, `.title`, `.sbttl`, `.nolist`, `.list`, `.psize`.
• It supports bignum math and emitting 8- and 16-byte integers from them.
• There's a "section stack" so you can assemble into a different section for a while, then pop back to where you were, or even swap back and forth between two sections without knowing which ones they are. Unfortunately, at the moment, the section stack is only partly implemented as documented.
• `.print` prints stuff out.
• ELF apparently has a bunch of section flags: "allocatable", writable, executable, "mergeable", and a few more
• there's sort of support for defining struct fields with `.struct`
• `.intel_syntax` supports Intel assembler syntax.

DHT bulletin board

Kragen Javier Sitaker, 2016-09-07 (7 minutes)

I think you can build a DHT bulletin board system duplicating the functionality of Usenet fairly simply.

Usenet

Usenet, a peer-to-peer communications system started in 1980, provides a bulletin-board or threaded-discussion system. It consists or consisted of a bunch of "articles", each of which was identified by a "message-ID", categorized in one or more "newsgroups", and "referenced" zero or more articles that it was a "follow-up" to, typically the transitive closure of the "references" relation on the article it was replying to, with the ID of the message being replied to last. Typically, a Usenet news server would provide access to articles recently posted to some finite set of newsgroups, replicated to other news servers using gossip.

Typically, Usenet newsreaders would display a tree of the followup relation while displaying the body of a single article, which would often include pieces of other articles it was commenting on. JWZ devised the standard algorithm for deriving the tree from the "references" headers. Experimental visualizations such as Yee's threadmap (paper) have been tried, echoing the two-dimensional hypertext layout used in the Talmud for millennia.

I'm speaking in the past tense here because Usenet has largely succumbed to spam; the gossip protocol's lack of scalability and the needs of spam filtering resulted in a progressive centralization of Usenet servers; and web-based systems have largely supplanted it for day-to-day discussion.

Making message-IDs unique was always a bit of a challenge, in particular since the gossip protocol in NNTP used message-IDs to determine whether it already had an article, so you could halt the spread of an undesirable message by posting a competing article with the same message-ID, if you got wind of it soon enough. Modern peer-to-peer systems like BitTorrent, Git, Bitcoin, and Tahoe-LAFS usually use self-certifying names (such as secure hashes of documents or of public keys) in order to avoid such collisions.

System design

The system consists of a DHT storage system for immutable data and feeds for mutable data.

The DHT, storage, messages, and newsgroups

The system's immutable data is stored, potentially permanently, in a DHT on the internet; the DHT's basic interface consists of `key = PUT(data)` and `data = GET(key)`. The `key` is a 192-bit unique ID, which is 24 bytes in binary or 32 bytes in base64, such as "oruMktRkd127bWh6av4tXhJXiEscirL/" or "SUrY99PC96aUjJttKFjmvWTFFqkNXmt1"; it consists of a randomly generated 96-bit symmetric encryption key to use to decrypt the article with an authenticated mode such as GCM, and a 96-bit secure hash of the encrypted data chunk (for example, the first

96 bits of SHA-256). Only the secure hash is sent over the network to the DHT storage nodes in the GET operation.

The DHT is only able to store fairly small chunks of data, up to 16 kibibytes or so, so a single article may be split across many DHT chunks. One of these chunks is the "root chunk" of the article, whose key is the message-ID, containing the following data, together with its typical sizes:

• an "in-reply-to" field, with the message-IDs of zero or more articles to which it is a followup (24 bytes);
• optionally, a "supersedes" field, with the message-ID of a article that this one is intended to replace, which must be signed by one of the same authors (24 bytes);
• zero or more signatures identifying the authors of the article (64 bytes), who may be bitcoins;
• other human-useful metadata such as the subject/title, timestamp, byte count, and tags (128 bytes);
• the key to the root block of a Merkle hash tree containing the article contents, including possibly other metadata (24 bytes). Typically this tree will contain a single node, which is the body itself.

This is a total of about 264 bytes, and it's roughly what a Usenet "overviews" entry would contain for the article.

The Merkle hash tree in this case is made out of 192-bit keys, so it can support about 682-way branching; a single level of branching gets you to message bodies of 11 megabytes, two levels of branching get you to message bodies of 7.6 gigabytes, and three levels get you to 12.7 terabytes.

There are two kinds of "newsgroups" in this system: an "unmoderated newsgroup" consisting of a tag query over whatever articles you happen to know about, and a "moderated newsgroup" which is a special message content-type containing the concatenation of many message-IDs, each with the "root chunk" of the message appended to it in encrypted form, just as the DHT node would send it to you, so that you don't have to query the DHT to get each message's overview.

With this structure, a moderated newsgroup with a history of 100 000 messages would be a message of about 26 megabytes. New versions of the newsgroup, as long as the moderator doesn't reorder the overviews of the existing messages, will generally only alter the last chunk in the Merkle tree — so you can update your view of the moderated newsgroup by downloading only the root chunk, two levels of branching chunks, and the newly-updated chunk. (At the cost of revealing, perhaps, how much of the newsgroup you had before.)

Purging/expiry

DHT nodes need to adopt some policy for purging data that nobody will ever query once their storage media begin to get full; otherwise, it will become impossible to post new articles, and this could even be carried out as a denial-of-service attack by a . Inevitably, the system as a whole will expire data as old DHT nodes go offline forever and new ones replace them. (Unless the system is, at the time, dying, like Usenet.) So all of the data that ought to be preserved, in anybody's opinion, has to get "refreshed" by being

stored again in the DHT, at intervals.

Feeds

None of the above allows you to go from old data to new data, because old data can only contain the keys of older data. uery

The Problem: Writing With One Access Pattern, Reading With Another

Kragen Javier Sitaker, 2007 to 2009 (19 minutes)

So I was talking to someone today about a network monitoring database problem I'd run into previously. A lot of network monitoring systems store many gigabytes of historical data about, say, bandwidth used per device, in order to support queries later on. Common queries include things like:

• what was the bandwidth used on device X in every five-minute interval over the last week?
• what was the aggregate bandwidth used by each of the devices in such-and-such a group?
• what were the five devices that used the most bandwidth over such-and-such a period?

It's nice to have queries like these be answered very quickly, but existing tools like Postgres and RRDTool don't seem to perform very well.

To be concrete, suppose that you have 100 000 devices, and you poll each one for input bytes, output bytes, input packets, output packets, input errors, and output errors once every minute. Each of these numbers may get too big to record in 32 bits, so it's good to use 64. So that's 8 * 6 * 100 000 = 4.8 megabytes per minute, or 7 gigabytes per day, or 200 gigabytes per month.

Disk Model

My standard model of a disk is that a disk is something that takes 8–10ms to start reading or writing at a random spot, and then reads or writes at 40MB/sec as long as it's reading or writing sequentially. Some disks (or disk arrays) are five times faster (bandwidth-wise) and some are five times slower, and most have faster seeks under some special circumstances, but that's generally the right ballpark.

An interesting number that comes out of this is the bandwidth-delay product, which is about 10ms * 40MB/s = 400kB. If you're alternating between reading or writing a chunk of some fixed size, and seeking to a new location, this is the chunk size at which you spend only half of your time seeking. Reading or writing in chunks much smaller than this means the disk spends most of its time seeking; reading or writing in chunks much larger means the disk spends most of its time transferring data.

Bandwidth varies between disks more than seek time, so bandwidth-delay products vary quite a bit.

Approaches to Solving It

The usual way of dealing with this is to use RRDTool, which stores each counter for each device in a separate file, and thins out old data so as to keep a fixed upper limit on the total number of samples in any one file. RRDTool makes queries about one or a small number

of devices quite fast, but updating of a large number of counters is slow, since each one is in a different file.

Because the data is so large, it's a bit expensive to keep it all in RAM, so it would be nice if both updates and queries had reasonable locality of reference. If you're updating 7 gigabytes of RRDTool files (11520 bytes per counter, to store 1-minute data for a day), you pretty much have to read and then write 7 gigabytes of data, which is going to take at least three minutes on a single disk; but we're hypothesizing that the actual amount of new data being written is maybe 4.8 megabytes. So the RRDTool approach imposes largish costs on mass updates due to poor locality of reference.

You could go to the other extreme and optimize for writes: write all the new counter data in one big 5-meg blob. But then reading the 1440 one-minute samples for a single counter over a day's time requires 1440 disk reads, 5 megabytes apart, and perhaps 10 seconds. This is not acceptable either.

My Proposed Solution: Tiling

This points at a solution I had suggested in "r-tree indices for database table clustered indices", http://lists.canonical.org/pipermail/kragen-tol/2004-January/000740 08.html which is to sort of divide the data into "tiles" of, say, 64 minutes by 1024 counters, each occupying a contiguous half-megabyte. We can assume (for now) that getting from any tile to any other tile requires a random disk seek. So if you're recording six new 64-bit readings for each of 100 000 devices, those 600 000 readings get broken up into 600 groups of 1024, and each of those 600 groups gets written into a separate tile. If each requires a separate seek, this should take about six seconds instead of six minutes. And if you're reading the 1440 one-minute samples for a single counter over a day's time, those will be spread across 23 tiles, so will require about 1/2 second.

That's an improvement, but there are several more directions of optimization possible: side files, tile ordering, thinned data, and grouping counters by type.

Side Files

First, we can initially append updates to a "side file" instead of sending them directly into their final locations, then eventually copy the data to the tiles where it will ultimately live. To start with, every query must read the entire side file, so you don't want it to get too big, and it cuts the theoretical write bandwidth of the database by a factor of three or four, since every update must first be written to the side file (with metadata), then read from the side file and written again to a new location.

But now writing 600 000 readings --- 5 megabytes without the metadata that tells what they are, and perhaps 10 megabytes with it --- takes a quarter of a second instead of six seconds, which seems like it's better than an order of magnitude speedup. However, the eventual writes to the tiles will still take time, but as explained below, we can accumulate several updates for each tile, and deliver them in the same number of seeks.

If we batch up four updates in the side file before flushing them out to the tiles, the side file will get to 40MB, which is maybe one second

of disk bandwidth. Copying it to the 600 tiles will take a second and a half of bandwidth and 600 seeks, so about 7–8 seconds to do the copying and 8–9 seconds in all --- about 30% of the total disk traffic the four updates would need without the side file. (This copying can be done incrementally rather than all at once, which allows you to batch up eight updates in the side file at a constant size of 40MB, or four at a constant size of 20MB. That's assuming it's practical to reorder stuff in the side file as some of it gets flushed out.)

A 40MB side file would take about a second to read off the disk, and in the absence of any disk buffering, every query would require that additional second. (The assumption is that since it's ordered by the time at which the updates were made, queries won't have particularly good locality of reference.) This would be a good reason to keep the side file small.

But, actually, you can probably keep the side file in RAM until it's a quarter of a gigabyte or more, which in this scenario would allow it to batch up roughly 500 full tiles --- and that's getting close to the point of diminishing returns, where maintaining a bigger side file doesn't actually save you any more disk seeks. Keeping the side file in RAM means that your queries don't suffer from this additional second of disk access time, although they may still have to access the data.

So, in this limit, if you buffer up all the new readings in memory, while also appending them to a side file (in case of a crash), and then writing them out to 600 new tiles when those tiles are full, then every 64 minutes, you write out 600 megabytes of data to the side file (sequentially --- about 15 seconds) and 300 megabytes of new tiles (with seeks in between, so 3 seconds of seeks and 7 seconds of data traffic, for 10 seconds of disk traffic). That's 25 seconds, or a little under half a second of disk traffic per update.

So the very approximate time taken for an update, including the amortized time to eventually write it to the tiles: *Without side files: 6 seconds* With a 40MB batchy side file: 2 seconds *With a 40MB streaming side file: 1 second* With an in-memory batchy 300MB side file: 0.5 seconds

Tile Ordering

So far, we've proceeded on the pessimistic assumption that all the tiles were a whole random seek apart. But, actually, they have to be laid out on disk in some sequence or other, so some of them will actually be sequential with one another. For example, we could lay out most or all of the tiles for a particular group of counters (mostly) sequentially on disk, while tiles for different times are laid out in different parts of the disk.

This doesn't make anything worse than our previous assumptions, but it can make them better. In particular, the 23 tiles in which a single counter can be found throughout a single day will generally be a single 10-megabyte read rather than 23 half-megabyte reads, so will take 1/4 second instead of 1/2 second to read. An entire week will take almost 2 seconds.

This optimization can't help by more than about a factor of 2 over the above design because I picked the tile size to guarantee that we don't spend more than half of our time seeking in the worst case. If you make the tiles a bit smaller, you can improve the results for reading in the direction the tiles are contiguous in, at the expense of

reads and writes in the other direction. For example, if we make our tiles 32 minutes by 512 counters, then they will be an eighth of a megabyte each, and reading the 1440 points for a single counter over a day will require reading 45 tiles totaling 6 contiguous megabytes, or about 0.16s, rather than 0.25. But reading a full column (say, to find out which devices used the most bandwidth over a certain period of time) would then require reading 1200 discontiguous tiles, for 1200 disk seeks (about 10 seconds) and 150 megabytes (about 4 seconds), for a total of about 14 seconds, rather than 600 disk seeks and 300 megabytes, for a total of about 12 seconds. (See below about grouping counters by type to improve this.)

Thinned Data

You probably want to add additional tiles containing subsets of the data --- perhaps a data point for each counter every five minutes, or every half-hour, or every hour, or every day. If you want to graph the performance of a particular network device for an entire month, you probably don't want more than 1000 or 2000 data points, and a data point for every 20 minutes adds up to 2000 data points in a month.

This way, you can have, say, 2016 points of five-minute data for a week, in a sequence of 32 contiguous tiles --- 16 megabytes, or 0.4 seconds of disk traffic --- so that you can generate weekly graphs quickly. Monthly or yearly graphs are an even bigger savings.

The thinned data will be small compared to the full-size dataset, so its size probably isn't that important.

RRDTool erases the full-resolution data after making up thinned versions, so that the database always remains the same size.

Grouping Counters By Type

In the section about tile ordering above, I mentioned that figuring out which devices used the most bandwidth over a certain period of time would require a really unreasonable query time, since it requires reading all the tiles for two particular times --- the beginning and the end of that period. There are about 600 tiles covering each of those times, totaling about 600 megabytes, which takes 15 seconds of disk I/O, plus 1200 disk seeks (10 seconds more), if you need to read them all.

But the reason we have 600 000 counters is that we're recording 6 different counters per device. Most queries, like the one suggested above, probably only touch one or two of the counters --- so if each tile only contains one kind of counter, we can improve this substantially.

If the desired results are available in a single counter type, we only need 200 tiles. Furthermore, if we have a thinned data set that happens to place the ends of the period in question in the same column of tiles, then we only need 100 tiles. This means we only need to read 50 megabytes of data and seek 100 times, so we can do the query in a little over 2 seconds instead of 25.

Queries that need data from every type of counter are very rare.

Delta-Compression

As proposed above, each counter has 64 values in a particular tile,

which total 512 bytes if they're 8 bytes each. But most of the time, we can probably get away with an 8-byte initial value and a sequence of changes from the previous value, each of which will usually be 8, 16, or 32 bits. (0 is probably the most common value.) If they're 16 bits on average, then we could fit about four times as many values into the same half-megabyte block, which means that everything needs a lot less I/O bandwidth and many fewer seeks.

In particular: - we only need 1.2 megabytes per minute of writes, or 1.7 GB per day, or 51 GB per month; - each tile can hold 128 minutes of 2048 counters; - the updates for each timestamp get written to 300 tiles; - the 1440 one-minute samples for a single counter are spread over 12 tiles, which can be read in 0.11 seconds if they're contiguous; - the 300 tiles currently being updated can live in an in-memory side file of 150 megabytes maximum or 75 megabytes steady-state (assuming steady-state is possible); this is assuming we keep things compressed in RAM as well; - writing out those 300 tiles (every 128 minutes) takes 4 seconds of write bandwidth and 3 seconds of seeks, or about 0.05 seconds (amortized) per update, plus the time to write to the disk version of the side file, which may still be bulky. - thinned data will probably comprise a larger fraction of the file, since its deltas will be larger; - reading 100 000 counters at each of two timestamps will probably require reading 50 tiles, which will be 25 megabytes of data, so it should be possible to find out which devices used the most bandwidth over some arbitrary period in under a second of disk time.

Further Redundancy

If you could afford it, then instead of tiling, you could just store the data twice --- once such that all the data for each counter is mostly contiguous on disk (i.e. broken up into chunks mostly bigger than the bandwidth-delay product), and again such that all the data for each timestamp is mostly contiguous on disk. Side files would batch updates as before to allow efficient updates.

This would allow queries that only care about a few timestamps or a few counters to run with very little I/O, and delta-compression of counter data might be feasible for the contiguous-by-counter data; it probably isn't feasible for the contiguous-by-timestamp data.

Network Bandwidth Requirements

If you were doing this monitoring using SNMPv2, you could probably do a bulk-get from each of, say, 10 000 devices, once a minute, and get back a 1000-byte-or-so response from each one. That's 10 megabytes per minute, or 1.3 megabits per second in each direction. You can get that kind of performance from ARCNet, or 1978-era Ethernet, or 802.11b, or old 4Mbps Token Ring cards that cost US$5 on eBay in 1997. I'm assuming you can poll switches or routers or something, one per ten devices, rather than having to talk to all 100 000 network devices directly.

An SNMP library that can handle talking to 10 000 agents within a minute --- perhaps 200 or 300 at any given time, if you have a reasonable timeout --- may be a little more difficult to come by. It's not technically very difficult to do, but you have to design your SNMP library to do it, and not require a separate thread for each concurrent request.

In Summary

It should be inexpensive to log and query several vital statistics of each device on a large corporate network with a single five-year-old laptop, maintaining historical data with hourly granularity indefinitely, using the following techniques.

Batch updates in memory, logging them in a file, flushing them to disk when necessary.

Each datum is addressed by a tuple (countertype, deviceid, timestamp). I recommend storing data in physically contiguous tiles of around half a meg (times or divided by four) addressed by tuples (tilerow, tilecol), where tilerow is a function of countertype and deviceid and tilecol is a function of timestamp, such that data from different countertypes are assigned to different tilerows, and each tilecol corresponds to a contiguous interval of timestamps adjacent to the intervals its neighboring tilecols correspond to. Then, tiles of the same tilerow and consecutive tilecols should be stored consecutively on disk most of the time.

Variable-length delta-compression of the data for a particular counter within each tile should provide very substantial benefits in responsiveness.

Data must be stored redundantly in two ways: - the file of logged updates eventually becomes redundant with the data stored in the tiles; - thinned-out data tiles contain selected timestamps from other tiles to facilitate queries that cover longer time intervals.

Smoky day

Kragen Javier Sitaker, 2008-04-19 (4 minutes)

(I wrote this 2008-04-19, when Buenos Aires was still under a blanket of heavy smoke.)

I went out in the smoke tonight, Saturday night, to try to get food from Chinatown, despite Beatrice's protestations that 20:00 was too late.

As I slowly walked the few blocks to the route 107 bus stop, three 107 buses passed me. I waited at the bus stop as two 107 buses passed going the other way; while I waited, standing in the street, other would-be passengers accumulated: a bald man with gray hair cuddling and kissing with his middle-aged girlfriend as they stood in the street behind me, and two teenagers.

Eventually I gave up on the bus and hailed a passing taxi, which I took to a Citibank near Chinatown, where I extracted money from my bank account via an ATM.

The sidewalk cafes in the commercial district were full of people, despite the smoke blanketing the city; I recognized an acquaintance waitressing at the the restaurant "1810", where we first tasted Argentine empanadas. A few blocks away, as I walked in the direction of the 107 bus route and Chinatown, I found a long line of mostly old people. I asked a young man standing in line what the line was for. He didn't answer for a moment, and then without meeting my eyes, he explained that it was for bread.

I walked along what I thought was the 107 bus route, but I arrived in Chinatown before seeing any more 107 buses. The store I had hoped to go to had closed at 20:30; I walked around looking for an open store, so I could buy peanut butter, ginger root, and packaged ramen. (Ramen only costs $2 a package there.)

I passed a couple of young men with small shopping carts full to the brim of 1.5-liter Quilmes beer bottles, waiting to be let into an apartment complex; elsewhere I passed one or another sentry waiting at a door, presumably to let in people who had gone out.

After walking about six blocks through almost all of Chinatown, I never found an open grocery store, so I went to Todos Contentos and ordered a couple of dishes to take home to Beatrice.

As I waited, I read some of the sports section of the paper. It had a list of the rugby and football games that had been canceled because of the smoke, although it explained that the air "wasn't toxic", just irritating and allergenic. Maybe "tóxico" means something different in Spanish than in English.

As I carried my order from the restaurant to the 107 bus stop, I stopped by "Dashi", a sushi restaurant near the Buddha Bar. The newspaper blurbs outside the door explained that the chef had spent a long time in Perú and had studied in California, so I hoped that perhaps they might have some of the sushi flavors I've been missing here in Argentina: maguro, uni, natto, unagi, ama-ebi, inari, and so on. I, went in to read the menu. Although it had several pages listing an impressive number of different kinds of sushi, more careful reading revealed that they were made from a small number of basic ingredients that did not include any of the above. I was a little

disappointed but not surprised.

I walked on. A couple sitting on some steps asked me what my mask was for --- I explained it was for the smoke. Wordlessly the man grinned and lifted his cigarette to his lips and took a long drag, filling his lungs with much denser smoke. I laughed.

I eventually caught the 107 home. Strangely, when I got on, the bus was empty.

Cartesian product storage

Kragen Javier Sitaker, 2017-03-20 (3 minutes)

A common way we organize storage in computer programs is as a Cartesian product of some set of entities and some set of attributes that pertain to those entities. We might represent entities as, for example, struct base addresses or array indices, and attributes as, respectively, offsets into a struct and array base addresses.

In both of these cases, at the machine level, we are representing both entities and items as machine words and combining them with binary addition, possibly composed with a bit shift or even multiplication by a constant. In some cases, you can use a simpler operation, dividing the memory address into one field for entities and another for attributes, which could save you an adder at the hardware level; this allocates memory space of a power of 2 to each entity and each attribute. Combining the fields in hardware can be done with some wires.

What happens if you try to use some other operation to combine the identifiers of entities and attributes? An easy example is to use a limited-width adder: given a 16-bit entity address and an 8-bit struct offset, use a 10-bit adder rather than a 16-bit adder to combine them, and then don't allocate structs that cross 1024-byte page boundaries. This is intermediate both in restrictions and in implementation complexity between the field-division approach and the usual approach.

In the same context, if you use XOR instead of an adder, you have the same memory-allocation restrictions as the field-division approach, but now you have the ability to reverse the order of the list of entities (or of attributes, or of power-of-2-sized blocks of either) by using an address with 1 bits in the field for the other kind of thing.

If you use OR or AND instead of XOR, you have the same restriction again — but now stray bits (ones in the OR case, zeroes in the AND case) allow a sort of "inheritance". Instead of reversing the order of the entities, or of entities in some subgroup (or correspondingly attributes), they allow an attribute to be shared among all entities, or all entities in a power-of-2 group; or, correspondingly, to allow an entity to have the same value for all attributes, or all attributes in a power-of-2 group.

This seems like it could be useful under some circumstances; you could imagine, for example, allocating memory for a potentially buffer-local variable in every buffer, then making the variable buffer-local by changing its "offset".

(The other possible 13 bitwise operations all seem to fall into the same category as one of OR/AND and XOR or be inapplicable. Operations with truth tables 0000 and 1111 discard both inputs, and 0011, 1100, 0101, and 1010 discard one of their inputs. 1000 (NOR) and 1110 (NAND) are simply AND and OR (respectively) with both inputs inverted; 1001 (XNOR) is XOR with one input inverted; 0010 and 0100 (implication and reverse implication) are AND with one input inverted; 1101 and 1011 (negated implication and negated reverse implication) are OR with one input inverted.)

A REST interface to a software transactional memory

Kragen Javier Sitaker, 2017-06-21 (2 minutes)

Suppose you design a REST system in which every GET or PUT includes a transaction ID, which is a URL, assigned by some kind of transaction serialization service. Any piece of code that wants to make changes to resources must allocate a transaction ID from the transaction serialization service.

Some resources are merely files, while others are synthetic, with their representations produced on demand from other resources. When you GET the URL of a file, the file notes your transaction ID, and if it changes in the future while your transaction is still active, it will post a change notification to your transaction ID. When you PUT a file, the new state is at first only visible to GETs with your transaction ID.

When a transaction is completed, you tell the transaction service to commit your transaction. It first verifies that none of the files you GETted have had changes committed to them by a previously committed transaction; if this is true, it tells all the files you PUTted to commit your change.

(It's unclear to me whether the transaction service has to do all of this dependency tracking or whether the file servers can do some of it.)

If, instead, one or more of the files have changed, then the transaction service refuses to commit your transaction, instead rolling it back. Then you can retry the whole transaction from the beginning, or give up and report failure.

Topics

Arduino safety

Kragen Javier Sitaker, 2018-12-10 (4 minutes)

I just watched a video on the YouTube channel "GreatScott" in which the author builds a modified-square-wave inverter using a MOSFET H-bridge driven through a couple of TC4427s.

I was somewhat horrified at the way he wrote the software; he writes `off()`, `lowon()`, and `highon()` functions which each set the transistors to the appropriate states. If you call the `off()` function often enough, everything is fine, but if you call `highon()` after calling `lowon()` without an intervening `off()`, you get shoot-through; the first thing it does is bring Arduino pin 9 LOW, which pulls pin 1, the gate of the P-channel MOSFET on the high side of the left of the H-bridge, to ground, turning on the MOSFET. But Arduino pin 8 is still HIGH, pulling pin 3, the gate of the N-channel MOSFET to ground on the left side of the H-bridge, to 12V, also turning it on. So you get shoot-through and a potentially damaging current spike through your MOSFETs. Similarly, you get shoot-through on the right side if you call `lowon()` after calling `highon()` without an intervening `off()`, because it brings pin 10 LOW, turning on the P-channel MOSFET on the high side of the right side of the H-bridge, before bringing pin 7 LOW, turning off the N-channel MOSFET on the low side of the right side.

So it is very important to make sure that you don't call these functions without calling `off()` in between. Furthermore, you would like to ensure that enough time elapses in between the call to `off()` and the subsequent function for the high-side MOSFETs to be entirely turned off, since in general they have a small RC delay, though in this case it's probably less than a nanosecond. (And for this reason, just rewriting the `lowon()` and `highon()` functions to turn things off before turning other things on is not necessarily adequate, though it would probably be a good idea.)

You'd like to be able to encapsulate this timing safety logic in some kind of tiny capsule of code that is small enough to be sure that it says what you think it does, then validate that it's called correctly at compile-time, since after you've already plugged your refrigerator into your homemade inverter, it's too late to report a timing constraints violation.

You could make this almost work in Arduino's dialect of C++ by adding a little bit of state and checking the current time when these functions are called. But what do you do when it's too early? You could delay until the appropriate time, but that hangs the whole system, which is really unfortunate if it's doing something else like updating an LCD. Or you could just return without doing anything, which would result in missing an output pulse in this case, which might cause real problems.

A slightly less shitty solution would be to allocate a timer to MOSFET control (as GreatScott does) and use it to delay the state transition until a later time, using an ISR. This approach doesn't block everything else on the device, but it does use up a timer; generalizing this to share a timer between multiple users essentially produces a real-time operating system. But it doesn't guarantee you

get the timing you asked for, just that the timing you get doesn't cause shoot-through and explode your MOSFETs.

To really encapsulate the timing constraint so that it's not spread across your entire codebase, you probably need some kind of theorem prover that can prove things about function execution times.

Charge transfer servo

Kragen Javier Sitaker, 2013-05-17 (2 minutes)

I just tore down a broken DVD player I found on the street. It has three motors in it, two of which are geared to some kind of linear-motion slide; but all three of them seem to be just DC motors with no builtin servo.

Accurately positioning a linear-motion slide is a big part of what you need for various kinds of machinery, so I immediately got to thinking about how you could do it.

Aside from the most obvious things (the optical tape sensor from a printer, using a webcam, using the inverse square law with LED and photodiode) it occurred to me that the plastic slide itself probably has a relative permittivity of two or three, and so if you could arrange metal plates fixed in place on each side of it, you'd have a variable capacitor. Better, you could put one metal plate on its surface and another one fixed in place above or below it, with a layer of plastic between them keeping them from touching as they slide against each other. This would give you a capacitance varying from the femtofarad range to the 1000-picofarad range with the motion of the slide.

Charge-transfer sensing supposedly allows inexpensive measurement of variable capacitances to precisions of fractions of a femtofarad. If that's really true in this case, it should allow the inexpensive measurement of such a variable capacitor to some six significant figures, or 20 bits, of precision. If this were to be fully transferred to the positional precision of the slide — that is, if nothing else affected the capacitance than the position of the slide — then we would be capable of measuring the 13-centimeter motion of the slide to within 130 nanometers, about 1300 atoms. Sufficiently intelligent motor control, then, might be capable of *positioning* the slide to within 130 nanometers, although due to the many sources of slack and vibration in the system, surely not arbitrary motion paths with such precision.

Complex linear regression (in the field ℂ of complex numbers)

Kragen Javier Sitaker, 2019-08-17 (updated 2019-08-18) (9 minutes)

In $1 recognizer diagrams (p. 1264) I speculated that applying linear regression to vectors of complex numbers might be a good way to match user interface gestures such as strokes to templates, since a linear function in ℂ amounts to a translation, rotation, and scaling. But I can't find any discussion of doing linear regression on complex numbers.

So I'm going to solve that problem here.

The stroke-matching problem

Suppose we have a sequence of points representing a stroke the user has drawn with their pen or a finger on a pen computer — whether something like the Fly Pen, something like the HP Itsy, something like a Wacom graphics tablet, or something like a modern Android computer. We want to determine how far this sequence is from being "the same as" a stored template representing, say, the letter "B", so we can see which of several stored templates it's closest to and thus determine the user's intent.

Let's suppose the sequence of points has already been resampled to regular spatial intervals, with the same number of points as the template (128 or something), so pairing up corresponding points is trivial.

The simplest thing that could possibly work is to take the sum of absolute differences of coordinates between corresponding points: $\Sigma_i |x_{ti} - x_{si}| + |y_{ti} - y_{si}|$, where i ranges over the number of points, x_t and y_t are the coordinates of the template points, and x_s and y_s are the coordinates of the stroke points. This loss function tells us how far the stroke is from being a "B" or whatever.

This may work under some circumstances, but it has some problems:

• The user may have written the stroke in a different *position* than the template, introducing *translational error* into all of the components of the loss function.
• The user may have written the stroke in a different *orientation*, introducing *rotational error* into most of the components of the loss function, except those points in the center.
• The user may have written the stroke at a different *size*, introducing *scaling error* into most of the components of the loss function, again, except for those in the center. Moreover the scaling may be nonuniform — the user may have stretched the stroke horizontally, vertically, or diagonally without intending to do so — introducing *skewing error*.
• Using the absolute difference means that an error of, say, 5 pixels diagonally, will count as 7 pixels; this introduces a *anisotropic bias* into the loss function which makes it harder to cleanly separate, for example, Bs from non-Bs.
• Using the absolute difference means that an error of 20 pixels counts

as just four times a 5-pixel error. But, generally, if the user really did intend to draw a B, four 5-pixel errors are much more probable than a single 20-pixel error. This, similarly, makes it harder to cleanly separate Bs from non-Bs. Using the absolute difference represents an implied probability distribution of errors that is exponential.

The "$1 recognizer" paper I was writing about has some solutions to these: translate the stroke so its centroid is at the origin to eliminate translational error, rotate it so that the start point is at a fixed angle to eliminate rotational error, rescale it nonuniformly horizontally and vertically so that its bounding box has size 1 in each dimension to eliminate scaling and skewing error, and use the sum of Euclidean distances rather than the sum of absolute differences to eliminate anisotropic bias. (They still have problem #5, unless I'm imagining things and it isn't really a problem.) As I wrote in $1 recognizer diagrams (p. 1264), this procedure seems unduly sensitive to noise.

But it occurred to me that this was very similar to the problem of linear regression, only with complex numbers. If we represent each point (x, y) as a complex number $(x + jy)$, then rotation and *uniform* scaling around the origin are merely multiplication by a complex number, and translation is merely adding a complex number. So if the stroke is precisely a translated, uniformly scaled rotation of the template, then there exist some complex numbers m and b such that $\forall i$: $x_{si} + jy_{si} = m(x_{ti} + jy_{ti}) + b$. Let's abbreviate the stroke point i as $s_i = x_{si} + jy_{si}$ and the template point i as $t_i = x_{ti} + jy_{ti}$, so that this becomes just $\forall i$: $s_i = mt_i + b$. And if the points of the stroke are perturbed slightly from those positions, then there exist complex numbers m and b that give a small sum $\Sigma_i |mt_i + b - s_i|^2$ (the L^2 norm of the vector $m\vec{t} + \vec{b} - \vec{s}$, where all the components of vector $\vec{b}$ are equal); that residual sum tells us how much error there is in the approximation, and by finding m and b to minimize that sum, we can find something that is in some sense the best fit.

This is precisely the everyday problem of linear regression, but in the field $\mathbb{C}$ of complex numbers, rather than the usual field $\mathbb{R}$ of real numbers. The squared modulus solves problems #4 (anisotropy) and #5 (nonuniform weighting), implying a Gaussian distribution of errors, which is probably a reasonable approximation even if not precisely correct; and, at least in $\mathbb{R}$, it makes the optimization problem easy by making it convex and differentiable in closed form.

If we can find the ideal rotation, scaling, and translation in this way, we can conceivably find a better fit than the one the "$1 recognizer" finds, and maybe we can find it more efficiently, too, especially if we can calculate it in closed form rather than using golden-section search to heuristically approximate the optimal rotation. We'd still need to stretch the stroke up front to correct for nonuniform scaling (skewing error), perhaps by calculating the x–y covariance matrix of its points.

This is easier than the more general problem of trying to match up two sets of possibly rotated, translated, and scaled points, such as star tracking, because the correspondence between the points is provided up front — it comes from the temporal sequence of points in the stroke.

Existing work on complex linear regression

Abdul Ghapor Hussin, Norli Anida Abdullah and Ibrahim Mohamed wrote a 2010 paper called "A Complex Regression Model" about using linear regression with complex variables to predict "circular variables" such as the direction from which waves are hitting a buoy. I don't really understand their derivation.

Math.stackexchange.com users Naetmul and hans have written up the general solution for finding a least-squares-optimal approximate solution to the linear system $\mathbf{A}\vec{x} = \vec{b}$ in complex numbers. I don't think I can transform the linear regression problem into this problem, because the output has too many degrees of freedom — I'm looking for a pair (m, b) regardless of how many input points there are, while that problem takes the matrix $\mathbf{A}$ and the vector $\vec{b}$ as given, then tries to find the vector $\vec{x}$ that gets you closest to it in the subspace defined by $\mathbf{A}$. This amounts to projecting $\vec{b}$ onto that subspace and then figuring out where you are in it.

Aha! John Cowan referred me to whuber's answer on the Cross Validated Stack Exchange, where they explain that the answer is

$\beta\hat{} = (X^*X)^{-1}X^*z$

along with R code to implement it and everything. Not sure it's rigorously proven to be the correct answer, but there are "appears to work" arguments.

Finding the least-squares solution to the univariate complex linear regression problem

So we want to find $\operatorname{argmin}_{m,\, b \in \mathbb{C}^2} \Sigma_i \, |mt_i + b - s_i|^2$. Although the complex modulus $|\cdot|$ isn't differentiable everywhere, the modulus squared $|\cdot|^2$ is, and therefore so is the whole sum. So we should be able to find all of its extrema by finding where its partial derivatives with respect to m and b are zero. And, if the situation is like the situation in $\mathbb{R}$, the derivative will only have a single zero, and it will be the minimum; intuitively, a similar situation ought to obtain here.

Let's define $\Delta_i = mt_i + b - s_i$, so we're trying to minimize $\Sigma_i \, |\Delta_i|^2$, so we set $\nabla[\Sigma_i \, |\Delta_i|^2] = 0$, so $\Sigma_i \, \nabla |\Delta_i|^2 = 0$, which is to say that $\Sigma_i \, \partial|\Delta_i|^2/\partial m = 0$ and $\Sigma_i \, \partial|\Delta_i|^2/\partial b = 0$, which are two problems we can solve separately. $\partial|\Delta_i|^2/\partial m = (\mathrm{d}|\Delta_i|^2/\mathrm{d}\Delta_i)(\partial\Delta_i/\partial m)$, and similarly for b, $\partial|\Delta_i|^2/\partial b = (\mathrm{d}|\Delta_i|^2/\mathrm{d}\Delta_i)(\partial\Delta_i/\partial b)$.

Quasiquote patterns

Kragen Javier Sitaker, 2007 to 2009 (9 minutes)

[Note added 2019: Darius Bacon is working on a pattern-matching dialect of Scheme called Squeam, and I may have gotten these ideas from talking with him about it. It's been long enough that I can't remember for sure.]

It occurred to me that if you wanted to write a tree-rewriting dialect of Lisp, you could use quasiquotation both for the pattern to match and the thing to rewrite it to. For example, in David Andrew Kranz's 1988 (1990?) dissertation, "Orbit: An Optimizing Compiler for Scheme," he describes much of the CPS-conversion process in tree-rewriting rules such as the following:

```
(convert <atom> <cont>) => `(,<cont> ,<atom>)
(convert '(<proc> . <arguments>) <cont>) =>
(convert <proc>
    (lambda (p)
        ,(convert-arguments <arguments>
                        `(,p ,<cont>))))
(convert-arguments '() <final-call>) => <final-call>
(convert-arguments '(argument . rest) <final-call>) =>
    (convert <argument>
    `(lambda (k)
     ,(convert-arguments <rest>
                (append <final-call> '(k)))))
```

It seems to me that these could be written in a pattern-matching Scheme dialect as follows, without breaking backwards-compatibility:

```
(def (convert atom cont) `(,cont ,atom))
(def (convert (proc . arguments) cont)
    (convert proc (lambda (p) ,(convert-arguments arguments
                          `(,p ,cont)))))
(def (convert-arguments () final-call) final-call)
(def (convert-arguments (argument . rest) final-call)
    (convert argument
    `(lambda (k) ,(convert-arguments rest (append final-call '(k))))))
```

(I'm using "def" as a synonym for "define" here. Or maybe a pattern-matching extension thereof.)

I suspect that the original syntax was not formally specified.

Here are some more things specified in this style.

```
(def (length ()) 0)
(def (length (a . b) (+ 1 (length b))))
(def (append () a) a)
(def (append (a . b) c) `(,a . ,(append b c)))
(def (assv a ()) '())
(def (assv a ((a . b) . r)) `(,a . ,b))
(def (assv a ((x . y) . z)) (assv a z))
(def (delv a ()) '())
```

```
(def (delv a (a . b)) (delv a b))
(def (delv a (b . c)) `(,b . ,(delv a c)))
(def (eval ('var var) env) (cadr (assv var env)))
(def (eval ('lambda args body) env) `(,args ,body ,env))
(def (eval ('apply (func-args body func-env) args) env)
    (eval body (augment-env func-args (eval-args args env) func-env)))
(def (eval ('if cond cons alt) env)
    (if (is-true (eval cond env)) (eval cons env) (eval alt env)))
```

Note the implicit pattern-matching equality tests in assv and delv.

This syntax has the disadvantage that the symbol "quote" is treated specially, in order to support tagged things like the last bit. I had considered using full quasiquote syntax, which avoids that problem, but it has two disadvantages: it's backwards-incompatible with Scheme's current syntax, and worse, it's more verbose.

(It also lacks a way of requiring, in the pattern, that a particular item be just a plain symbol, rather than a list or an array or something. You could specify, say, "unquote" or "symbol" to mean this, and write (symbol x) or ,x to mean "some x, which is required to be a symbol".)

If you add special treatment for the symbol "..." to the declaration syntax, as in the Scheme macro system, then you get an arguably superior syntax for list tails with a special secret feature.

```
(def (append () x) x)
(def (append (x xs ...) y) `(x . ,(append xs y)))
(def (assv a ()) '())
(def (assv x ((x xs ...) zs ...)) `(x . xs))
(def (assv x ((y ys ...) zs ...)) (assv x zs))
(def (delv x ()) '())
(def (delv x (x xs ...)) (delv x xs))
(def (delv x (y ys ...)) `(,x . ,(delv x ys)))
```

The special secret feature is that it generalizes to some kinds of restructuring:

```
(def (augment-env () () env) env)
(def (augment-env (var vars ...) (val vals ...) env)
 (augment-env vars vals `((,var . ,val) . ,env)))
```

(The above definitions of augment-env, assv, and eval constitute a complete interpreter for a Turing-complete language.)

Pattern-matching simplifies writing compilers in general. Here's a compiler into the language above from a subset of Scheme:

```
(def (compile ('lambda vars body)) `(lambda ,vars ,(compile body))))
(def (compile ('if cond conseq alt)) `(if ,cond ,conseq ,alt)))
(def (compile (f args ...))
 `(apply ,(compile f) ,(compile-args args)))
(def (compile-args ()) '())
(def (compile-args (arg args ...))
 `(,(compile arg) . ,(compile-args args)))
(def (compile x) `(var ,x))  ; or (def (compile (symbol x)) `(var ,x))
```

Here's a little recursive-descent compiler for the following

grammar. (Our input strings here are Lisp lists.)

```
mul-expr  ::= atom-expr * mul-expr | atom-expr / mul-expr | atom-expr
atom-expr ::= <number> | <symbol> | (expr)
expr      ::= mul-expr + expr | mul-expr - expr | mul-expr
```

Each parse routine takes a suffix of the whole input string, and returns a list of two lists: the compiled version of what it parsed, and the remaining suffix.

```
(def (compose-parser inner outer tokens)
 ((lambda ((inner-result leftovers))
    `(,(outer inner-result) ,leftovers))
  (inner tokens)))
(def (parse-atom ((expr) stuff ...)) `(,(parse expr) ,stuff))
(def (parse-atom (x stuff ...))
 `(,(if (symbol? x) `(var ,x) `(const ,x)) ,stuff))
(def (parse-expr stuff) (parse-expr-tail (parse-mul-expr stuff)))
(def (parse-expr-tail (compiled ('+ rest ...)))
 (op-node '+ compiled rest parse-expr))
(def (parse-expr-tail (compiled ('- rest ...)))
 (op-node '- compiled rest parse-expr))
(def (op-node op compiled rest inner)
 (compose-parser inner
        (lambda (parsed-rest) `(,op ,compiled ,parsed-rest))
        rest))
(def (parse-expr-tail (compiled other)) `(,compiled ,other))
(def (parse-mul-expr stuff) (parse-mul-expr-tail (parse-atom stuff)))
(def (parse-mul-expr-tail (compiled ('* rest ...)))
 (op-node '* compiled rest parse-mul-expr))
(def (parse-mul-expr-tail (compiled ('/ rest ...)))
 (op-node '/ compiled rest parse-mul-expr))
(def (parse-mul-expr-tail (compiled other) `(,compiled ,other)))
```

That's pretty ugly! And it doesn't even quite compile into RPN; you still need this:

```
(def (rpnify ('+ a b)) (rpnify-op '+ a b))
(def (rpnify ('- a b)) (rpnify-op '- a b))
(def (rpnify ('* a b)) (rpnify-op '* a b))
(def (rpnify ('/ a b)) (rpnify-op '/ a b))
(def (rpnify-op op a b) (append (rpnify a) (append (rpnify b) `(,op))))
(def (rpnify ('var x)) `(var ,x))
(def (rpnify ('const x)) `(const ,x))
```

That's kind of ugly in its runtime; a cleverer implementation would walk the op tree from right to left, passing along an accumulator of ops as it went:

```
(def (walk ('+ a b) ac) (walk-op '+ a b ac))
(def (walk ('- a b) ac) (walk-op '- a b ac))
(def (walk ('* a b) ac) (walk-op '* a b ac))
(def (walk ('/ a b) ac) (walk-op '/ a b ac))
(def (walk-op op a b ac) (walk a (walk b `(,op . ,ac))))
(def (walk ('var x) ac) `((var ,x) . ,ac))
```

```
(def (walk ('const x) ac) `((const ,x) . ,ac))
```

I should probably write a version that does that in a single pass. But first! Something to run the pattern-matching.
(match pattern actual bindings).

```
(def (match () () vars) vars)
(def (match () other vars) #f)
(def (match ('quote x) x vars) vars)
(def (match ('quote x) other vars) #f)
(def (match ('symbol x) (symbol y) vars) (match x y vars))
(def (match ('symbol x) other vars) #f)
(def (match (ap . bp) (a . b) vars)
 (let ((new-vars (match ap a vars)))
      (if new-vars (match bp b new-vars))))
(def (match (ap . bp) other vars) #f)
(def (match (symbol x) y vars) `((,x . ,y) . ,vars))
```

That leaves out the equality-testing logic --- in both the ('symbol x) and the (symbol x) cases, we need to verify that there's no existing conflicting binding for x.

Recasting that (mostly) in a form that doesn't rely on pattern-matching:

```
(define (match pattern actual vars)
  (cond ((null? pattern) (match-null actual vars))
    ((symbol? pattern) (match-symbol pattern actual vars))
    ((pair? pattern) (match-pair pattern actual vars))
    (else (error "invalid pattern"))))
(define (match-null actual vars) (if (null? actual) vars #f))
(define (match-symbol pattern actual vars)
  `((,pattern . ,actual) . ,vars)) ; XXX doesn't check for dups
(define (match-pair pattern actual vars)
  (cond ((eq? (car pattern) 'quote)
     (and (equal? (cadr pattern) actual) vars))
    ((eq? (car pattern) 'symbol)
     (and (symbol? (cadr pattern))
      (match (cadr pattern) actual vars)))
    (else
     (let ((new-vars (match (car pattern) (car actual) vars)))
       (if new-vars (match (cdr pattern) (cdr actual) new-vars) #f)))))
```

And here's a fix to match-symbol that does equality testing:

```
(define (match-symbol pattern actual vars)
    (let ((existing (assq pattern vars)))
  (cond ((not existing) `((,pattern . ,actual) . ,vars))
    ((equal? (cdr existing) actual) vars)
    (else #f))))
```

From there, it's a simple extension to supporting multiple patterns:

```
(define (match-many patterns functions actual)
  (if (null? patterns) (error "match failure")
(let ((bindings (match (car patterns) actual '())))
```

```
  (if bindings ((car functions) bindings)
    (match-many (cdr patterns) (cdr functions) actual)))))
```

Ideally we'd really like to compile the pattern-matching down to efficient Scheme code which does a reasonably small number of tests and doesn't re-examine the pattern as well as the actual, each time around. I don't think I'm quite up for that yet.

Unsurprisingly, this is not a new idea; Andrew K. Wright's 1996 proposal for pattern-matching in Scheme uses a slight superset of this pattern syntax, with the same semantics. (I switched to using equal? instead of eqv? in the above code after reading his paper.) However, I think it's interesting to allow definition of new cases on existing functions this way, rather than shoving it off into a "match-define" ghetto as Wright does.

Cheap frequency detection

Kragen Javier Sitaker, 2017-06-29 (updated 2019-06-19) (50 minutes)

Most audio and radio signals are passed through some unknown linear time-invariant system, such as linear circuits or multipath fading, before we get them. So it's often to our advantage to try to detect features of these signals that survive such mangling. Those features are sinusoids, or, more generally, complex exponentials.

If you want to detect sinusoidal components in a signal, the standard approach is to use the Fourier transform. This has a couple of disadvantages:

• It requires a substantial amount of computation per sample, specifically (for the radix-2 FFT) 2 lg N real multiplications where N is the window size and lg is the base-2 logarithm;
• When a signal is only present during part of the window, its energy is smeared across the whole window, which may remove aspects of interest (you may want to know when it happened) and may push it below the noise floor;
• It more or less requires floating-point computation, which increases the number of bit operations substantially.

There are a number of other approaches which can be used in cases where the Fourier transform's disadvantages are fatal, but I haven't found a good overview of them. Here I'm going to talk about counting zero crossings, SPLLs, CIC decimation, the Minsky circle algorithm, the Goertzel algorithm, Karplus-Strong delay line filtering, linear predictive coding, and uh this thing I just came up with in the shower, and finally an extended zero-crossing approach.

Counting zero crossings

A very simple and commonly used nonlinear filtering or demodulation approach is to count the number of times the signal crosses the X-axis.

If the majority of your signal power is in a single frequency (perhaps because you've already filtered it) the count of zero crossings is a reasonable approximation of the frequency. A step up from this is to measure the time interval of the last N zero crossings, maybe the last 16 crossings or the last 64 crossings, in order to get an estimate whose precision is limited by your sampling rate rather than by both your sampling rate and your time window.

The simplest approach is just this, assuming 8-bit samples being returned from `getchar()` (unsigned, as is `getchar()`'s wont):

```
volatile int crossings = 0;
...
for (;;) {
    while (getchar() < 128);
    crossings++;
    while (getchar() >= 128);
    crossings++;
}
```

However, this allows any arbitrarily small amount of noise near a slow zero crossing to add extra zero crossings. Normally in circuits we deal with this by adding a Schmitt trigger, as described in Otto Schmitt's 1937 paper, "A Thermionic Trigger"; as Schmitt says, "in another application, [the thermionic trigger circuit] acts as a frequency meter more linear than one of the thyratron type, and one immune to locking," whatever that means. The Schmitt trigger adds a little bit of hysteresis through positive feedback, and indeed roughly any kind of positive feedback on digital inputs nowadays is called a "Schmitt trigger".

In code, adding this hysteresis is even simpler:

```
volatile int crossings = 0;
...
for (;;) {
    while (getchar() < 128+16);
    crossings++;
    while (getchar() >= 128-16);
    crossings++;
}
```

This requires the noise to move the needle by at least 32 counts before it qualifies as a "crossing", which you would think is 18 dB below full-scale, but of course it's not an average over the whole signal, but an increment at that point. Impulsive noise can overcome this while totaling well below -18 dB by being at -∞ dB in between impulses.

The other problem is that unless the actual signal is substantially higher than those -18 dB, this will miss crossings, maybe all of them. You can adjust the hysteresis to compensate with, for example, a peak detector (note I haven't tried this):

```
volatile int crossings = 0;
...
int threshold = 0, x;
for (;;) {
    int peak = 0;
    while ((x = getchar()) < 128 + threshold) {
        if (128 - x > peak) peak = 128 - x;
    }
    crossings++;
    threshold = peak >> 3;

    peak = 0;
    while ((x = getchar()) > 128 - threshold) {
        if (x - 128 > peak) peak = x - 128;
    }
    crossings++;
    threshold = peak >> 3;
}
```

This may count a few extra crossings at the beginning of the process until it warms up; from then on, it notes the peak of each half-cycle to use to adjust the hysteresis threshold for the next crossing. If the signal you're detecting drops suddenly (by a factor of

8, as specified by `>> 3`) within a single cycle, it could suddenly stop counting cycles; similarly, if there is a noise spike that exceeds the signal by a factor of 8, it could suddenly stop being able to detect the signal.

Per sample, this requires two subtractions, two comparisons, a conditional assignment, and a conditional jump, plus a couple more operations after each zero crossing.

A more robust version of this algorithm would use perhaps the median peak, the median, or some percentile over the last several cycles, rather than simply the peak, and would decay the threshold toward 0 over time in order to recover from the kinds of situations described above. This requires a few more operations.

For frequency detection of a signal, the zero-crossing approach may be superior to the linear FFT-based approaches discussed below. For example, if you want to control a synthesizer using your voice, you need to be able to discriminate at least between musical notes. If you want to distinguish between 110 Hz (A) and 106 Hz (closer to G#) with an FFT you need your frequency bins to be 4 Hz apart, which means you need to be running the FFT over a 250 ms window. But at 48 ksps, the zero crossings of a 110-Hz square wave are 436 samples apart, while the zero crossings on a 106-Hz square wave are more like 453 samples apart, and it seems like you could probably use the median of the last 4–8 intervals between zero crossings. 8 half-waves at 106 Hz would be 38 ms.

However, I suspect that all of these variants are strictly inferior to using a phase-locked loop, which is almost exactly the same amount of computation but has truly impressive noise immunity, and can additionally tell you the power of the frequency it's detecting (at a little extra computational expense.)

Software phase-locked loops

A phase-locked loop is a nonlinear filter that measures the frequency, phase, and possibly power of a signal with constant or slowly changing frequency. You use a phase detector to set the frequency of a local oscillator to match the frequency of the signal, and the phase detector uses that local oscillator as its reference. The simplest phase detector is just a chopper and a low-pass filter; here's a software implementation in one line of C, suitable for tone frequency tracking:

```
/* A PLL in one line of C. arecord | ./tinypll | aplay */
main(a,b){for(;;)putchar(b+=16+(a+=(b&256?1:-1)*getchar()-a/512)/1024);}
```

This is potentially quite efficient, taking almost exactly the same amount of computation as counting zero crossings; at its base, it involves four additions or subtractions per sample, plus a bit test, a conditional, and a couple of bitshifts.

This takes a signal (by default at 8 ksps) from the ALSA audio driver with one sample on `getchar()`; `b` is the current phase of a local oscillator with period of 512 counts, whose free-running frequency is one cycle per 512/16 = 32 samples, so 250 Hz. The phase detector accumulates its error signal in `a`. The input sample is chopped by the ≈250Hz square wave from `b`, then either added to or subtracted from `a`, which has an exponential low-pass filter applied to it by way of

subtracting a 512th of itself, yielding a time constant (I think?) of 512 samples or 64 ms. The range of `a` extends up to where a == a+255-a/512, which is to say when a == 512*255 == 130560; the lower limit is analogously -130560. So `a` is scaled down by dividing by 1024 to get `b`'s free-running increment, which means that in theory it could cause `b` to run backwards or at up to 130+16 = 146 counts per sample, thus about 3.5 samples per cycle or 2280 Hz. (Actually, not even that much, because half the time you have to be feeding it zeroes, so its maximum stable magnitude oscillates around 130560/2.)

(In practice I've never managed to get the above code even up into the kHz range.)

`putchar()` then outputs the low 8 bits of `b`, forming a sawtooth wave from it with twice the chopper frequency, around 500 Hz.

More conventionally formatted and without the uninitialized-read undefined behavior, the above code reads as follows:

```
int main()
{
    int a = 0, b = 0;
    for (;;) {
        a += (b & 256 ? getchar() : -getchar());
        a -= a/512;
        b += 16;
        b += a/1024;
        putchar(b);
    }
}
```

This kind of phase detector tries hard to keep the chopper in quadrature with the detected signal. If you want to know the power of the detected signal, you can chop the input signal with a second chopper in quadrature with the first and sum its (squared) output.

Note that this kind of phase detector is optimized for detecting square waves, and thus can lock onto odd harmonics of the signal it thinks it's detecting. This may be an advantage or a disadvantage in a particular application.

The 1/512 in the above code, which is a low-pass filter on the phase detector output (and oscillator frequency input), directly limits how fast the PLL can track a changing frequency; less apparent is that it also limits how much noise immunity the PLL has, and how far the PLL's frequency can jump to achieve lock (the "capture range"). The proportionality factor by which the phase output adjusts the local oscillator frequency (the 1/1024) limits how far the PLL can track before losing lock (the "lock range"). A couple of hacks to improve these tradeoffs are to sweep the natural frequency of the LO when it hasn't yet achieved lock, to use several concurrent PLLs with different natural frequencies, and to tighten the low-pass filter once lock is achieved.

With a different kind of phase detector, a PLL is also useful for things like beat detection and beat matching, which is in a sense its primary use in hardware — generating clock signals with a predetermined relationship to existing clock signals, including clock and data recovery for asynchronous data transmission.

The one-line program is about the same length in machine code as

in C. An amd64 (but LP64) assembly listing for the 63 bytes of this loop is as follows, keeping `b`, the local oscillator state, in %ebp, and `a`, the phase detector, in %ebx. GCC -Os did not optimize the multiplication and divisions into a conditional and bitshifts as you might expect:

```
40                  .L3:
43 0011 89E8            movl    %ebp, %eax
44 0013 25000100        andl    $256, %eax
44      00
45 0018 83F801          cmpl    $1, %eax
46 001b 4519ED          sbbl    %r13d, %r13d
47 001e 31C0            xorl    %eax, %eax
48 0020 4183CD01        orl $1, %r13d
49 0024 E8000000        call    getchar
49      00
51 0029 4489E9          movl    %r13d, %ecx
52 002c 0FAFC8          imull   %eax, %ecx
53 002f 89D8            movl    %ebx, %eax
54 0031 99              cltd
55 0032 41F7FC          idivl   %r12d
56 0035 29C1            subl    %eax, %ecx
57 0037 01CB            addl    %ecx, %ebx
59 0039 B9000400        movl    $1024, %ecx
59      00
60 003e 89D8            movl    %ebx, %eax
61 0040 99              cltd
62 0041 F7F9            idivl   %ecx
63 0043 8D6C0510        leal    16(%rbp,%rax), %ebp
65 0047 89EF            movl    %ebp, %edi
66 0049 E8000000        call    putchar
66      00
69 004e EBC1            jmp .L3
```

There are many ways to improve this simplified PLL.

A simple one is to use a simple-moving-average filter instead of an exponential filter to smooth the phase detector; this gives you better tracking of frequency changes for the same noise immunity, or better noise immunity for the same tracking of frequency changes.

Different phase detectors are best for different kinds of signals. For sinusoidal signals with no significant harmonics, like a person whistling or an FM radio signal, you can get a better phase detector by weighting samples toward the middle of the sample interval more highly than samples toward its edges; multiplying by even a triangle wave (a square wave convolved with a simple moving average) gets you most of the way there. For signals where only, say, leading edges are significant, you can use a phase detector that only considers the few samples near that leading edge.

The shower algorithm

Let's suppose you want to detect some fixed frequency f and you've already resampled your signal to a sampling rate of 4f. Two orthogonal sinusoids at frequency f then are [-1, -1, 1, 1] and [1, -1, -1, 1]; two others are [0, 1, 0, -1] and [1, 0, -1, 0]. If you can find the dot

product of your signal with a pair of these sinusoids, then you can use their Pythagorean sum to precisely compute the energy in that frequency component of the signal.

If you're dumping the decimated samples into a four-sample circular buffer x0, x1, x[2], x[3], with some incrementing pointer xp:

```
x[xp++ & 3] = new_sample;
```

Then you could imagine using x[xp], x[xp-1], x[xp-2], and x[xp-3] with the appropriate modulo math. However, this is totally not necessary, because you actually don't care how these sinusoids are aligned with the signal; you only care that they are orthogonal. It's totally valid to compute one phase component as x0 - x[2] and the other as x1 - x[3] and then compute their Pythagorean sum:

```
return pythsum(x[0] - x[2], x[1] - x[3]);
```

So far, though, we've gotten away without requiring the potentially large number of bit operations required to even square a number. For low-precision data types, like 8 bits, it would be totally valid to use a lookup table of squares, then binary-search it to find the square root. However, there are more approximate alternatives that may be good enough in many cases.

Specifically, max(|a|, |b|) and |a| + |b| are both approximations of the Pythagorean sum that are never wrong by more than a factor of √2 and can be computed in a small linear number of bit operations. Both are precisely accurate when a or b is 0 and have their worst case when |a| == |b|; max(|a|, |b|) is low by a factor of √2 then, and |a|+|b| is high by a factor of √2. Both have level sets that are square, but rotated 45°. If we sum them, the resulting octagonal level sets have a worst-case error of a bit under 12%, just under 1 dB.

This Pythagorean-sum-approximation algorithm looks like this:

```
if (a < 0) a = -a;
if (b < 0) b = -b;
return ((a < b ? b : a) + a + b >> 1);
```

YMMV. On something like an AVR ATMega, the necessary three comparisons, three conditional branches, pair of additions, and right shift are probably slower than just computing the Pythagorean sum with the two-cycle multiplier. In the other direction, the 3 dB worst-case error of max(|a|, |b|) or |a| + |b| is insignificant in many frequency-detection contexts, where you're trying to determine whether a signal is more like -15dB or more like your -50dB noise floor.

In many cases you might want to be integrating the wave over a significant period of time. In a case like that, there are a few different cheap approaches you can take. A circular buffer of four simple-moving-average filters provides optimal noise immunity for a given step response; you can do the same thing with the accumulators for single-pole exponential filters; and a chain of two or three moving-average filters inexpensively gives you something approaching a Gaussian window. Finally, you could simply use a buffer of four accumulators to sum the corresponding samples across

some rectangular window, without attempting any kind of nonuniform weighting.

The problem of frequency response in rectangular windows

The disadvantage of rectangular windows in general (whether simple moving average filters or fixed windows of a few hundred samples or whatever) is that their Fourier transform is sinc. Implicitly multiplying your signal by the rectangular function in this way effectively convolves its frequency spectrum with sinc, which dies off relatively slowly (1/n) as you get far away from its center. Even a simple triangular window, which can be achieved by convolving two identical rectangular functions together (and thus squaring their frequency response), dies off at a much more reasonable pace ($1/n^2$). And, in a sense, this is the basis for CIC decimation.

CIC decimation

CIC decimation does not itself detect signals; it just (linearly, with linear phase, essentially with a convolution of simple moving averages) low-pass filters them and reduces the sampling rate. However, an Nth-order CIC decimation filter involves only N integer additions (using N accumulators) per input sample plus N subtractions per output sample (using N previous output samples). As explained above, though, there are very efficient ways to detect signals in such decimated data.

Here's a second-order CIC decimation filter (untested) that reduces the sample rate by a factor of 73. It uses unsigned math because in C unsigned overflow is well-defined and guarantees the property that (a+b) - b == a, regardless of overflow, and the CIC algorithm needs that.

```
enum { decimation_factor = 73 };
unsigned s1 = 0, s2 = 0, d1 = 0, d2 = 0, i = decimation_factor;
for (;;) {
    s1 += getchar();  // integrator 1
    s2 += s1;         // integrator 2
    if (0 == --i) {
        i = decimation_factor;
        unsigned dx = s2 - d1; // differentiator ("comb") 1
        d1 = s2;
        unsigned dx2 = dx - d2; // differentiator 2
        d2 = dx;
        putchar(dx2 / (decimation_factor * decimation_factor));
    }
}
```

For each input sample, this involves two additions, a decrement (or increment), and a jump conditional on zero. Each output sample additionally requires two subtractions; in this case, I've also rescaled the output by dividing by a compile-time constant (which usually costs a multiply), so that it will be in (I think precisely) the same range as the original samples; however, this loses precision and dynamic range, and in many cases, no such rescaling is needed.

A 440 Hz signal (A above middle C in A440 standard pitch)

sampled at 8 ksps is 18.18 samples per cycle. The factor of 73 above resamples an 8 ksps signal such that a signal of roughly 438.4 Hz, about 6 cents flat, will occupy 4 output samples, as recommended above for the shower algorithm. How well an actual precise 440 Hz signal will be detected depends on how long you integrate the results over.

The second-order nature of the above filter effectively windows each sample with a triangular window.

Here's an (n-1)th-order version (untested):

```
enum { decimation_factor = 73, n = 4 };
unsigned s[n] = {0}, d[n-1] = {0}, i = decimation_factor;
for (;;) {
    s[0] = getchar();
    for (int j = 1; j < n; j++) s[j] += s[j-1];
    if (0 == --i) {
        i = decimation_factor;

        unsigned dj = s[n-1];
        for (int j = 0; j < n-1; j++) {
            unsigned djprime = dj - d[j];
            d[j] = dj;
            dj = djprime;
        }

        printf("%d\n", dj);
    }
}
```

There's a quasi-inverse of CIC decimation, which is CIC interpolation; in essence, this amounts to using the Method of Finite Differences that Babbage used to tabulate polynomials on the Difference Engine. I say it's a quasi-inverse because it doesn't undo the low-pass filtering that CIC decimation does, I think not even the part that's below the Nyquist frequency of the decimated signal.

I think it's feasible to control the CIC decimation rate using a phase detector, like a PLL, and it may be possible to dither the decimation rate with something like the Bresenham algorithm; however, since the signal out of the comb filter is amplified by a linear factor of the decimation rate, this may be somewhat tricky, as oscillations of the decimation rate turn into oscillations of the output signal amplitude, which needs to be controlled for.

If you are resampling to several different frequencies, the initial per-sample integration steps, and even the counter increment, can be shared between them.

The Minsky Circle Algorithm

In HAKMEM (MIT AI Lab memo 239), item 149 (p. 73) describes an algorithm attributed to Minsky for drawing circles — or, more precisely, very slightly eccentric ellipses:

```
NEW X = OLD X - ε * OLD Y
NEW Y = OLD Y + ε * NEW(!) X
```

Rendered into C:

```
int x = 255, y = 0, n = 1000;
while (--n) {
    x -= y * epsilon;
    y += x * epsilon;
    pset(x0 + x, y0 + y);
}
```

As Minsky comments, "If ε is a power of 2, then we don't even need multiplication, let alone square roots, sines, and cosines!"

Here's a version that outputs a sine wave in minimized C:

```
main(x,y){for(y=100;1+putchar(x+128);x-=y/4,y+=x/4);}
```

Of course, division by 4 can be implemented by an arithmetic shift right by 2 bits.

HAKMEM items 150–152 go into some more detailed analysis.

We can think of the epsilons as rotating the (x, y) phasor by some angle (specifically, $\cos^{-1}(1-\frac{1}{2}\varepsilon^2)$, according to item 151; note that Baker's transcription contains an erroneous omitted superscript 2). If we add input samples to x (or y) then it will sum whatever frequency component is in sync with the rotation:

```
for (;;) {
    x -= epsilon * y;
    y += epsilon * x + getchar();
    putchar(x * scale);
}
```

Frequency components that are not in sync with the rotation will average out to zero. Frequency components that are in sync will grow without limit.

You can use two different ε factors for the two multiplications, which gives a more elliptical "circle" and a denser range of frequencies. In particular, one of them can be 1, which means you can generate a tone of arbitrary frequency with only a single scaling operation per cycle, plus the addition and subtraction:

```
main(x,y){for(y=100;1+putchar(x+128);y+=x-=y/8);}
```

In somewhat more standard formatting, although with a still somewhat eccentric use of `for`:

```
/* Output an audio sinusoid with Minsky's ellipse algorithm */
#include <stdio.h>

int main()
{
  for (int x=0, y=100; EOF != putchar(x+128); x -= y >> 3, y += x)
    ;
  return 0;
}
```

The loop here compiles to this amd64 machine code:

```
  400450:   89 e8                   mov    %ebp,%eax
  400452:   c1 f8 03                sar    $0x3,%eax
  400455:   29 c3                   sub    %eax,%ebx
  400457:   01 dd                   add    %ebx,%ebp

  400459:   48 8b 35 e0 04 20 00    mov    0x2004e0(%rip),%rsi # 600940 <__bss_st
art>
  400460:   8d bb 80 00 00 00       lea    0x80(%rbx),%edi
  400466:   e8 b5 ff ff ff          callq  400420 <_IO_putc@plt>
  40046b:   83 f8 ff                cmp    $0xffffffff,%eax
  40046e:   75 e0                   jne    400450 <main+0x10>
```

Unfortunately, this version spends almost all of its time calling and returning from `_IO_putc`. A version that writes into a 512-byte buffer instead, achieving 850 megasamples per second on my laptop, is as follows:

```
#include <stdio.h>

int main()
{
  char buf[512];
  int x=0, y=100;
  for (;;) {
    for (int i = 0; i != sizeof(buf)/sizeof(buf[0]); i++) {
      x -= y >> 3;
      y += x;
      buf[i] = 128 + x;
    }
    if (fwrite(buf, sizeof(buf), 1, stdout) != 1) return -1;
  }
}
```

Its inner loop compiles to the following nine instructions (again, on amd64):

```
  400460:   89 ea                   mov    %ebp,%edx
  400462:   c1 fa 03                sar    $0x3,%edx
  400465:   29 d3                   sub    %edx,%ebx
  400467:   48 63 d0                movslq %eax,%rdx
  40046a:   83 c0 01                add    $0x1,%eax
  40046d:   8d 4b 80                lea    -0x80(%rbx),%ecx
  400470:   01 dd                   add    %ebx,%ebp
  400472:   3d 00 02 00 00          cmp    $0x200,%eax
  400477:   88 0c 14                mov    %cl,(%rsp,%rdx,1)
  40047a:   75 e4                   jne    400460 <main+0x20>
```

The book "Minskys and Trinskys," by Corey Ziegler Hunts, Julian Ziegler Hunts, R.W. Gosper and Jack Holloway, explores the variations of this algorithm in more detail; I don't have the book, but according to Nick Bickford's 2011 post on the subject, they prove that, using δ for the ε factor that multiplies Y:

$$X_n = X_0 \cos(n\,\omega) + (X_0/2 - Y_0/\varepsilon) \sin(n\,\omega)/d$$
$$Y_n = Y_0 \cos(n\,\omega) + (X_0/\delta - Y_0/2) \sin(n\,\omega)/d$$

where

$$d = \sqrt{(1/(\delta\ \varepsilon) - 1/4)}$$
$$\omega = 2 \sin^{-1}(1/2\sqrt{(\delta\ \varepsilon)})$$

If this is correct, Gosper's earlier result in HAKMEM that $\omega = \cos^{-1}(1 - 1/2\varepsilon^2)$ should be a special case of it (where $\varepsilon = \delta$); it isn't immediately obvious to me why this is so, but these do seem to be consistent for a couple of trial values:

$$\cos\ \omega = 1 - 1/2\ \delta\ \varepsilon$$
$$\sin 1/2\omega = 1/2\ \sqrt{(\delta\ \varepsilon)}$$

I hypothesize, but haven't proven either experimentally or rigorously, that if you start with 0 and add each new input sample to x, you will accumulate a phasor in x and (possibly, depending on the algorithmic variant, scaled) y of all of the samples encountered so far, rotated by the appropriate angle. This will give you the total you've encountered so far of a given Fourier component.

The Goertzel Algorithm

The Goertzel algorithm (sometimes more specifically "the second-order Goertzel algorithm") is an optimized version of Minsky's algorithm, requiring only one multiply or quasi-multiply per input sample. It's actually older than Minsky's formulation, dating from 1958. At its heart is the oscillator $s[n] = (2 \cos \omega)\ s[n-1] - s[n-2]$, which oscillates with an angular frequency of ω per sample; to look at it another way, it's the state transition function $(s, t) \leftarrow ((2 \cos \omega)\ s - t, s)$. To this you just add each input sample x: $(s, t) \leftarrow (x + (2 \cos \omega)\ s - t, s)$; in this way, the energy in the desired frequency accumulates in s and t, and at the end of the accumulation process, you can measure it.

Since $2 \cos \omega$ is constant, this is just a constant multiplication — and some values are inexpensive to multiply by. For example, you can multiply a value a by $1-2^{-4}$ as follows:

```
a -= a >> 4;
```

This is what I mean by "quasi-multiply".

$\cos^{-1}(1-2^{-4}) \approx 0.3554$, and consequently this works out to an oscillation period of $2\pi/0.3554 \approx 17.68$ samples. Here's a C version that emits a sine wave that repeats precisely, due to roundoff error, every 53 samples, for a period of 17.66 samples, 452.8 Hz (lamentably about halfway between A and A# above middle C) in linear unsigned 8-bit samples at 8 ksps:

```
/* Generate a 452.8 Hz sine wave. ./goertzel | aplay */
#include <stdio.h>

int main()
{
  int s = 0, t = 32;
  for (; EOF != putchar(s + 128);) {
    int tmp = s;
```

```
    s += s;
    s -= s >> 4;
    s -= t;
    t = tmp;
  }
}
```

Not counting the output bias addition, this requires an addition, two subtractions, and a bit shift per sample. Here's a one-line version:

```
main(s,t,u){for(t=32;u=s,1+putchar(128+(s-=t-s+s/8));t=u);}
```

(For the special case where $\omega = \frac{1}{3}\pi$, $\cos\omega = \frac{1}{2}$, so $2\cos\omega = 1$; we can thus get a 6-sample cycle with only a subtraction per sample; in that case $(s, t) \leftarrow (s-t, s)$. At 8 ksps this is $1333.\bar{3}$ Hz, 19 cents sharp of E6.)

In a sense, this oscillator works by obtaining the derivative information — stored as an explicit second variable in Minsky's algorithm — from the difference between s[n-1] and s[n-2]. We can rewrite the recurrence relation as follows:

$$s[n] = (2\cos\omega)\, s[n-1] - s[n-2]$$

Let's suppose:

$$s[n-2] = k\cos\theta_0$$
$$s[n-1] = k\cos(\theta_0 + \omega)$$

Presumably in this case s[n] should be identically $k\cos(\theta_0 + 2\omega)$. Is it?

$$\begin{aligned} s[n] &= 2\cos\omega\, s[n-1] - s[n-2] \\ &= 2\cos\omega\, k\cos(\theta_0 + \omega) - k\cos\theta_0 \\ &= k(2\cos\omega\cos(\theta_0 + \omega) - \cos\theta_0) \end{aligned}$$

As you would remember from high-school trigonometry if you were smarter than I am,

$$\cos(t + h) = \cos t\cos h - \sin t\sin h$$
$$\sin(t + h) = \sin t\cos h + \cos t\sin h$$
$$\cos 2\omega = \cos^2\omega - \sin^2\omega$$
$$\sin 2\omega = 2\sin\omega\cos\omega$$

So

$$\begin{aligned} \cos(\theta_0 + 2\omega) &= \cos\theta_0\cos(2\omega) - \sin\theta_0\sin(2\omega) \\ &= \cos\theta_0\cos^2\omega - \cos\theta_0\sin^2\omega - 2\sin\theta_0\sin\omega\cos\omega \\ \cos(\theta_0 + \omega) &= \cos\theta_0\cos\omega - \sin\theta_0\sin\omega \end{aligned}$$

$$k\cos(\theta_0 + 2\omega) = k(\cos\theta_0\cos^2\omega - \cos\theta_0\sin^2\omega - 2\sin\theta_0\sin\omega\cos\omega)$$

$s[n] = 2\cos\omega\, s[n-1] - s[n-2]$
if
$s[n-2] = k\cos\theta_0$
$s[n-1] = k\cos(\theta_0 + \omega)$

then

$$
\begin{aligned}
s[n] &= 2 \cos \omega \, k \cos (\theta_0 + \omega) - k \cos \theta_0 \\
&= k (2 \cos \omega \cos (\theta_0 + \omega) - \cos \theta_0) \\
&= k (2 \cos \theta_0 \cos^2 \omega - \cos \theta_0 - 2 \sin \theta_0 \sin \omega \cos \omega) \\
&= k (\cos \theta_0 (2 \cos^2 \omega - 1) - 2 \sin \theta_0 \sin \omega \cos \omega) \\
&= k (\cos \theta_0 (\cos^2 \omega + \cos^2 \omega - 1) - 2 \sin \theta_0 \sin \omega \cos \omega) \\
&= k (\cos \theta_0 (\cos^2 \omega - (1 - \cos^2 \omega)) - 2 \sin \theta_0 \sin \omega \cos \omega) \\
&= k (\cos \theta_0 (\cos^2 \omega - \sin^2 \omega) - 2 \sin \theta_0 \sin \omega \cos \omega) \\
&= k (\cos \theta_0 \cos^2 \omega - \cos \theta_0 \sin^2 \omega - 2 \sin \theta_0 \sin \omega \cos \omega) \\
&= k \cos (\theta_0 + 2\omega)
\end{aligned}
$$

$\therefore \cos (\theta_0 + 2\omega) = (2 \cos \omega) \cos (\theta_0 + \omega) - \cos \theta_0$ QED

This shows that given two points on a sinusoid of the right angular frequency and any amplitude or phase, the Goertzel algorithm will continue extrapolating further points on it indefinitely.

Measuring the energy is inexpensive (requiring two real multiplies, a subtraction, a couple of squares, and an addition) but not entirely obvious if we only keep around the last two samples of s. The standard presentation is that we transform them into a complex number encoding the magnitude and phase of the signal:

$$y[n] = s[n] - \exp(-i \omega) \, s[n-1]$$

Which is to say:

$$y[n] = (s[n] - (\cos \omega) \, s[n-1]) + i \, (\sin \omega) \, s[n-1]$$

Note that that, if ω is small, the exponential gives a value close to 1, so this is very nearly the difference between the two last values of s.

The idea is that the basic recurrence relation given above for s will rotate this resultant phasor around by an angle of ω without altering its magnitude. Does it?

In the case of an arbitrary multiplier, the Goertzel algorithm beats Minsky's circle algorithm by almost a factor of 2, since Goertzel requires only a single multiply per sample, while Minsky requires two multiplies per sample. But in a case where the multiplication can be achieved by a bit shift and is basically free, Minsky requires just

```
s += t >> n;
t -= s >> n;
```

while Goertzel requires

```
u = s;
s += s - t - (s >> n);
t = u;
```

So you have three additions or subtractions instead of two, and maybe a bit of shunting as well, but one less bit shift.

Another factor to consider is that, for a given multiplier precision, the Minsky algorithm covers the frequency spectrum much more densely; for a multiplier ε (2^{-n} in the example above) the Minsky frequency is $\cos^{-1} (1-\frac{1}{2}\varepsilon^2)$, while the Goertzel frequency is $\cos^{-1} (1-\frac{1}{2}\varepsilon)$. So, for example, if we are multiplying x, y, and $2 \cdot s[n-1]$ by 1/256 to get the value we subtract, Minsky gives us a 3.9-milliradian

rotation and a 1608-sample period, while Goertzel gives us a 63-milliradian rotation and a 100.5-sample period. This is somewhat intuitive, in that the Minsky algorithm applies the multiplier twice per iteration.

The single-scaling version of Minsky's algorithm is presumably similar to Goertzel in its angular resolution, but with two additions or subtractions per sample instead of three; the results I mentioned above for that algorithm should be sufficient to show whether that is true.

You can think of the Goertzel algorithm (or the Minsky algorithm) as integrating the complex phasor y at a particular frequency over the input signal — that is, y is a sum table (or prefix sum or cumulative sum) of the input signal at that frequency. This suggests that if you want to know the amount (and phase) of signal at that frequency between two points in time, you can subtract the corresponding points in y, just as with a first-order CIC filter, and thus inexpensively apply a moving average filter to it. (You will need to rotate the two phasors into phase with a rotation appropriate to the window size, costing two multiplies.)

Goertzel and Minsky as complex integrators

This of course suffers from the rectangular-window problem I mentioned in the shower-algorithm section. You can apply the CIC approach, making a second-order or third-order sum table and then infrequently taking differences at some window width, giving you the amplitude and phase of the chosen frequency windowed by a triangular or near-Gaussian function. However, I think computing these sum tables will require accumulating them as complex numbers and doing the rotation by the appropriate phase before adding each new sample — which, in the general case, requires a complex multiplication (four real multiplications).

However, in the case where we can do the multiplication inexpensively, as in the examples above with a bit shift and a subtraction or addition, this may be a reasonable approach. (See also the section below about avoiding multiplications.)

Karplus-Strong delay line filtering

The Karplus-Strong string synthesis algorithm consists of nothing more than a recursive unity-gain comb filter with a little bit of low-pass filtering. Originally, the delay line was initialized with random noise, but it's the resonances of the filter that provide the envelope and most of the frequency response. Here's a one-line C implementation initialized with just an impulse:

```
s[72]={512};main(i){for(;;i%=72)s[i]+=s[(i+1)%72],putchar(s[i++]/=2);}
```

This version does two indexed fetches, two indexed stores, three divisions, an addition, and a couple of increments per sample, but the divisions can be replaced by equality tests and conditional stores, except for one which is a bit shift. So you need an indexed fetch, an addition, an indexed store, a index increment, a bit shift of 1, and the compare-to-threshold-and-reset operation on the index to implement the circular buffer.

Here's the same algorithm written in a more reasonable way, with a

time limit:

```
#include <stdio.h>

enum { delay = 72 };

int s[delay] = { 512 };

int main()
{
  int i = 0, i2 = 0;
  for (int n = 8000; n--; i = i2) {
    i2 = i + 1;
    if (i2 == delay) i2 = 0;

    s[i] += s[i2];
    s[i] >>= 1;

    putchar(s[i]);
  }

  return 0;
}
```

As a recurrence relation, this is computing

```
s[n] = ½s[n-71] + ½s[n-72]
```

Of course, you can start with an empty buffer and add input signal to it, which will be convolved with the infinite impulse response of the recurrent filter — which response is precisely the sound you hear when running it with no input starting from the above buffer with just an impulse in it. That impulse response has every frequency that fits an integer number of times into the input buffer — the fundamental of 72 samples (111.$\bar{1}$ Hz), but also 36 samples (222.$\bar{2}$ Hz), 24 samples (333.$\bar{3}$ Hz), and so on. The averaging of adjacent samples attenuates higher frequencies.

If you negate the recurrence, it will instead allow signals with an odd number of half-cycles to resonate. For example:

```
s[n] = -½s[n-71] - ½s[n-72]
```

This will preserve signals with a period of 144 samples, 48 samples, 28.8 samples, 20.57 samples, 16 samples, and so forth. This allows you to shorten the buffer by half and eliminates all the even harmonics, which may be a drawback or an advantage, depending on the signal you're trying to detect.

Autoregressive filtering

CIC's integration and comb filters, the Karplus-Strong comb filter, and the Goertzel s recurrence are all special cases of autoregressive filtering, as used in linear predictive coding for speech — they "predict" each new sample as a linear combination of the previous samples. There exist efficient algorithms for finding the optimal autoregressive filter to minimize the (squared?) residual, such as the

Yule–Walker equations. The coefficients of this filter are the coefficients of a polynomial in the z-domain whose zeroes are the formants of, say, a speech signal.

Avoiding multiplication with single-addition and dual-addition multipliers

Several times in the above, we've referred to cases where it's possible to use just a bit shift instead of a constant multiplication, or merely to subtract or add a shifted number. This is interesting because bit shifts are, in hardware and occasionally in software, free — they require zero gates, zero bit operations, and zero time. An interesting question, then, is what set of multipliers we can achieve with a single addition (or subtraction, which requires the same number of bit operations):

```
>>> numpy.array(sorted(set(x for a in range(8)
                           for b in range(8)
                           for x in [(1 << a) + (1 << b),
                                     (1 << a) - (1 << b)])))
array([-127, -126, -124, -120, -112,  -96,  -64,  -63,  -62,  -60,  -56,
       -48,  -32,  -31,  -30,  -28,  -24,  -16,  -15,  -14,  -12,   -8,
        -7,   -6,   -4,   -3,   -2,   -1,    0,    1,    2,    3,    4,
         5,    6,    7,    8,    9,   10,   12,   14,   15,   16,   17,
        18,   20,   24,   28,   30,   31,   32,   33,   34,   36,   40,
        48,   56,   60,   62,   63,   64,   65,   66,   68,   72,   80,
        96,  112,  120,  124,  126,  127,  128,  129,  130,  132,  136,
       144,  160,  192,  256])
```

So, for example, in the neighborhood of 127, we can compute multiplications by 120, 124, 126, 127, 128, 129, 130, 132, and 136 with a single addition or subtraction plus some bit shifts.

Suppose we can manage two additions or subtractions, not just one. Then we can, for example, multiply by 27 with two additions:

```
x += x << 1;  // multiply by 3
x += x << 3;  // multiply by 9
```

Multiplying by 27 in the usual way would have required three additions: x + (x << 1) + (x << 4) + (x << 5).

This approach gives us 1052 separate multipliers with bit shifts of up to 8:

```
>>> singles = set(x for a in range(8)
                  for b in range(8)
                  for x in [(1 << a) + (1 << b),
                            (1 << a) - (1 << b)])
>>> len(numpy.array(sorted(set(a*b for a in singles for b in singles))))
1052
```

Additionally, though, we can add or subtract the original number, possibly with a shift. So, for example, to multiply by 59, although its Hamming weight is 5, we can calculate (x << 6) - (x << 2) - x.

Combining this approach with the previous one gives us 1366 multipliers with bit shifts of up to 8:

```
>>> len(sorted(set(x for a in singles
                   for b in singles
                   for x in [a*b, a+b, a-b])))
1366
```

Allowing larger bit shifts actually extends our range further; with shifts of up to 16, we can multiply by any constant integer factor in (-256, 256) with two shifted additions or subtractions except for the following handful:

```
>>> singles = set(x for a in range(16)
                  for b in range(16)
                  for x in [(1 << a) + (1 << b),
                            (1 << a) - (1 << b)])
>>> doubles = set(x for a in singles
                  for b in singles
                  for x in [a*b, a+b, a-b])
>>> numpy.array([x for x in range(-255, 256) if x not in doubles])
array([-213, -211, -205, -203, -181, -179, -173, -171, -170, -169, -165,
       -149,  -85,  171,  173,  179,  181,  203,  205,  211,  213])
```

This implies that, given an appropriate constant scale factor, we can always do an approximate multiplication with two shifted additions and subtractions while introducing an error of one part in 2·171 = 342 or less. In fact, more than three-quarters of the multipliers in (-1024, 1024) are reachable:

```
>>> len([x for x in range(-1023, 1024) if x not in doubles])
499
>>> len(doubles)
24418
```

This is especially beneficial for higher-precision operands — for example, 16-bit or 32-bit operands, for which the $O(N^2)$ bit operations of a full-precision multiply could be prohibitive.

In cases like the Minsky algorithm and the Goertzel algorithm where constant multiplication is being used to rotate a phasor progressively over time by a constant angle, it may be reasonable to "dither" the angle by alternating between two different inexpensive rotations; this introduces phase noise or jitter, but when it amounts to a small fraction of a cycle, it shouldn't make much difference.

The extended zero-crossing approach

A problem shared by the Minsky algorithm, the Goertzel algorithm, and the shower algorithm is that they are all ways to calculate or approximate a component of the Fourier transform or the short-time Fourier transform (which I think is the best any linear algorithm can do), and as a result they are fundamentally limited by the same uncertainty principle: to distinguish between, in my example, 110 Hz and 106 Hz, they need at least 250 ms of data, regardless of the sampling rate.

I think, however, that phase-locked loops and zero-crossing

detection can do better. In the absence of noise, or with relatively low noise, they can provide a very accurate measurement of frequency with very little data; in the extreme, by measuring the time of a single half-cycle.

However, even that is poor performance; in theory, in the absence of noise, we need only three sequential samples of the sine wave! Any three samples, as long as they're much less than half a wavelength apart! Their first differences give us two slopes, and their second difference gives us the second derivative; the ratio between this second derivative and the central value gives us the negated squared angular frequency. (Roughly; hmm, I should work out what it is for real, because especially for high frequencies this is only approximate.)

The problem is that the phase-locked loop with the square-wave edge-detector that I showed is only getting information from the samples immediately next to the zero crossing — as is the zero-crossing detector. But usually there is lots of useful information further away from the zero crossing, too. We should be able to take advantage of that information to more precisely estimate the phase of the wave at each point in time.

The phase of a pure sine wave of unity amplitude and angular frequency is just atan2(x, dx/dt); for angular frequency ω and an arbitrary amplitude, it is atan2(x, dx/dt/ω), as the amplitude is a common factor of both arguments and thus cancels.

We don't really need to know the precise derivative to uniquely identify a part of the cycle, though. We only need to know the value at that sample and whether the derivative is positive or negative. (Alternatively, we don't really need to know the precise value; we only need the derivative and whether the sample is positive or negative.)

If we count the time interval since we last passed the current phase angle, this should give us some kind of guess at the period of the wave — potentially a new guess on every sample! If we accumulate these guesses over some period of time, we can take the median of the accumulated guesses (rather than, say, the mean) as the period of our wave.

This is like zero-crossing time measurement, but instead of measuring time between crossings of just the X-axis, we're counting the time between the crossings of every single phase. Some degree of hysteresis is appropriate, but now the hysteresis threshold can be more or less an angle rather than an amplitude.

If we're concerned about computation time, though, we probably don't actually want to calculate the arctangent precisely, even if that were possible for an unknown-frequency signal. Instead we would like to lump each sample into some kind of angle bin based on something that's cheap to compute about that sample.

For example, we could draw a square around the origin, with the sides meeting where x[n] == x[n] - x[n-1] and where x[n] == x[n-1] - x[n]. On the right side of the origin, crossing the real axis, we have a side where x[n] > 0; on the left side of the origin, crossing the real axis, we have a side where x[n] < 0; on the top side, crossing the imaginary axis, we have a side where x[n] - x[n-1] > 0; on the bottom side, crossing the imaginary axis, we have a side where x[n] - x[n-1] < 0. Which side we put a given sample on depends on which of these is greatest, subject to a somewhat arbitrary scaling decision

that will double performance for frequencies around some optimal frequency. So if we're on the right side, that means that x[n] is higher than all of 0, x[n] - x[n-1], and x[n-1] - x[n]; if we're on the left side, it means it's lower than all three; if we're on the top side, x[n] - x[n-1] is higher than 0 and higher than either x[n] or -x[n]; if we're on the bottom side, it's lower than all three.

More on phase detection and frequency suppression

Frequecy detection is sort of intimately interwoven with frequency suppression. Consider the following example.

You want to suppress a 50Hz interfering signal introduced into electrical measurements by a nearby 50Hz fluorescent tube. The waveform is periodic at 50Hz, and indeed symmetric, but very far from sinusoidal.

The simplest approach is simply to apply a feedforward comb filter: by adding the signal to itself as it appeared 10ms ago, you will completely suppress the noise from the fluorescent tube, because that comb filter has nulls at 50Hz, 150Hz, 250Hz, etc. But it does some violence to the remaining signal, since each impulse in the signal now appears twice, 10ms apart, thus smearing things out in the time domain and adding 6dB to components of 0Hz, 100Hz, 200Hz, etc. And, of course, if the lamp turns on or off suddenly, you'll have half a cycle of bleedthrough at the end, which is attenuated but not suppressed if the turnoff is gradual.

Within the linear-filtering paradigm, you can trade some of these undesirable characteristics against one another by using more than one previous sample. For example, instead of merely adding the signal 10ms ago, you can add half the signal 10ms ago and subtract half the signal 20ms ago. This results in further temporal smearing of whatever gets through, but the echo signals are now 6dB quieter. If we carry this further and use the average of ten samples (the corresponding points in the last ten half-cycles, half negated), the added echo is now 20dB down.

However, I think we can do better with some nonlinearity. For example, if we use median filtering rather than mean filtering over the corresponding points in the last ten half-cycles, random impulses will not be echoed at all. Or you can use a hybrid: instead of purely the median, use the mean of the six medial values, discarding the two highest and two lowest values as outliers; or use a weighted mean with weights not restricted to 0 and 1. And we could extrapolate an expected amplitude for the waveform to suppress, allowing us to completely suppress sufficiently gradual turn-ons and turn-offs.

Human-voice sounds are periodic, entirely asymmetric, and also very far from sinusoidal due to their laryngetic origin as impulse trains. It's common for the second harmonic to be even stronger than the fundamental! For such signals we couldn't subtract negative half-cycles; we'd have to use the corresponding points in the last ten cycles, instead. And, since they're not very stable in frequency, we'd need to extrapolate frequency shifts as well.

How do you detect the frequency shifts, though? You can look to see if the waveform is to the left or the right of the expected waveform, but of course it's a question of how far to the left or right

you're looking, which perhaps you can reformulate as a question about how to approximate its derivative. Or you could do a full cross-correlation between signals.

One alternative I've been thinking about is to use the signal and a high-pass-filtered version of its *integral* to do phase detection. That way, you don't have the extreme amplification of noise that derivatives get you.

If we can have a prophecy budget, we can use subsequent cycles of the signal as well as previous cycles to estimate the current cycle.

Web prefetch

Kragen Javier Sitaker, 2017-06-15 (1 minute)

I saw this article: "Ludicrously Fast Page Loads - A Guide for Full-Stack Devs" https://lobste.rs/s/mj7w3d and I thought, 'I wonder what counts as "ludicrously fast"? It turns out the article never actually explains what he means by "ludicrously fast" except that it should be less than 5 or 10 seconds, but it still seemed like a thought-provoking question.

I'd like to get below 10ms, so that even at 100fps it's never more than a screen refresh away. On this shitty DSL, even pinging other people on the same /24 as me takes 50ms, so basically nothing outside my house is under 10ms. So we have to prefetch.

(The article has good points on how to reduce your page rendering times, but I despair of getting HTML5 and CSS to under 10ms. By contrast, some simpler layout models can get much faster indeed.)

15:15 < xentrac> on most internet connections, that unavoidably involves push, but my internet connection is currently about 2.4 megabits per second, and I can only read about 70 bits per second, so the push selection algorithm could have an 0.003% hit rate (i.e. 0.003% of what it downloads is something I actually choose to look at) and still be useful 15:17 < xentrac> huh, 15:18 -!- akurilin2 [~alex@208.80.70.250] has joined #lobsters 15:20 < xentrac>

A mechano-optical vector display for animation archival

Kragen Javier Sitaker, 2014-12-28 (updated 2015-09-03)
(28 minutes)

DRAFT

I was sitting in Christmas Mass, sweating in midsummer, and the reflection of the lights off the oscillating fans pointed out to me the immense unrealized potential for mechano-optical laser displays, like the kind we used for psychedelic light shows back in my childhood. In particular, we can use them for archival of moving pictures.

However, it looks like opacity holograms will continue to be more practical and have comparable information density.

Reflecting a laser to a desired point on the wall

Point a laser pointer obliquely at a mirror-surfaced cylinder rotating around its axis. The laser pointer bounces off the cylinder and makes a spot on the wall, at an angle that depends on its angle to the surface; because the surface is curved, it diverges a bit in the plane perpendicular to the cylinder's axis. It doesn't move as the cylinder rotates.

Now suppose we cut a flat mirror-finish facet into the cylinder, parallel to the axis, such that it will rotate into the beam at some point. When this happens, the spot on the wall will jump to a new position as the surface under the beam abruptly changes angle; then, as the cylinder continues rotating, the rotation of that surface will move the spot perpendicular to the cylinder's axis; and finally, when the beam runs off the other edge of the facet, the spot will jump back to where it was originally.

If we rotate the cylinder fast enough that the motion isn't visible, it will draw a short dash on the wall around the point where the beam normally ends up.

The angle subtended by the dash, as seen from the center of the cylinder, is exactly twice the angle subtended by the facet.

If the facet, instead of being flat, describes a logarithmic spiral centered at the center of the cylinder, then instead of a dash, we will just be drawing another point on the wall.

If, instead of making it a spiral, we angle the facet so that it's not flat and parallel to the axis of the cylinder, but conical instead, we can displace the point parallel to the axis as well.

By combining conicality and spirality, we can place the point anywhere on the wall.

From here on, I'm going to use "up" and "down" to mean the directions on the wall parallel to the cylinder's axis, "right" to mean the direction in which the point reflected from a flat axis-parallel facet would be moving, and "left" to mean its opposite.

If a facet, rather than being perfectly flat, is slightly concave, we can focus the initially-collimated beam to a smaller point on the wall,

if we know the focal distance to the wall, so that the point can be smaller than the illuminated part of the facet. This actually isn't going to be useful for the rest of what I'm discussing here.

Animations by scanning the beam over the medium's surface

By forming a series of many such facets on the circle that the beam describes on the surface of the cylinder, we can draw many points on the wall in quick succession, forming an arbitrary image --- indeed, one that changes over time. If the facets are smaller than the spot on the cylinder illuminated by the beam, several of them will be illuminated simultaneously, and indeed we can run several parallel tracks of them. Smaller facets allow us to program a larger number of points.

Fresnel reflectors allow you to keep surface nonflatness to small scales

There isn't a guarantee that the facets will form an approximately cylindrical shape if we put them edge to edge. Consider, for example, the case where the animation is just a single stationary point to the left of center; your shape is a logarithmic spiral. And, of course when one point is significantly above or below its predecessor, there is a gap between the facets, which must be bridged in some fashion. You can do this Fresnel-lens-style by introducing discontinuities in the surface that won't be illuminated, so that the aforementioned single-point-left-of-center has the shape of a circular-saw blade rather than a continuous spiral.

If you bias the image to be in one particular direction from the centerline, such that an unbroken surface encoding it would be roughly a logarithmic spiral expanding as it rotates, you can ensure that the discontinuities introduced by the Fresnel-reflector operation are never illuminated, so you don't lose any light to them.

Edges of facets will tend to diffract: a planar wavefront reflected from the center of a flat facet will be reflected as a planar wavefront, but the part that reflects from the edge of that flat facet will form cylindrical wavefronts spreading out from the edge. If the facet is very large compared to the wavelength of light, the diffraction from the edges will not be significant, but if it is small, a significant amount of incident light will end up reflected as stray light by this mechanism. Worse, if these edges occur at regular intervals (like the sawblade shape mentioned previously) the diffracted light will form planar wavefronts going in other directions, but divided up by color, like any other diffraction grating. It's possible that you could use this mechanism to get an arbitrary color picture from a white light source, but I'm not sure you have enough degrees of freedom; alternatively, randomizing the discontinuities should break up such patterns and result in the stray light being just a generalized wash.

Diffraction-limited microradian pixel density is around one frame per 4 sq mm

opattern.svg" > Public-domain Airy disk image by :en:Sakurambo.

Also, though, the divergence of the reflected beam is diffraction-limited: a small facet is like a small aperture, and so you end up with the projected point being an Airy disk. This is what imposes the information capacity limit on this medium: if you try to light up more pixels by making smaller facets, you have more stray light and you unavoidably light them up with bigger spots.

So how many pixels can you have?

This depends on the Airy limit. Suppose we use 600nm as our relevant wavelength, which is a slightly orangish yellow and very nearly as sensitive as our daytime spectral sensitivity peak of 555nm.

So how far off the center axis of a facet at right angles to the light source do you have to go before the far edge of the facet is a whole wavelength further from you than the near edge, so that you're in the first null? Consider if we try to make our pixel facets 20μm across. The sine of that angle is 600nm / 20 microns, or about 1/32 to 1/40, so it turns out it's about 1.4 to 1.8 degrees --- and the whole bright beam reflected from that facet, inside that first null, is therefore a cone of 2.8 to 3.6 degrees. (1.22 λ/d is the Airy formula typically given for a round aperture, which is a little smaller than the 2 λ/d I'm using here.)

Public-domain laser diffraction Airy disk photo by :en:Anaqreon.

To put that in more normal terms, a visible-wavelength light beam passing through a 20-micron aperture will be diffracted into a cone with about 3 or 4 degrees of divergence.

(To see if I was smoking crack here, I checked the Wikipedia article on "beam divergence". It says, "Gaussian laser beams are said to be diffraction-limited when their radial beam divergence [half the cone angle] is close to the minimal possible value, given by $\theta = \lambda/\pi w$, where λ is the laser wavelength and w is the radius of the beam at its narrowest point, which is called the 'beam waist'." In this case, λ/w is about 1/16 to 1/20, so our divergence in radians should be a πth of that, which is only slightly narrower than the answer I got above, and the difference may depend on where you set your cutoff.)

This stands in sharp contrast to what we normally expect from, say, a megapixel display, which is pixels of something like 2 arcminutes, 0.03 degrees, two orders of magnitude better. You can improve things by putting the projector closer to the wall than your eye is, but you're still only going to get reasonable resolution over about one radian in each dimension, before things start to kind of sketch out around the edges due to the super oblique angles.

If you want to get megapixel-sharpness images out of this thing, you're going to have to use bigger facets so that you can get milliradian-level resolution. So you can't get 2500 pixels per square millimeter in a useful way.

You can use curved facets if your image is made out of lines; the curvature is equivalent to a bunch of facets that are very narrow in one dimension, and so scatter the light more in that direction, along the line of light, at right angles to the long skinny facet.

A mixed model may provide the best information density: use

small facets toward the center of the beam to direct the overall brightness of a scene to the right places (with necessarily high divergence) and larger or curved facets, perhaps in the dimmer outer parts of the beam, to draw outlines with milliradian-resolution definition. Such a facet might be 10 microns by 1mm, diffracting the incident beam into a line about 100 milliradians by 1 milliradian, in some arbitrary orientation, placed in some arbitrary place on the screen. You have space for, say, 75 such lines in a square millimeter, with another 400 facets in the range of 24 microns across, each directing some brightness onto an area something like 30 milliradians in size. 1–4 square millimeters should be enough to encode a "frame" of video, and getting a spot of light down to 1–4 millimeters is easily feasible. It isn't necessary to get it *up* to 1–4 millimeters, because instead of using a diffuse spot, you can just scan the spot quickly over a long distance of the surface.

This means that a second of animation is something like 100 square millimeters, or a square centimeter, of reflective medium.

There's an additional degradation of resolution in the left-right direction caused by the beam striking the reflected medium being of nonzero size and the medium rotating through it, but I don't think that's important for two reasons. First, there's no fundamental obstacle stopping you from making that beam be however small you decide to make your individual facets; second, you can diminish that rotation arbitrarily by using arbitrarily large cylinders, or even using a flexible cylinder that you depress to be locally flat so that its movement under the beam is purely translational, or rotational around its focal point on the wall. If you don't take such measures, though, a 1mm-diameter beam illuminates about 1/50 radian on a 10cm-diameter cylinder, so you get a left-right smearing of about 1/25 radian from the rotation.

As a point of comparison, fancy professional laser shows often use galvanometer-driven mirrors capable of 25000 points per second, and what I've proposed above (475 "points" per square millimeter and 100 square millimeters per second) is about 47500 points per second; so this is clearly capable of producing visually arresting animations.

Solar illumination instead of using a laser

If we don't have a laser pointer, we can use a sunbeam through a hole the size of the desired beam. The divergence of the beam, and thus the resolution of the projected image, will be limited by the angular size of the sun in the sky, about half a degree. This resolution can be improved substantially, at the cost of brightness, by putting a pinhole between the hole and the sun, blotting out most of the sun's disk. If the pinhole is fairly near, that will introduce substantial nonplanarity in the light wavefront, which will change the effective focal length of concave facets.

A milliradian-sized pinhole to blot out most of the sun will blot out about 74/75 of it, reducing the illuminance available to light the image by about 20dB, down from, say, 100 kilolux down to, say, 1000 lux at the point where the beam hits the facets, so the illuminance on the screen will be something like 1 lux, if it's being spread out over a screen area around 1000 times the size of the illuminated area on the facets. This probably means that such an animation will require a dark room for viewing by sunlight at full resolution without

concentrating the sunlight using some kind of nonimaging optics.

(Of course, if you just illuminate it with direct sunlight, you'll get the image anyway, just blurred by convolution with the sun's disk.)

Non-cylindrical media

So far I've been talking about cylinders, but all of this continues to work just as well for animation if we're talking about a disc, too, or even just a flat sheet. Any illuminated circle on the surface corresponds to some image; as the circle shrinks, it will include images from fewer and fewer physically adjacent frames of video until it starts including only certain drawing elements of a single frame; and any path the circle takes over the surface will produce an animation. Purely translational motion also eliminates the rotational left-right intraframe smearing mentioned in an earlier section, which can easily reach tens of milliradians.

Low-resolution text

Suppose that, instead of shooting for milliradian-resolution line drawings, you just want to put an animation of readable text onto your surface. Maybe you only need to be able to display a word or two at a time, or even a letter. Does this help? Remember, before, we were looking at something like only 100 vectors per square millimeter, because of milliradian-level sharpness requirements at visible wavelengths.

How many vectors do you need per letter?
<img src="http://canonical.org/~kragen/bible-cropped.png" >

I designed a 6-pixel-tall proportional pixel font a while back, with the objective of conserving text with laser-printed microscopic letters on paper, which encoded my 4.45-megabyte test Bible in 4866x19254, or 21 black-and-white pixels per letter, which means that each letter averages 3.5 pixels wide, including the space needed between the letters to make the text readable. It's black on white, and it's about 29% black, so that's about 6.1 black pixels per letter. Based on that, let's figure that we probably need about 4 vectors per letter and a resolution of about 0.05 radians.

Well, this lets us use the originally-hoped-for 20-micron-wide facets, which do in fact give us about 0.05-radian resolution. For lines, again, we can use narrow facets that diffract light into a streak in the desired direction, so that they actually take up *less* space. For example, a lowercase "i" might require a full 20-micron-square facet for the dot, but only a 20-micron-wide by 6-micron-tall facet for the vertical line beneath it.

If we figure that the average facet is then half of that 20-micron-square configuration, then we can get about 5000 vectors per square millimeter, or 1250 letters. That is similar to my laser-printed microprint approach, which at 1200dpi only gets 2232 pixels per square millimeter, which works out to about 1100 letters; but it doesn't need a microscope to read it. (A laser-printed 1200dpi pixel is about 20 microns in size, so this comparability is not totally surprising.)

Now, though, we run into a different problem. An average word might need only about 20 vectors to display it, but it's going to be projected over 0.3 by 0.9 radians, which means that you only have room for about three or four words to be displayed at a time. But

that's 60–80 vectors, which fit into a 200-micron-square area. Maybe you can get a laser pointer down to 200 microns square, but getting a sunbeam that small is hard.

If, instead, we figure that we need something more like 0.015-radian resolution, and thus our facets need to be 60 microns across when they're full points, we can fit 30 or 40 words onto the screen at a time. But now we only have about 500 vectors per square millimeter, which is also about 40 words. 40 words per square millimeter is somewhat inferior to microfilm, but dramatically higher than traditional printing's 0.014 words per square millimeter.

It's probably best to organize the words such that they "scroll" around the screen like the words in an old ytalk session: rather than attempting to move old words, after filling up the last line, you wrap around to the top and put new words on the top line. If your spot of light is too small, you'll have less than a 30–40-word screenful of text visible, while if it's too large, you'll have new words overlapping old words, maybe several screensful. Ideally, as you scan your light beam over the text, new words fade in shortly after old words fade out. You can display some kind of position indicator in some fixed part of the screen; it can be quite a long streak, so it can use up very little space on the medium.

Solar sundials

You can use this technique to make a super awesome solar sundial which not only projects the time, to the minute, onto the wall, but also tells you what day of the year it is, although typically you'll have two choices for that.

Fabrication techniques

How would you go about fabricating such a demandingly-shaped reflector? If it's a one-off, I think you can probably use electrochemical machining, which is sort of the opposite of electroplating --- you make your workpiece the anode, pumping electrons out of it, which it then hungrily obtains from negative ions floating around in water, which then combine with metal atoms from the surface; you limit the current flow to a tiny part of its surface area by moving the cathode around very close to it; and you wash away the electrolyte rapidly enough to prevent the metal ions from the anode from being reduced onto the cathode. Due to anodic leveling, it produces a mirrorlike finish.

You probably want to use a sort of rake-shaped cathode to produce the desired surface complexity, dragging many wire points over the surface, each with its height controlled separately to within a fraction of a micron, say, 50 nanometers. They should probably be spaced something like 10 microns apart, 100 of them to a millimeter. Each one will tend to cut out a spherical shell into the metal around it, cutting a cylindrical trench through the metal as it moves. We want to keep the deviation from the desired shape of the metal down below, say, 100 nanometers, to avoid fucking up the light wavefront too much, and there's 5 microns from the center to the edge of the trench; acos(1 - (100nm/5 microns)) = 0.2 radians, so we want those wire points to be carving out 25-micron-radius spheres. That's going to make it a little tricky to control the angles of 10-micron-wide facets, but I think it's doable.

A 25-micron inter-electrode gap is smaller than is typical for electrochemical machining, but not outrageously so; 80 to 800 microns is typical. Some "pECM" processes use an inter-electrode gap of as little as 10 microns, along with vibrating electrodes and pulsed current.

We can do a little electropolishing afterwards to try to anodically smooth the surface, but we'd like to be removing very little material. Electropolishing is also going to round off the Fresnel-reflector knife edges and result in more stray light.

How much overall material do we need to remove?

Suppose our facets have angles varying over more or less a quarter of a radian in every direction from the overall surface, and that we can generally choose to alternate them to minimize discontinuities. In the above, the biggest facets were up to a millimeter in size. If we're cutting millimeter-sized facets at a quarter-radian from horizontal, we have to cut up to a quarter-millimeter deep! On average, we might be removing 100 microns of the surface of the material, 100 milliliters per square meter, or 0.01 milliliters per square centimeter.

If we're doing this in aluminum (which may not be the highest-quality choice, but millimeter-thick gold is expensive) that's 27 milligrams per square centimeter. Aluminum is conveniently 27 grams per mole, so that's a millimole per square centimeter. We have to pump off three electrons from each aluminum atom in order to turn it into aluminum chloride, so we need three millimoles of electrons per square centimeter. A coulomb is only 6.2e18 electrons, while a millimole is 6.0e20, so that's 97 coulombs per square centimeter, plus whatever gets wasted in electrolyzing the water; at 1 ampere, that's about a minute and a half per square centimeter, or 280 micrograms per second.

Some random paper about the material removal rate of electrochemical machining (Sudiarso, Latifah, Ramdhani, and Mahardika 2013) says that at 0.6 to 1.09 amps on aluminum 1100 with a 2-mm-diameter brass cathode, at 15 volts, they were able to remove 79 micrograms of aluminum per second. That's a factor of almost four less efficient than the calculation I pulled out of my ass above, which is far more accurate than that calculation had any damned right to be.

That also works out to be about (79 micrograms/sec) / (0.8 amps * 15 volts) = 6 or 7 micrograms of aluminum removed per joule. 27 milligrams per square centimeter is then 4 kJ/cm^2. This is a very small amount of energy.

How can you control the position of 100 metal points per millimeter to within 50 nanometers, with a total range of vertical motion of 250 microns (5000 times the resolution)? This seems very challenging indeed. The most promising approach would seem to be using a small number of points, such as 10 to 30, with a separate piezoelectric actuator for each one; a small hydraulic actuator might also work.

I conclude that it's probably feasible to do electrochemical machining of these surfaces, but it requires making some advances in electrochemical machining.

Electrical discharge machining (EDM) is reportedly somewhat more advanced than ECM and can typically produce even better surface finishes, but it doesn't seem like it is applicable to this process,

because it consumes its electrodes. Wire EDM is a common process, using a consumable wire electrode, but it runs the wire through the workpiece and then discards it; so it can't be used to make concave shapes. Perhaps it might be possible to perform a kind of wire EDM that consumes the end of the wire, completely, rather than merely spark-eroding the side of the wire somewhat.

It might make more sense to press or stamp the facets into the surface using a hard tool, one press per facet, particularly if you're using a soft metal like aluminum or gold. You need five degrees of freedom (two to control the reflection angle of the facet) with 10-micron positioning precision, and, in the Z-axis, enough force to stamp plastically 125 microns deep into the surface.

For reproduction, there are existing models of mass-production of reflective metallized surfaces with micron-level detail, specifically for diffraction gratings. Master gratings are cut into glass on a ruling engine at the Grating Lab in upstate New York, which has three ruling engines, one made by the hands of Michelson himself; and then casts are taken in plastic from the glass, and then other casts from the casts, and so on. Each grating can only withstand a few casting operations, perhaps five or ten, before being damaged enough to degrade its quality, but you can make several generations of them, which is sufficient to supply the world demand for lab-quality diffraction gratings. The final gratings are metallized, typically by vacuum deposition of aluminum.

Exactly the same process would work for these animations, although the particular resin and hardening process used for the gratings seems to be a secret.

Gold leaf trusses

Kragen Javier Sitaker, 2019-08-31 (11 minutes)

Everything we make has some minimum mechanical strength to keep it from breaking at undesirable moments, whether a spoon, a skyscraper, a scarf, a sedan, or a circuit; and this strength has several different components, including resistance to tension, compression, shear, flexion, and impact, which trade off against one another to some extent. Also, we make many things with more material than is needed for its mere mechanical strength, in order to make them more rigid. As described in Sandwich theory (p. 2450), scaling laws are such that many of our large structures fail by buckling, which is limited by rigidity rather then tensile strength, compressive strength, shear strength, or impact toughness; and we take advantage of this by producing structures like I-beams, structural tubing, and sandwich panels which have greater rigidity for the same mass.

But I got to thinking about the implications for very small structures, and I came to some astonishing conclusions about the possibilities of massively parallel automated fabrication, even without molecular nanotechnology.

Think about the aspect ratio of the legs of a daddy-long-legs.

Scaling down a highway sign

But consider scaling down a highway sign. It's cantilevered out over the highway on a steel truss to support its weight and occasional wind loadings. The truss is made of angle irons, L-shaped profiles extruded or bent from sheet steel. To make up some dimensions, let's suppose the angle irons are 6 mm thick, and each leg of the L is 30 mm long, and the truss is in the form of a square beam 500 mm across and 5 m long, any given cross-section of which has 8 angle irons running through it for a total of almost three thousand square millimeters of steel out of the 250,000 square millimeters of the cross-section. (This puts the weight of the truss itself in a bit over 100 kg.) Perhaps the truss can safely support a tonne of road sign and whatnot at this 5-meter lever arm, despite being almost 99% empty space.

Now, suppose we scale it down by a linear factor of 100. Now it is 50 mm long and 5 mm across, weighing a bit over 100 milligrams, and the road sign has shrunk from a tonne to a gram. The moment at the base of the truss has gone from 49 kN m to .00049 N m, a decrease of not six but eight orders of magnitude. But the steel cross-section in tension at the top of the truss has diminished by only four orders of magnitude. So, while previously it was near stressed to near its yield stress, now it is four orders of magnitude away from its yield stress. Suppose its Young's modulus is 200 GPa; its elongation might previously have been 0.07%, or about 3 mm, but now it is 0.000007%, or about 3 nanometers.

This means that we can thin out our angle irons quite a bit. We scaled them down from being 6 mm thick to being 60 microns thick, which is about six times as thick as common aluminum foil (see Single-point incremental forming of aluminum foil (p. 769)). If we managed to scale them down by four orders of magnitude, they

would be 6 nanometers thick, and would still be able to hold up the one-gram model highway sign, with the same relative deformation and safety factor under its scaled-down load as the original full-scale highway sign.

This change would change our model truss from being 99% empty space, or rather air space, to being 99.9999% empty space. Instead of 100 milligrams, it would weigh 10 micrograms, which it turns out is about 0.8% of the weight of the air in its air space. It's 99.2% air by mass now, lighter than the lightest silica aerogel.

However, removing 99.99% of its remaining solid material has also removed 99.99% of its tensile and compressive strength. While previously its tensile and compressive strength was proportionally 100 times greater than those of the full-scale highway sign, now they are 100 times less. So perhaps it will fail in some other way when trying to support the model highway sign; we might need as much as a full milligram of steel to provide the necessary tensile and compressive strength. But at this scale we are no longer obliged to provide massive amounts of unnecessary tensile and compressive strength merely to get adequate rigidity and flexural strength.

(The very light model highway sign would probably be unable to withstand much of a breeze.)

Now, we can't actually do this with steel; it isn't malleable enough to roll that thin, and in contact with air, I doubt 6-nanometer-thick steel foil would last long.

Gold leaf

However, we can do it with gold leaf, which is typically 0.2 microns thick (according to Compressed sensing microscope (p. 306)) and stable in Earth's atmosphere. Normally we think of gold as being an extremely expensive material to build things out of; it currently costs US$1480 per troy ounce. But if we only need a milligram of gold to build our model, that's only 5 cents at that price. We also think of it as being impractically soft and weak, but with the relative strength boost we get from scaling down in this way, we no longer need the brute strength of steel for most things.

Gold leaf is delicate enough that you need to use special hand tools and blowing of air to manipulate it without breaking it. More practical for many uses may be gold foil, which comes in thicknesses of 1 micron to 10 microns.

Carbon nanotubes

Carbon nanotubes are thinner than gold leaf as well as stronger, and they are also stable in air. They may provide a better material than gold leaf or gold foil.

Glass fiber, basalt fiber, and silica crystals

These materials are also stable in air and are stronger than gold as well as lighter; short enough spun fibers (or cut crystals) will not buckle under compression. You can build trusses out of them if you can make joints, but often at these scales the problem is not so much getting things to stick together as avoiding catastrophic accidental stiction and cold-welding.

Metamaterials: rigidity instead of strength?

More generally we can think of the existing nearly-isotropic bulk materials we routinely build things from — steel, cement, brass, glass, and so on — as meeting their rigidity requirements at a low space cost by virtue of spending a lot of mass on the problem. Historically we've been able to sometimes get lower mass (and lower cost!) by using wood instead, when we can afford a larger volume. Wood is a nanostructured metamaterial, but it, too, is somewhat optimized for low volume, perhaps so that trees can resist wind but I think largely so that they can resist predation. Balsa wood, pith-core trees and the remarkable moringa demonstrate the existence of other possibilities.

Suppose that by using trusses made of gold, glass fiber, or carbon nanotubes, we can produce metamaterials with much better stiffness-to-density ratios. Will this enable us to use only enough material to provide the tensile and compressive strength and impact resistance we need, in macroscopic structures? Maybe not, because the rigidity of a structure and the modulus of elasticity of a material (or metamaterial) are different things.

In Plastic cutters (p. 1074) I say ASTM A36 steel has a Young's modulus of 200 GPa, and like iron and steels in general, a density of 7.9 g/cc; that makes its stiffness-to-density ratio 25 kJ/g. Balsa wood has density ranging up to 0.38 g/cc and axial Young's modulus up to 9 GPa, giving a surprisingly lower, and similar, 24 kJ/g.

Why are these so similar? Maybe because balsa wood's axial elasticity, like steel's, comes from straining crystal lattices and atomic bonds, and the particular crystal lattices and atomic bonds involved aren't enormously different, perhaps by a factor of 2. Balsa wood spreads them out over a larger cross-sectional area, the rest of which is air, which contributes insignificant mass and stiffness; it thus decreases its density and its Young's modulus proportionally. The same is true of, for example, steel tubing, which is as light as balsa wood once its width is on the order of 100 times the thickness of its walls.

There are really three contexts where we have to brute-force thicken things up to get the rigidity we need instead of just spreading the mass over a larger area. One is where there's some mechanical constraint that makes the extra space unavailable: your truck has to fit under bridges, your boring bar has to fit into the hole being bored, your axle needs to fit through the bearing. A second is where we need something like *hardness*: the force that must be resisted is being applied at a point or over a small area, and so we need a concentration of material in that area to resist it. A third is where making the truss or honeycomb structure or whatever is difficult or expensive because of the limitations of our fabrication technology, and in general that's a question of things being very small.

(Balsa wood is still better than any artificial material so far, though.)

Flight

Very-low-density nanostructured materials made out of thin members have a long history in flight; dandelion seeds, feathers, and parachuting spiders are three examples. Aside from the possibility of lighter-than-air flight (a gold-leaf balloon made of two sheets sealed together at the edges should be able to fly if you can fill its middle

with at least 4 mm of hydrogen or helium) the possibility of ultralightweight metamaterials enabling insect-scale structures would seem to offer many fascinating options. Also, structures so delicate that they could easily be blown away might be best off if far from the ground.

Electrolytic anodizing, with a small movable electrode

Kragen Javier Sitaker, 2018-10-28 (2 minutes)

You can produce different brilliant colors on titanium, or on metal coated with a titanium sputtered coating, by producing different thicknesses of titanium dioxide surface layers. Because titanium dioxide has such a high refractive index — 2.5–2.6 — the reflection from the top of the coating is much stronger than from other similar metal oxide coatings, resulting in almost complete interference and thus strongly saturated iridescent colors.

The conventional way of making such oxide layers on titanium is by heating it in air, with the temperature of the surface largely determining the thickness of the oxide, but this carries the drawback that it can generally only produce very gradual variations of thickness across a surface, because if there are large temperature differences over small distances in the surface, they will quickly disappear. Perhaps with localized laser heating, this disadvantage could be removed.

But I have another idea in mind. Rather than heating the material to promote diffusion of oxygen through the oxide layer, let's anodize it. This involves applying a positive voltage to the titanium in an aqueous electrolyte, stealing electrons from the surface metal atoms and giving them to water molecules, liberating oxygen from them to combine with the metal.

Anodizing titanium to produce different colors is a known technique: https://thekidshouldseethis.com/post/anodizing-titanium-the-rainbow-metal, for example.

If this is done with a cathode very close to the surface of the anode, it should produce a very localized coating; and applying varying amounts of current to different spots on the anode should produce different coating thicknesses, and thus different colors.

This should enable the production of brilliantly colored patterns on titanium surfaces. I don't know if the full gamut of visible colors can be thus produced by dithering light from nearby dots, but I suspect so.

Oval cam lock

Kragen Javier Sitaker, 2019-11-26 (5 minutes)

Reading Victor Papanek and James Hennessey's inspiring 1974 *Nomadic Furniture 2* and looking at the interesting "Jim's Peg-Lock System" on p. 108, I got to thinking about camlocks as a substitute for screws.

Jim's Peg-Lock System inserts a short wooden dowel into a round hole through a square piece *intersecting* a wooden dowel of the same size run through another round hole in the same square piece at right angles to it --- slightly skew to it but without enough distance between their axes to prevent interference. This is reportedly explained in more detail in *Nomadic Furniture 1* pp. 126-7; from this volume, though, it's not clear whether you cut a bite out of the other dowel or just compress the heck out of the wood. If there's a bite out of the other dowel, it will be under no force, but cannot be withdrawn from its hole unless the peg is removed. If there's no bite, or a bite that's slightly too small, the wedging mechanical advantage is potentially enormous.

This got me to thinking about the celt, a type of stone axe, and oval dowels. If you stick an oval dowel in an oval hole made to fit it loosely, it can slide linearly but binds up if you start rotating. If you apply further force, you may be able to get it to rotate 90°, depending on how oval it is. (In the circular limit, the mechanical advantage is infinite, but the displacement is zero, so the force is limited by the sponginess of the wood.)

If the short axis of the oval hole runs across the grain of the wood, then the rotated oval dowel will be pressing against endgrain, like a well-made celt; in this configuration it will not fall out from moisture changes and will not tend to split the wood. At the 90° rotation angle, it is in an equilibrium; it does not have a tendency to twist back one way or the other. There are no stress risers because the wooden surfaces are smoothly curved. Some kind of wax, drying oil, or soap might be a good way to lubricate the initial assembly in a way that stabilizes it further without making disassembly impossible; glue would make the joint permanent.

If instead the oval hole's long axis is parallel to the wood grain and a slit cut is made to the end of the wood, through the oval hole, and some distance beyond, the rotation of the wooden dowel can force the holed wood to expand laterally, pressing on the inside of some other slot or hole, rather like a wedge tenon, but reversible. If the slot or hole is closer to the fulcrum than the hole is, this can provide a further mechanical advantage. An unoccupied round hole at the base of the slit can eliminate stress risers there and increase compliance for this use.

Alternatives to an unobtainium oval dowel might include two round dowels with equal flats cut on one side and face-glued, and an eccentric round dowel, like a crankshaft. The eccentric round dowel is easier if the two cylinders are of different sizes so that one is entirely contained in the hypothetical extension of the other. This crank configuration, if used to power a prismatic joint by sliding in a slot, provides a variable mechanical advantage that reaches a

zero-displacement singularity, like a Vise-Grip or similar toggle linkage. If movement is permitted a bit past this singularity and then stopped, for example by the end of the slot, it can support a *stable* equilibrium not dependent on friction and thus not vulnerable to vibration.

A similar stable equilibrium can be provided in the oval-hole mechanism by pooching out the sides of the oval hole a bit at the ends of the short axis, thus converting the unstable equilibrium into a stable equilibrium (with unstable equilibria near it on each side), and eliminating the need for linseed oil or whatever as a form of wood Loctite.

If, instead of sliding against the wall of a slot near the end of its travel, the eccentric dowel is rolling another disc or dowel along a track, it may be possible to make this mechanism work without any sliding friction, just rolling friction. If the two eccentric arcs are cut into opposite edges of a piece of material, it may be possible to make the entire wedging mechanism planar with sheet cutting.

Mechanisms like these are viable alternatives to screws in many situations.

Constant space lists

Kragen Javier Sitaker, 2018-12-10 (10 minutes)

We can manipulate arrays of (equal-sized) objects in constant time without the possibility of failure and without creating garbage. It would be desirable to also manipulate flexible, irregular data structures in constant time without the possibility of failure and without creating garbage. These three desiderata are nearly in increasing order or specificity — allocation implies the possibility of allocation failure, and if you are occasionally creating garbage, then eventually you will run out of memory if you don't allocate any more; and allocation almost always implies non-constant-time behavior, except in extreme cases such as stack allocation and allocation from a fixed pool.

The Lisp memory model and failure

The Lisp memory model, an arbitrary directed object graph with garbage collection, is very flexible; it lets us treat arbitrarily large and irregular objects as if they were register values, just by using their memory addresses to name them, as long as we don't mutate them. That's why most modern programming languages have adopted it: Python, Java, Lua, JS, and many others. (Others, like C++ and Golang, use a hybrid scheme in which some objects are embedded in other objects.)

The fundamental object graph construction operation is to create a new object from a tuple of (references to) existing objects; its simplest form is Lisp's `cons`. As long as you stick to this operation, reference counting is adequate, though slow, to manage memory; generational garbage collection without a write or read barrier is also adequate, and fast. However, note that this operation can fail. The price of using this memory model is that memory allocation is ubiquitous, so nearly any computation can fail or take an arbitrarily long time, so it is best used for programs where failure is an option.

Rather than constructing new objects, we could mutate existing objects. In this case, the fundamental operation is to overwrite a field with a reference to some existing object. Since this permits creating references from older objects to newer ones, generational GC becomes more complicated, and cyclic references make refcounting dangerous. The operation cannot fail, and it's constant time if you're not using refcounting, but it can create garbage, and you cannot tell whether it has created garbage or not without a global reference graph computation.

The Z-machine

The Zork Z-machine memory model was designed for flexibly simulating virtual worlds on tiny microcomputers where memory exhaustion was a constant danger, and one which really harshes the buzz of dungeon exploration if it comes to pass. It runs in constant space and constant time and does not create garbage, and although it is not as flexible as the Lisp memory model, it is more flexible than most of the alternatives.

All objects in the Z-machine are arranged into a single hierarchy by

way of three pointers per object: parent, first child, and next sibling. The fundamental hierarchy mutation operation is to change the parent of an object, which cannot fail. In Zork and similar games, this was used to express physical containment.

(I lied somewhat here when I said that it runs in constant time and does not create garbage; if you allow an object to become a descendant of itself, it can create garbage, because then it becoes disconnected from the rest of the hierarchy; and if you check to see if you are doing this, that check will not run in constant time, and it may fail.)

Sketchpad's ring structure

In Ivan Sutherland's Sketchpad, each type of object participated in one or more "rings", which were intrusive circular doubly-linked lists in memory. XXX add more info

Zzstructure

Ted Nelson's "ZigZag" program relates objects along an arbitrary number of "axes", which can be traversed in either direction; hierarchies are expressed with two axes, a "first-child" axis and a "next-sibling" axis, which traversed in reverse are "is-the-first-child-of" and "previous-sibling". To preserve his "ZigZag" trademark, Nelson recommends calling this kind of structure "Zzstructure". A straightforward implementation of it in memory just uses doubly-linked lists, like Sketchpad but without the circularity, or like the Z-machine generalized to many hierarchies, but without the constant-time traversal to the parent.

The fundamental operation of zzstructure is, as I understand it, to change the next or previous object of an object along an axis. If previously next-sibling(A) was B, then also previous-sibling(B) was A; if we set next-sibling(A) ← C, then next-sibling(A) will be C, and previous-sibling(C) will be A. What happens to previous-sibling(B)? I assume it must become nil, and similarly with next-sibling(D) where D was the former value of previous-sibling(C), if any.

So this operation need not allocate, and it cannot fail, but it can create garbage, because B and previous-sibling(C) may have become unreachable.

Pipeline and magtape processing

A popular alternative in some environments is to use "streams" or lazy lists rather than reifying the entire list in memory. So, for example, in Python you can compute a maximal nondecreasing subsequence of a sequence in "constant space" as follows:

```
def mnds(xs):
    xs = iter(xs)
    last = xs.next()
    yield last

    for x in xs:
        if x >= last:
            last = x
            yield last
```

One or another kind of iterator pattern like this is common to many languages — CLU had a special-purpose iterator construct, Smalltalk uses a general-purpose closure mechanism to implement it as a pattern, and Ruby bears the traces of having switched from the CLU approach to the Smalltalk approach, plus a little syntactic sugar. The C++ STL is famously based entirely on "iterators", but they use a totally different design which is not as amenable to streams. Python's approach is somewhat derived from Icon's, whch is derived from SNOBOL's, which is derived from backtracking for string processing. Prolog implementations can also generate a sequence of possibilities in constant space by backtracking.

This approach goes back to the earliest days of computing; not only did business data processing in COBOL typically work by reading one or a few records into the very limited memory of the time, but some early machines like Turing's Pilot ACE exposed the sequential nature of their delay-line memories. And in some sense, this is what's happening at the lowest levels of a CPU: the CPU registers are constant space, and they are used to lazily materialize sequences of values laboriously retrieved from main memory.

Constant-space lists

This may just be Sutherland's idea from Sketchpad, but what if our fundamental memory mutation operation is to move an object from one list to another?

Let's say a given type of object participates in a given set of intrusive lists, which we can treat as fields of the object. These lists are doubly-linked, so removing a linked object from one such list is easy, as is inserting an unlinked object before or after a linked object. Combining these two operations gives us an atomic move-between-lists operation.

This move-between-lists operation is constant-time and cannot fail. Can it create garbage? Yes, because the object you are moving may have been the only surviving external reference to the list you are removing it from.

(Heterogeneous lists presumably need some kind of run-time type identification information to get from the list header to the entire object, since different types of objects might have their list links at different field offsets.)

I give up on the microscopic view

I was hoping to find a set of one or more operations that would give me what I wanted: a way to manipulate flexible, irregular data structures in constant time without the possibility of failure and without creating garbage. Clearly you can write a program that does some kind of computation on flexible, irregular data structures in constant time without the possibility of failure and without creating garbage, and you can even prove these properties, but you I don't know how to do it by pushing those requirements down to the atomic level of the program.

However, although you need some kind of less-local proof to establish the safety of any of these approaches, the different sets of primitives have different sets of proof obligations. The Z-machine approach, for example, only requires that you prove that you aren't reparenting a node to be its own descendant; in many cases this is

easy, like when the node is a leaf node, or a node of a type that is statically known not to occur in the ancestors of the destination, or when the destination is closer to the root than the node being reparented. Similarly, the constant-space lists approach just requires you to prove that there's a reference somewhere else to the list you're removing the node from, or alternatively that it was the only node in the list.

By contrast, the immutable Lisp approach requires you to prove that there's enough space for the node you're allocating, perhaps because you preallocated it — also simple, but very different. It's very similar, though, to the kind of proof you need to do for constant-time code, where instead of proving an upper bound on the amount of allocation done by a function call, you prove an upper bound on the amount of time it can use.

Hot water bottles

Kragen Javier Sitaker, 2018-07-14 (4 minutes)

Sleeping with a hot-water bottle is an extremely efficient and relatively safe way to deliver heat to your bed — no heat is wasted on warming up the air, your mattress, or the walls. It just slowly leaks out through your blankets.

It's also relatively safe, in that it is very unlikely to cause a fire (unlike a malfunctioning electric blanket, space heater, or kerosene or wood stove). And it can effectively harness abundant low-grade solar heat, such as from flat-plate collectors.

A traditional approach is to fill a rubber hot-water bottle of 1ℓ or so with boiling water, which is somewhat dangerous; sooner or later the rubber will crack and the hot water will escape, and if this happens rapidly while the water is still near to boiling, it can seriously fuck you up. Also, the rubber hot-water bottle is somewhat expensive, so many houses only have zero or one of them, even in otherwise economically developed countries.

A cheaper alternative is to fill discarded PET bottles with hot water, well below PET's usual softening point of 90°. The PCO1810 and PCO1881 caps normally used on soft-drink bottles are easy to secure, resilient to pressure, abrasion, and impact, and very reliable, although for extended warm use, I trust the gasketless all-polypropylene caps more than the caps with a separate gasket inserted into the cap. The water need not be potable, although it's probably a safer situation if it is potable, in case someone drinks it by accident or in desperation.

The energy provided by a hot-water bottle is proportional to its mass and to its ΔT above your body temperature. Sooner or later, under the blankets, your skin will reach nearly 37°, so that's the reference point; a bottle at 38° has, in effect, half the energy of the same bottle at 39°.

Up to about 45° there is no real hazard from hot water under normal circumstances; if it does leak, it can burn you, but slowly enough that your instincts will probably protect you adequately. I think 50° is probably a good balance point between burn severity and energy capacity, even though PET can handle temperatures up to 80° with ease.

People generate about 100 watts each (2000 kcal/day = 97 W), so sleeping with a 100-watt hot-water bottle should warm you up about as much as sleeping with another person, which is pretty comfortable on nights ranging from cool to quite cold. More, perhaps, since it is hot enough for heat to flow from it into your body, rather than just stopping the heat loss from one side of your body.

So how much water would you need to be really luxuriously warm, say, 300W for 8 hours? That's 8640 kJ or 2063 kcal (which should be unsurprising, given the 1 person ≈ 100 W equation in the previous paragraph) which requires 159 kg of water at ΔT = 50° - 37° = 13 K.

This is a dismayingly large number, 53 3ℓ bottles. If you go up to 80°, you get down to 48ℓ, 16 3ℓ bottles, at the expense of potentially serious scalding if one of the bottles springs a leak. A 1ℓ bottle starting

at 100° only averages 13 watts over 8 hours, though it can provide over 100 watts for 1 hour if its insulation is thin enough.

I conclude that phase-change materials like Glauber's salt (is its freezing point high enough?) and active thermostats like the ones in waterbeds are a more practical ways to warm up your bed, and hot-water bottles are more a question of comfort than of actual temperature control.

Pipe dome

Kragen Javier Sitaker, 2017-07-19 (7 minutes)

The 20mm PVC pipe I tried to use for the Fuego Austral dome wasn't stiff enough to support much weight, let alone wind loading; it supported maybe 10kg above and beyond its own weight at the crossing of three pipes in the center of the six-pointed star dome. It was 1mm thick and cost AR$27 (US$1.80) for three meters. The largest pipes available in the category were 46.8 mm inside diameter, 50.8 mm outside diameter, and are thus 2mm thick: twice the wall thickness, 2.4 times the lever arm, and 2.4 times the perimeter, for a product of 11.5 times stiffer. I'm not absolutely sure, but I think it cost AR$95 for three meters, 3.5 times more cost (and thus 3.3 times more cost-effective at buying stiffness), and would have weighed 4.8 times as much per three meters. 11.5 times stiffer would imply it could carry about 110 kg of load at the center of the dome.

I paid some AR$700 for 26 three-meter lengths of the 20mm pipe. At AR$95 per three-meter length, this would be AR$2470 (US$164). Adding the AR$1450 cost of the 81 square meters of used advertising vinyl we bought to cover it, the total comes to some AR$4000 (US$263). This amount of vinyl is a bit of overkill: only 57 square meters should be necessary, costing only AR$1026. But then, the whole design is kind of overkill.

The longer lever arm means that the roughly 500mm radius of curvature I established in destructive testing in Parque Lezama would be about 1.2 m. This still seems like a pretty tight curve: a 2.4-meter-diameter circle is quite tight compared to the 6-meter diameter of the desired dome. Thicker pipe walls would help more with resilience; spreading the same material over more area would help more with stiffness.

If this amount of pipe encloses a 5-meter-diameter circle of effectively usable floor space, that's 19.6 square meters of floor space, at a cost of about US$13 per square meter.

How does this compare to the cost of a hexayurt?

A standard 18-panel H18 12-foot hexayurt is 8 feet (2.4 m) on each hexagonal side and 2.4 meters tall at the inside of the wall; I suppose that means it's 2.1 meters from the center to a wall, making its interior consist of six 2.1-meter-height, 2.4-meter-base triangles, for a total of 15.4 square meters of usable floor space.

http://www.appropedia.org/Category:Hexayurt_project says it costs "around [US]$300 per unit". It originally used 1" (25mm) Tuff-R foil-faced polyisocyanurate foam panels, according to http://www.appropedia.org/Hexayurt_playa#Which_Hexayurt.3F, but http://www.appropedia.org/Hexayurt_Safety_Information says that's a fire risk. Also apparently the necessary four rolls of tape cost like US$150, and FOAMULAR 150 panels of 1" thickness (without even the aluminum facer!) currently costs US$19 at Home Depot, for US$342 total cost for the foam and thus US$490 for the total hexayurt, US$31/m². This is about 2.4× the cost of the dome.

(Rmax Thermasheath-3 1-inch 4'×8' R-6 polyisocyanurate panels with aluminum facers cost US$19.25 each at the Emeryville Home Depot, so this is probably actually about the right cost.)

Another interesting comparison is the weight. The dome probably weighs about twice the weight of its vinyl coating, which is, say, 400g/m²; that's 22.8kg of vinyl in the dome, or about 46kg total, or 2.3kg/m² of usable floor. The Thermasheath-3 boards weigh 7 pounds each, according to http://www.homedepot.com/p/Thermasheath-Rmax-Thermasheath-3-1-in-x-4-ft-x-8-ft-R-6-Polyisocyanurate-Rigid-Foam-Insulation-Board-787264/100549260, which works out to 57kg, or about 3.7kg/m² of usable floor.

So, this dome is several times cheaper than a hexayurt and a bit lighter, but it might also be significantly less livable because it provides little to no insulation. A closer comparison might be a plywood hexayurt, which is US$132 for those same 15.4m².

A minimal-cost composite dome covering might consist of Tyvek, Mylar, and bubble wrap. I don't know if this can get near the cost of AR$18/m² (US$1.20/m²) that we're paying for used opaque billboard covering, but I suspect so.

http://articulo.mercadolibre.com.ar/MLA-611584214-cinta-de-aluminio-puro-de-30-micrones-ideal-para-aislacion-_JM offers 30-micron aluminum reflecting tape for AR$400 per roll of 45 m × 48 mm, a product of 2.16m².

http://articulo.mercadolibre.com.ar/MLA-612633055-membrana-burbuja-10mm-aluminizada-aislante-termico-_JM is 3.5mm-thick aluminized bubble-wrap membrane for insulating uses for AR$289, 1m × 15m, or AR$19/m². It says "10mm" in the description, but this is misleading; that's the diameter of the bubbles.

http://articulo.mercadolibre.com.ar/MLA-604333399-aislante-aislacion-termica-para-techos-rollo-x-25-m2-_JM is a roll of 25m² of bubble wrap (polyethylene, I suppose) without an aluminum facing for AR$121, or AR$4.84/m². No thickness is specified, but I suspect 3.5mm.

http://articulo.mercadolibre.com.ar/MLA-612656558-membrana-aislante-espuma-tipo-isolant-tba10-10mm-aluminizada-_JM is a 1m × 20mm roll of 10mm-thick aluminized flexible polyethylene foam for AR$530, or AR$26.50/m².

http://articulo.mercadolibre.com.ar/MLA-614120886-aislante-termico-burbujas-aluminizado-20-m2-_JM is 19.4m² of 3.5mm-thick aluminized bubble wrap for AR$320, or AR$16.50/m². This is probably the best bet so far.

Various space-blanket products on Mercado Libre are about 4m² for about AR$150, or about AR$40/m². It seems like aluminized Mylar ought to be available for less money, but I'm not seeing where.

One of the geodesic domes I saw at Fuego Austral was covered with silage plastic (for covering heaps of grains). This is perfectly opaque and airtight, and it's white to keep down solar heating of the grain pile. It seems likely to have a lower cost per square meter than

other reflective, opaque substances; http://articulo.mercadolibre.com.ar/MLA-614005553-bolsa-para-silo-agrinplex-9x60-f-forraje-segura-_JM is a bag of such plastic of 9 feet diameter and 60 meters of length, "Agrinplex" brand, for AR$7000. (Silobolsa and Siloplast are two other brands.) If we figure that 9 feet diameter means 28 meters of circumference, which is 8.6 meters, that's 517 m², or AR$13.50/m². If combined with bubble wrap, it might make an adequate dome covering. However, it's probably not as strong or stiff as Tyvek.

http://articulo.mercadolibre.com.ar/MLA-614441671-tyvek-rollo-130-x-12-m-_JM is a 1.3 m × 12 m roll of Tyvek for AR$479, or AR$30.70/m². This by itself is considerably more expensive than the billboard vinyl it replaces in this use.

http://articulo.mercadolibre.com.ar/MLA-614133525-wichi-roofing-igual-a-tyvek-membrana-hidrofuga-x-m2-_JM is a 1.16 m × 26 m roll of off-brand Tyvek clone ("Wichi" brand) for AR$484, or AR$16/m², about the same cost as the billboard vinyl.

http://articulo.mercadolibre.com.ar/MLA-606787652-tyvek-aislacion-hidrofuga-techo-superior-a-ruberoid-_JM is a 1 m × 30 m roll of Tyvek for AR$1050, or AR$35/m². It gives the weight of the roll as 2.8kg, or 93 g/m². This is something like 20% of the weight of the billboard vinyl (the vendors say 30%, but my tired back says otherwise, although maybe the vinyl was wet or something.) The publication clarifies that it's 100% HDPE and weighs 80.6 g/m² (maybe the other 12g/m² is the cardboard it's wound around) and is 220μm thick.

UHMWPE clothes could be lightweight and sturdy

Kragen Javier Sitaker, 2018-06-05 (3 minutes)

UHMWPE seems like it might be an interesting material for clothes, and indeed, there is a startup ("SheerlyGenius"? I forget) making sheer UHMWPE pantyhose — the idea is that they will be considerably sturdier than nylon pantyhose, which is somewhat surprising to me.

UHMWPE fiber has 2.4 GPa of tensile strength, apparently. You could imagine a cloth sort of like rip-stop nylon made from it, with somewhat thicker fibers every millimeter and very thick fibers every centimeter. Say, 3× and 10× thicker than the regular fibers.

I don't have a super great reference handy for the tensile strength of cellulose, but Heckballs: a laser-cuttable MDF set of building blocks (p. 2782) says MDF's UTS is 18 MPa, which is probably low but in the ballpark. ASTM A36 steel has a yield stress of 290 MPa, HIPS has 32 MPa UTS, and annealed aluminum's yield stress is around 15–20 MPa.

So let's say cotton's tensile strength is 40 MPa. I have some sturdy cotton serge shorts here whose cloth is about 700 μm thick. Achieving similar strength with UHMWPE would require 40/2400 of the average thickness, or 12 μm; you could have 160 or so 6-micron-thick threads per millimeter, with an 18-micron thread each millimeter, and then a 60-micron thread each centimeter. This gives us an average thickness of roughly (60·60 + 18·10·18 + (10000-(60+18·10))·12)/10000 = 12.396 microns. Actually the extra 0.396 microns from the thicker and very thick threads should probably be doubled, making it 12.8 microns.

However, each 60-micron thread would break under a force of some 7 newtons, the weight of 700 grams. If you really want rip-stop strength, you likely need another approach. Something like knitting, for example, so that the force at the tip of a rip is distributed over more cloth, but ideally with knots frequently enough to prevent runs from spreading. Alternatively, you could scale the 60-micron threads up to, say, 300 microns — still half the thickness of the cotton, but now with a breaking force of 170 newtons, which would make the cloth unlikely to tear by accident.

Let's suppose that we knit some shorts from 20-micron-thick UHMWPE threads, then, and that the knitted cloth is about 60 microns in thickness and about 60 microns per row of knits or purls. This might require 1100 mm × 550 mm of cloth, totaling 36 cubic centimeters and about 25 grams. The 550 mm of length is a bit over 9000 rows of knitting. The tensile strength of a leg of the shorts as a whole would be something like 2.4 GPa · 20 microns · 550 mm · 0.5, which works out to 13 kN, a bit over a tonne. You could still cut the cloth with scissors, but ripping it might not be feasible.

To make this garment opaque, you'd probably need to mix in a substantial amount of some very opaque pigment, such as finely divided titanium dioxide, carbon black, or gold. If this is within the body of the fibers, which is advisable for durability, it will weaken

them, requiring a compensating increase in thickness.

Individual Dyneema fibers are supposedly 12–20 μm in diameter, as currently manufactured.

Quadratic opacity holograms

Kragen Javier Sitaker, 2015-09-03 (7 minutes)

I think I know how to print 140 to 200 pages of comfortably naked-eye- readable text and full-color images on a transparency foil using a regular 1200dpi laser printer with reasonable resolution and only a factor of 10 or 20 loss of contrast; you will see different pages of text from different angles.

In 2001 I came up with this idea of opacity holograms, which is a multi-image nonsecure version of Naor and Shamir's visual cryptography, and in 2007 I figured out how to extend Naor and Shamir's idea directly to grayscale. I've been thinking about using opacity holograms for low-cost text archival in order to take advantage of the high storage capacity of laser-printed paper without needing a microscope to read it; but a major problem has been that the technique I'd come up with, like lenticular 3-D, reduces image brightness/contrast/resolution by a factor of N to encode N images; while real holography, using interference patterns you can't plausibly print on a regular laser printer, only reduces these by a factor proportional to √N. So real holography has, so far, been vastly superior for encoding large numbers of images in a single image.

I finally think I have a √N technique, but I haven't tried it yet.

You have N low-resolution truecolor input images to encode, plus a bilevel "key" image at the resolution of your actual output device, which could be random but need not be; the crucial features of the "key" image is that its autocorrelation is very small at all small spatial shifts other than 0, and that its correlation to any input image at some small spatial shift is also very small. As the key is bilevel, each of its pixels is either black or white, which we will consider as -1 and 1. Its autocorrelation at small shifts being very small requires that it be almost exactly half black. When laser-printed on a transparency film, the black pixels of the key will obscure corresponding pixels of the output image, while the white pixels will remain transparent.

Each of the N input images is encoded with the key at a different spatial shift, one at which it is effectively uncorrelated with the key. Each encoded pixel is equal to the corresponding input pixel if the corresponding key pixel is white, or color-inverted from the corresponding input pixel otherwise: black for white, white for black, red for cyan, 50% gray for 50% gray, and so on. That is, we multiply the spatially shifted key by the input, considering medium gray as 0, black as -1, and white as 1. Since the "key" image contains very little large-scale variation in black-pixel density, each of the encoded images will appear entirely as a flat medium gray from a distance, or random noise, close up; but if either multiplied by or obscured by the key image, a close approximation of the input image is visible.

What's the distribution of that random noise? It's guaranteed to have a mean of medium gray, but beyond that, it could be anything from constant medium gray to a bimodal distribution where all the pixels are either white or black.

Then, we sum all of these encoded images (without saturating!) to produce a combined encoded image. From the perspective of any

individual encoded image, this amounts to adding Gaussian noise whose variance is proportional to the number of other input images (multiplied, I guess, by how far they tend to get from medium gray). So we can expect that the noise from adding 100 images will be only about 6× worse than the noise from adding 3.

Converting this into something you can actually see on the screen or print is a little tricky. The combined encoded image will probably have a nearly Gaussian distribution of color, which means it's barely using most of its dynamic range. To display on the screen, it's probably okay to lop off the tails of the distribution at a point that most (say, 99%) of the pixels are accounted for; but then dithering is a problem, because regular dithering will shift errors to neighboring pixels on the theory that your eye will kind of blur them together. But that doesn't work if your eye can't see the neighboring pixels because they're obscured by the key image. Fixed dithering would work, and so would random dithering, but you've already effectively done a bunch of random dithering by adding other effectively random images. So nearest-neighbor "dithering", which amounts to mere thresholding at the median in the case of a bilevel device like a B&W laser printer, is probably just fine.

You could print the key on one side of transparency film (preferably archival polyester, not acetate, which is prone to vinegar syndrome) and the combined encoded image on the other. The pixel shifts you can get with the parallax between the different sides of normal transparency film add up to somewhere around a hundredth of an inch total, so you should be able to get up to about, say, 12 to 14 by 12 to 14 (144 to 196) separate spatial shifts for the key; so you can encode that many different documents on a sheet.

The noise will reduce the contrast. If you have 144 documents adding together, the noise will be about 10 or 20 times larger than the "signal" of the input image you're trying to decode. This means that input features that are smaller than about 30 to 200 pixels will be swamped by the noise. 100 pixels (10 pixels square) at 1200dpi is a 120th of an inch square, which compares favorably to normal computer monitors and old dot-matrix printers, although it's lower-quality than we're used to seeing on laser printers. At that resolution, my 6-pixel-high font could still fit 20 lines of text per inch (a point size of 3.6 points), which is too small for normal people to read comfortably. Six lines of text per inch was traditional for computer printers.

You could also use this technique to share a single computer monitor between different people, or between the two eyes of a single stereoscopic user, or even to provide an easy hands-free way to shift between virtual desktops: mount the key image on transparency film some hundreds of microns in front of the monitor, and merge the video images for the different angles by using different shifts of the key.

José, the Galician mover

Kragen Javier Sitaker, 2015-11-09 (2 minutes)

On my way home today (2015-11-09) in T-shirt and jogging shorts, I met an retired Galician furniture mover named José, digging a ditch in the sidewalk with a battered shovel under an overcast sky. Sweat dripped off his face, and he showed me his knee-replacement scar, and I felt his rock-hard Popeye forearm. There on the sidewalk, we talked about what motivates people to honesty and about the difficulties he had had with police demanding bribes when he was in business and the difficulties with employees. I told stories about Diogenes of Sinope.

He told me of a time, 40 years ago, when he was moving furniture for the former propaganda chief of the SS, who had retired to Argentina after the war. The man told him that propaganda could persuade brothers to kill one another.

He also told me of a time when he was 17, working as a mover for his father. After finishing up the job, he presented the bill to the customer, a friend of his father's. The customer said he would pay his father. He went home and told his father, and his father asked, "Why didn't you collect then?"

"I figured he'd pay you. He's your friend!"

"I don't have any friends!" laughed his father.

And, sure enough, the man never paid.

As I said goodbye to José, the lightning began, and then the hailstorm. I shivered in my soaked T-shirt in the freezing rain.

A unicast phased-array ultrasonic "radio"

Kragen Javier Sitaker, 2013-05-17 (4 minutes)

Suppose you set up a high-Q acoustic resonator strongly coupled to the air at, say, 102kHz, with its output connected to some kind of acoustic rectifier. If your Q was 20, you could tune in to about a 5100-Hz-wide band. This would be enough to receive and demodulate an ultrasonic AM signal with "telephone quality", i.e. low-pass filtered to about 4kHz.

It's feasible to focus a 102kHz ultrasonic signal in air to a spot about 0.3 centimeter across, or to transmit a low-loss collimated ultrasonic beam of such a frequency that's only a few centimeters across. This could allow substantial-distance ultrasonic AM communication through air despite the way that air attenuates high frequencies (about 1.5 dB/ft at 100kHz, and increasing linearly with frequency from 0.5 dB/ft at 50kHz up to 5 dB/ft at 250kHz). For example, if you started with a ten-square-meter dish or phased-array transmitter transmitting at 120dBa (1 W/m², 10 W total) and focused it on a square-centimeter receiver, you'd get an antenna gain of 50dB. If 40dB was an acceptable listening volume, and your "rectifier" was able to recover -10dB of the original signal, you'd need 50dB at the receiver, which means you could afford 120dB of attenuation along the signal path: 80 feet.

At this distance, your Airy disk radius angle ($1.2\lambda/d$) is about 1.2 * 0.003 m / √10 m = 0.001, which at 80 feet gives you an actual radius of 3cm, or 6cm diameter. So you're diffraction-limited by your transmitting antenna rather than scale-limited by the wavelength of the signal. This limits your actual antenna gain to 40dB instead of the 50dB in the previous paragraph, so you'd only be able to actually transmit about 75 feet.

If you could get by with a narrower-band signal, you could use a lower frequency. At 51kHz, where you could transmit three times as far with the same path attenuation (at the cost of less antenna gain, since your Airy disk diameter doubles with the longer waves and triples with the greater distance to 18cm, making it 36 times greater in area, bringing the maximum antenna gain down to about 25dB), your Q=20 receiver could handle a 2.6kHz band. If you were only transmitting speech, you could probably get by with that with a simple hack: frequencies over 2kHz in speech are almost always part of a burst of white noise, such as a sibilant. If you hook up a high-pass filter to the decoded signal and run its output to something nonlinear, you should be able to generate strong harmonics up to a few kHz, which would imperfectly approximate the high-frequency component of the original signal. (I think this is the reason that audio clipping in walkie-talkies improves comprehensibility.)

Being able to transmit comprehensible speech, to a passive receiver with no moving or electronic parts, anywhere in a 225-foot radius (comparable to Wi-Fi) sounds pretty cool, even if not a real improvement over just hollering. The receiver needing to be 36cm across would seem to somewhat blunt that, though, although you

could get a proportionally smaller receiver by making a proportionally larger transmitter.

With this level of spatial demultiplexing, however, you might not need frequency division multiplexing at all. Even at 26kHz, which ought to give you a greater transmission distance (450 feet?), your 10m² transmitter can focus down to a 1.5-meter-diameter spot. A larger transmitter could both transmit more energy and focus it on a smaller spot.

What if instead of transmitting the signal through free air, you transmitted it down a string, like a higher-tech version of paper cups connected with string?

Text editor design for e-ink displays

Kragen Javier Sitaker, 2018-10-28 (23 minutes)

(Previously published at http://canonical.org/~kragen/eink-design.)

NinjaTrappeur built the Ultimate Writer, a cypress TV typewriter for undistracted writing, and reports that writing in it is tolerable despite the e-ink display's 3-second update delay, but editing is intolerable.

If you want to design a text editor for low-power e-ink displays, you probably want to minimize the number of pixels you update per character (and especially minimize full-screen refreshes) and also avoid unexpected full-screen refreshes. That's because full screen updates take longer than partial screen updates and because they use a lot more energy.

This means that running vi or even ed on a standard terminal emulator is not going to work very well. Scrolling the whole screen up every time you want to display a new line at the bottom involves a waste of time and energy.

Variations of scrolling

You can get a substantial improvement over scrolling, without changing the underlying typewriter model of ed/ex, in at least a couple of ways: the ntalk/Tek4014 approach and the Emacs approach.

In ntalk, when your typing reached the bottom of your text window, you would wrap back around to the top, which would erase a couple of lines there. Erasing then proceeded one line at a time, always leaving a blank line below the text you were currently typing and above the oldest surviving text. No text ever moved; it remained until it was erased. This was a good match for the capabilities of "intelligent" terminals like the ADM3A which could put text anywhere on the screen but had no way of moving it once it was there.

The Tektronix 4014 did something similar, except that it had two columns (the screen was wide enough that typical lines of text fit into a single column) and couldn't do partial display erases — its "direct-view bistable storage tube" could only be erased all at once, although it permitted incremental drawing. So if you wrapped around to the first column again, you usually needed to request a screen erase in order to see more text.

In Emacs, when you reach the bottom of a window and try to go further down, it scrolls — but not by a single line. Instead, it scrolls by a whole half screenful. This is more expensive than the ntalk approach, and it does involve a full screen refresh (slow on either e-ink or the serial lines common when GNU Emacs was being designed), but it's a reasonable balance of efficiency and hysteresis:

• If you're typing lines one after another in this system, each line gets displayed twice: once when you initially type it, and a second time

when it scrolls up by half a screenful. After a second scrolling event, it's no longer visible. This thus implies a multiplier of 2× over the minimal possible expense of displaying and erasing the line once, as in the ntalk approach. This compares to 30× for the standard line-by-line approach, if the display is 30 lines high.
• If you're moving down, and then you decide to move back up, this does not require scrolling, unless you move up by an entire half-window-height. The maximum possible distance over which you could avoid scrolling would be a whole window height, which is what the usual scrolling algorithm provides.

So, the Emacs approach provides half the hysteresis of the best possible hysteresis, and half the efficiency of the best possible efficiency.

However, the problem with editing doesn't end with an efficient simulation of a teletype.

Editing and repainting

Screen editors like vim and Emacs display a window onto the document you're editing on your display and keep it constantly updated; the slogan at the time was "WYSIWYG", "what you see is what you get". (Later that slogan was repurposed to distinguish editors that did on-screen justification and multiple fonts, rather than displaying raw markup.) For changes that amount to adding or removing text at the beginning or end of the document, or overwriting text in the middle, the only required repainting of existing text consists of scrolling, which can be minimized as described above. But most changes in screen editors consist of inserting or deleting text in the middle of a document. In the WYSIWYG paradigm, this requires repainting a lot of existing text either after every new line or even after every keystroke, which is a major cost on these displays.

The pre-WYSIWYG editor paradigm was the "line editor" paradigm, exemplified by ed, ex, or EDLIN. Line editors are designed for teletypes: you type lines of commands at them, and they "print" lines of results back at you, always adding lines at the bottom. You could clearly use this approach with one of the "variations of scrolling" mentioned above.

However, it won't be very efficient, because sooner or later you'll want to see if you modified the text the way you intended. And the only way the line-editor paradigm has to show it to you is for you to "print out" some lines, including both modified and unmodified text. So you may end up redisplaying the same unmodified text several times within the same screenful of typeout, which is an inefficient use of e-ink, and furthermore of screen real estate, unless the edit history was really what you wanted to focus on, as opposed to the end result.

Here's a short example ex session, although it's using the somewhat ersatz implementation of ex included in vim. Note the abundance of redundant text repaints:

```
$ ex eink-design

Blanks and strikethrough

vi, as opposed to vim, was largely written on an ADM-3A, which didn't have any capability of moving around text that was already on the display; the best you could do was to redraw it in a new place. Perhaps as a result, in vi, when you use the "c" change command, which deletes a specified span of text and puts you in insert mode to type new text to replace it with, vi doesn't delete the text on the display, shifting the following text to the left. Instead, it marks the end of the deleted text with a $, and no text moves unless you insert more text than was deleted. It doesn't even remove the deleted text from the screen until you leave insert mode. This reduces repaint traffic considerably on terminals like the ADM-3A.

On an e-ink display, something like vi's approach here might be useful, but we could carry it further. For example, if you start inserting into the middle of a line, we could open up a big blank for you to type in, maybe half the length of the line. It might look like this, using | for the cursor (which wouldn't really take up space) and displaying successive screen states on successive lines:

```
On an e-ink display, something like| might be

On an e-ink display, something like |_____________________________________ mighoot be

On an e-ink display, something like vi's ap|_____________________________ mighoot be

On an e-ink display, something like vi's approach h|_____________________ mighoot be

On an e-ink display, something like vi's approach here|__________________ mighoot be

On an e-ink display, something like vi's approach here__________________ mi|goht be
```

This way, there's a single erase and repaint of "might be" at the beginning of the process, and perhaps another one later if you type enough into the blank, followed by a final one when the system decides you're done editing there, perhaps because you moved to a different line, or started inserting text somewhere else:

```
On an e-ink display, something like vi's approach here might be
```

For deletion rather than insertion, you could use strikethrough analogously to avoid moving other text around, as Microsoft Word does in Track Changes mode. If the text previously read "something like this might be", and the user deleted "this", it might display at that

point as follows:

```
On an e-ink display, something like ~~this~~| might be
```

The horizontal insertion space may not be adequate once text has to move vertically as well as horizontally to accommodate your edit. In that case, you might want to do something analogous vertically: open up half a screenful of blank space in order to insert new text into, expanding it a half-screenful at a time. You'd probably want to mark it somehow to indicate that it "wasn't real".

This scheme is fairly close to the buffer-gap scheme Emacs uses internally to represent its text buffers. In order to avoid having to move text around in RAM after every character inserted, it maintains a gap after the last character inserted; whenever a character is inserted somewhere else, it moves the gap by copying text as necessary from one end of it to the other. It normally maintains only a single gap, and it can be arbitrarily large, since it doesn't need to worry about keeping the two ends of the gap close enough together that you can see them at the same time.

Double-spaced text

A disadvantage of all of the above approaches is that *any* text insertion in the middle will involve *some* repainting of text in order to open up a space for it. The traditional typewriter-era approach to this problem was to type the manuscript originally "double-spaced", with a blank line in between each pair of lines of text, in order to allow sufficient space for markup to include text to be added. With this approach, the above-explained edit would start looking like the following:

```
text from the screen until you leave insert mode.  This reduces

repaint traffic considerably on terminals like the ADM-3A.

On an e-ink display, something like might be

useful, but we could carry it further.  For example, if you start
```

And the insertion might leave it looking like the following, with a caret positioned below the insertion point and the inserted text above:

```
text from the screen until you leave insert mode.  This reduces

repaint traffic considerably on terminals like the ADM-3A.

                                    vi's approach here
On an e-ink display, something like might be
                                   ^

useful, but we could carry it further.  For example, if you start
```

This approach avoids any need to redisplay existing text to accommodate small insertions.

Another approach along the same lines would be to pop up a speech balloon or something over the existing text to contain the edit,

although this obscures some of the existing text. For example:

```
text from the screen until you leave insert mode.  This reduces
repaint traffic considerably on terminals like the ADM-3A._____
                                    |vi's approach here|_______|
On an e-ink display, something like|/ight be
useful, but we could carry it further.  For example, if you start
```

For grayscale displays, it might help to make the popup balloon translucent, display the text within in a larger size, and filter the text to soften its edges, all with the intent of leaving the obscured text readable.

Cursor display and movement

A separate problem is that the long display latency makes it hard to tell what your cursor is pointing at when you're moving it around in text. This is a problem I have a lot of experience with in vi, which I used to use routinely over modem connections with tens of seconds of latency, and I still use routinely over Tor connections with seconds of latency. vi was originally developed under conditions that often included seconds of latency due to not only modem bandwidth but also host machine load, and its command set copes well with this situation.

The basic problem is that, under these conditions, you can't position the cursor effectively using arrow keys (or vi's hjkl), and you can't delete text with the backspace key, especially if you're using key repeat ("Typematic", to use IBM's trademark), because those depend on closed-loop control. The long and unpredictable latency in the feedback control loop between your fingers and your eyes means that you face a painful tradeoff between long settling times and overshoot: if the cursor hasn't reached the desired point and you press the arrow key one more time, you may have caused it to move past the desired point if you didn't wait long enough.

The solution is to use movement commands that are *convergent* and at a sufficiently *high level* to not depend on tight closed-loop control. "Convergent" means that commands cause similar editor states to converge to a single editor state, so initial divergences between the editor state and the user's belief about it, due to the latency, will not compound over time. So, for example, the `{` command moves back by a paragraph. If you believe you're on the third line of the paragraph, but you're actually on the line below the paragraph, it will still take you to the same point before the beginning of the paragraph, eliminating your error. The Vim command `ci(` similarly replaces the entire contents of the `()` parentheses you are within with whatever you type next; it doesn't matter if those parentheses contained 20 or 25 characters, or whether you were on the first or tenth character of the parenthesized expression, the same text gets replaced either way. At a more trivial level, the

These commands, unfortunately, impose a substantial cognitive load and a great deal of practice to use effectively. Jef Raskin's design of "LEAP", a single quasimodal movement command, enjoys the advantages of being strongly convergent and fairly high level, but with a much lower cognitive load.

Briefly, LEAP is similar to the incremental-search found in Emacs and Vim;

Raskin's Canon Cat keyboard has two LEAP keys to be pressed with the thumbs, one on the left for searching backwards and one on the right for searching forwards, which initiate the search when the user begins pressing them and terminate it when the user releases them. In either case, the user is left at the beginning of the matched text, rather than the end, so there is no penalty for typing more characters than needed, and no special provision is needed for special characters such as newlines.

Raskin claimed that in user tests LEAP was substantially faster than using a mouse to navigate text. I haven't done the rigorous tests he claims to, but from my experience, this claim seems plausible to me.

The Cat had no ↑↓ keys, just ←→ "creep" keys and the LEAP keys, the idea being that if the user was moving far enough to need ↑↓, they'd be faster if they didn't have the cognitive load of making a decision between arrow keys and LEAP.

E-ink latency is long, but it's shorter than the kinds of latency vi can cope with. I think LEAP might be a good way to position a cursor quickly on an e-ink display without needing to see the cursor in order to know precisely where it was.

Deletion is more problematic, since LEAPing from one end to the other of the text to delete is usually going to be far too much overhead.

I routinely use ^W in terminals and vim, and Alt-⇐ or Ctrl-⇐ in Emacs, to delete the entire previous word; this is generally much more efficient than deleting just the incorrect letters and retyping them, and often more efficient than going back a word or two to insert a corrected word. It's often easier just to retype the last few words.

Explicit screen refreshes

When I first used AutoCAD (2.14K+ADE), it was on an IBM PC-XT. The XT was capable of executing about 250,000 16-bit instructions per second, with a 320×200 CGA graphics display and an 80×25 MDA text display side by side. Redrawing the entire contents of the CGA monitor from the in-memory CAD drawing typically required a second or two. Therefore, it was undesirable to perform a redraw after every mouse movement, or even after every new line or arc added to or removed from the drawing. Consequently, AutoCAD on this platform would update the display with an approximation of the change; rubberband lines and arcs for the mouse were drawn with XOR so they could be quickly erased, newly drawn lines would overwrite whatever other lines were on the display (even if they were in a layer below them), and deletion of lines and arcs was reflected by drawing them in the background color, leaving visible holes at any intersection. These operations could be done many times per second, permitting a real-time interactive feel.

(A more difficult problem was choosing points on the screen with the mouse, since the display resolution was insufficient to make anything other than very crude drawings by eye. Typically I would specify INT or TAN or whatever on the keyboard, and then point with the mouse to indicate the intersection of which things, or tangent to which arc; or I would directly enter relative coordinates in polar or rectangular form.)

When the damage to the drawing on the screen made it sufficiently difficult to see what was going on, you would issue the REDRAW command from the keyboard, which has the merit of being possible to type without removing your right hand from the mouse. There were

other operations that also required a redraw, notably zooming and panning the drawing.

(This kind of pragmatic and very clever compromise was what made it possible for Autodesk to sell a usable CAD system in the early 1980s on hardware costing a tenth of what existing CAD systems cost.)

Since a screen refresh on the Ultimate Writer takes some 3000 milliseconds, it's in the same ballpark as this PC-XT with AutoCAD, so it might be worth using a similar approach to screen updating: do a full-screen refresh only when the user requests it explicitly, or when you're displaying most of a screenful of new information.

Several of the choices suggested above include a non-WYSIWYG display of edits: line-mode editing, strikethrough, speech balloons, double-spaced interlineal markup, large insertion blanks, and so on. The idea is that these reduce the visual feedback latency from the 3000 milliseconds NinjaTrappeur is suffering now to a mere 600 or so , so that you can reasonably do edits. But it should be easy for the user to request a WYSIWYG redisplay whenever they want to see the final result of the edit and are willing to wait the requisite seconds.

Golang bugs

Kragen Javier Sitaker, 2018-09-13 (updated 2018-10-28) (6 minutes)

I thought I'd try to keep track of the bugs I have in my Golang programs, including compile errors. These aren't bugs in Go, but bugs I wrote in Go.

• Wrote = instead of := (7×)
• Wrote types before variables instead of vice versa (5×)
• Forgot to `import "io"` (3×)
• Forgot to discard the index when iterating over a slice `range` (2×)
• Incorrectly thought `regexp.Compile` returned a `Regexp` rather than a `*Regexp` (2×)
• Accidentally referred to the variable `name` as `string` because it was declared as `name string`, and the variable `data` as `byte` because it was declared as `data []byte` (2×)
• Tried to quote a string with apostrophes (2×)
• Left off a `return` at the end of a function that had already assigned its return values (2×)
• Tried to pass a string instead of a []byte to net.Conn.Write (2×)
• Used `%#v` instead of `%+v` even though I didn't want hexadecimal printing of my struct fields (2×)
• Forgot to `import "log"`
• Forgot to `import "strconv"`
• Forgot to `import "fmt"`
• Imported "os" unnecessarily
• Imported "bytes" unnecessarily
• Imported "io" unnecessarily
• incorrectly assumed `print()` output goes to stdout, not stderr
• Forgot to include quoted spaces around variable values in `print` argument lists
• Tried to pass a `[]byte` to `print`, which rendered as hex garbage
• Tried to call `ioutil.ReadFile` with a file instead of a filename
• Expected `ioutil.ReadFile` to return a string instead of a []byte
• Tried to use `ioutil.ReadFile` on a 1GB file on a machine with only 4GiB of RAM
• Left out a `range` in a `for`
• Called `Regexp.FindAll` with no count argument
• Confused `Regexp.FindAll` with `Regexp.FindAllIndex`
• Left "\n" off a `print` call
• Forgot to cast `int` to `int64` explicitly
• Referred to `File.Name` instead of `File.Name()` in a `print`, printing out a hex string
• Failed to capitalize `os.Args`
• Forgot to handle errors on `suffixarray.Index.Write`, which the compiler doesn't catch
• Failed to capitalize `File.Read`
• Didn't remember the server needs to start out an RFB conversation by sending the version banner
• Did `copy(result[8:10], ...)` and then `result[11] =..` not noticing the skipped item 10
• Tried to use a `bytes.Buffer` instead of a `*bytes.Buffer` as an `io.Writer`

• Tried to call my `putTo` method, which returns an error, as if it were `Write`, returning two things
• Tried to ignore only one return value from `bytes.Buffer.Write` instead of two
• Tried to call `panic()` with multiple arguments as if it were `print()` or `log.Fatal()`
• Forgot to cast len(name) to uint32 in a field initializer
• Left off a trailing comma in a struct initializer
• Wrote nonexistent variable names `width` and `height` rather than the constants I intended
• Called `log.Fatal` instead of `log.Fatalf`, which produced a particularly confusing error because the last argument happened to contain a "\r", overwriting most of the error message on the screen
• Didn't check the error return from `binary.Write`, since I was writing to a `bytes.Buffer`, but it was actually trying to tell me, "binary.Write: invalid type *main.NServerInit".
• Tried to use `binary.Write` on a struct whose fields weren't exported (no, that isn't a bug, never mind; the bugs were those below)
• Tried to use `binary.Write` on a struct containing a pointer to another struct, instead of containing the other struct by value
• Tried to use `binary.Write` on a struct containing a `[]byte`
• Oh actually you *do* need to export the struct fields for `encoding/binary` after all! But for `binary.Read`, not `binary.Write`.
• Tried to initialize a three-element struct with just one element positionally, thinking that the other elements would default to zero; I guess I have to use named struct fields for that?
• Named a constant `type_SetPixelFormat` and then tried to `case SetPixelFormat:`
• Declared some byte-count-return variables that I didn't use because in one case `Reader.Read` was reading into a buffer of size 1, and in the other case, `io.ReadFull` is guaranteed to read the right number unless it fails (which I was handling already)
• Used `%+v` instead of `%#v` even though I did want hexadecimal printing of my struct fields
• Tried to declare two variables of different types with a comma in between, in a `var` statement
• Tried to use a member variable in a method without a preceding `self.`, as if I were in Java or C++
• Used `log.Printf` instead of `log.Print` and got this `%!(EXTRA)` error in my log message: 2018/09/13 19:51:58 closing %!(EXTRA *net.TCPConn=&{{0xc82006a0e0}}, string= because of error ,* errors.errorString=EOF, string= in , string=message-type)
• Forgot the first argument of `io.ReadFull`
• Got the syntax for a map literal wrong; it isn't `var x map[foo]bar = { ... }` but `var x = map[foo]bar { ... }`
• Forgot to cast a uint16 to int in order to compare it to an (implicitly declared) int
• When aping a log.Printf() line that printed a variable, aped the variable too and consequently didn't print out the value I wanted
• Left out an argument to `log.Printf` and got a `%!q(MISSING)` error in my log message
• Tried to change the type of parameters by shadowing them with `x, y := uint32(x), uint32(y)` at the top level of a function, which totally doesn't work

• Tried to use an int as a uint16
• Wrote := instead of =, unintentionally shadowing an outer-scope variable with one of a different type
• Passed a struct to `binary.Read` by value instead of passing a pointer, which resulted in an error not caught until runtime (which caused the VNC server to drop the connection)
• wrote `format.big_endian_flag` when I meant `format.Big_endian_flag`
• tried to use a byte as a boolean value
• tried to call `string.SplitN` instead of `strings.SplitN`
• tried to pass '\n' instead of "\n" to bufio.Reader.ReadString

Transmission line diode computation

Kragen Javier Sitaker, 2016-07-30 (3 minutes)

Consider a transmission line shunted at some point with a diode and an ac pulse (a wave packet, say) propagating along it. When the pulse reaches the diode, if the diode is forward-biased, the wave packet will see a short and will reflect back, inverted. On the other hand, if the diode is reverse-biased, the wave packet will see an open circuit (with perhaps some extra capacitance, which can be mostly compensated for by reducing the distributed impedance of the transmission line or by adding inductance) and will pass through unimpeded.

Perhaps by this means you can compute the bitwise OR of two bitstreams stored in a transmission line with a diode, by looking at the signal past the diode; and perhaps you can calculated their bitwise AND by isolating the reflected signal.

Off-the-shelf PIN diodes like the US$2.73 (US$1.27 in quantity) M/A-Com MADP-011027-14150T operate at up to 12GHz. So you could imagine doing this operation on bits that were 13mm long traveling through a transmission line at 0.5c.

With an ordinary diode, unfortunately, this provides no way to amplify the signal.

Specialty parts like Gunn diodes (available as USSR new-old-stock on eBay for US$8–20) can operate at higher frequencies, up to some 40GHz in some cases (supposedly up to 200GHz in some devices I haven't seen for sale), and additionally have a negative differential resistance region which can serve to amplify signals. Supposedly, gallium nitride Gunn diodes can reach 3 THz. (Tunnel diodes, which are also specialty parts, are also a possible option, although they do not reach such high frequencies; they are available on eBay at much lower costs, like US$1.)

These frequencies are far, far higher than any transistor.

Suppose that you found a way to do universal computation with some kind of network of transmission lines and 3 THz Gunn diodes. You could very reasonably use 100 meters of coaxial transmission lines in a desktop-sized device. At 3 THz and a transmission speed of 0.5c, the transmission lines would contain about 200 million oscillations at any given time, each about 50 microns long. You could imagine this waveform containing 400 million bits. With a reasonable number of bitwise computing elements, such as 32, the device would perform 96 trillion bit operations per second. A Skylake CPU with three 256-bit arithmetic units might perform 1536 useful bit operations per cycle (if we count an add with carry as two bit operations), which would be 6.144 trillion bit operations per second at 4GHz. So such a device could be computationally useful even without integrated circuits.

A nonscriptable design for the Wercam windowing system

Kragen Javier Sitaker, 2018-10-26 (updated 2018-11-13) (6 minutes)

A simpler design as an alternative to the latency-minimizing design in the Scriptable windowing for Wercam (p. 1256).

Modern CPUs are fast enough that we ought to be able to get by, at least for many applications, without any kind of graphics acceleration at all. The role of the window system in such a system is just to multiplex screen space among different windows, composite the windows, and route events to the relevant applications.

The simplest approach — the same one used in xshmu — is to let each application draw on a window buffer, and when it's done, display that window buffer.

Let's assume that window flicker is intolerable, that latency is important, and that more enough RAM is available for several framebuffers. Then we need to ensure that the display is never reading a partially-updated window buffer; at any given time, either the display or the application owns the buffer. Since latency is important, we would like to initiate the redraw as late as possible before the vertical synchronization, so that the window contents can get composited into the framebuffer only 8ms before they're drawn (assuming 60Hz) instead of, say, 24ms.

But Wercam can't ensure that the application finishes drawing into the buffer and relinquishes ownership in time for compositing. Even if it could forcibly steal the buffer away when the deadline passed, it would have a partially-drawn window image to work with. So it needs a backup plan — it needs the previous contents of the window.

It isn't good enough to keep the previous contents of VRAM, because the window may be translucent and something *underneath* it may have changed. In fact, I would like to ensure that this happens as often as possible.

So we need at least two buffers for each window — the current contents and the previous contents in case the current contents are unavailable when the deadline passes. When we get the current contents back, we can relinquish the other buffer back to the application so that it can draw the next frame when the time comes.

The Porter–Duff **over** operation — the one we'll use for compositing translucent windows — involves a multiply-accumulate per pixel component, typically in 8-bit integer arithmetic. I think my Intel Gen8 GPU (see Notes on the Intel N3700 i915 GPU in this ASUS E403S laptop (p. 2033)) can do about 100 billion 16-bit floating-point multiply-accumulates operations per second (400 MHz · 128 FP32 ALUs · 2 16-bit ops per ALU), and my CPU can do 128-bit SIMD (32 bytes) on I think four cores at 1.6 GHz each, which works out to 204.8 billion such operations per second, or 52 billion pixels. My screen draws 1920·1080·60Hz = 124 megapixels per second. This suggests that the CPU should be able to handle on the order of 419 layers, or the GPU half that (although the GPU also has a special-purpose blitter, which is probably competitive with the CPU.)

If the depth of translucent windows starts approaching this limit, it should be possible to request updates from windows deeper in the stack less frequently, perhaps every other frame. Then the foreground windows only have to be composited with the pre-composited background window stack.

We can go even further in this direction since the "over" operation is associative. We can group the windows by Z-order in groups of, say, 3, and composite each group separately, then composite the groups in supergroups of 3, and so on, until we have composed the whole scene. Then we can update any subset of windows, regardless of where they are in the Z-order, with a relatively small logarithmic cost. (But using saturating arithmetic might violate this associativity.)

The Dep kernel (see Speculative plans for BubbleOS (p. 2128)) provides the application and the window system the facility to securely transfer the window buffers back and forth such that each can be sure that the other has relinquished access before it starts to write. (When running Wercam on other platforms, we just have to hope.) Normally, the application doesn't allocate window buffers; it lets Wercam do that. If the application doesn't have possession of a buffer, it has nowhere to draw, and this is one way Wercam can limit the frame rate of background windows when necessary, or indeed eliminate the frame rate of invisible windows entirely. Also, though, normally applications will wait for a paint event from Wercam before drawing and sending a new frame. And they may not send a frame for a long time.

In the degenerate case where no windows are being updated, Wercam could avoid spending CPU time on compositing entirely; similarly with no windows being updated in a certain part of the screen. But its design goal is good worst-case performance, not good average-case performance.

Performance tests

I write a simple dumb alpha-compositor test in C. It appears to work, and it runs smoothly. At 828×512, just drawing a background, it runs at 1.13–1.16 ms (user CPU) per frame. Alpha-compositing an (opaque) copy of the background on top of itself, it runs at 4.23–4.31 ms (user CPU) per frame, implying a cost of 3.07–3.18 ms of compositing per frame, or 7.2–7.5 ns per composited pixel. Some preliminary analysis with Cachegrind finds 0.9 instructions per pixel without compositing plus 29.7 instructions per pixel added with compositing, but almost no difference in D-cache misses (0.125 per pixel with background only, 0.127 with compositing).

A little work with GCC vector extensions gets this down to, if my tests are valid, 1.46 ns per pixel, which is fast enough to put 5.5 layers on the screen, or 22 layers on all four cores.

Framed-belt DSP

Kragen Javier Sitaker, 2018-04-27 (3 minutes)

Framed-belt-per-sample-rate signal-graph DSP on CPU

Lots of DSP stuff (time-domain FIR filters, IIR filters, Goertzel filters, PLLs, a lot of music synthesis stuff) can be formulated as computing a bunch of quantities for each input sample. The quantities may depend on the input sample, the current values of other quantities (let's call them variables), or even past values of other quantities at some fixed lag into the past.

For a given sample rate, I think you can store these quantities very efficiently in a ring buffer of "frames". Each frame has a specific fixed offset for each variable, at least those that are used in the future; they are like structs or function stack frames. A piece of straight-line code computes the new contents of all of the variables of interest, storing them into their appropriate places in the frame; it can index off a frame base pointer to refer to other values in the current or previous frame (although hopefully it already has those in registers) or even earlier frames.

When the ring buffer is close to being full, you must write each new frame in two places: a place near the end, and a place near the beginning. In this way, when you need to reset the frame pointer to near the beginning of the buffer, you don't need to copy a bunch of frames at that point, and your indexing operations don't all need bitmasks on them in order to make the ring buffer circular. The buffer must be at least twice the size of your processing window (the furthest into the past you ever need to reach, e.g. the number of FIR taps) for this to work.

Perhaps there might be some values computed that you don't save in this belt of frames, thus reducing the space needed.

FIR filters implemented in this way will access memory with a larger stride than FIR filters implemented in the normal way, but I'm not sure that will cause memory bandwidth problems with modern CPUs.

Any fixed topology of single-rate signal transformers can straightforwardly be transformed into a straight-line piece of code that works in this way.

For image processing, where you generate a frame per pixel, you might want to arrange access to belts for previous rows as well. The idea is that any reasonable (Δx, Δy, varname) tuple maps to some constant and reasonably small offset from the current frame base pointer. Tiling might make this more feasible, by preventing the Δy aspect from generating unreasonably huge offsets.

A comparison of prices for different forms of energy

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

Different ways of buying energy, and their costs.

A pound of rice (453g) costs about US$0.35, or 0.08 cents per gram. Each gram is about 5 kilocalories, or 21kJ, so in the form of rice, you can get energy for about 27 megajoules per dollar. If a 2000-calorie-per-day person got all their energy from rice (which would result in dying of kwashiorkor) they would use 60 000 calories in a month, or 12 kg of rice, or 26.5 lbs., which would cost US$9.27 at the above rate.

Vegetable oil is slightly cheaper as a source of calories, but it's in more or less the same range.

Protein is considerably more expensive; pure protein costs around US$7 per pound, but there are natural foods that are 25% protein by weight, such as pinto beans, which cost about the same as rice, with the remainder being carbohydrates. This means you can meet your protein needs without increasing the cost of your food from the all-rice diet above.

Of course, you need other nutrients to survive as well, but none of them in multiple-gram-per-day quantities, and none of them are things you derive energy from.

However! Both rice and beans require extra energy to cook them --- minimally, enough to heat them and a similar mass of water from ambient temperature to near boiling. If that's from 25C to 100C, that's 75 calories per gram of water --- figure maybe 100 calories per gram of food. But that's only 0.1 kilocalories, or an additional 2% "tax" needed on top of the energy in the food.

Around here, gasoline currently costs about US$3.00 per gallon. Each gallon is about 130 megajoules, so in the form of gasoline, you can get energy for about 43 megajoules per dollar.

Electricity in the US costs between US$0.06 and US$0.15 per kilowatt-hour, with an average just under US$0.10. A kilowatt-hour is 3.6 megajoules, so in the form of electricity, you can get energy for about 36 megajoules per dollar.

These costs are surprisingly much more similar than I expected.

Microsoft Windows uses \ for filenames because OS/8 programs used / for switches

Kragen Javier Sitaker, 2019-05-25 (2 minutes)

A response to Michal Necasek's "Why Does Windows Really Use Backslash as Path Separator?", also posted on the orange website.

This is almost correct, but MS-DOS derives from the DEC small systems line (the PDP-8 and PDP-11), not the large systems line that ran TENEX, which took the name "TOPS-10" in the DEC Witness Protection Program (the PDP-6 and PDP-10). TENEX's only real descendant in modern computing systems is the command-line editing (and filename completion?) in bash and zsh.

Much to my surprise, it seems to be true that CP/M did not actually use / for flags, even in PIP, although other incarnations of PIP (like that in Heath's HDOS) did use /. The CP/M 2.2 manual is at http://www.cpm.z80.de/manuals/cpm22-m.pdf and documents the command lines of all the standard utilities, including the assembler, PIP, and the text editor. (It also, in passing, documents the full 8080 instruction set and OS API.)

TENEX was born in 1969 but grew up in the 1970s, but the use of / for switches in DEC-land predates it; https://en.wikipedia.org/wiki/Concise_Command_Language is somewhat confused, but it currently describes how the PDP-6 monitor program used / for switches in, presumably, 1964.

DEC operating systems like the ones CP/M aped used / liberally for switches, and third-party programs we used on CP/M certainly did use / for switches. This was not limited to the PDP-10 large systems operating systems; it was also true on OS/8 for the PDP-8, as described in https://www.pdp8.net/os/os8/index.shtml (though, as you can see, some commands used - instead, like the later Unix). The PDP-8 shipped in 1965, but OS/8 might be more recent than that.

Notes on circuitry for the Nutra seed activator

Kragen Javier Sitaker, 2018-08-16 (20 minutes)

The Nutra has a fan (I'm guessing something like a 12V PC cooler), a ¼HP agitator motor, a small pump motor, a water inlet valve, and a heating element.

Lucía tells me the target is for a year's lifetime.

I'm thinking that probably the control solution for these is to hook up an STM32 to a ULN2003 or something similar, then use the ULN2003 to run some relays. None of them needs subsecond response times; I think they are each turned on and off less than ten times during a cycle, which lasts roughly a day, so a lifetime of 20000 openings/closings and an MTBF of 100 000 openings/closings is probably adequate. Most of them will run on line power rather than a lower voltage, so the ULN2003 can't handle them directly.

Heating element

I back-of-the-envelope estimated the heating element at 300 W, but maybe 600 W is a safer level (in the sense of "we are sure it will work", not in the sense of "less likely to cause injury in case of malfunction".) 600 W is about 2.6 amps at 240 VAC (RMS), so a 3-amp relay is probably fine.

But wait, this needs to be PWM-controlled. PWM through a relay is not a good idea; if the PWM cycle is 20 seconds in length (50 mHz), 100 000 openings and closings only gets us to 555 hours of dehydration time. An SSR would achieve higher levels of reliability, but 500 hours is probably already a year, since the overall cycle might have an hour or two of dehydration in it.

Power

The most challenging objective is dehydrating 5 kg dry weight of soaked, activated beans to more or less their original dry weight. They will have absorbed roughly 5 kg of water. Water's enthalpy of vaporization is about 2.4 MJ/kg, so this is 12 MJ which get turned into latent heat. Doing this in one hour would require 3000 watts, which would be 12 amps. At my previous guess of 600 watts it would take five hours, which might be long enough for the beans to rot.

If we could use an air-countercurrent recuperative condenser like the ones in modern condensing clothes dryers, we could perhaps reduce that somewhat, but I'm not sure how much. (There are also heat-pump dryers, basically air-conditioner-based dehydrators in a box, which cost an extra US$1200 or so.) Traditional vented clothes dryers use 4–6 kW and vent 100–225 cfm, or more broadly 3–9 kW, while non-heat-pump condenser dryers typically use 2 kW, and heat-pump condensers use ≈ 1 kW.

Let's say we don't have a recuperator, but 2 hours is adequate, so we can get by with 1500 watts. And let's say the air stream is limited to 40° in order to make sure we don't heat the food past 42°. My psychrometric chart doesn't go to 100% humidity at 40°, but it says that 30 mg H_2O / g air is 64% humidity at 40°, so I guess 100% is

about 47 mg H_2O / g air, and 95% would be about 44 mg H_2O / g air. This means that removing 5 kg of water vapor would require passing about 114 kg of dry air through the beans, or a bit more, since the air in Buenos Aires already contains something like 10 mg H_2O / g air.

Air is about 1.23 kg/m³, so 114 kg of air is 92 m³. This is enough air to fill a 35 m² room of 2.6 meters height, and we're proposing to turn it all into the kind of fog that fills your bathroom after a shower. So you really, really need to vent it outside or run it through a condenser.

Either way, those 92 m³ of air need to be blown through the dehydrator during those 2 hours, which works out to about 12.8 ℓ/s, 770 ℓ/minute, or 27 cfm. This is the kind of airflow associated with bathroom fans with 8 cm ducts, or with small or quiet fans for computer cases — definitely feasible.

You don't want to blow *too much* new air in because you have to heat it all up — air's heat capacity is 1.01 kJ/kg/K, so each additional ℓ/s is 1.23 g/s and 1.24 W/K, and with $\Delta T \approx 20$ K that works out to about 24 W of extra heater power, plus whatever the fan uses. This isn't very much extra energy use but it's energy use that doesn't evaporate much extra water.

(Or is it?)

Here in Buenos Aires, we have abundant municipal water which we could use to chill a condenser, and the Nutra already needs access to both a water intake and a drain. How much water would it waste? If we drop the dewpoint of the air to 25° (thus removing more than half the water) by running it through a countercurrent heat exchanger cooled by tap water starting at 15°, well, we would need 290 ℓ of water to dump those 12 MJ of heat. This might be okay in some kind of objective sense but people who run dietéticas are not going to tolerate it.

Lucía previously calculated that she would need a 2000-watt heater.

Water inlet valve

I have no idea what the water inlet valve is like. I'm guessing it's a solenoid driven by line power (through a diode) at under an amp.

Small pump motor

The pump needs to drain 6 liters (I think) of water within, I don't know, 20 minutes. 5 mℓ/s, 0.08 gallons per minute, 5 gallons per hour. This is a very small pump; a US$11 aquarium pump on Amazon is 227 GPH, 45 times as big, and it's 18 watts. So I think this is more like a 1-watt pump. The intrinsic work being done is very small, possibly even negative, but pumping 5 milliliters per second against a pressure of 1 meter column of water would be 50 milliwatts, plus whatever mechanical inefficiencies are encountered.

It might be feasible to run this directly off the ULN2003.

¼HP agitator motor

This is 190 watts output, perhaps 220 watts input — 1 amp at 240 volts.

Fan

A typical PC fan is like 100 to 300 milliamps at 12 volts. This could possibly be run directly off the ULN2003, which can handle 500 mA on a given pin at up to 50 V, though only one pin at a time.

Relays

So we probably need a couple of 1-amp relays, a 3-amp relay, and maybe another sub-1-amp relay for the pump. If we simplify this to four 3-amp relays, well, the usual suspect seems to be something like the Omron G5LE-1A4 DC12, which costs US$1.30 in quantity 1 and switches 10 amps at up to 250 VAC when you apply 12 VDC and 33.3mA to the coil. It's SPST, normally open. Or the TE Connectivity/Brumfield OJE-SH-112HM,000, apparently identical in every way except for costing US$1.32 and drawing 37.5 mA.

However, the Omron datasheet has a chart that shows durability of 200 000 operations at 3 amps and a 250 VAC resistive load or 120 VAC inductive load. With a 120 VAC resistive load, it's rated for twice the lifetime. The TE relay is only rated for 10 000 ops, though there's an "LM" variant rated to 100k.

All four relays at once would only be 133 milliamps, well within the ULN2003's limits.

There do exist mercury-wetted reed relays with lifetimes of a million operations, but these probably aren't necessary for a lifetime of one year.

Some kind of triac-optoisolator thing might be a reasonable alternative, but a typical triac drops 1.5 volts, so 3 amps would dissipate 5 watts, requiring a hefty heatsink and posing potential reliability problems of its own.

ULN2003 hookup

The ULN2003 only has a guaranteed β of 1000, so getting 33 milliamps on its output requires 33 microamps on its input. Except that actually the curves in the datasheet show that you need over 100 microamps to get anything to happen. This means that, at 3.3 V, the base resistor shouldn't be over 33 kilohms, which means you can't quite use the pullup resistors integrated in the STM32 I/O pins, since they could be as high as 50 kΩ according to the datasheet. You could maybe parallel two I/O pins, but it would probably be better to use external resistors, thus avoiding the chance of a software error burning up the STM32 or the ULN2003.

The ULN2003's maximum base current is 25 mA; 1 mA per pin should be plenty, so anything between 3.3kΩ and 33kΩ is adequate. 10kΩ, everybody's favorite resistor, is probably optimal, giving 330 µA, and thus 330 mA or better on the output pin.

Speaker

We can hook up a speaker to an extra output of the ULN2003 and control it through the built-in PWM of the STM32. If it's a ¼W 8Ω speaker, we need to keep current through it under about 100mA; a dc-blocking capacitor is probably worthwhile here, so that if the ULN2003 is on we don't have a constant current through the speaker with no sound, but also it would be a good idea to limit the current of ac signals and also perhaps filter out inaudible high frequencies. More

precisely, with 8Ω, to keep $I^2R < ¼W$ we need $|I| < 177$ mA, so a series resistance of 68Ω or greater is called for with 12V. Except with dc-blocking that's 12V P-t-P, so 6V RMS with a perfect square wave, so 33Ω would be adequate. The resistor is going to have most of that 6V RMS across it, like about 5V, so it needs to be pretty hefty, nearly a watt in the worst case. Probably prudent to limit the output power further, using 100Ω or so.

At 100Ω series resistance, an instantaneous 12V spike would push 120 mA, and 6V RMS would dissipate 360 mW in the resistor, which requires a largish resistor but nothing ridiculous; it would experience spikes to 1.3 watts. The 60 mA RMS would output 29 mW from the 8Ω speaker. You can see why people prefer to drive these damn things through transformers. Still, 29 mW is probably still audible; it's less than 10 dB below what I guessed was the maximum output for the speaker.

Now, what about filtering out ultrasound? If we shunt the speaker with a capacitor, we'd like its RC time constant to be in the tens of microseconds somewhere, so that 64 kHz (2.5 µs per radian) is strongly attenuated but 10 kHz (15.9 µs per radian) is minimally attenuated, if at all. But the relevant R here is not the 100Ω that's being used to limit the current, but rather the parallel combination of that 100Ω (plus the dc-blocking capacitor, which is hopefully negligible at the relevant frequencies) and the 8Ω of the speaker, which works out to be 7.4Ω. So we need something like 1.3 µF, not the 100 nF you would expect. At 1 µF, we get 7.4 µs, which puts the knee around 21 kHz, which means that we only have about 3× attenuation at 64 kHz (like 10 dB). If we use 2.2 µF, the knee is at 9.8 kHz, which gives us an extra 6 dB.

The dc-blocking capacitor needs to have a sufficiently long time constant with the series resistance to not mess up the bass too bad. Say we want its time constant to be below 40 Hz (4 ms per radian), then we need at least 40 µF. 100 µF is probably fine; at 12 volts this holds 7.2 mJ, which is what gets dissipated in that 1.3-W spike in the series resistance.

Perhaps a second RC section is worthwhile in this case: 10 ohms before the 100 ohms, then a 1µF to ground. So the whole output circuit from the ULN2003 pin would be `{ 100 µF 10 Ω { 1 µF gnd } 100 Ω (1 µF || speaker) 12 V }`, where concatenation is series combination, `{}` is a branch, `()` are grouping, and `||` is parallel combination. In a Falstad simulation, this configuration gives us about -4 dB at 40 Hz, -0 dB from 80 Hz to 5 kHz, -1 dB at 7.5 kHz, -2 dB at 10 kHz, -4 dB at 15 kHz, -5 dB at 20 kHz, -15 dB at 40 kHz, and -22 dB at 65 kHz. However, at high frequencies, this puts the whole 6 V RMS across this new 10Ω resistor through the capacitor shunt to ground, which means it will be dissipating 3.6 watts! And of course the PWM output from the ULN2003 is *always* close to 6 V RMS, except when it's close to dc.

So the second RC section is a bad idea. Probably much less hassle to use an inductor in series with the resistor, one whose impedance becomes large relative to 100 ohms at somewhere around 10 kHz, like a 4.7mH inductor. In a Falstad simulation, this gives about 3 dB attenuation at 3.5 kHz, 6 dB at 6.3 kHz, 10 dB at 10 kHz, 17 dB at 20 kHz, 27 dB at 40 kHz, 30 dB at 48 kHz, 38 dB at 80 kHz, and 42 dB at 99 kHz. Simulation also suggests about a 13.7 mV peak amplitude

part of a 48 kHz PWM modulating square wave would remain across the terminals of the speaker, compared to some 440 mV peak for the actual signal. (Maybe it works even better with L speaker || C instead of L (speaker || C), with a +6dB peak around 6kHz.)

Wait, actually the whole thing is bad in that form. I need a 220Ω pullup resistor on the ULN2003 to get current. And then maybe I don't really need an inductor. Here's the Falstad design:

```

Oh, I think I have a reasonable approach that eliminates most of the inefficiencies. {100Ω (L || 100µF speaker) 12V}, where the L provides a dc path around the speaker and capacitor, and the capacitor basically just protects the speaker from dc. The resistor in series with the whole shebang limits the current, but maybe it could be bypassed with a capacitor so that it can be bigger than would be desirable for ac. And you can still shunt the speaker alone with a capacitor to reduce ultrasound.

A potential problem with this is that it could introduce a kind of distortion when the conduction switches from being through the Darlington to being through the freewheel diode, just because of the forward voltage drop of the freewheel diode.

How much inductance does the shunt inductor need? Ideally it

shouldn't steal much current from the speaker at audio frequencies, which means its impedance at audio frequencies should be large compared to the speaker's 8Ω, although maybe the capacitor can help compensate for this. But let's say we want its impedance at 40 Hz to be 16Ω. This requires a fairly hefty 68-mH inductor (like, 8 mm × 12 mm.)

Or you could just drive the speaker through a little 4:1 100Ω-ESR audio-frequency transformer, which will probably filter out the ultrasound as a side effect.

What *is* the PWM frequency? The STM32F030x4 etc. reference manual RM0360 says, "If the APB prescaler is 1, the timer clock frequencies are set to the same frequency as that of the APB domain," which is normally 48MHz except for power saving. I think that means that if you want 8-bit PWM, you can get 187.5 kHz PWM. At such a speed, 1mH of inductance should be plenty — and how much does the speaker itself have? 1mH series and 1µF in parallel reduces the 187.5 kHz square wave to 5.6 mV peak, while the AF signal is like 440 mV peak.

Display

A Nokia 5110 84×48 display ought to be adequate and might fit in well with the overall feeling of the device, although OLEDs are nicer on several axes nowadays.

Sensors

Monarca sells a DHT-22 temperature and humidity sensor for $220. Nubbeo has the cheaper DHT-11 for $60, but its precision is ±2°, which would be terrible for the Nutra, restricting it to a temperature of 40° or below. By contrast, the DHT-22's precision is ±0.1°.

Apart from cost and precision, the sensors are otherwise quite similar.

Topics

Planar lookup tables

Kragen Javier Sitaker, 2014-04-24 (2 minutes)

I've written previously about heightfields for mechanical computation: http://lists.canonical.org/pipermail/kragen-tol/2010-June/000919.html. One difficulty mentioned therein is that fabrication technologies capable of producing individual one-off parts like the three-dimensional heightfields called for are rather expensive; drilling a single hole in a hard material can cost tens of cents, and thousands, if not tens of thousands, of such precise holes will be needed for a complete computing device.

Planar fabrication techniques such as acid etching, laser cutting, sawing with a jigsaw or fretsaw or coping saw or piercing saw, waterjet cutting, oxy-acetylene or plasma cutting, or cutting with a hot or abrasive wire are dramatically cheaper, but they can't cut only partway through the material, either with precision or at all. It would be very convenient to be able to achieve the two-dimensional LUT effect using only such planar fabrication techniques.

This is possible by using a tapered probe that measures the width of the hole, rather than its depth; this allows a flat plate containing holes of various widths to be used instead of the cube containing round holes of various depths I proposed before. The holes can be slot-shaped rather than round, since the taper will be cut from a flat plate. The friction and tensile forces resulting from the taper will be the limiting factor on the number of bits in the machine; this can be improved somewhat by making holes shaped like plus signs or rectangles and using two separate tapers in a plus-sign-cross-section-shaped probe, and perhaps by using stepped tapers.

Alternatively, of course, you could construct the three-dimensional heightfield by squeezing together a bunch of parallel plates, like the body of the common stamped-and-riveted laminated Master padlock, perhaps with glue between the plates to improve precision. But that requires some 33 plates for a single 16×16 heightfield rather than one.

Spring energy density

Kragen Javier Sitaker, 2016-05-28 (updated 2016-06-06) (13 minutes)

Suppose you want to make springs out of tool steel, which may not be the best possible choice but is close to feasible at least. (Normal people use music wire, apparently.)

http://www.matweb.com/search/datasheet.aspx?matguid=5abd35ce06bd64254b6db980b83683f27&ckck=1 says that AISI type A2 tool steel (which can be hardened by air-cooling after heating) has a modulus of elasticity of 203 GPa, a shear modulus of 78 GPa estimated from the elastic modulus (presumably with $E = 2G(1 + \nu)$, where E is Young's modulus, G is the shear modulus, and ν is Poisson's ratio), and a density of 7.86 g/cc. Unfortunately this doesn't supply the strength data that we need to figure out when it will break.

http://www.matweb.com/search/datasheet.aspx?matguid=8188603e05f954e53b479aaa4b07cdffb is a page about particular brand of A2 tool steel, giving its yield stress as 1580 MPa, its ultimate tensile strength as 2050 MPa, and its modulus of elasticity as 203.4 GPa, with a 1% elongation at break. (This makes sense because 2050 MPa is about 1% of 203 GPa.)

https://en.wikipedia.org/wiki/Shear_strength says that in steels, the shear yield stress is about 0.58 of the tensile yield strength (this is called the von Mises yield criterion, and apparently applies to ductile materials in general?)

This suggests that the shear yield stress of A2 should be about (* .58 1580) = 916 MPa, at which point it's distorted at a slope of (/ .916 78) = 0.0117, or 1.17%.

Let's consider the case of twisting a cylindrical torsion bar made of this material, say 1 m long, 200 mm diameter, and 1 mm thick, thin enough that we can mostly ignore the difference in radii between inner and outer walls, but thick enough that it won't collapse as we twist it. Twisting it by 1.17% means a twist of 11.7 mm over that meter length, which is 0.117 radians of twist. The cross-sectional area there is about $1\text{ mm} \cdot 200\text{ mm} \cdot \pi \approx 628\text{ mm}^2$. At the yield stress of 916 MPa, this cross-sectional area generates (* 916 628) = 575248 N of force, which is almost sixty tons. (We could convert this to a torque by multiplying by the 100 mm radius, but we don't need to.) Building linearly to that force over 11.7 mm of travel distance gives us (* 575248 .5 .0117) = 3365 J of energy stored in the bar.

What's the energy density of that? The metal occupies 0.628 ℓ of volume, so that's (/ 3365 .628) = 5358 J/ℓ. At 7.86 g/cc or kg/ℓ, that's (/ 5258 7.86) = 669 J/kg. This is close to, but larger than, the 300 J/kg cited in https://en.wikipedia.org/wiki/Energy_density_Extended_Reference_Table.

If we were somehow able to stress the metal in tension instead of torsion, we'd get to 1580 MPa at an elongation strain of (/ 1.58 203) = 0.0078 or 0.78%, or 7.8 mm, at a force of (* 1580 628) = 992240 N, and an energy of (* 992240 .5 .0078) = 3870 J, which is better, but

only by 15%. (/ 3870 .628) = 6162 J/ℓ; (/ 6162 7.86) = 780 J/kg.

Nested torsion tubes in series offer the opportunity to exploit this entire 669 J/kg energy capacity; normal coil springs only manage about two thirds of it, and springs such as garage door torsion springs that are stressed in bending rather than tension or torsion only get to half of the tension number. You need some space in between the tubes, and some mass in the coupling between the tubes at the ends, but those can be very small numbers. So 5kJ/ℓ should be a totally reachable energy density in practice.

Unfortunately, these specific energies are substantially lower than I want for the compact application I have in mind, in which I would like to hold several hundred to several thousand joules in a spring weighing under 200g, then release it in submillisecond timescales. 200g · 669 J/kg = 134 J, barely acceptable.

I should investigate whether spring steels, beryllium copper, or nitinol can provide larger energy capacities. Apparently ASTM A228 music wire is a common spring material, as are SAE 1074 and 1075 steels, while AISI 1095 steel (ASTM A684) is used for more demanding applications.

The speed of sound in a material is $\sqrt{(K/\rho)}$, where K is the relevant modulus of elasticity and ρ is the density of the material. In this case, for transmission of shear, sqrt(78 GPa/7.86 (g/cc)) comes out to 3150 m/s. This means that it takes 317 μs for a movement to travel a meter through the spring; the suggested meter-long torsion bar won't be able to respond faster than that. You can, in effect, fold up the spring and nest it inside itself into a series of nested torsion tubes, which in theory won't affect either the response time of the spring or its rate. You can decrease the spring rate (i.e. increase the compliance) by using thinner-walled tubes, up to a point where the spring buckles and collapses; but, if you do that while keeping the energy capacity and mass constant, you have to increase the response time proportionally.

If your torsion spring is a single tube of constant diameter, it is useful to give it a constant thickness as well; otherwise, the thinner part will fail before the thicker part is fully charged. This is because the torque is constant along the entire length of the tube, but that torque translates into different stresses at different thicknesses. Once you start nesting the tube inside of itself in series, you still have the constant torque, but now you have different radii in different parts of the spring, which translates to different tangential forces inversely proportional to the radii; this means that the wall thicknesses also need to be inversely proportional to the radii in order to keep the stress constant through the entire spring.

This has the problem that once the radius is small enough, the inner and outer radii start to differ significantly, which means that the stress on the inside radius of the tube is significantly lower than the yield stress. For example, the 1mm-thick 20mm-wide tube in the example above, in which the stress is below optimal by only 10% on the inner wall, could be put in series with a 10mm-wide 5mm-thick tube — which is no tube at all, but merely a rod! It has no torsional stress at all at its center.

The upshot of all of this is that you can get arbitrarily fast reaction times only at the cost of arbitrarily high forces or arbitrarily low energy capacities per spring.

What about Dyneema? If it has an ultimate tensile strength (and also yield stress!) of 2.5 GPa and a Young's modulus of 100 GPa, and we somehow stress it in tension instead of torsion, then that same 628 mm² cross-section rope of it would hold up to 1.57 meganewtons, about 160 tons; if it were 1 m long and stretched by 2.5%, or 25 mm, then we'd have 19.6 kJ stored, 31.25 kJ/ℓ. And it would weigh only 609 g, so it's 32.2 kJ/kg.

In energy density per kg, that's *48 times better than* the steel spring. Per liter, it's only about six times better. And that's without getting into weird effects like rubber's hyperelasticity or nitinol's pseudoelasticity which I worry might convert their theoretically higher energy capacities into delusions at these time scales. According to ARL's tests http://www.dtic.mil/get-tr-doc/pdf?AD=ADA606636 Dyneema is capable at least of absorbing energy at these moduli at a kilostrain per second.

http://www.sciencedirect.com/science/article/pii/S1877705811005640
9

This suggests that maybe nylon would be an even better place to look for spring energy density! It's not as strong as Dyneema, but it has a dramatically lower modulus, and I think it also avoids the weird pseudoelasticity thing where the "elastic" energy gets lost as heat. http://www.engineeringtoolbox.com/engineering-materials-properti
es-d_1225.html claims that nylon 6/6's density is 1.15 g/cc, its tensile modulus is 2 to 3.6 GPa, its tensile strength is 0.082 GPa. Dividing, that gives it 24% (or more) elongation at break; 24% .082 GPa/2 = 9.8 kJ/ℓ. That's not as good as Dyneema, but it's still volumetrically better than most steels, and a *lot* better per mass, at 8.6 kJ/kg. Nylon springs would easily meet the 200g limit I'm trying for: 200 g 8.6 kJ/kg = 1.7 kJ. In fact, you could probably get by with 100g or 50g. And nylon is a *lot* cheaper than Dyneema still.

The √(K/ρ) speed of tensile sound in nylon, by these numbers, should be 1318 m/s, only four times its speed in air, and low enough that you can only get 1300 mm of nylon spring to respond in a millisecond. However, this should be plenty of time. I really only need a millisecond or so; 100μs response time is more than adequate, and I have in mind for the entire spring to be under 100mm long.

Disappointingly, it seems that nylon is indeed hyperelastic and behaves much more stiffly at high strain rates; http://scholarbank.nus.edu.sg/bitstream/handle/10635/37891/PhD%
20Thesis,%20Habib%20Pouriayevali%20(%20Mechanical%20Dep)%20
0HT081385J.pdf?sequence=1 and http://www.sciencedirect.com/science/article/pii/S1877705811005640
9 show the results of H. Pouriayevali with respect to the issue, showing that his nylon sample compressed 30% under a 50 MPa strain under quasi-static conditions, but at strain rate of -3203 per second, it had only compressed 2% at that same strain (which I suppose means he reached it in 6 μs). At a more moderate strain rate of -980 per second, it had compressed some 8% at that strain, in, I suppose, about 80 μs. The dissertation also, alarmingly, says that nylon "is notably rate-dependent and exhibits a temperature increase under high rate deformation", but it turns out that he's talking about like five kelvins for fairly large strains like 21%.

Pouriayevali's 6-6 nylon samples failed in quasi-static tension at strains which appear to have been around 1.0, 1.2, and 1.4, with stresses around 80 or 100 MPa, which seems improbably rubbery, but fairly plausible strength. He reports a quasi-static elastic modulus of 958 MPa at small strains, but as the graphs show clearly, this drops precipitously at higher stresses.

This stiffness varying with strain rates presumably means you have high hysteresis losses in nylon, more usually known as "vibration dampening ability".

However, I'd probably be fine with >50% losses, as long as I can get the rest of the energy out in well under a millisecond. 12% strain in a millisecond is a strain rate of 120 strains per second, which may be low enough that nylon will have low losses.

Pouriayevali did do lower-rate experiments under tension. His lowest-rate dynamic tension experiment involved an impact of 150 strains per second, reaching some 30 MPa and 5% strain; the quasi-static condition had only 20 MPa at that same 5% strain. That means that if you stretched your nylon by 5% at 150 strains per second, you'd've put in 30 MPa * 5% / 2 = 750 J/ℓ, and then if you unloaded it slowly, you'd only get out 20 MPa * 5% / 2 = 500 J/ℓ. In this case I propose to do essentially the reverse: load it slowly, then unload it quickly. It looks like this will probably be in the neighborhood of that 50% efficiency.

(Actually the stress-strain curves aren't very linear, and they're actually maybe a bit closer together than that makes it sound.)

In chapter 5 of his dissertation, Pouriayevali fits numerical models to the properties of the nylon which seem to suggest something like 10% or 20% energy losses at 150 strains per second when extended to larger strains, with actually much lower losses at higher strains, up to 0.6. Also, the stresses at higher strains are more nearly constant, which should ease design substantially.

Simple persistent in-memory dictionaries with log² lookups and logarithmic insertion

Kragen Javier Sitaker, 2014-02-24 (6 minutes)

An in-memory dictionary with O(lg² N) lookups, O(lg N) amortized insertions, O(lg lg N) key-ordered traversal, dramatically better memory usage and cache behavior than binary search trees, persistence in Okasaki's sense, and very simple code.

Search trees store sets or bags in logarithmic time. The simplest search-tree algorithms are very simple indeed, although they use a lot of memory and a lot of random memory seeks; but they degrade to linear search in the worst case. Advanced search trees like red-black trees and B*-trees fix these problems, but at the cost of great algorithmic complexity.

A perfectly-balanced binary search tree can be represented without pointers, as an array; the usual binary heap algorithms work this way, taking the nodes at 2N and 2N+1 as the children of the node at N (or 2N+1 and 2N+2, if you're zero-based.) Alternatively and equivalently, you can use binary search: a subtree of 2N+1 nodes is comprised of the concatenation of a left subtree of N nodes, a single root node, and a right subtree of N nodes. These two representations are equivalent and interchangeable, and they share the problem that inserting into them is O(N) rather than O(lg N). (The binary-heap approach seems like it should have better cache behavior for lookups, and worse for sequential traversal.)

Lucene handles a similar problem by maintaining its index as a set of O(lg N) "index segments", each of which is sorted. Insertion takes the form of generating a new index segment, while a search requires doing an O(lg N) search in each of the O(lg N) segments. Creating a new index segment may result in merging some existing index segments into larger index segments.

(Lucene's data structure, because it requires only sequential writes to new segments and never random writes, is also well-suited for concurrency and variable-sized data items.)

The simplest version of this approach would make the index segments powers of two, with a maximum of one index segment of each possible size. So if you had index segments of sizes 1, 2, 4, 16, and 64, then after inserting a new datum, you would have index segments of sizes 8, 16, and 64, having merged the three smallest segments together. (It might simplify the search of each individual index segment to use powers of two minus one: 1, 3, 7, 15, 31, and so on. But then you'd need to allow up to two segments of any given size.)

It's straightforward to see that you'll have between 1 and lg N segments, and that the average case will be ceil(lg N)/2. An insertion will cause zero merges half the time, one merge a quarter of the time, two merges an eighth of the time, three merges a sixteenth of the time, and so on, for an amortized constant of two merges per insertion. Those merges are mostly small and fast: four-item merges

are half as common as two-item merges, eight-item merges half as common as four-item merges, sixteen-item merges half as common as eight-item merges, and so on. However, this series still fails to converge, which makes sense since in its infinite form it represents the work of inserting into an already-infinite set. If you terminate it after N terms, it represents the work of inserting into a set of 2**N items, and it adds up to N.

As with trees, this approach supports "persistent" data structures, where you can hang on to a previous version of the structure simply by holding onto a pointer to it, sharing state with current versions — as long as you store it as a linked list, going from the smallest to the largest index segments. You lose the amortized time guarantee, though; if you save off a version with 1023 items in it and then make 100 modified versions of it with one item added, you'll do a 1024-item merge for each of those 100 modified versions, for 102400 total work.

This data structure is asymptotically slower than a binary tree for lookup, since doing a lookup takes $O(\lg^2 N)$ probes — for example, in a 42-item dictionary, you must search in the 2-item array (1½ probes), the 8-item array (3⅛ probes), and the 32-item array (about 5 probes), for a total of 9⅝ probes, while a perfectly balanced binary tree would take slightly over 5. In a 2730-item dictionary, you must do that and also carry out 7 probes in the 128-item array, 9 probes in the 512-item array, and 11 probes in the 2048-item dictionary, for a total of a bit over 36 probes, while a perfectly-balanced tree would take under 12 probes. I've chosen the numbers 42 and 2730 because they're uncharacteristically average.

(Here I'm assuming that you must examine every candidate location, either because your lookup is unsuccessful or because you could theoretically have more than one value for a given key, but don't. In the case where keys are guaranteed unique, you may be able to stop earlier, but I think that doesn't affect the asymptotic time; and if you actually do have multiple values per key, the worst case is that you have to return every value.)

If we allow index segments with less than the maximum possible number of keys, it's possible to run an $O(N \lg \lg N)$ "optimization" pass on the data structure, sorting everything into a single array. Thereafter lookups will be $O(\lg N)$.

Object embedding

Kragen Javier Sitaker, 2014-02-24 (13 minutes)

In Java (as in Smalltalk, Lisp, Python, ML, and many other languages) when an object A "contains" an object B, the in-RAM representation of object A contains actually just a *pointer* to B, i.e. the address at which B's in-RAM representation can be found. This is in some ways convenient, but it has some drawbacks — not only for efficiency, but even for program correctness.

In C, instead, "A containing B" means that the in-RAM representation of B is actually contained inside the in-RAM representation of A. I don't know of a standard term for this, so I'm calling this "object embedding." (Object embedding is one aspect of one possible implementation of what is sometimes called "compound value types", for example in C# and in *Elements of Programming*.) C, C++, Pascal, and Golang do the same thing; they all inherit it from COBOL's "group items", from which Algol got "record types", which C renamed "struct".

The benefits of by-reference object fields are significant:

• A's **reference to B is polymorphic**, i.e. you can use an object of any subclass of the type that A is expecting. This means that objects-by-reference are absolutely essential to the Liskov Substitution Principle. C++ has a terrible bug resulting from its misguided attempt to make embedded objects polymorphic, known as the "slicing copy". C, Pascal, and Golang do not suffer from this because embeddable objects do not have subtypes, unless you think of the variants of a union type ("sum type") as being subtypes of it.
• B can be **aliased**: several different objects A can "contain" the same object B. This can be desirable if B is large or if it has mutable state that many objects need access to.
• A's reference to B is **nullable**, which is particularly important in languages like Smalltalk, C++, and Java, where you can access an incompletely initialized object (from inside its constructor, if nothing else).
• Pointers allow circular references.

However, compared to Java's approach, it occurs to me that the embedding approach has some real benefits. More than once, I've written code like this:

```
public class LogFileParser {
    private Map<String, String> messageIds;
    public void sawMessageId(String messageId, String queueId) {
        messageIds.put(queueId, messageId);
    }
}
```

This has the tendency to throw a `NullPointerException`, because of course declaring that your LogFileParser objects *could* have a `Map` from `String`s to `String`s doesn't give them one. You need to say:

```
    private Map<String, String> messageIds =
        new HashMap<String, String>();
```

`final` on instance variables is not nearly as useful as you might think when you're obligated to use mutable objects for a lot of those final instance variables. It does, however, avoid the above problem.

By contrast, embedded objects aren't nullable. If you say:

```
struct foo {
    struct foo *next;
    struct bar my_bar;
    int weight;
};
```

then you can never have a `struct foo` whose `my_bar` is `NULL`, because it's not a pointer. So the above NullPointerException cannot arise, not even as a compile error. In C++ you can even have a default constructor for `bar` that ensures that its memory doesn't contain random garbage; in Golang it's initially zero, and you get the same guarantee in C if you use `calloc` or initialize a local `struct foo f = {0};`.

The consequence is that in C++, if you say

```
std::map<string, string> message_ids;
```

— either as a local variable or an instance variable — you have a full-fledged empty `map` sitting there, without any need to repeat again the fact that you wanted one. This kind of thing, in combination with the STL container library, allows you to write entire useful C++ programs that don't mention heap memory allocation at all, because it's all hidden away inside the STL.

(ML and its descendants take another approach to this problem, one which inspired the `final` mechanism in Java: although relationships by objects are by means of pointers, there is no `null` value, and so you can't create an object without supplying values for all of its fields.)

Aside from this **implicit nullability imposed on every object field**, there are a few other problems with by-reference objects.

• **They allow for aliasing**, which is to say, many-to-one relationships: a subobject included merely by reference can also be included in many other objects. Sometimes this is what you want — it's a major reason for using pointers in languages that do support object embedding — but aliasing, like nullability, is bug-prone, and therefore **probably a bad default** for mutable objects.

(Of the languages I've mentioned, only Pascal actually forbids you from making an alias to an object embedded inside another object, e.g. in C, writing `&my_foo.my_bar`. But it's relatively uncommon in practice to store such a reference into another object.)

• They **greatly increase the number of separate memory allocations**. This means that the graph that your garbage collector has to traverse is very much larger, and it correspondingly must do a great deal more work. This is one reason why ML garbage collectors tend to be very efficient — they have to be to make ML practical at all — and also the reason that Golang is reasonably efficient even though its garbage collector is still kind of crappy.

• In themselves, the **pointers take up memory**. If the only pointers in your memory are for object fields that you decided *ought* to be

nullable or aliasable, then most of your memory will probably be spent on the data that your program unavoidably has to manage. By contrast, in a language like Java or Python, it's easy to spend most of your memory on pointers, especially on 64-bit CPUs.

(Having more pointers also makes the garbage collector's job a lot harder, since it has to traverse the pointers in your live objects.)

Quantitatively, it seems that half to two-thirds of a typical Java program's memory is taken up by pointers, because moving to 64-bit increases the needed heap size by 50%.

• CPUs **can't generally prefetch pointer targets**, and they won't be in the same cache line; so accessing subobjects is a lot more likely to generate cache misses. By contrast, accessing embedded subobjects takes not only *less* time, but often *zero* instructions and zero time! See the section below, "zero instructions".
• Allocating every object on the heap means that **any part of your program that creates objects can fail unpredictably** if you run out of memory; in very memory-restricted environments like an Arduino, the heap can start to overwrite the stack and vice versa. Error handling mechanisms can control how the failure is handled, but they can't turn failure into success. (Worse, if your error handling creates objects, it can fail too.) In practice, under many circumstances, it's probably better to recover from memory allocation failures by immediately aborting the program.

This sounds like a bigger problem than it is in practice, because most software can be called upon to handle arbitrarily-sized problems, which means that you can always find some way to make it run out of memory and fail. Dynamic memory allocation is built into the problem, not just your solution to it. So increasing the number of places you can get an out-of-memory error isn't a big deal.

But there is some software that needs to work *all the time* instead of sometimes failing unpredictably, and that software should be written without dynamic allocation, which means it should not be written in a language where object fields are by reference. It's not acceptable if your antilock braking system, your jet engine controller, or your air-traffic control system gets an out-of-memory exception and reboots while you're using it.

On the other hand, if it's okay for your software to fail every once in a while, and it's just a matter of reducing the frequency to once a day, once a year, or once a millennium, dynamic allocation is not a big deal. In fact, dynamic allocation can help a lot with that. One of the major reasons the Fuzz paper found that the GNU tools were so much more reliable than the Unix tools they replaced is that they use dynamic allocation all over the place, so they have few arbitrary limits. Every dynamic allocation is a potential failure in your program; but every arbitrary limit is a potential bug.

However, these disadvantages are irrelevant if you want to practice OOP, because if you don't have ubiquitous LSP polymorphism, you aren't practicing OOP. So, in a way, these can be seen as five disadvantages of OOP.

(In theory I don't see why you couldn't have a functional programming language where object embedding was the norm, but I haven't seen one. Perhaps this is because functional programming languages have mostly adopted other approaches to solving the

problems here that are not questions of mere efficiency: for nullability, sum types like ML's `Option` or Haskell's `Maybe` and constructor expressions; for aliasing, a default of immutability; and, to some extent, for garbage collection, sophisticated generational garbage collectors.)

Parametric polymorphism

One big disadvantage of object embedding is that it requires you to implement parametric polymorphism (aka generics, generic types, or parametrized types) by means of generative programming, which can create a combinatorial explosion in code size. ML-family languages get parametric polymorphism basically for free, because every value is the size of a machine word (ironic that the 1980s explosion of functional programming traces back to Backus's misplaced attack on the "conceptual von Neumann bottleneck"!) so you only need one copy of the machine code for `List.map`, not one copy for each size of list item.

Zero instructions!

My assertion above that accessing embedded objects is not only cheap but actually *free* may seem dubious. What I mean is that, often, what you're doing with an embedded object is accessing fields within it, and if those fields themselves are embedded objects, you can easily end up with an entire chain of three or four or more field accesses compiling down to a single indexed fetch instruction, rather than a series of three or four of them.

As an example, in My Very First Raytracer, I have a function which begins:

```
static bool
find_intersections(ray rr, sphere ss, sc *intersections)
{
  vec center_rel = sub(rr.start, ss.cp);
…
}
```

which invokes these functions:

```
static vec
add(vec aa, vec bb) { vec rv = { aa.x+bb.x, aa.y+bb.y, aa.z+bb.z }; return rv; }
static vec
sub(vec aa, vec bb) { return add(aa, scale(bb, -1)); }
static vec
scale(vec vv, sc c) { vec rv = { vv.x*c, vv.y*c, vv.z*c }; return rv; }
```

So, given all this, the `center_rel` code works out to

```
vec center_rel = { rr.start.x + ss.cp.x * -1,
                   rr.start.y + ss.cp.y * -1,
                   rr.start.z + ss.cp.z * -1 };
```

Even mild inlining optimization can turn that into six indexed memory fetches and three subtractions, followed by three stores, but as far as I can tell, GCC actually somehow manages to allocate an SSE

register to each of the six values, and so those 12 field accesses are incorporated into three instructions. (I can't follow the generated assembly at all, even with the aid of `-g -Wa,-adhlns=raytracer.lst`. GCC has inlined basically the entire raytracer program into a single giant recursive function called `trace` of some 500-plus instructions.)

Again, that's 12 field accesses, plus some math, in 3 instructions, thanks to object embedding.

Further alternatives

What was the name of that guy who advocated using parallel arrays in C, Fortran-style? He was also pretty unhappy about the decline in hi-fi audio systems since the 1970s.

Topics

General purpose layout syntax

Kragen Javier Sitaker, 2017-11-10 (updated 2019-09-01) (34 minutes)

(Quicklayout (p. 2189) concerns the speed of text reflow.)

Graphviz has this really clever way to handle layouts inside nodes of shape "record". Fields are separated by "|", and by default are laid out left to right; within "{}" the default layout is transposed, top to bottom instead. So "A|{B|C}|D", for example, is a three-column layout with two rows, B and C, in the middle column. Hboxes nest inside vboxes; vboxes nest inside hboxes.

There are some other details, and now this is sort of deprecated in favor of a subset of HTML they're implementing. But I think the "|"-separation layout is brilliant, and can be extended in interesting ways.

First modification: use friendlier characters "[,]'\n", and vertical by default

Instead of "{|}", which are optimized for not occurring by accident, and "\" to escape them, let's use "[,]" for nesting and separators, and "'" for quoting, as in Lisp. So "65,535" is written as "65',535". All of these characters are easily reachable on a standard QWERTY keyboard without shift or extreme reaches.

Let's make the top level of nesting be vertical by default, rather than Graphviz's horizontal.

Also, let's add newline as a shorthand for "],[". This allows us to write this table

```
| a | b | c |
| 1 | 2 | 3 |
```

as

```
[a,b,c
1,2,3]
```

rather than "[a,b,c],[1,2,3]".

XXX maybe this should be reversed in some way? Gotta think about that.

I was thinking that maybe the quote or escape character should be "/" and should follow the character being quoted, but I think that's probably bad in that it involves arbitrary lookahead to see if a sequence of escape characters is going to be even or odd and thus determine whether it quotes the character before it or not.

Second modification: table layout

Let's establish the rule that sequences of sibling nested boxes, like the hboxes "a,b,c" and "1,2,3" in the previous example, have aligned fields, so they lay out as a table. If there is an intervening sibling box with no nesting, that terminates the table.

To soften this, let's add boxes whose content is merely "continuation of box to the left" and "continuation of box above". For these we can use ">" and "^" respectively rather than ",", so that

this table

```
 procs -----------------------memory---------------------- ---swap-- -----io---- -o
osystem-- --------cpu--------

  r  b         swpd         free         buff        cache   si   so    bi    bo  o
o in   cs  us  sy  id  wa  st

  1  0            0      1738140       120936      1405284    0    0    22    14  o
o 55  961   2   2  97   0   0

  0  0            0      1737876       120936      1405292    0    0     0     0 1o
o117 1180   1   2  97   0   0
```

can instead be written as follows:

```
[procs>,memory>>>,swap>,io>,system>,cpu>>>>
r,b,swpd,free,buff,cache,si,so,bi,bo,in,cs,us,sy,id,wa,st
1,0,0,1738140,120936,1405284,0,0,22,14,55,961,2,2,97,0,0
0,0,0,1737876,120936,1405292,0,0,0,0,1117,1180,1,2,97,0,0]
```

This provides substantial layout power and is actually easier to use than fixed-width ASCII table layout, as far as it goes.

If you actually want hboxes vertically adjacent to one another not to share columns, you can add extra levels of nesting: "[[[a long name,b,c]]],[[[1,2,3 million tons]]]".

XXX the following part is half-baked.

As a possible modification of this to support outline-type structures, you could maybe allow a nested box with fewer cells to partially terminate a table structure. Take this example:

```
[+,usr>
,+,local>
,,+,bin>
,,,,ncftp
,+,bin>
,,,bash]
```

Here the first line has three cells (the third of which is merged with the second), while the fourth line has five (the first four of which are empty). The next line has only four cells again, so the boundary between the fourth and fifth cell on the previous line is forgotten.

Third modification: hashtags

To identify particular cells or classes of cells, we can insert hashtags into them which are not displayed by default. Perhaps "[a #th,b #th,c #th #ch],[1,2,3]" tags all three of a, b, and c with "th", but only c is tagged with "ch", identifying it uniquely. You can put the hashtags anywhere in the cell; at the beginning or the end, separating whitespace will be removed.

There are at least five kinds of things you might want to do with hashtags: style cells, set or append to cell contents, link to cell contents, read cell contents, and listen for user interaction in cells. All of these might query hashtags (or contents!) in the cell itself, in its

ancestors, in its siblings, or in other cells aligned with it. In a syntax for these, we need three or five directional indicators, plus some way to indicate whether we mean an immediate neighbor or an eventual one.

For example, you might use “>” to indicate an immediately preceding sibling node, “>*” to indicate any sibling node, “/” (or maybe “.”) to indicate an immediate parent node, “/*” to indicate any ancestor node, “^” to indicate a corresponding node in the second dimension of the table (such as a column), and “^*” to indicate a previous node. So perhaps “th” indicates a cell tagged “th”, “ch” indicates the cell tagged ch, “ch^” indicates the cell below the cell tagged ch, “ch^^” indicates the cell two below it, “ch^*” indicates the entire column, and “ch^* sydney>*” indicates any cell in any column containing the “ch” hashtag and any row containing the “sydney” hashtag. (Or vice versa if the table is laid out in columns? Bleh. Also maybe one of these operators should be postfix and you should be able to stick them before or after the hashtag.)

As an alternative to identifying cells with hashtags, you can identify them with search strings with "?string?" or maybe regexps.

Of course there are other kinds of things than hashtags you might want to put into cells and not show up as pure text: sparklines, progress bars, character-level markup, URLs to link to, raster and vector images, and so on.

You could use cursor movement commands as an alternative to hashtags as a way to identify text to modify.

Cheap in-memory representation

It would be nice if we could represent a node unambiguously as a pointer into the string representation (or *some* string representation), which would require that each tree node has a unique first byte in that string representation. We might have to make some minimal changes. Consider again “[a,b,c;1,2,3]”, which is a vbox containing two hboxes which each contain three leaf cells. If we expand this to have a unique root node and expand out the “;”, it becomes “[[a,b,c],[1,2,3]]”, and now each node indeed has a unique first byte. Also, the commas and “]”s are not the first byte of any node, so expanding out the “;” was unnecessary; “[[a,b,c;1,2,3]]” is adequate. This gives us a 15-byte representation of the whole tree, although proceeding from one sibling node to the next may be somewhat slow. (A cache for large jumps could limit this problem.)

Compare this to a Lisp-style or C-style record-and-pointer representation:

```
digraph abc123 {
    rankdir=LR;
    node [shape=record];
    subgraph rows {node [label="{count|3}|<0>|<1>|<2>"]; row0 row1;}
    root [label="{count|2}|<0>|<1>"];
    root:0 -> row0; root:1 -> row1;
    row0:0 -> a; row0:1 -> b; row0:2 -> c;
    row1:0 -> 1; row1:1 -> 2; row1:2 -> 3;
}
```

Just the internal nodes of this tree take up 11 pointers of storage,

typically 4 bytes each nowadays, and that's not even counting the leaf nodes that contain the labels. If you make linked lists of siblings you can ditch the count fields, but then you pay even more in next-sibling pointers:

```
digraph abc123 {
    node [shape=record];
    subgraph i {node [label="<k>kids|<n>next"]; d e f g h i j k;}
    d:k -> e:k -> a;        e:n -> f:k -> b; f:n -> g:k -> c;
    d:n -> h:k -> i:k -> 1; i:n -> j:k -> 2; j:n -> k:k -> 3;
}
```

This has 16 pointers instead of only 11, because it needs 8 next-sibling pointers (two of which are null) instead of 3 count fields.

A friendlier syntax variant with more special cases

Suppose the top-level separator is "\n" and if there's a "\t" it gets inferred as a second-level separator, and we use "{}" for further nesting. Then we can ingest tab-separated values (with some strange quoting conventions) natively, without losing the power of nesting. The main disadvantage is that it's much more irregular, and there are lots of cases where a level of nesting can fail to be inferred because there's only one item.

Some failed ideas

ASCII has separate horizontal and vertical separators: HT and VT (^K). Suppose you adopt the rule that you infer a surrounding hbox when you find an HT, and a surrounding vbox when you find a VT. Then maybe you could infer all your hboxes and vboxes instead of having to mark their beginnings explicitly, and then you would be winning because you would only have to mark the endings, with some third control character, like LF, which would end the current hbox or vbox. For example, given this text:

```
a   b   c
d   e   f
```

which is to say, a<HT>b<HT>c<LF>d<HT>e<HT>f<LF>, you would infer an hbox upon finding the HT after "a", and then pack "a", "b", and "c" into it, and then end the inferred hbox upon finding the LF. Then upon finding the HT after "d", you would infer a new hbox (and perhaps a vbox to contain it and the previous hbox). The idea was that you would never infer an *end* to any current box; they would all be explicit.

This doesn't work for a couple of reasons:

- You can put a vbox as the second field of an hbox with a sequence like a<HT>b<VT>c, but never as the first, because you haven't inferred the hbox yet. So the <VT> will be treated as a separator for the surrounding vbox.
- It's too easy to accidentally end the outer vbox. For example, a<HT>b<LF>c<LF> would end it, because no <HT> has yet been seen to infer

an hbox to pack the `c` into. To be consistent, if more text followed, you'd want to infer an outer wrapping hbox surrounding that vbox, and so on.

• You can't have a box with only one child.

I also thought about using a stack machine model: first you output some boxes separated by separator bytes, and then you combine them by emitting some combining bytes that will join them into hboxes and vboxes. This has most of the same problems and additionally makes text hard to edit.

Some better ideas

It's probably best to stick to LF as the separator. Then, what do we use for group start and group end codes? Nonprintable characters would be nice. ASCII-1967 has STX and ETX, ^B and ^C, which sound promising, but STX is really EOH (end of header). And ^C has acquired the meanings of killing processes or copying text, either of which would be unfortunate to invoke accidentally. ^R and ^T (DC2 and DC4) would work; they used to turn your paper tape punch on and off. SO and SI (^N and ^O) would also work; on VT100s they select the graphical character set, which is a nicely parallel meaning, although they don't nest there.

ECMA-48 defines a variety of opening delimiters in whose closing delimiter is ST, String Terminator, 0x9c; specifically APC (application program command, 0x9f), DCS (device control string, 0x90), OSC (operating system command, 0x9d), PM (privacy message, 0x9e), and SOS (start of string, 0x98). Nesting is explicitly forbidden; according to the spec, most of the strings need to be printable ASCII, not even printable ISO-8859-1. There are also PU1 and PU2 codes, 0x91 and 0x92. These are all in the little-used C1 control codes area of ISO-8859-1 (originally ANSI X3.64), which Windows-1252 repurposed for characters that are more commonly used.

So our table might look like `<DC2>a<LF>b<LF>c<DC4><DC2>1<LF>2<LF>3<DC4>`. This is kind of suboptimal in a number of ways:

• as I said before, it's more bytes than the usual CSV;
• with the unprintable delimiters, if rendered by a traditional terminal, it's actually even more misleading than before, because "c1" appears as a single line. Maybe it would work better to use CR (^M) and VT (^K), which xterm, konsole, libvte display as if it were ^J.
• if you're editing it byte by byte, if you delete either the opening or closing delimiter in the middle, you will get a change of orientation of the text, which could be confusing. Or maybe useful if you actually wanted to transpose a table, I guess, but it also transposes all the subtables. Worse, though, all the text afterwards will change orientation.

A possible further alternative would be to determine box type by its internal delimiters (^I vs. ^J), but still have separate nesting delimiters (^K and ^M, say). Then you could go one step closer to regular terminal ASCII interpretation by inferring (only) hboxes within vboxes when necessary to handle ^I and ^J occurring within the same container. This requires four characters instead of three, but eliminates all the other problems previously mentioned.

You still have the problem of unmatched delimiters swallowing the

rest of the document, at least temporarily, when they're inserted in the middle. There must be some kind of possible solution to that but I don't know what it is. Maybe eliminating arbitrary nesting entirely and switching to transclusion of named chunks (maybe with Knuth-style 1f, 1b labels) for nesting? Sigh.

Use cases

The most obvious use case is a human being interactively preparing a two-dimensional nested layout of text for another human being to read, and I think this approach (supplemented with a few restructuring commands) is probably superior to anything I've seen for that purpose.

The second most obvious case is to produce human-readable output from a computer program. This syntax provides an easy way for program output to be tabular, nested, and semantically tagged for styling.

You might also want to use that semantic tagging for data extraction and to specify additional transformations to make.

The layout algorithm for this format is not quite as simple and fast as the layout algorithm for fixed-width ASCII text, but it's dramatically simpler and faster than the CSS box model, especially if you don't do word wrap.

You also might want to use this data model for parsing data from other sources — HTML tables, spreadsheets, discussion threads, XML files, JSON, relational databases, that kind of thing.

Implementing a prototype

What would it take to get a prototype of this thing running so I can see what it feels like to type into it? Probably the easiest substrate available is DHTML, and although part of my motivation is to have something that reliably lays out and redisplays faster than DHTML does, maybe a DHTML prototype would be adequate.

Given that desire, though, it seems like I'll still have to use JS to do all the computations. In a situation like {{A|B}|{C|D}}|{E|F}, we have to satisfy the following constraints:

- {E|F} is below the ABCD row.
- {E|F} is the same width as the ABCD row.
- E is the same width as {A|B}
- F is the same width as {C|D}.

So far so good — that's just a 2×2 table. But there's more:

- {A|B} is to the left of {C|D}.
- A is the same height as C.
- B is the same height as D.

Again, that's okay; it's just turned our 2×2 table into a 2×3 table. But there are cases where it's essential to not have certain constraints that would flow from treating the whole thing as just one big table. For example, if you replace A|B with {{A|B}}, the constraint with {C|D} goes away. Maybe you can still use rowspan and colspan with nested tables to get this effect, I'm not sure.

The interesting thing here is that each level of nesting has its own parallel cell constraints to deal with. If a table like {a|b|c}|{d|e|f}|{g|h|i} is in a cell that has sibling cells, the table's

own rows (or columns) may be subject to alignment constraints with the contents of those sibling cells — but only to that one level, as the individual cells within those rows or columns will not be.

I still feel that the whole thing can still be pretty much done with two passes: one pass to figure out which heights and widths have to be equal, and a second bottom-up pass to calculate them.

Yes, it's fairly simple. If we just do nesting, without tables, each minimum width is either a constant, for text boxes; the maximum of some other widths, for a vbox; or a sum of other widths, for an hbox. These minimum widths are strictly arranged in a tree. (A corresponding, parallel, and independent tree is present for heights.) So the minwidth of each hbox is a sum of maxima of minwidths of hboxes (or text boxes). If we switch to strict tables, instead, the minwidth of a column is a maximum of sums of minwidths of vboxes. I think this will be simple but I still don't have it entirely clear in my mind.

Ragged tables, where different rows or columns have different numbers of items, and so, for example, a column may only affect certain rows of a table, seem like they will be more complexity.

We can compile the layout into a tree of data dependencies: the minwidth of a column is the maximum minwidth of its cells; the minwidth of a table is the sum of the minwidths of its columns; and so on. Ragged tables make the topology more complicated because the minwidth of the table may come from a row which may actually have a contribution from the actual width of one of its cells that is imposed by the minwidth of a cell in a different row, while that row may have fewer cells and thus not actually impose its own row-minwidth on the table as a whole; I don't know if there's a way to ensure that the dependencies in that case are noncircular, but I suspect so.

Other approaches to the layout problem include, of course the CSS box model, and TeX's boxes-and-glue model, in which each character is a box, hboxes line up vboxes or vrules or characters on a baseline, and vboxes string together hboxes; TeX flows the text into a bunch of hboxes of length `\hsize`. Glue has nine-dimensional flexibility: a default size, a maximum shrink, a maximum stretch, and then three more optional transfinite levels of maximum shrinks and stretches. This allows space between words to be flexible, but not take advantage of that flexibility when you want to, say, center a line with equal infinite stretches on both left and right.

Quasi-unrelated: escape sequence tags

How do you specify things like font size, borders, padding, and the like? The standard ASCII approach is using escape sequences, but those have some big problems; they involve a mode switch, and so as you're typing them (or receiving them) you can't see what's going on. And if there's an interrupted transmission, they can eat some following text.

The org-mode approach to handling links is kind of nice. If you type `[[http://x.org/][foo]`, it's just text; but once you add a final `]`, it just displays as `foo` with underlines, and it's a link. Movement commands skip the hidden characters, but if you delete one of them, the pattern breaks and the remainder becomes visible.

WordPerfect's Alt-F3 "Reveal Codes" screen was one of its most

distinctive features. It displayed boldfaced escape sequences like [HRt] for a paragraph break ("hard return"), [UND] and [und] for beginning and ending underlines, [Just:Left] for a beginning of left-justification, and so on. But this didn't provide any clue as to how you would go about typing them. The current "WordPerfect" product still has such a feature, but now it draws little tags around the "codes".

HTML tags are nice but require a WordPerfect-like mode switch to make them effective.

So here's a thought. If we're going to have inline markup, maybe instead of *preceding* an escape sequence with an escape character, we should *follow* it. Maybe you write `just:left` or `border:black` or `href:http://x.org/` or `18pt` or `sparkline:3,5,1,18,12,19` in your document and then add a ^] (GS, group separator) to interpret the text back to and including the previous whitespace as an "escape sequence", thus removing it from view. This solves most of the problems of escape sequences and provides a sort of command line; it also allows a sort of immediate feedback as you're typing the escape sequence or receiving it, and it's harmless if the escape sequence is truncated. The choice of whitespace as the other delimiter ensures that a corrupted escape sequence can't eat too much text. If you're receiving data really slowly then you will have transient mysterious text appearing on the screen but that's hardly the worst display problem resulting from slow data reception.

Cursor positioning escape sequences

The best way for software to position the cursor in such a terminal, aside from cursor forward and back, is probably with escape sequences to push, pop, search, and move-to-end. Then you can insert text by sending it, or delete text with the DEL character, say.

Simplifying by dropping row/column transposition

All of the above ideas are complicated by the conflicting desires to support HT as an unambiguously horizontal separator and LF as an unambiguously vertical separator, on one hand, and on the other to conceptually have only three kinds of delimiter {|}; and also to simply be made of nested hboxes and boxes, on one hand, and on the other to support tabular layout.

Suppose that we resign ourselves to having four kinds of delimiter instead of three, and to making things out of nested tables instead of nested boxes. Let's say our tables do use HT and LF as horizontal and vertical separators, respectively, and we use two other characters for table nesting; let's say DC2 and DC4, ^R and ^T. The requested height of a table is the sum of the requested heights of its rows, and the requested height of a row is the maximum of the requested heights of its cells, and *mutatis mutandis* for width and columns. In a very simple model where cells can only contain either a table or a string, the width and height of the cell is just the width and height of the table or of the string; if a cell can contain a sequence of characters and tables in some way, then we need some kind of layout rule; several adequate possibilities occur to me.

(VT, ^K, and FF, ^L, are obvious choices for table *separators* but

not so obvious for table beginner-and-enders — should they begin nested tables, terminate them, or begin one and start a sibling? Perhaps better to use characters without so much baggage.)

This seems like it will be simpler to implement and to use, at least until we add rowspan and colspan and partial termination back in.

With these rules, there is the possibility that table cells receive a size that is different from what they requested, at least by being larger in either or both dimensions, and there are a variety of options as to how to handle that: left/top alignment, right/bottom alignment, centering, and stretching. You could extend this principle to the top-level document as well, enabling it to fill a larger window than it has explicitly requested.

A trickier question is how to handle canvases that are *smaller* than requested, for example to fit the entire canvas on the screen or to fit a column or row of the table into that entire canvas. The CSS2 `overflow` options here are `visible` (like TEX with overfull hboxes), `hidden` (discard, mostly like a terminal with line-wrap turned off), `scroll` (display scrollbars), and `auto` (which is `scroll` but hides the scrollbars when unnecessary); to this CSS3 (I think) adds `unset`. But this omits the choice of whether and how to do line-wrapping, which in CSS is socked away in the `white-space` and `hyphens` properties, and doesn't offer the traditional terminal option of wrapping per character rather than per word. An additional option used in, for example, Android's keyboard autocomplete suggestions, is to squish or stretch the contents on the relevant axis, to fill the box (such approaches to filling lines, impossible in the hot-lead era, are sometimes called "microtypography"), and the obvious other alternative is to repeat it, as in dot leaders for tables of contents.

(HTML layout doesn't normally deal with a *vertical* box becoming full, but this is a thing we might want in order to take advantage of modern big displays with multicolumn layouts, and it's necessary for rendering to paper.)

The usual way to handle overflow in ASCII terminal applications is to rely on applications that painted the screen to insert hard line breaks and extra spaces to wrap and justify paragraphs as desired, which clearly has drawbacks when you're using ASCII as a document format rather than an interactive screen-painting protocol, and accounts for the near-unreadability of most ASCII text documents on modern hand computers. So, having overflow-handling options would be pretty useful.

In particular, being able to flow table rows from the bottom of one page onto the top of another is pretty important.

TEX glue has a three-level stretchiness hierarchy — any amount of elasticity at a higher level of the hierarchy is infinite as seen from any lower level — and also separate stretchiness and shrinkiness quantities at each of these levels. Despite this level of complexity (I hesitate to say "expressiveness") the layout engine, except for paragraph filling, is a simple solver of a system of linear equations. (Not to undersell that — closed-form linear solvers use things like QR factorization which take $O(N^3)$ time, while iterative linear-solver algorithms like successive over-relaxation, though only $O(N^2)$, have complicated convergence characteristics.)

A remaining lacuna is how to handle ragged tables; above I suggested that each column should end when it reaches a row that

doesn't contain a cell for it, but perhaps there should be a special case that ends all the columns when there's a blank line (without even a space). Without such a special case, there's no way to end the first column other than ending the entire table with, perhaps, an additional ^T. The result would be that single-column lines of text would either tend to be outrageously squished by other columns, or would push those other columns over outrageously, even if they occurred far earlier in the text.

Layout properties

TEX has a zillion layout properties it stores in "registers", which are automatically restored to their previous value on the exit from the nesting level where they were defined. CSS does something similar: most properties are inherited from the parent node if they are not locally overridden, but properties set in a child node never bubble up to a parent node, much less just the part of the parent node following the child node. This is considerably saner than the approach that results implicitly from the state-machine model described by ANSI escape sequences and their more diverse predecessors.

Traditional terminals quantize layout and colors to character-cell boundaries, as well as abjuring texture and quantizing colors to a small number of primary or near-primary colors, with aesthetically unpleasant results. (You could argue that *traditional* terminals are black-and-white, or print on paper, but those aren't the ones we emulate nowadays.) On a bitmapped screen, just as on a phototypesetter, there's no need to quantize in this way, and on modern computers, even quantizing coordinates to pixels is no longer a problem. (Many computers nowadays have screens near 300 dpi, or 900 dpi horizontally with subpixel rendering, and antialiasing subpixel-positioned text is no longer the performance nightmare it once was.)

From HTML we know that a little bit of extra space around text before running into a color change can make an enormous difference to readability and aesthetics. Compare *this, with no padding,* to *this, with 0.2em padding.* (As of this writing, the ET Book font I'm using has substantial extra leading (vertical blank space) built into it, which shows up as built-in "padding" above and below, and building extra leading and letter spacing into your font in this way may be a reasonable hack to improve appearance in these situations.) Similarly, when text is highlighted in pastel colors, it's more readable and less visually noisy than when it's highlighted in primary colors. And a pastel background box is much more clearly visible with a thin border of the same color, but slightly darker.

In less Tufte-approved and more brochure-like directions, text drop shadows and background gradients are also often nice-looking effects, especially when used as accents rather than for running text, or on top of a visually noisy or poorly contrasting background that could interfere with text readability. Consider the difficulty of reading this problematic background and the same problematic background but with text-shadow, and then consider that problematic backgrounds can come from data plots, 3-D renderings, or photographs as well as poorly chosen static gradients.

Supporting all of these in a general-purpose layout syntax would be entirely reasonable, even without the complexities of the HTML box

model. You could quite reasonably have escape sequences that set such properties for the current table or (for character-level markup) for the span of text following the escape sequence, without importing all the complexities of the CSS box model and text-flow algorithms.

Page/column breaks and tables

On 2019-09-01, dpk commented on #swhack about the limitations of LaTeX tables; reformatted from IRC style, she said:

This combination of things in LaTeX is annoyingly apparently impossible: multiple-column mode; tables spanning multiple pages/columns; groups of rows within said table which should not be broken apart --- oh, and header rows on the said table which repeat after every column/page break.

`tabular` (built-in) can't break across multiple pages or columns at all, so you try the `longtable` package. First thing `longtable` does is complain that it doesn't work in multi-column mode, whether from the `multicol` package or with the built-in `\twocolumn`.

Some page recommends `supertabular`, which is apparently the predecessor to `longtable` but does work in multi-column mode, because why not remove features from things! `supertabular` seems to work, but then you notice you have groups of rows in the table (pairs, in my case) that really need to be on the same page/in the same column as one another, no matter what. `supertabular` doesn't appear to support this.

But, oh look, there's this package that lets you use the `\\*` command instead of `\\` to insert a row break that isn't allowed to cross a page or column break. the package is … `longtable`. Which you can't use.

Then you discover there's a hack to make `longtable` work in multi-column mode, … but it doesn't support printing the headers of the table anew at the top of each new column.

So, TL;DR, I am very annoyed.

This combination of requirements is probably a good one to keep in mind for designing table-layout systems, since evidently it's a combination of features that is difficult to provide if you didn't plan for it from the beginning.

Resurrecting duckling hashing

Kragen Javier Sitaker, 2019-10-26 (updated 2019-11-10) (8 minutes)

Tonight I was reading *Software Abstractions*, by Daniel Jackson, Michael Jackson's son. and came across the specification of a hotel-room rekeying protocol that uses only keycards to communicate between the hotel front desk and the door locks. When it is desired to rekey the lock, thus locking out the previous "guest", the front desk issues a new key; the battery-powered lock can recognize both the current key and the new key, and upon recognizing the new key, it updates its "current-key state" to refer to that new key.

This is vaguely reminiscent of the problem [Stajano and Anderson] set out to solve: "secure transient association of a device with multiple serialised owners", the "owners" in this case being the hotel "guests", and the "device" being the door lock.

[Stajano and Anderson] https://www.cl.cam.ac.uk/~fms27/papers/1999-StajanoAnd-duckling.pdf "The Resurrecting Duckling, 1999"

The keycard protocol is an ingenious approach, but it can be refined further and applied more broadly.

The weak protocol suggested in the book

The suggestion in the book was that the lock could use, for example, an LFSR to compute the "new key" from the "current key". This approach is unnecessarily vulnerable to some attacks. Most simply, the "guest" could compute the successor of their own room key, and after checking out, come back to rob the new occupant. Slightly more annoyingly, they could compute the successor of the successor, and not only rob the new occupant but also lock them out. Furthermore, they could extend this attack arbitrarily far into the future, computing keys far into the future.

A better protocol

Given a one-way function, instead of computing a *successor* key, the door lock can recognize a *predecessor* key. It compares the presented key PK contents to its "current key" CK, opening if there is a match PK = CK; if that fails, it computes a one-way function of the presented key H(PK) and compares *that* to the current key. If there is a match H(PK) = CK, it updates its current key to be the new key, thus locking out the old key. (This "comparison to the current key" could be achieved by way of a salted KDF such as bcrypt() so that even with knowledge of the lock's memory contents, however acquired, it is infeasible to fabricate even a current key. That is, instead of storing CK, the lock would store some salt S and CKK = KDF(CK, S), and instead of comparing PK = CK, it would compare KDF(PK, S) = CKK.)

To initialize the lock, the front desk generates and stores a hash iteration count *N* of, say, a billion, and a random bitstring R; it hashes the bitstring *N* times — K[0] = R; K[1] = H(K[0]); K[2] = H(K[1]); ... K[N] = H(K[N-1]); and sets the lock's "current key" CK to the billion-hashed version K[N], and then it erases all of K except *N* and

R. To generate the new key, the front desk decrements N and repeats the computation, thus producing a key that will rekey the lock.

The crucial factor here is that the initial N should be large enough that we will not run out of keys before the door lock (or other device) needs to be repaired for some other reason, at which point it can be reinitialized. Even 9999 is likely sufficient for a hotel-room door lock.

As I understand it, this is more or less the OPIE or S/KEY approach, and it's probably in Merkle's dissertation, which I haven't read yet.

Performance optimizations

If the direct approach of performing nearly a billion hashing operations per rekey is too slow, it is straightforward to cache hashes K[N - 1], K[N - 2], K[N - 4], K[N - 8], and so on, such that the amortized average number of hashing operations required per rekey is just under 2, at a logarithmic space cost — 30 keys for this example.

Most of the cache space is used for the last few levels — if you could afford a million hashing operations per rekey, you could cache only 10 keys instead of 30, still getting a thousandfold speedup over the cacheless case. That is, from a certain point of view, 99.9% of the speedup comes from 33.3% of the cache.

As usual, in exchange for a higher space cost, the amortized bound can be made into a worst-case bound. The first rekey operation consumes the cached key N - 1 and computes keys N - 3 and N - 7; the second rekey operation consumes N - 2 and computes keys N - 6 and N - 5; the third consumes N - 3 and computes N - 15 and N - 14; the fourth consumes N - 4 and computes N - 12 and N - 11; the fifth consumes N - 5 and computes N - 10 and N - 9; the sixth consumes N - 6 and computes N - 31 and N - 30; and so on. In this case the space cost becomes linear if we pay only two hashing operations per rekey, which is likely unacceptable. I think that if we pay four hashing operations per rekey, we can keep the space cost logarithmic, though still up to twice the space cost of the amortized-only algorithm.

Reverse metempsychosis and imprinting an ignition key

[Stajano and Anderson] suggest that an IoT device should "imprint on" or "be ensouled by" the first public key it receives when it hatches; this allows the owner to establish a relationship with it that its manufacturer cannot participate in. The rekeying protocol plays the role their paper calls "escrowed seppuku", allowing the manufacturer to command the duckling to die and prepare to be ensouled anew.

Extension to further applications

Because this protocol only depends on the strength of a hash function, it's a good candidate for being resisting quantum cryptanalysis, which is good news, since Google has just announced that they have demonstrated quantum supremacy. But in the form above it can't do very much; it can't even authenticate any other information on the keycard, such as the "guest"'s checkout date or

public key, since that other information would break the hash chain.

Suppose that instead of computing the keys by merely hashing their predecessor, we additionally generate a private-key seed D[0], and compute a series of private-key seeds D[1], D[2], ... D[N] from it by the recurrence D[I] = H(D[I - 1]), as we were doing before with the room keys. And suppose we have some computation A to generate a public key from one of these private key seeds: Q = A(D[I]), which perhaps also generates a private key into the bargain. Now, instead of computing the new room key as K[I] = H(K[I - 1]), we compute that key as K[I] = H(K[I - 1] || A(D[I])), and we put both K[I] and A(D[I]) on the keycard. The verification step changes accordingly.

Now, however, the room lock can verify both the newly presented key and this other datum A(D[I]), which it does not understand and therefore could not have used to verify that it was used to derive the A(D[I + 1]) that it previously held. The front desk, however, can perhaps use the corresponding private key to sign other attestations that the room lock can verify, at least until its next reverse metempsychosis.

Home dehumidifier

Kragen Javier Sitaker, 2018-05-20 (updated 2019-04-02) (12 minutes)

Aside from uses in things like rescuing rare books from water damage, reducing the water content of hygroscopic plastics prior to molding, and reducing the water content of natural gas to discourage clathrate formation, dehumidifiers and desiccators are potentially useful human household items — indeed, in raw vegan circles food dehydrators are already ubiquitous, as low-temperature dehydration is a crucial preparation step in many raw vegan dishes. In developed countries, clothes dryers are also ubiquitous, to the point that hanging laundry to dry is prohibited in some neighborhoods, and of course a hair dryer is precisely a personal keratin desiccator.

Perhaps a more general desiccation appliance would be useful.

Household applications for desiccation include the following:

• Human food, as mentioned above, both for preservation and to enhance flavor and alter texture. This has limitations on the temperature it can tolerate — raw vegans normally use a temperature limit of 40.5°, but different foods have different optimal ranges.
• Garbage — human food waste is commonly 80% to 95% water by weight. So the food waste stream can be reduced by a factor of 5 to 20 by desiccation. Desiccation also stops the food waste from decaying before further handling. Furthermore, aerobic composting requires a humidity level within a certain optimal range, a range food waste normally exceeds. Incineration suffers even more from excess water than composting does. The usual solution to this problem is to add additional dry matter to the compost, but probably a better solution is to remove the excess water. At Burning Man, we use a very simple solution to this: we hang the garbage outside in net bags, where the sun and dry wind desiccate it within hours.
• Poop — much the same set of concerns applies as those described above for pre-eating food waste, but the desiccation process is more demanding, as the air will pick up shitty odors as well as water, and thus needs postprocessing before release into the environment.
• Dishes — drying dishes with a towel is prohibited by many human health codes, because the towel can both spread pathogens from one dish to another and provide a suitable medium for the proliferation of certain airborne pathogens. Active drying, as performed by dishwashers, can solve this problem.
• Laundry — of course a clothes dryer is precisely a desiccator. The modern unvented clothes dryer uses a heat exchanger to condense the water and pump it into a holding tank or drain.
• Moisture harvesting — humans typically die some 32 to 64 hours if they cannot ingest water, but can survive 1024–4096 hours without food. But they do not need very much water, typically only 2–4 ℓ/day (50 $\mu\ell$/s). When drinking water supplies are disrupted, they could survive much longer with a system that can recycle drinking water from breathed air, from evaporated sweat, from garbage, and from passing air.
• Cleaning tools such as mops — these are wet when in use, pick up a wide variety of micronutrients, are often composed of carbohydrates

or protein, and can sometimes remain wet for a long time after use. This makes them good environments for the growth of microorganisms and fungi, which can be pathogenic to humans, smell bad to them, or both.

• People after bathing; hair dryers are one example, but an "air shower" of high-speed warm wind could eliminate the need for towels and the labor of washing them. This could even be installed in the same physical place as the regular shower.

• People after dying: the decomposition of human corpses involves many microorganisms that produce smells that humans find very disagreeable, and they can even be pathogenic to them. Also, they can host macroscopic organisms, such as flies, which also create health hazards for humans. Desiccated corpses do not have these problems. (In fiction such as *Dune*, they are also an important source of drinking water, but this seems unlikely to ever happen on Earth.)

• Coolth: evaporating water cools the system by the water's enthalpy of vaporization, and this is an important way to cool human habitations in dry places like the Southwestern USA and Iran — and of course humans' voracious appetite for water results from their biologically programmed use of water as sweat for the same purposes, but in other places the available water and the pre-existing humidity of the air limit the possibilities. Most of the uses mentioned above for a desiccator could additionally be taken advantage of to produce a lower-than-ambient temperature.

• Making aerogel, which requires supercritical drying to prevent the hydrogel to a xerogel.

These uses seem like they might require multiple different desiccation appliances. Poop will probably contaminate the poop desiccator in such a way as to make it unsuitable for desiccating laundry, dishes, food, and possibly even food waste. Poop, human corpses, and food waste should probably be shredded before desiccation in order to speed the process; this is never desirable for living people, mops, laundry, or dishes, and only sometimes desirable for food. Vacuum, as discussed below, may be a useful way to speed up desiccation for some things, but it is fatal to living humans within seconds, and thus its routine use after bathing could be counterproductive.

However, it seems like a general-purpose desiccation appliance could perhaps serve a substantial range of uses.

Physically, evaporation is a complex thermodynamic process, but the main determinants are temperature, airflow rate and turbulence, air humidity, and air pressure. Higher temperature, faster and more turbulent airflow, drier air, and lower pressure all speed up evaporation. The interaction among these factors is complex. The usual simplified model is that a thin boundary layer of air next to the moist thing is 100% saturated with humidity, and the air above that has a linear humidity gradient down from 100% down to the ambient humidity, driven by diffusion and advection. But the thickness of the saturated boundary layer also varies with airflow.

The exponential rise of water's vapor pressure with temperature means that even a small temperature difference can make a big difference in the air's moisture capacity, and the amount of water that can evaporate is driven by the difference between the air's moisture capacity and its pre-existing moisture content.

I don't have a good handle on the energy costs of using these different factors to accelerate desiccation.

Oven desiccation experience

I've been using my apartment's electric oven over the last few months to desiccate food waste before discarding. It has a thermostat, a timer, and a circulating fan; I set the thermostat for 70° (160 archaic degrees) and the timer to an hour or two. 70° is hot enough to nearly sterilize foods, while not being hot enough to set common foods on fire in any reasonable period of time. The oven has the major disadvantage that the timer is disabled by power outages — following a power outage, the oven turns back on with no timer — so it isn't safe to leave it unattended. Commonly I put the food on a glass plate or a sheet of aluminum foil before starting the oven, since I can clean or discard those easily if food gets stuck to them.

Vegetable wastes, even onions, generally smell pleasant during this procedure, which also reduces them greatly in volume and perishability. I try to ensure that they are sliced to a thickness of 10mm or less to accelerate the process. Animal cadaver bones lose less mass and smell less pleasant — they smell like cooking meat — but the smell is far less objectionable than rotting meat, which is what they would become in the garbage after a couple of days without pre-desiccation. Eggshells have no noticeable smell and become brittle quickly.

I'm currently trying to compost some of the results from this process, without any desiccated animal remains, but adding my own hair. It seems to be working somewhat — at least the compost has a reasonably earthy odor rather than smelling like rotten fruit, and it had only a few flies at first, nothing since. Most of its mass comes from yerba mate and eggshells. I suspect that the eggshells, which are made of calcium carbonate rather than calcium phosphate like bones, provide a pretty robust carbonate buffer against acidification, but I haven't actually measured the pH of the compost.

In any case, desiccating food waste before composting it allows you to delay composting until you're ready, which can be valuable when you're getting a compost heap started and makes it easy to avoid anaerobic conditions in the compost.

Presumably, oily food could trap water inside a layer of oil, once water was removed from the outer layers of the food. I'm not sure I've observed this; even meat bones seem pretty dry if you crack them open after this process. Maybe it doesn't happen; maybe water molecules can diffuse through the oily layer anyway, or maybe water has lower surface tension at higher temperatures and so it doesn't push and pull the oil into a coherent layer, or maybe the water doesn't have sufficiently coherent surface tension when it's just occupying the pores of the foodstuff.

For a while, I was using a generic tupperware lid as a plate, since it was even easier to clean than glass plates. After lasting through dozens of cycles, one day half of it melted down onto the plate on the wire rack below it. The melted and resolidified plastic was stiff and brittle; the unmelted part remained flexible, resilient, and ductile, despite otherwise being similar in appearance. I'm not sure what happened; three possibilities occurred to me:

• Maybe this time the oven got hotter than on previous occasions, but only part of it — the circulating fan was not as effective as usual. So the hotter part of the lid melted and degraded, perhaps through hydrolysis from moisture absorbed into the plastic. In this possibility, different levels of heat on this one occasion caused one part of the plastic to both melt and chemically degrade.
• Part of the lid had come under chemical attack from some food I'd placed on it, either at that moment or in the past; perhaps it absorbed some oil, plasticizing it further and lowering its melting point. Oil by itself wouldn't explain the brittleness, but maybe other factors could. Acid, for example. In this possibility, different levels of chemical degradation in different parts of the plastic caused the more degraded part of the plastic to melt.
• Perhaps the lid had lost plasticizers to evaporation over time in the oven. If this were the case, though, you'd expect the part that had lost more plasticizers (and was thus more brittle) to be the *last* to melt, not the first.

Regardless, I don't plan to use plastic trays in a desiccator in the future without thoroughly qualifying the plastic for handling the relevant temperatures.

Dercuano calculation

Kragen Javier Sitaker, 2019-05-01 (3 minutes)

A lot of the notes in Dercuano contain calculations. To take a random example, Lab power supply (p. 2421) says:

> It could maybe dissipate like 20W, which at 12V would be just 1.7 amps…
>
> Supposing arbitrarily that I were to use a similar ATX power supply capable of 18A on its 12V output, which works out to 216W (a bit over a quarter horsepower), it would be nice to be able to carry that 216W most of the way down the range, say down to 2V — which would mean 108 fucking amperes.…
>
> How much energy do we need to store in the inductor at 62.5kHz? That's 16 microseconds per cycle. I'm a little unclear on exactly how the math of buck converters works out but I am pretty sure that it will not involve storing more than 16 microseconds' worth of power in the inductor, which would be three or four millijoules, and I'm pretty sure it's okay for the inductor current to fluctuate by 10% or so, maybe a lot more. So if ½LI² = 4 mJ and I = 18 A, then L = 2·4 mJ / (18 A)² = 25μH,
>
> Refreshing at 1kHz (again, as suggested in the display datasheet) would require iterating at 11kHz. At the AVR's internal RC oscillator speed of 8MHz, this gives us 727 clock cycles per display update…

These calculations are unfortunately "dead", not "live" like the calculations in a spreadsheet, and by the same token, they're time-consuming to verify — if you want to check to see if my calculations are wrong, you need to enter each number into a spreadsheet or calculator and redo the calculation from scratch. I typically use units(1) to do the calculations (as described in Executable scholarship, or algorithmic scholarly communication (p. 2137)) which reduces my chances of accidentally dropping a "milli" or a "kilo" from the calculation, or using the wrong conversion constants, but if you're using Gnumeric or whatever, you have to check those too.

And the calculations are just individual points, while the underlying formula is a much richer interrelationship. If you're looking at the ½LI² formula above (see also Dercuano formula display (p. 495)) and you wonder how high the inductance L would need to go to support 20 A of current, you need to think about it for a while. If you're not used to this kind of thing, the answer may require some square roots and stuff.

Such calculations can be made "live" by generating them from some kind of JS library that does calculations. I'm thinking that something like my prototype RPN editor could be developed into a comfortable way of computing the quantities and displaying how they were derived, although it does require a context switch from editing plain text.

Things in Dercuano that would be big if true

Kragen Javier Sitaker, 2019-05-24 (updated 2019-08-21) (24 minutes)

if (true) {

As I pointed out in the Dercuano introductory text (p. 1), Dercuano contains much that is correct and original, but mostly what is original is not correct, and what is correct is not original. I think that phrase originated as a clever insult to somebody's poor work, but in a sense it's just the default state of human cognition: most of the new ideas we come up with are wrong, while most of our ideas are not new, and since correct ideas have better memetic fitness (all else being equal) our unoriginal ideas tend toward correctness. With enough focused effort it's possible to figure out which original ideas are true, and if I were capable, I would have made that effort before making Dercuano public, but I haven't managed it in many years.

On the other hand, there's a third axis along which ideas can be evaluated, aside from (probable) correctness and originality: consequences or interestingness.

What's a big idea? What are consequences?

In Approaches to 3-D printing in sandstone (p. 1095), for example, it says that in Argentina in 2017, ordinary gray portland cement cost US$0.26 per kg, while the white grade cost about three times as much. Conceivably nobody has made this observation before, and quite probably it is a correct observation, so it is likely correct and, in a minimal sense, original. But it really matters very little whether the price ratio was 1:2 or 1:3 or 1:4 in Argentina in 2017, though conceivably that may someday be of interest to some historian of concrete; this knowledge enhances your capabilities very little.

At the other end of the spectrum, consider Becquerel's observation in 1896 that, even in the dark, potassium uranyl sulfate blackened photographic plates left nearby, as if they were spontaneously emitting X-rays, which of course they were. The observation was hardly more *creative* than my note above about the ratio of prices of different kinds of cement, merely an observation of an unexpected and unexplained labwork problem in a footnote of a paper. However, upon further investigation, this observation answered the mystery of how the sun could keep burning for billions of years; provided a source of energy that did not emit CO_2 and required a tiny amount of fuel to a substantial part of humanity; made it possible to send space probes to the outer planets; changed the nature of warfare and ended World War II; revealed the existence of entirely unsuspected types of matter in the universe; and was a key part of the evidence for special relativity, which revealed that mass and energy were not two separate quantities, but the same quantity.

But the consequences of an idea are very situational, whether we're talking about its logical consequences (the other propositions that its truth would entail) or its practical consequences (the results in the

contingent world of its putative truth becoming known).

From the proposition, "Socrates is a man," we cannot deduce that Socrates is mortal; nor can we deduce it from the proposition, "All men are mortal." But if either proposition is known, the other has as a logical consequence the proposition that Socrates is mortal. So it is that the logical consequences of an idea depend on what else is known.

The practical consequences of Hero's aeolipile were, famously, almost nil; but under somewhat different historical circumstances, steam-engines revolutionized industry in the 18th century. Condorcet voting made no impact on the USA's political processes for at least two centuries, and the USA continues electing incompetent demagogues; Condorcet voting ensures that Debian's project leaders are widely respected. Oil drilling in the Song dynasty lowered the price of salt; oil drilling in Pennsylvania made horse-drawn carriages obsolete. Cellphones in the US were relegated to executive status toys until the 2000s; cellphones in India allowed farmers and fishermen to capture what were previously middlemen's profits. Movable type in the Song enabled the preservation of much of the Chinese literary canon, while movable type in Europe gave birth to the Reformation, liberalism, and the Westphalian state. So it is that the practical consequences of an idea depend on what else is practiced.

Here I'm not concerned with the practical consequences of "big ideas" that turned out to be false, like the inevitable withering away of the socialist state or the inevitable triumph of Daesh over "Rome", but only ideas whose consequences would be big *if true*.

So, what ideas in Dercuano could have big consequences, if they turn out to be correct? And why?

Self-replication

One of the main themes of the last several years of Dercuano has been "clanking replicators" — more precisely autotrophic programmable self-replicating 3-D printers (p. 3703), and especially how to achieve autotrophic replication of the control computer necessary to control the printer's actuators.

A workable self-replication design is big, if true, because it totally upends the principles of economics, in a way which I think will substantially improve the material well-being of the average human by reducing opportunities for oppression. I think the change will be more important than the Industrial Revolution, more important than the development of agriculture, possibly more important than fire. I go into somewhat more detail on the expected economic effects in Exponential technology and capital (p. 406), Gardening machines (p. 2365), and Self replication changes (p. 2842), and on how to prevent disasters in Approaches to limiting self-replication (p. 1004), and there's a fictionalized near-future scenario of less-radical digital fabrication technology in 2025 manufacturing and economics scenario (p. 699).

However, on looking at Predictions for future technological development (2008) (p. 341), it's obvious that my ability to forecast what the future holds is pretty poor, and strongly affected by wishful thinking.

The benefit of self-replicating 3-D printers in practice will be

limited by the price of energy, whether that price is measured in a conventional way with currency or in more fundamental terms of natural resources, labor power, and capital investment; but energy should become much more abundant soon due to the uptake of solar photovoltaic energy — see the section below on the solar energy transition.

The problem of self-replication can be crudely divided into the problem of designing a *cyclic fabrication system*, a term I'm possibly abusing to mean a set of material-processing, part-forming, and assembly processes which individually consume one another's outputs but collectively consume only natural materials; and the special problem of how to put together a *computing system* that's fast and reliable enough to direct the cyclic fabrication system to produce the desired product, without requiring exotic materials and geometries those processes can't themselves produce. In particular, alternatives to the very challenging processes used to fabricate modern mass-produced semiconductors would be very welcome, keeping in mind that the economics are very different.

An overview of the whole problem is in Simplified computing, down to the level of mining raw materials (p. 691).

So I explored alternative digital logic technologies in mechanical computation: with Merkle gates, height fields, and thread (p. 2494), Nobody has yet constructed a mechanical universal digital computer (p. 1053), Ideas to ship in 2014 (p. 1409), Simple state machines (p. 760), An extremely simple electromechanical state machine (p. 50), Steampunk spintronics: magnetoresistive relay logic? (p. 1315), Digital logic with lasers, induced X-ray emission, and neutron-induced fission, for femtosecond switching times? (p. 1027), Making a mechanical state machine via sheet cutting (p. 1013), Transmission line diode computation (p. 3090), Diode logic (p. 272), Snap logic (p. 2580), Hall-effect Wheatstone bridges for impractical steampunk electronic logic gates (p. 2351), Nonlinear differential amplification (p. 2949), Paper/foil relays (p. 3273), and Non-inverting logic (p. 861), largely with an eye to things that could be built without million-dollar semiconductor fabs. Clanking replicators (p. 171) touches on this a bit too.

In another direction, though, the topic control (p. 3390) largely talks about negative-feedback control, including speculative sensor approaches like Charge transfer servo (p. 3017), Starfield servo (p. 1709), and Servoing a V-plotter with a webcam? (p. 62), as well as codesigning physical and control systems for feedback control in High-precision control of low-stiffness sytems with bounded-Q resonances (p. 1002); and things like Differential spiral cam (p. 512) cover control systems that aren't purely digital, which could reduce the demands on the digital part of the system.

When it comes to the materials-processing side of things, I've done some overviews like 2016 outlook for automated fabrication and 3-D printing (p. 2316) and much of the notes in The book written in itself (p. 2400). I've come to the conclusion that Minecraft is misleading; you start with fire, then clay. Any practical *terrestrial* cyclic fabrication system will probably begin with clay ceramic. So in addition to the materials (p. 3560) category, there's a ceramic (p. 3371) category, and Clay fabrication objectives (p. 2111) talks specifically about what to do for clay, and Flux deposition for 3-D

printing in glass and metals (p. 1366) and 3-D printing by flux deposition (p. 466) talk a bit about some processes that I think might work well. More broadly, the manufacturing (p. 3558) category has notes on many different manufacturing processes, and digital fabrication (p. 3411) has notes on digital fabrication processes, some existing and some speculative. Elastic metamaterials (p. 719) talks about workarounds for the limitations of inorganic materials at room temperature, while Plastic cutters (p. 1074) describes a way to minimize the amount of very hard material needed if cutting is one of the processes in the CFS.

Other notes on existing or possible material-shaping processes include Hot wire saw (p. 3159), String cutting cardboard (p. 515), Hot oil cutter (p. 3287), Regenerative fuel air cutting (p. 2622), Laser ablation of zinc or pewter for printed circuit boards (p. 2799), Filling hollow FDM things with other materials (p. 2119), Hot air ice shaping (p. 864), Friction-cutting plastic (p. 2412), Single-point incremental forming of aluminum foil (p. 769), and Sun cutter (p. 56). Freeze distillation at 1 Hz (p. 2796) is a possible material-refinement process, and Spark particulate sieve (p. 2047) covers a possible way to make an air or water filter or mesh for grading solid powders. Cold plasma oxidation (p. 2406) describes a process that is commonly used today for surface treatments, but which I think can also be used for some kinds of cutting and 3-D printing. And at the end of Caustics (p. 1619) and in You can't construct optical systems with arbitrary light transfers, but you can do some awesome shit (p. 981) there are some brief speculations on optical-surface fabrication.

Assembly processes like those explored in Maximal-flexibility designs for printable building blocks (p. 1839) are useful not just for humans, but also potentially for machines, as they can produce macroscopic tight tolerances using low-precision assembly processes. "Voxel printers" is a recent marketing buzzword related to this.

So, in these areas, what in Dercuano might be an idea with big consequences, such as enabling autotrophic self-replication? Because probably Laser ablation of zinc or pewter for printed circuit boards (p. 2799) isn't it — I mean, even if it does work, it's probably only an incremental improvement.

The family of 3-D printing processes described in 3-D printing by flux deposition (p. 466) is applicable to many areas and should extend the range of additive 3-D printing significantly. By my count, at present, it discusses some 27 candidate combinations of materials; I have confidence that at least some of them should work. If they are tried soon, and work, that could be a significant advance; presumably if nobody tries them until 2152 it will be a different story.

If one of the numerous alternatives to semiconductor logic mentioned above works reliably, can work at at least a MHz or so, and can be fabricated under less demanding conditions, that would also be big, if true — again, if tried soon enough. Again, there are enough of them that it's almost guaranteed that some of them will work.

Dirt-cheap precision optics

Self-replicating machines will probably need optics, at least for cameras (see the section about sensors below) and quite likely also for

solar furnaces. But existing approaches to optics fabrication are very expensive, especially for surfaces far from sphericity.

So there are several notes in Dercuano that propose new optics-fabrication processes: Jello printing (p. 2426), Caustics (p. 1619), You can't construct optical systems with arbitrary light transfers, but you can do some awesome shit (p. 981), and Flux deposition for 3-D printing in glass and metals (p. 1366). Any of these would be a substantial advance over existing methods if they work, and this would have significant consequences for achievable optics, entirely apart from self-replication.

Much better sensors

The sensors (p. 3706) category right now consists of five big ideas.

Starfield servo (p. 1709) outlines a way to make some simple physical objects and less-simple algorithms that would enable a cheap webcam to become a remote multiple-degree-of-freedom sensor with, in some dimensions, submicron resolution over a range of a few meters. If it works, and I think it will.

Compressed sensing microscope (p. 306) describes the same technique applied to light microscopy, where it should enable subwavelength near-field imaging without lenses.

Measuring submicron displacements by pitch bending a slide guitar (p. 905) outlines a totally different way to measure submicron displacements over a range of a few meters with inexpensive equipment — electric-guitar pickups, this time, rather than webcams.

The Tinkerer's Tricorder (p. 72) outlines a variety of hacks to build an inexpensive LCR meter similar to the popular M328.

Ghettobotics: making robots out of trash (p. 2747) (and category ghettobotics (p. 3472)) explores how to build

> a self-sustaining industrial economy that consumes nothing but discarded electronics and other trash and produces, with a minimal amount of human effort, useful robots.

It's sort of Self Replication Lite™.

Archival

The archival (p. 3322) category covers lots of possible ways to archive the humans' knowledge to keep it from being lost, at many levels of the stack: physical substrates for information, ways of mass-producing the physical substrates to reduce chances they will all be destroyed, file-format compatibility, and archival virtual machines to guarantee file-format compatibility.

So, for example, Atmospheric pressure harvesting phoenix egg (p. 2081) describes a power source that enables you to build a computer that could continue to run for centuries even while buried, barring too many hardware failures; Archival of hypertext with arbitrary interactive programs: a design outline (p. 2472) discusses how to structure interactive hypertext to make archival possible, as do Instant hypertext (p. 630) and Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257).

Some extensions of William Beaty's scratch holograms (p. 2536) describes a way to archive large amounts of information on inexpensive, durable materials in a way that the humans can read without needing a working computer, as do Caustics (p. 1619), Data archival on gold leaf or Mylar with DVD-writer lasers or sparks (p.

1455), Rosetta opacity hologram (p. 98), Holographic archival (p. 766), Piezoelectric engraving (p. 1070), Quadratic opacity holograms (p. 3073), Archival transparencies (p. 1345), and A mechano-optical vector display for animation archival (p. 3047).

In between those approaches, there's the possibility of archiving large amounts of information in an executable digital form, but providing a specification for an "archival virtual machine" that can execute the archived information, as proposed by Raymond Lorie and by Nguyen and Kay's "Cuneiform Tablets" paper. Attacks on this problem include Bootstrapping instruction set (p. 459), A simple virtual machine for vector math? (p. 986), Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952), Designing an archival virtual machine (p. 3203), XCHG: An Archival Swap Machine (p. 2997), Archival with a universal virtual computer (UVC) (p. 399), and The Dontmove archival virtual machine (p. 2113).

As an alternative to making time capsules to bridge periods of time when the humans are uncooperative, we might be able to preserve history by enlisting their cooperation; Viral wiki (p. 1024) discusses one approach to that.

If one or more of these approaches is successful at rescuing the humans' knowledge from the Digital Dark Age, that would indeed be Big. (But it's not clear how much of that depends on correctness; it probably depends more on implementation effort.)

Hessian-free quasi-Newton methods

In Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) it is claimed that quasi-Newton methods require maintaining in memory an approximation of the Hessian, while perhaps a similarly quadratic order of convergence can be obtained with just the gradient by using Newton–Raphson iteration along the direction of the gradient, while gradient-descent methods only have linear convergence. If all of that is true, which is unlikely, then it contains a numerical optimization method that is many orders of magnitude faster than the state of the art in high-dimensional spaces.

More generally, I think mathematical optimization (p. 3611) is a significant candidate for including in More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) as a basic element of computer systems design; $1 recognizer diagrams (p. 1264) gives an example of how you can use it to replace ad-hoc procedural algorithm design with something much simpler, which I'm pretty confident will work.

High-density fractal heat exchangers

In Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) it is claimed that a particular three-dimensional fractal design for a recuperator-type heat exchanger could provide recuperators with orders of magnitude higher performance, rivaling that of regenerators. This could be a crucial enabling technology for many kinds of thermodynamic machines, including heat engines (possibly including micro-turbine generators) and climate-control systems (for example, A design sketch of an air conditioner powered by solar thermal power (p. 2233)).

The solar energy transition

One of the largest changes in the material culture of the humans during the 21st century will be the transition away from fossil fuels as their main source of harnessed energy, since the alternative is global warming that may be sufficient to cause a mass extinction; right now it looks like they'll change to solar photovoltaic energy during the late 2020s.

Since most of the resource cost of producing photovoltaic panels is an energy cost, but their EROEI is already quite high, this probably means a rapid exponential growth in the amount of energy available to be harnessed for human activities. This will make energy much cheaper than it's ever been.

The economics of solar energy (p. 1175) is a somewhat dated overview of the basic issues, which are also discussed in The future of the human energy market (2014) (p. 1846), Japan can achieve energy autarky via solar energy, but not much before 2027 (p. 2819), and parts of Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566).

One of the predictable effects of abundant marketed energy is cheaper desalination and an end to water stress. See A quintuple-acting vacuum cascade to recycle heat for more efficient distillation and desalination (p. 519), Fast sea salt evaporator (p. 1087) , and Calculations about desalination in Israel (p. 2827).

Among the more dramatic results of this transition is that, until there are intercontinental HVDC lines or breakthroughs in utility-scale energy storage, energy is going to be a lot cheaper during the day than at night, which means that "demand response" is going to be really important for taking advantage of the available energy. In Salt slush refrigeration (p. 1230) and Household thermal stores (p. 1533) it is discussed how to do household refrigeration and climate control in a demand-response-friendly way.

It is, however, *possible* to build enough storage with existing lithium battery technology to sustain current energy usage levels during the night; Terrestrial lithium supplies provide adequate energy storage to reach Kardashev Type 1 (p. 2123) discusses the available resources, and Energy storage efficiency (p. 1300) discusses the economics in more detail.

Replacing fractional-reserve banking

The evils of fractional-reserve banking are a favorite hobbyhorse of economic cranks and conspiracy theorists. I don't think it's evil, and moreover I think the standard economic-crank position dramatically overstates its importance, but it does have some real problems, such as bank runs, and I think that now we can do better; Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333) explains how.

Fast parsing

A dismaying quantity of current computer software amounts to ways of caching parsing results because parsing is so slow. One attack on this problem is to use a data structure serialization format like FlatBuffers that permits random access; another is to use faster parsing algorithms. In Profile-guided parser optimization should enable parsing of gigabytes per second (p. 2283) I suggest ways to

increase parsing speeds to a sufficiently high level that much of that caching code can be thrown away. They might work.

Unified caching

The old joke is that there are three hard problems in computer science: naming, cache invalidation, and off-by-one errors.

"Cache invalidation" is the process of determining when some cached result should be updated, which is a very general concept, and different kinds of caches are ubiquitous in computer systems architecture, at every layer from RTL design up to container orchestration, for reasons that include improving throughput, protecting privacy, tolerating faults, reducing average latency, and reducing worst-case latency. The vast majority of complexity in computer systems does in fact amount to logic that manages different kinds of caches.

I have found several promising ways to unify many, though not all, of those caches in a single caching subsystem, which will dramatically simplify computer systems design at the same time as dramatically improving performance, if one of them works.

In A minimal dependency processing system (p. 911), Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870), Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257), Automatic dependency management (p. 881), and Immutability-based filesystems: interfaces, problems, and benefits (p. 1672), I discuss ways to architect computer systems that simplify this problem; Transactional screen updates (p. 2907), Caching screen contents (p. 2362), and Cached SOA desktop (p. 2229) focus specifically on the problem of GUI caching, because it's a particularly demanding aspect of the problem that illuminates it from a particularly useful angle. In Memoize the stack (p. 2021) and Amnesic hash tables for stochastically LRU memoization (p. 502) I discuss particular generic algorithms that might be useful.

More generally, the topic "caching" (p. 3361) covers many different aspects of the problem.

Paper/foil relays

In Paper/foil relays (p. 3273) I describe an electrostatic relay design that might be feasible at millimeter scale and below to get reasonably-fast digital logic without any advanced materials processing. Unlike electromagnetic relays, these work better at smaller scales.

Very efficient 2-D convolution with flat kernels

In Real-time bokeh algorithms, and other convolution tricks (p. 2661) I explored a number of algorithms for simulating camera bokeh and discovered a general convolution algorithm for kernels with a small number of discrete multiplier values which occur in large contiguous blocks — such as, for example, camera bokeh kernels for ideal lenses. If it works, it's an order of magnitude or more faster than any previously published algorithm for this problem, beating even McGraw's approximate algorithm (although it can handle cases with

spherical aberration, which my algorithm can't.)

"Interaction models"

In Dehydrating processes and other interaction models (p. 3208) I propose a sort of taxonomy of computer systems architectures based on something called "interaction models", which has to do with the relationship between individual programs and the rest of the system. It could stand to be sharpened up a bit.

Expressive multitouch

Historically, human–computer interaction (p. 3493) has mostly been through a keyboard, screen, and mouse. The screen provides perhaps 10 megabits per second of output bandwidth, while the mouse provides perhaps 50 bits per second of input bandwidth (but limited to about 6 bits per second in practice, according to the experiments in Some musings on applying Fitts's Law to user interface design and data compression (p. 1164)), and the keyboard another 15 or so, for a total of about 25 bits per second. While this vast disparity hasn't been much of a limitation for consumption-type activities like watching the Gangnam Style video or playing Flappy Bird, it's a major limitation for using the computer as a means for creative expression — "magic ink" or a "bicycle for the mind", in the phrases of Steve Jobs and Bret Victor. And it is ultimately through creating great things, not consuming great things, that the humans can become great themselves.

Multitouch input devices have dramatically higher input bandwidths than mice or keyboards, so in theory they might offer dramatically greater expressive freedom to computer users. Sadly, despite some promising prototypes demonstrated by Bret Victor and other researchers, the humans mostly interact with them by scrolling vertically with one finger, selecting pre-existing options by tapping on them, or using an on-screen keyboard.

We could escape this multitouch Skinner-box Sheol with the ideas in Two-thumb quasimodal multitouch interaction techniques (p. 1765), Interactive calculator (p. 2771), drag-and-drop calculator for touch devices (p. 1045), Interactive geometry (p. 508), $1 recognizer diagrams (p. 1264), Multitouch livecoding (p. 122), and Dercuano drawings (p. 64), if those ideas work out.

The Magic Kazoo

Maybe you can build a synthesizer kids of all ages can play by humming into it, and that would be a big hit; that's what The Magic Kazoo: a synthesizer you stick in your mouth (p. 1873) is about.

Ultralight tunnel personal rapid transit

In Ultralight tunnel personal rapid transit (p. 706) I calculate the performance of a new kind of rapid transit system, one so much more efficient and frugal that it would enable entirely new kinds of urbanization, combining the benefits of suburbia with the benefits of dense cities; Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) speculates on the kinds of sustainable, resilient community living that could result.

Topics

Incremental roller comb forming

Kragen Javier Sitaker, 2019-11-27 (4 minutes)

If you drag a weighted rake over gravel, it forms the gravel, sort of plastically, leaving little valleys behind the rake tines. Similar phenomena occur with many soft materials and metamaterials: sand, styrofoam, oil films, wet clay, wet concrete, foamed metals, foamed waterglass, hot glass, mashed potatoes, and so on. With sufficient pressure, you can get it to happen in plastic materials like wax, aluminum, steel, and so on; lubrication and a super-hard, well-polished comb may be necessary.

Suppose that you put rounded wheels, shaped like rollerblade wheels but made of harder materials, in the tips of the comb tines. This should allow you to do this kind of plastic or pseudoplastic forming to fairly hard materials by virtue of increasing the force you can feasibly apply before the friction becomes prohibitive. Sheet-metal "spinning" is done this way, though usually with only a single handheldd wheel.

By itself, this is not a very interesting capability, because it just makes parallel lines on the surface, in fact with a fixed spacing. You can peen metal this way, but the standard ways to do that (with a hammer or with shot peening) are almost certainly better. But now suppose the comb tines are *movable* under precise servo control?

By varying the heights of the comb tines as you move over the surface, you can form it into any heightfield shape within some limits: you can't get inside radii shorter than the wheel radii or, in the other direction, features finer than the tine spacing; and you can only deform the surface within the plastic limits of the material. By making multiple passes over the surface you can achieve deeper deformation, especially in materials without too much work hardening. In relatively hard materials, it may be more useful to servo-control the pressure (i.e., the mechanical impedance) rather than the position of the roller; this should allow dimensional precision in the finished product that is superior to the measurement precision of your servomechanism.

Unsupported metal and paper sheets are among the easiest materials to plastically deform, but in addition to work hardening, they suffer from a limitation: it's hard to deform them into multimodal curves, because if you push down on both sides of an area, the middle goes down with them. There are several possible solutions, including supporting the sheet with a second comb of rollers, with wood, with some other deformable foam, or with an incompressible fluid, as used in hydroforming.

As with deep drawing, work hardening can be handled by normalizing or annealing the metal between stages of the process. In the particular case of sheet aluminum, which can anneal almost instantly, this can be achieved in a continuous-flow process with an air impingement oven like those used for cooking pizzas, with the air at a carefully controlled temperature a safe distance below the aluminum's melting point.

Extremely plastic materials like wet clay or wet cement might be better formed with an elastic spatula running across the ends of the

comb tines rather than wheels or rollers. A similar approach might work for cutting metals or wood using an elastically-deformed cutting tool.

In all of these cases you will need some degree of FEM material simulation in the toolpath planning and perhaps even the real-time feedback system. I suspect that this has been the major reason for the great popularity of metal-cutting processes such as milling and lathe turning: although the resulting product is weaker than a forged product, the necessary planning and control is simple enough to be done by the humans' brains and massive, stiff metal frames.

Pulley generator

Kragen Javier Sitaker, 2016-09-05 (2 minutes)

Could you use a low-friction pulley system to directly drive a tiny micro-DC motor as a micro-generator from a hanging weight? A typical US$3 micro-DC motor can handle about 1–2W of power and produce .49 mN·m of torque, which at a wheel radius of 5mm, is 9.8mN, the Earth weight of 10g. If your weight is, say, 10kg, you need a 1000:1 pulley system; if it is raised through 2m of distance, a simple block-and-tackle would mean you need 500 pulleys at the top, 500 below, and 1000 iterations of thread running between them, for a total of 2000 meters of fine thread. (The thread would ideally be impractically fine: 28 microns of most materials would be sufficient, for a total cross-sectional area of 2.4 mm², and much less of high-strength materials.)

To avoid this massive number of parts and threads, it's probably better to use a multi-stage system: five sequential 4:1 reductions, for example, using gears or pulleys or whatever. A regular 40/3 cotton thread at 4 grams per denier should be able to support 2.7 kg, so maybe 4 to 16 threads running between 4 to 16 pulleys, followed by a 64:1 to 256:1 reduction gearbox or belt drive. (A 32:1 belt-drive reduction could perhaps be done in a single stage, reducing losses, with a 32-cm wheel and a 1-cm wheel; two 16:1 stages would provide 256:1.)

Weregild

Kragen Javier Sitaker, 2019-03-24 (3 minutes)

As a measure aimed at reduction of wars, we should perhaps accept weregild again. The traditional Scandinavian weregild rate was 200 solidi for a churl, the least noble category of person for which weregild was due, which works out to 900 g of gold, about US$40k at today's gold prices. I think the current Saudi diyya is a hundred thousand riyals for the noblest category of victim (Muslim men), which is a bit less than US$30k (US$26.7k as of 2015). These prices are a bit lower than modern wrongful-death awards in US courts, which I think are commonly in the hundreds of thousands of dollars, sometimes up into the millions. Presumably the Saudi prices do not apply to members of the royal family.

In Scandinavian times somewhat larger amounts were due for nobler victims: 600 solidi for a duke or archbishop, 300 solidi for a low-ranking cleric (or 400 if they were reading mass at the time), or at another time 1200 for a nobleman, 15000 for an archbishop, or 30000 for the king. The Mercians paid a lower weregild of 110 solidi for Welshmen, or less if they owned no property.

For modern times, probably the prices measured in gold should be higher, partly since we live in a society that is much wealthier, but also because we aspire to egalitarianism; we don't consider women to be worth half a man, as Saudi Arabia does and Iran used to, or Christians to be worth half a Muslim, or dukes to be worth three commoners. Perhaps a reasonable number would be 64 bitcoin, which is currently about US$240k, but will fluctuate with the value of bitcoin. Bitcoin is still very short-term unstable but will probably be a stabler measure of value over the next century or two than the dollar or gold.

Traditionally, wergild (and diyya, wrongful-death awards, and similar concepts) are payable to family members of the victim. Modern sensibilities would demand this to be under the voluntary control of the victim: the payment should be made to the heirs of the victim whoever they be, whether family members or not, as surely it would pile injustice upon injustice to, for example, award the wergild for a transgender hate crime victim to their disowned transphobic parents.

Nonlinear bounded leaky integrator

Kragen Javier Sitaker, 2019-09-11 (8 minutes)

An integrator or prefix sum is a linear low-pass filter with no rolloff: 6 dB per octave all the way down to dc, where it diverges. Sometimes it's desirable to have a similar kind of filtering action with BIBO stability, and there are a couple of standard linear ways to do that. A nonlinear approach just occurred to me, which is what this note is about.

The integrator and its standard variants

The discrete integrator is the linear filter

$y_i = y_{i-1} + x_i$

also known as the prefix sum, plus-scan, summed-area table, and other terms; it's the discrete analogue to the antiderivative operator. It amplifies frequencies by a linear gain factor proportional to their wavelength, which means that it's not BIBO stable: a bounded input sequence with any dc bias will eventually produce an arbitrarily large magnitude of output. It's marginally stable — if you stop stimulating it with a dc bias, its output won't keep growing. Its impulse response is the Heaviside step function.

It's extremely inexpensive to compute.

If you're doing this on a computer, sometimes this instability can be bad. In C, it can be undefined behavior. In integer arithmetic, it can overflow from positive to negative values or vice versa, which is a problem under some circumstances. In floating point, it results in a gradual loss of precision which eventually becomes total, although, for a signal with 16 bits of dynamic range being represented in a 64-bit IEEE-754 float, loss of precision doesn't begin until you have processed at least 2^{37} samples. In arbitrary-precision arithmetic, which is generally not used for signal processing, it starts to use more memory and become slower.

If you're using the integrator as a model of some physical system, such as a capacitor charging from an operational transconductance amplifier, you have a potentially more serious problem: the system almost certainly has some kind of physical bounds on its response, and if your linear model has unbounded behavior, that means its approximation of the physical system is going to be unboundedly awful under some circumstances.

The really long boxcar and its variants

Consider composing the integrator above with the following sparse FIR comb filter, producing a filter that is overall FIR and thus BIBO:

$y_i = x_i - x_{i-20480}$

This boxcar has the same output as the integrator on signals of less than 20480 samples and on frequencies whose wavelength is much shorter than 20480 samples, but for lower frequencies, its gain has an asymptote of 20480, although the gain isn't very well behaved; it has sharp nulls at $2\pi = \omega$ 20480 samples and its harmonics.

You could soften this a bit to something like

$y_i = 3x_i - x_{i-33137} - x_{i-20480} - x_{i-12657}$

so that you don't have any really sharp nulls like that, just some 1.8-dB attenuations.

However, you still have striking time-domain artifacts in the form of echoes: one at 33,137 samples, one at 20,480 samples, and one at 12,657 samples.

If you pass a signal through a filter with a Gaussian time-domain response, followed by an integrator, you get a unstable filter with a sigmoid impulse response, a sort of softened Heaviside step function. You can approximate this closely with four integrators and three combs like the comb above. If you delay the output of this filter, scale it down to unit magnitude, and subtract it from an integrator, you can similarly tame the integrator and get it to be FIR and thus BIBO stable, without much echo except at low frequencies and, I think, without any sharp nulls; the impulse response of the combination is a pulse with a sharp beginning, a flat top, and a slow sigmoid decline to zero. It costs one multiply, five adds, and four subtracts per sample.

The stable approximation of an integrator provided by these LTI hacks may be adequate for many purposes.

Exponential leakage

A simpler way to make the integrator BIBO stable without altering its high-frequency response and LTI nature is to add a little bit of exponential decay:

$y_i = k y_{i-1} + x_i$

Here k is a decay factor between 0 and 1, say something like 0.99 or 0.999, analogous to a bleeder resistor across an accumulating capacitor. The impulse response of this filter is a pulse with a sharp onset followed by an exponential decay back to zero with a time constant $\tau = -1/(f_s \ln k)$.

This has no echoes or sharp nulls, but it's not FIR like the boxcars.

Nonlinear leakage through saturation

Suppose we harshly clip our integrator output as if it were the output of an ADC:

$y_i = -k \vee y_{i-1} + x_i \wedge +k$

(Here $a \vee b$ is a if $a > b$, b otherwise, and $a \wedge b = -(-a \vee -b)$.)

This guarantees that it's BIBO stable because its output is bounded to $[-k, +k]$, no matter what the input is. (This approach is commonly used to limit integrator windup in PID controllers.) It gives up linearity, and in the process creates all kinds of potential for interaction between frequencies.

An interesting thing about this approach is that if the integrator is floating around near its limit when some high-frequency oscillation starts, say with amplitude 0.1, that would force it beyond the limit, the first quarter-cycle of that oscillation gets clipped; but thereafter the whole oscillation proceeds without incident, having added enough of a negative step function (a component at dc!) to make room for the rest of its waveform below the saturation level.

Another interesting thing about it is that there are a lot of natural phenomena that behave to some degree like this, including saturation

in transformers and ionic polarization in dielectrics (see Measuring the moisture content of coffee and other things with dielectric spectroscopy (p. 1033)); the optical Kerr effect can manifest such effects at near-exahertz timescales.

Softer saturation

Suppose we'd like to get some of this effect, but with gentler nonlinearity; we'd like to smoothly tilt the playing field for x so that it can move y back toward zero a little more easily than it can move y further away from zero. This way, maybe we can get the BIBO stability of the hard saturation thresholds, the same no-cutoff-frequency low-pass filtering action of the pure integrator, and minimal waveform distortion, except where these three conflict.

Maybe something like

$$y_i = (1 - kx_i^2)y_{i-1} + x_i$$

would do. But I feel like this is maybe *too* nonlinear, since it fails at BIBO. Also requiring three multiplications per sample seems like a lot, since the standard LTI exponentially-leaky integrator only requires one.

$x_i y_{i-1}$ is negative when x_i is trying to decrease the magnitude of y_i, and positive when it's trying to increase them. So an alternative, simpler approach might be to use this factor to adjust the gain on x_i smoothly:

$$y_i = y_{i-1} + (1 - kx_i y_{i-1})x_i$$

This still requires three multiplications per sample. The parameter k, maybe in the range 0.0001 to 0.1, sets the maximum amplitude of the output, which also depends on the frequency (relative to the sampling rate) and the other existing frequencies.

This is imperfect — in particular, the gain goes negative if $kx_i y_{i-1} > 1$ — but it seems to be giving reasonable results on some simple test signals. It can produce extreme harmonic distortion with undesirable values of k.

```
def nlf(x, k=.025):
    y = x.copy()
    for i in range(1, len(y)):
        y[i] = y[i-1] + (1 - k*x[i]*y[i-1])*x[i]
    return y
```

Bitstream dsp

Kragen Javier Sitaker, 2015-09-03 (updated 2019-06-23) (3 minutes)

I've been wondering if you can do DSP operations usefully with bitwise operations on infinite streams of bits, perhaps representing a signal in PDM, with a pipelined graph of binary-signal combinators. This is tempting both because you can get 64-way or 128-way parallelism on modern CPUs and because you can perhaps conserve area in FPGA implementations.

For example, to detect a frequency, you could generate two 1-bit-deep square waves in quadrature at the frequency, XOR them with the input bits, and then run a population count of the bits. This has the disadvantage that you're getting contaminated with the correlation with odd harmonics of the square-wave probe signals; I think you can maybe reduce this problem with upconversion?

Upconversion, of course, is also XOR.

Population count can be done with streaming full-adders on the bitstreams, after ANDing them with wavelength-2, wavelength-4, wavelength-8, etc., square waves and their complements, then delaying the output of the complemented version by 1, 2, 4, etc., bit times, before adding it back to its counterpart. This crudely converts the bitstream into PCM, but the full-adders can remain oblivious to the PCM sample boundaries. Thresholding the PCM can perhaps use a single bit test in each sample (generated by AND with a low-duty-cycle wave of the same frequency). AND and OR may be adequate approximations for min and max.

For other practical operations, a perfect-unshuffle operation would be useful, converting one bitstream into two bitstreams at half the speed.

A FIR filter might be a fixed-length word that you XOR against the bitstream at every bit offset, emitting perhaps the majority-rule of the XOR output bits.

2019 update: it turns out that there is some substantial research on a bitstream approach, but it uses very different primitives than I was thinking. The fundamental operations are NOT (1 - X), AND (X·Y), selecting bits at random from either of two bitstreams (½(X+Y)), and of course delay with a D flip-flop. The random-selection idea is very clever! My thinking was stuck in the deterministic paradigm, which is perhaps an unnecessary constraint when we're talking about bitstreams that by necessity incorporate a lot of error.

(I wish I could remember the names of the bitstream DSP papers or researchers.)

I've also read more about oversampling 1-bit ADCs and DACs since I wrote the above (mostly in Horowitz & Hill) and what I read leads me to believe that this approach could be more effective than you might think, since a third-order ΔΣ converter can hit an ENOB of 16 at only a 64× oversampling ratio, only 4× worse efficiency than PCM. I don't know that the noise shaping of these incredible devices will survive the kinds of operations described here.

If not, a sort of ΔΣ converter might itself be in some sense a safer way to do these computations. For example, if you want to attenuate

the signal represented by a ΔΣ bitstream by 9dB, you could very reasonably build an all-digital feedback system using a couple of up/down counters which attempts to maintain the input counter at 8× the value of the output counter.

Median filtering

Kragen Javier Sitaker, 2019-01-17 (11 minutes)

I want to do some median-filtering image processing. First I want to do it in a janky way that will work for 2×2, 3×3, 4×4, and 5×5 square filter kernels, to see if the results I get are reasonable. Then I want to see if there's a better way to do it.

Median filtering by brute-force sorting

The janky way is to copy the pixels in the window into a buffer, sort the buffer, and then take the middle pixel, or like an average of the two middle pixels. These buffers are small enough that insertion sort is probably the way to go. Insertion-sorting a 5×5 square requires 300 comparisons, though, which is enough to make it slow.

A weighted-median filter could be an interesting way to cut down on resonance artifacts: count the pixels toward the center as having more weight than they really do. One way to do this is, after sorting, you calculate the CDF of the weights in the sorted order, then take the pixel with the CDF in the center of the range.

Median filtering by quickselect

Quickselect should be about 6× as fast, but it will still do 50 comparisons, I think.

Subjectively, quickselect on my laptop becomes unbearably slow once the window is bigger than about 12×12, at which point it's doing 548 comparisons per window; I think that with the usual partition algorithm it would be doing 288, but I'm using Lomuto's algorithm because it's simpler.

Incremental median filtering

Can you reuse some of the work from one window position to the next window position? For example, if you're shifting a 5×5 square (or whatever 5-pixel-tall window) to the right by one, can you replace the original 5 pixels with the new 5 pixels and then move them to the right place? On average they'll move 12 positions, so this involves about 60 comparisons — probably still slower than quickselect.

Incremental quickselect

How about incrementalizing quickselect itself? Once you've found the median, the buffer is partitioned between less-than-median and more-than-median items. If you replace 5 of them, they may need to move to the other side of the buffer, pushing the median over a bit — but you don't a priori know which element from that expanded side is the new median. You have to run quickselect on it again, which is only a speedup of 2, giving you about 50 comparisons.

Median of medians

What if you calculate the median of each pixel column and then take the median of their medians? This turns out to also save you only about two thirds of the work, down to half in larger cases. Here are how the partitioned items relate to the median of medians, having sorted the columns by their medians

```
? ? + + +
? ? + + +
- - = + +
- - - ? ?
- - - ? ?
```

That is, one of them is the MOM itself, two medians to the left are known to be less, and the two to the right are known to be greater. Transitively, the elements earlier in the left two columns are also known to be less than the MOM, because they're less than their own column median, which is less than the MOM. Analogous remarks apply to the right. But we don't know anything about the other 8 elements; any of them could be the overall median.

I'm not sure how to get from this to the actual median in an efficient way, although this might be a good approximation to the actual median.

Merging for incremental sorting

What if we sort the new column and then merge it into the sorted order of the non-deleted pixels in a single pass, 1950s business DP style? This seems like it is going to be a win; sorting the new column with insertion sort takes 10 comparisons, and then merging it into the sorted order takes I think 25, for a total of 35 or so.

Heaps for incremental quantiles

What if we maintain a max-heap of the elements in the window that are less than the median and a min-heap of those that are greater? We can replace the old pixels with new pixels and then sift them up or down as appropriate, possibly shifting elements through the median to keep the heaps the same size. Consider the 5×5 case; with 12 elements in each heap, we will typically sift about 2 steps, for about 10 steps per window shift.

In the 12×12 case, quickselect needs about 548 comparisons in my current implementation. The heap approach would have 72-element heaps, which would be mostly 6 levels deep, so we would typically sift each element by about 3 steps, for 36 comparisons.

Incremental overhead

The data structure for such an incremental approach probably needs to be a little more complicated than a simple array of pixel values, because we need to be able to efficiently find the 5 samples to replace when we shift. We need one map from (x, y) pairs to buffer positions so that we can find the buffer positions to replace and a second map from buffer positions to (x, y) pairs so that we can access the actual pixel value or swap the positions of two pixels. When you swap two positions, you have to update both arrays. I don't know if there's a simpler way than this. This will probably impose enough update overhead that the crossover from non-incremental quickselect will come at a larger size than 5×5, since non-incremental quickselect can work on mere pixel values.

Histograms

Suppose you have only, say, 256 different possible color values in the image. Then you could represent the distribution of those values in a window with a histogram, an array of 256 numbers counting the

number of pixels that has each value. The prefix sum of the histogram, the empirical CDF, would cross half the size of the window precisely at the median.

A desirable property of the histogram is that it can be updated incrementally quite efficiently: to shift a pixel out of the window, decrement its value in the histogram, and to shift one in, you increment its value in the histogram.

Instead of maintaining all 256 values, you could maintain a reduced histogram with, say, 16 buckets; and instead of maintaining just a count in each bucket, you could maintain an array of the colors that fell into that bucket. The bucket at which the empirical CDF crossed the median would tell you approximately the median, but to find it precisely, you would need to compute some arbitrary order statistic over the pixels in the bucket, which could be done with quickselect. Removing a pixel from the bucket now requires a linear search through the bucket for its value, but the number of pixels in each bucket is small.

Perhaps, in the form described above, the ideal number of buckets is roughly the square root of the window size; for example, for a 12×12 window, perhaps 8 to 16 buckets would be best. This is because for each new output pixel we must recalculate the empirical CDF, which takes time linear in the number of buckets, and then we must calculate an order statistic inside some bucket, which (under dubious but probably approximately correct assumptions) takes time inversely proportional to the number of buckets.

An incremental prefix sum data structure would change the cost function to favor a larger number of buckets, and the recursive binary-tree form in particular can update the prefix sum in logarithmic time; in its sparse form, it reduces to a binary trie over pixel values in which each trie node knows the total number of descendants it represents.

(As an alternative to going all the way to the trie structure, you could use some structure other than a linear list inside each bucket. But nothing occurs to me that would be a real speedup.)

The bucketing and trie techniques allow the histogram approach to scale to large color spaces, such as 12-bit grayscale or 24-bit color.

The complexity cost of this technique is nontrivial. My quickselect implementation is 18 lines of C and worked the first time; my prototype trie implementation, which crashes, is 157 lines, although to be fair it was probably a premature optimization to use node pools before I had it working at all.

Rank order filters

An interesting thing to note about median filtering is that it can be generalized to a family of quantile filters; you could use any arbitrary percentile rather than just the 50th percentile. The result is a filter that tends to suppress local noise and leaves uniform-color areas of the image unchanged, but tends to contract or expand brighter areas according to whether the percentile is less or greater than 50. In the extreme cases of 0 and 100, where we take the minimum or maximum of the neighborhood, the filters are the familiar erosion and dilation operations from mathematical morphology; the other percentiles provide a more or less smooth variation between erosion and dilation, which are the maximally contractive and expansive

filters of the family, respectively, and the most sensitive to noise, while the median filter itself is neutral between contraction and expansion and the least sensitive to noise. With a 25-element kernel with equal weighting, there are 25 quantile filters in the family, three of which are erosion, median, and dilation.

These are commonly known as "rank order filters" or sometimes "order-statistic filters".

The data structures discussed above for median filtering are all applicable to these more general filters, but their efficiency properties vary. The median-of-medians mentioned above provides a better estimate in any case other than the median case, for example:

```
? + + + +
? + + + +
? + + + +
- = + + +
- - ? ? ?
```

And in the extreme cases of erosion and dilation, it has no unknown pixels, amounting to the standard decomposition of a rectangular erosion or dilation kernel into horizontal and vertical kernels.

The trie algorithm, in particular, can effortlessly handle arbitrary rank-order filters.

Hot wire saw

Kragen Javier Sitaker, 2015-12-28 (updated 2019-06-02) (10 minutes)

An idea based on watching Grant Thompson's description and demo video of his "Styro-Slicer" hobby hot wire cutter.

As an alternative to laser-cutting wood or MDF, you could cut it with a hot wire, like the one in a hot-wire styrofoam cutter. Some hot-wire styrofoam cutters are already capable of cutting soft woods with some difficulty.

The conductive wire bandsaw

I am envisioning a sort of bandsaw in which an endless loop of thin wire is run through the kerf, heating up on its way into the kerf and then being quenched as it plunges into the material, dumping its heat into the wood. Two conductive rollers, one above and one below, feed electricity through it; the distance between the rollers is so much shorter than the distance around the other part of the loop that the other part of the wire is not dangerously heated.

To be concrete, let's consider 80-micron-thick (40 AWG is 79 microns) nichrome wire cutting 3mm MDF with 50 watts of power, leaving, say, a 100-micron-wide kerf, with the two electrical-feed rollers at a distance of 45mm between them and an additional 900mm in the loop. Nichrome's resistivity is about a μΩm and apparently 800 mA is enough to keep an 80-micron wire radiating at 1100°, which is plenty hot enough. In this case the resistance of the 45mm should be about 1 μΩm * 45mm/((80μm/2)²π) or about 9 ohms, so you need about 2400 mA to get to 50 watts:

```
You have: micro ohm meter * 45 mm / ((80 microns/2)^2 pi)
You want: ohms
        * 8.9524655
        / 0.11170107
You have: sqrt(50 watts / (micro ohm meter * 45 mm / ((80 microns/2)^2 pi)))
You want:
        Definition: 2.3632718 A
```

This means your power supply needs about 22 volts, which is eminently feasible.

The resistance of the 900mm part is 20 times greater, or 180 ohms, so it will be carrying 120 mA and dissipating about two or three watts --- enough to require management but not an overwhelming problem.

This machine seems nearly feasible, but a problem with this is that the exposed 45mm of wire is going to be not only radiating like a motherfucker, perhaps losing most of its energy into the void, but also possibly getting rather hotter than the 1400° that it can in fact withstand before melting. And don't forget that the MDF needs to have air blowing on it the whole time to keep it from catching on fire, which is also going to cool off the wire, although maybe this problem can be limited by careful management of the air blowing, so that it's only blowing in a very thin layer.

So consider a revision: 127-micron-diameter (36-AWG) wire

cutting a 150-micron-wide kerf (still at only 50 watts) with only a 12-mm gap between the conductive rollers. This drops the resistance per mm by 2.5 and the distance by 4x, getting us down to about 930mΩ, which means that we now need 7 amps running through the wire, powered by about 7 volts, and a power-supply output impedance of below an ohm or so to keep efficiencies reasonable. That's still hot enough to melt the wire if there's no thermal load on it, but I feel that it's possible to keep it running through the rollers fast enough to keep it passively safe, even without rapid-response electronic control to keep it from burning. And it's mechanically strong enough that it might survive encounters with things that unexpectedly fail to burn on contact with it.

(180-micron (33-AWG) nichrome wire is commonly used for styrofoam-cutting machines like the popular Argentine brand "Segelin". Thicker gauges are common; thinner gauges are somewhat exotic. One Aldo Vignolo sells them on Mercado Libre here in Buenos Aires.)

What do we do about splicing the wire? One possibility is to simply not worry about it, instead merely reversing direction when the time comes, maybe turning off power to let the wire cool in between.

How much thermal energy can be stored in the gap before the wire melts? Nichrome has a specific heat of 450 J/kg/K and a density of 8.4 kg/liter, which works out to 3.8 kJ/liter/K. At 127 microns, that's 48 microjoules per millimeter per kelvin, or 67 millijoules per millimeter, or about 800 millijoules in all, to melt the wire in the gap. The situation is slightly worse because nichrome's resistance increases slightly with temperature, so it can experience a kind of thermal runaway where hotspots heat up faster, and also slightly better because the hottest spots are also radiating away energy most rapidly. Disregarding these, this means that keeping it passively safe at 50 watts involves feeding a gap's worth of wire onto a quench roller about every 16 milliseconds, a speed of about 750 mm per second. But that's just to barely keep the wire from melting.

I'm not sure that shortening the gap was a big improvement. It does lower the amount lost in the other part of the loop, but it also reduces the heat capacity of the wire in the gap, thus requiring faster response if we decide to use active feedback for safety, and so it doesn't actually affect the necessary passive-safety wire speed. And, because it lowers the resistance, it requires a higher-quality power supply and heavier wiring. And, because it raises the required current, it also increases the possibility of melting the wire --- resilience is likely of more value than efficiency here.

A third revision, where we increase the gap size to the accursed 25mm, leave the wire thickness at 127 microns, and drop the power to 40 watts, requires less current, only 4.5 amps:

```
You have: sqrt(40 watts / (micro ohm meter * 25 mm / ((127 microns/2)^2 pi)))
You want:
        Definition: 4.5020328 A
```

This is low enough that it is *almost* passively safe even for copper, which melts at 1084°, even without the quench rollers. The resistance in the gap is up to 2Ω, which means you need 9 volts, a very

convenient number indeed. You no longer need quite such big hairy power cables or a high-quality power supply; Duracell's spec for their MN1604 nine-volt battery lists a 1.7Ω impedance, so even that would be almost good enough; a dozen or so in parallel would do, though obviously a line-powered power supply would be more cost-effective. The gap can now hold 1.7 J of thermal energy before melting:

```
You have: 450 J/kg/K * 8.4 kg/liter * ((127 microns/2)^2 pi) * 25 mm * 1400 K
You want: J
        * 1.675935
        / 0.59668186
```

Lowering the power to 40 watts means that it takes 42ms to reach melting temperature in the absence of any heat-loss mechanism, such as radiation, conduction into the workpiece, or the quenching roller. For the quenching roller alone to be sufficient, the wire needs to move at 600 mm/s:

```
You have: 25 mm * 40 watts / (450 J/kg/K * 8.4 kg/liter * ((127 microns/2)^2 pi) o
o* 25 mm * 1400 K)
You want:
        Definition: 0.59668186 m / s
```

The 150-micron kerf I expect from this is not quite as good as the 100-micron kerf I see from laser cutters. Contrast this with the Olson No. 2 spiral scroll saw blade, which nominally gives you a kerf of .035 inches in US folk units (890 microns), losing six times as much material and thus with six times as much opportunity for imprecision.

I don't know if it will work as well as a 40-watt laser cutter at cutting wood, even if you blow air down the wire. I think the laser cutter is usually heating up a tiny point rather than a whole contact surface, so it might heat the wood or MDF to a higher temperature. But maybe this will instead work better, since it has some mechanical sliding action and won't be impeded by smoke.

CNC foam cutters commonly use inconel rather than nichrome.

US patent 5,429,163 is relevant; it claims 600° to 800° is sufficient for cutting wood, and suggests using either a reciprocating or an endless wire. It says the wood itself need only heat up to 240° to 270°, and that irregularities in the wood pretty much require closed-loop temperature control, and claims 10 to 21 mm/sec of cutting speed. Unfortunately it doesn't go into any detail about power usage, preheat gap size, wire speed, or wire diameter.

Induction heating

As an alternative to heating the wire by running electricity through it lengthwise, you could run it through a high-frequency induction heater and thus induce eddy currents in it, particularly if it's ferromagnetic. Rudnev et al.'s *Handbook of Induction Heating, Second Edition* tells us on p. 38, in §2.2.4, that induction heating of wire is commonplace, using frequencies from 10 to 800 kHz and wire speeds through the inductor around 2 m/s. They cite a particular system they built for Radyne that heat-treats 1060 carbon-steel spring wire in

the 4–8-mm diameter range with a 400 kW, 10 kHz inverter for heating up to its Curie temperature, then a 420 kW, 200 kHz for heating above its Curie temperature; but they don't give a wire speed.

Fast mathematical optimization with affine arithmetic

Kragen Javier Sitaker, 2019-09-15 (5 minutes)

Suppose that, like most days, we're trying to find a local minimum of a univariate function $f(x)$ we can automatically differentiate with a continuous derivative. By using affine arithmetic, we should be able to get both quadratic convergence to the minimum, under Newton–Raphson-like conditions, and a guarantee of global optimality.

Newtonish–Raphsonish root finding with affine arithmetic

Suppose that the derivative is continuous (though not necessarily Lipschitz) and our automatic differentiation procedure supports reduced affine arithmetic, so that we can evaluate the function's derivative $f'(x)$ at "points" that are really affine forms describing some interval $[x_0, x_1]$, such as an interval with a zero in it, and get back an affine form that gives a linear approximation $k + a_0x$ and a fairly tight worst-case error a_1 from that approximation $x \in [x_0, x_1] \Rightarrow \exists\varepsilon \in [-1, 1]: f'(x) = k + a_0x + a_1\varepsilon$. (Affine arithmetic is discussed at some length in An affine-arithmetic database index for rapid historical securities formula queries (p. 2275) and Affine arithmetic optimization (p. 2801).)

This allows us to bound the zero of the derivative, and thus the critical point of $f(x)$, to a generally much smaller interval: x must be between $-(k - a_1)/a_0$ and $-(k + a_1)/a_0$. In fact, *every* zero of the derivative within the original interval is guaranteed to be within that new interval, so in cases where the new interval is larger or fails to be sufficiently smaller than the original, we must be prepared instead to subdivide the interval and recurse on each subinterval.

Rate of convergence and global optimality

I was thinking about trying to do a rigorous proof here but instead I'm just going to handwave because it's almost 4 AM. Generally the (vertical) error bounds affine arithmetic gives you are proportional to the second derivative of the function you're calculating (which is itself a derivative in the above), unrelated to its first derivative, and inversely proportional to the square of the interval width. This is pretty much the same situation as Newton–Raphson iteration or the method of secants, so you should expect it to converge quadratically under the same conditions that they do.

If you can figure out how to make an initial interval that is big enough to contain all the local optima, then this approach is guaranteed to find all the local optima and in fact all the critical points; you can use branch-and-bound to avoid recursing too deeply in areas where the local optima are not as good as the worst case in other areas where you are also searching, so even functions with a large number of critical points may be tractable.

Indirect multidimensional optimization, and root-finding in general

This can, of course, be used to find zeroes of functions that aren't derivatives of anything of special interest, and I think that's where I got the idea — from people using this approach for raytracing of implicit surfaces, specifically Gamito and Maddock's paper from 2004 or 2005, "Ray Casting Implicit Fractal Surfaces with Reduced Affine Arithmetic", §4.3, p. 6, fig. 2. But it seems like an approach that could be extremely fruitful for mathematical optimization. In Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) I suggested cutting a multidimensional function along a gradient line to get a one-dimensional function that's easier to optimize, an approach I haven't tried yet, but it seems like this approach would work for it.

Direct multidimensional optimization

Alternatively, it might be feasible to use this approach more directly for multidimensional optimization. There's a paper out a few years back about a correct algorithm using interval arithmetic for multidimensional optimization, using a branch-and-bound approach, but as I understand it, it has the problem that it is very slow on high-dimensional spaces. Suppose you look for a zero of some gradient $\vec{g}$ as $\Sigma_i g_i^2$ or $\Sigma_i |g_i|$ using a variant of the method above, using reduced affine arithmetic to compute bounds on this (squared) gradient magnitude or other gradient norm over some multidimensional box; I think this should take time merely proportional to the dimensionality.

The magnitudes of the coefficients in the resulting affine form should tell you how sensitive the gradient is to your location within the box along each dimension; to some extent you can trade off shrinking the box along one dimension against shrinking it along another dimension, but it's hard to know which dimension is optimal to shrink most in.

Maybe if we automatically differentiate our reduced-affine-arithmetic program, we can get the gradient of the error bars on the (original function's) gradient norm, with respect to the bounds of the box we're evaluating the gradient over. This would tell us which dimensions of the box are most important to shrink in order to reduce the uncertainty in the gradient.

Techniques for, e.g., avoiding indexed-offset addressing on the 8080

Kragen Javier Sitaker, 2019-07-20 (updated 2019-07-24)
(27 minutes)

Reading the 8080 instruction set and watching David Givens's recorded livestream of writing a text editor for CP/Mish, I'm struck by the nonexistence of indexed-offset addressing modes, and the relatively large cost of emulating them; so I was thinking about ways to avoid this cost.

8080 indexed-offset memory access

If your program wants to access a one-byte variable the C compiler has allocated at offset 4 from the stack pointer in its stack frame, it needs to do something like the following:

```
LXI H, 4     ; HL := 4; 10 cycles; "X" means 16-bit
DAD SP       ; HL += SP; 10 cycles; "X" is implicit
MOV B, M     ; B := M[HL]; 7 cycles
```

This takes 27 clock cycles, which is 13.5 µs at the 8080's 2MHz maximum clock speed. In some cases, the MOV at the end might be replaced with something like `INR M` to increment the variable (10 cycles, 5 more than incrementing a register) or `ADD M` to add it to the accumulator without loading it into a register first (7 cycles, 3 more than adding a register). So you could reasonably argue that the cost is something like 23 cycles rather than 27.

Just as fast as `MOV Y, M` is `LDAX` or `STAX`, which load and store the 8-bit A register from or to the address in BC or DE in only 7 cycles; unfortunately, you can't store addition results in BC or DE.

(I haven't looked at the actual code generated by ACK or BDS C, and I'm not that familiar with 8080 assembly language, so I might have gotten something wrong here.)

The code is pretty much the same if you're indexing a record† rather than a stack frame, just that the base address doesn't come from SP:

```
LXI H, 4
DAD B        ; or D
MOV B, M
```

And it's almost the same if you're indexing into an array (without bounds-checking), except that you might need to multiply the index by the array-item size; for fetching the first 8 bits of a 16-bit item, for example:

```
LXI H, 2834H ; the array base address
DAD B
DAD B        ; an extra 10 cycles
```

```
MOV B, M
```

By contrast, if the variable is at a fixed location in memory, you can avoid the DAD bit, cutting the cost from 27 or 23 cycles to 17 or 13, depending on how you figure it:

```
LXI H, 2082H ; HL := 0x2082; 10 cycles
MOV B, M     ; B := M[HL]; 7 cycles
```

But wait! You can do better! If you're willing to load it into A rather than some other register, you can instead use the 13-cycle LDA (resp. STA) instruction, which takes up 3 bytes:

```
LDA 300H     ; 13 cycles
```

If you're doing indexed-offset addressing, sequential reads can be significantly faster, because you can increment or decrement HL in only 5 cycles. Here the initial indexed load takes 27 cycles, but the subsequent sequential load takes "only" 12 more:

```
LXI H, 4     ; 10 cycles
DAD SP       ; 10 cycles
MOV B, M     ; 7 cycles
INX H        ; HL++; 5 cycles
MOV E, M     ; E := M[HL]; 7 cycles
```

Chasing pointers involves loading 16-bit values; the LHLD and SHLD instructions (16 cycles each) load and store the value of HL at fixed addresses. Loading it from an address pointed to by a register is more involved; you can load it one byte at a time, for a total of 23 cycles (if you want the result to be in HL and not, say, DE). For an apples-to-apples comparison with the 8-bit situation, it's 43 cycles if we first point HL at an offset into the stack frame:

```
LXI H, 4     ; 10 cycles
DAD SP       ; 10 cycles

MOV E, M     ; E := M[HL]; 7 cycles
INX H        ; HL++; 5 cycles
MOV D, M     ; D := M[HL]; 7 cycles
XCHG         ; HL, DE := DE, HL; 4 cycles
```

Or you can use SP as a pointer and then POP H, taking 10 cycles. Pointing the stack pointer at a random address with SPHL only takes 5 cycles, but that probably requires you to save the stack pointer ahead of time so you can restore it later. Unfortunately, I think the only way to access the old value of SP is with DAD SP, so the whole sequence is gnarly and takes 52 cycles:

```
XCHG         ; HL, DE := DE, HL; 4 cycles (save old HL)
```

```
    LXI H, 0      ; HL := 0; 10 cycles
    DAD SP        ; HL += SP; 10 cycles
    XCHG          ; HL, DE := DE, HL; 4 cycles (save old SP)

    SPHL          ; SP := HL; 5 cycles
    POP H         ; HL := M[SP]; SP += 2; 10 cycles

    XCHG          ; HL, DE := DE, HL; 4 cycles (restore old SP)
    SPHL          ; SP := HL; 5 cycles
```

But the `SPHL, POP H` sequence in the middle is only 15 cycles, so if you need to follow a chain of pointers, that's probably a faster way to do it. However, in the middle of this mess, you don't have access to the old stack pointer, which would further complicate access to local variables allocated in the stack frame.

The 8080 implicitly uses the stack to handle interrupts, so under most circumstances, you'd need to disable interrupts to use the above trick; otherwise an interrupt at the wrong moment will overwrite stuff before the pointers you're trying to chase.

Finally, you could use self-modifying code, which takes 32 cycles — slower and more code than just doing byte-at-a-time access, but doesn't trash DE:

```
    SHLD $+4      ; store HL into the address field of next insn; 16 cycles
    LHLD 0        ; load HL from address to be inserted; 16 cycles
```

This has the potential advantage that the two instructions can be at separated places, and in particular you might be able to set the address once and load from it many times.

For some special cases, there were faster ways to access data on the stack, the most obvious being simply by popping it, but there were others. For example, Alan Miller's *8080/Z80 Assembly Language: Techniques for Improved Programming* suggests that if you have passed an argument to a subroutine on the stack:

```
    PUSH B        ; i.e., BC
    CALL FOO      ; i.e., PUSH PC and then JMP
```

Then that subroutine best can get the argument (inconveniently hidden beneath its return address) into a register using `XTHL` (p. 38):

```
FOO POP H         ; i.e., HL; 10 cycles
    XTHL          ; M[SP], HL := HL, M[SP]; 18 cycles
```

This also works for return values.

In summary, on the 8080, it's dramatically faster to load data from memory at statically allocated addresses than at addresses on the stack or in records or arrays:

address	bits	cycles to read into register	bytes of code
static	8	13	3
in HL	8	7	1
offset from SP, BC, or DE	8	27	5
static	16	16	3

in HL	16	23	4
offset from SP, BC or DE	16	43	8

The first CP/M machines used the 8080, but the backwards-compatible Z80 was the CPU most CP/M machines used. It had index registers IX and IY which apparently ameliorated these problems noticeably, but did not remove them entirely. I haven't tried these exercises on the Z80.

† A record is called a "struct" in C-derived languages, a "tuple" in ML-derived languages, and an "object" in Smalltalk-derived languages.

Dynamic scoping with shallow binding in LISP

Many other old computers had similar problems, and I think this is the reason for the conventional wisdom among 1970s LISP implementors that, although lexical scoping was a good idea in theory and simplified the understanding of programs, in practice, the performance cost was too high, relative to then-conventional dynamic scoping with shallow binding, in which the current value of each variable was stored in a fixed memory location, but upon entering and exiting a subroutine that has it as a local variable, its previous value is pushed onto a stack, then restored upon exit.

Similar considerations, plus the then-popular technique of storing subroutine return addresses in the return instruction through self-modifying code rather than using a stack, prompted the omission of recursion from COBOL and older versions of FORTRAN.

`static` variables in C

At one point (about 45' into the livestream, I think), Givens gets a noticeable speedup in redrawing his screen by changing a couple of 16-bit stack-allocated variables (`auto`, the default storage class in C) to the `static` storage class, thus enabling the use of static-address instruction sequences like those above rather than (presumably) the offset-from-SP sequences.

At first, this optimization introduced a bug, since local `static` variables are initialized upon the first entry to the subroutine, while `auto` variables with initializers are initialized upon every entry.

You could imagine an optimizing source-to-source translation that would simply add a `static` to every implicitly `auto` local variable in your program and separate its initialization into a separate statement. This transformation would be sound — it would not break previously correct code — except in the case of recursive functions, or more specifically variables in recursive functions whose values are read after at least one recursive call without being written to again first.

This translation improves things, but it has a few problems. First, you can't declare function parameters `static` in C. Second, it could result in your program using more memory than before, because while previously you only needed enough space, on the stack, for the functions in the single deepest call chain (weighted by activation record size), now you need enough memory for all the activation records to be alive at once, because functions can no longer share memory with other functions that aren't active concurrently. Third, access to variables in recursive functions is still slow.

(How important are recursive functions? They enormously simplify recursive-descent parsing, some computations on trees and

graphs, interpreters, and simplified regular-expression matching, as well as many mathematical computations like Aryabhata's pulverizer algorithm, so they are an important feature to have in the language, although they are hard to use safely. But typically only a small minority of code is inside the recursive loop, and it's not performance-critical code. Many programs entirely lack recursive loops; Givens's qe.c is 956 lines of C which, despite its use of function pointers, is entirely nonrecursive.)

Compile-time stack allocation

We could imagine instead statically allocating the activation records of a nonrecursive program on a sort of stack, at compile-time. You could allocate the activation record of `main` at some address `local_variable_start`, and all other activation records at one more than the greatest address used by any of their callers' activation records. This allocates a single static address to every local variable.

So, for example, given call chains main[6] → a[3] → b[5] → c[2] and a → d[7] → c, where the number in brackets is the number of bytes needed for each activation record, you would allocate main at 0, a at 6, b and d each at 9, and c at 16. b and d overwrite the same memory, but that's okay because they're never running at the same time. When b calls c, two bytes are left unused, but that's also okay, because c isn't getting its local variables' addresses from b; they're compiled into it.

To extend this to recursive programs, we can break each recursive loop, or potential recursive loop, by introducing a "trampoline" function into it at some point; a greedy approach may not be optimal but is likely adequate. The "trampoline" has the job of saving the variables from the functions participating in the recursive loop onto a run-time stack somewhere, then forwarding the call to the next function in the recursive loop, then restoring the saved variables when it returns. There may be some variables that don't need to be saved because their saved values are statically never used after the recursive call. It may be worthwhile as an optimization to simply `memcpy()` a relevant chunk of the compile-time stack rather than enumerating all the necessary variables.

(Incidentally, since it only gets invoked once per recursive loop and knows exactly how much stack space it needs, the trampoline is in a position to efficiently check for stack overflows and report them in a usable fashion, something C runtimes usually fail badly at.)

C, however, has another feature that complicates this: you can take the address of a local variable and pass it to other functions. (In C, you can also store it in data structures; the Pascal family including Oberon (see A review of Wirth's Project Oberon book (p. 431) and IMGUI programming language (p. 103)) instead provides a "var parameter" mechanism analogous to downward funargs, which, however, poses precisely the same potential problem for this mechanism.) It is expected that such an address will remain valid until the function it's in returns, despite possible recursion. If such a variable occurs in a recursive loop, it needs to be immediately allocated on a run-time stack, rather than being initially located at a static address and possibly saved and restored later.

For calls via function pointers, the function pointer type, rather than a specific function, can be a node in the call graph which "calls"

all the functions whose addresses are taken and coerced to that pointer type. More conservatively, we could consider all function pointers to be a single node in the call graph.

This approach thus gives us the full semantics of C or Oberon at a much lower run-time cost on machines like the 8080. However, it requires whole-program analysis to precisely calculate which functions potentially participate in a recursive loop, and that might pose some difficulties for self-hosted development.

You could pretty much solve this problem with a linker, though. Each reference to an in-memory statically-allocated local variable gets relocated by the function's activation-record base address, and the linker is responsible for assigning those base addresses at link time and fixing up the relocations, as well as inserting trampolines, which would probably have to copy entire activation records rather than just the "live" parts. Probably you also have to runtime-stack-allocate every variable whose address gets taken, too, and you need to expose function-pointer types to the linker.

This is a nontraditional sort of linker, and it has to do more relocations than the usual kind, but it seems like it still ought to enable fairly powerful self-hosted development with separate compilation, because the object files should be about the same size as before.

It can even solve the problem of parameter passing — the caller gets relocations for the callee's activation record so that it can poke the arguments into the proper locations in memory and get results from the proper place, assuming you aren't passing arguments in registers.

This might still be useful on more modern small computers like the AVR and the STM32, because they are usually run in environments where they don't have a sensible way to report a failure. (See Patterns for failure-free, bounded-space, and bounded-time programming (p. 925).) Under normal circumstances, there is no way to statically bound the stack usage of a C program, because C supports recursive loops, and ruling them out requires whole-program analysis. If your stack overflows into your heap, which can easily happen on an Arduino, you may get incorrect results or your program may just crash.

As an even more nontraditional alternative, you could use a BibTeX-style two-stage compilation process; first, you compile each module based on certain assumptions, such as "function foo is nonrecursive", "function bar is possibly recursive", and "function baz takes an int and a char* and returns a char*", and "function quux preserves the contents of the BC register", which can only be validated by a whole-program analysis, and annotate the compiled module with the assumptions that were used, as well as the useful properties that were discovered (for example, foo calls bar). Then, at link time, you collate all the properties discovered into a database of useful properties, and check whether all the assumptions still hold true. Any module compiled with assumptions that turned out not to hold is then recompiled using the newly collated database, and the link step is repeated. If the properties discovered don't depend on the assumptions made, this will converge after just two iterations.

This approach has the additional advantage of eliminating the need for C header files.

Context switching with "buffer-local variables"

Multics Emacs was the first Emacs to be scriptable in Lisp, during the 1970s period I mentioned above. In Emacs, there are a lot of frequently-accessed variables that are local, not to a function call, but to a particular editor buffer; if you open two files at once, for example, you probably want to maintain independent cursor positions in them. The modern approach to doing this is to store all those variables in a record, allocate a record for each buffer, and maintain a pointer to the "current buffer" record, and associate a buffer pointer with each open window on the screen. Switching buffers is achieved by changing the value of the current-buffer pointer. This requires, as explained above, indexed-offset addressing to all these variables.

To avoid this extra cost, Multics Emacs used an approach similar to shallow binding: all the variables for the *current buffer* are stored in constant places in memory, and when you switch buffers, those variables are copied into the record for the old buffer, then copied out of the record for the new buffer. The rationale for this was that accessing things like the current cursor position is so much more frequent than switching buffers that it doesn't make sense to slow down access to the cursor position in order to speed up switching buffers.

(I suspect GNU Emacs uses the same mechanism even today, but I haven't looked.)

This principle is applicable to many kinds of records that enjoy a certain sort of locality of reference. It's common for a program to do a number of things to one file before switching to doing things to another file, for example, and many GUI programs, if they even use more than a single window at all, do many things in sequence to the same window. Image-processing programs frequently do many things in sequence to the same image, parsers frequently do many things in sequence to the same input stream, network programs frequently do many things in sequence to the same network socket, and database programs frequently do many things in sequence to the same table or cursor.

Such programs can probably work better on an 8080 by using the copy-in/copy-out approach used by Multics Emacs for its buffer-local variables. They may even be able to do this as an optimization — for example, your file access functions could take a file-number argument, maintaining the "current file" state entirely internal, but checking that argument against the current file number upon entry.

However, there are other uses of records that do not work as well in this approach. Pretty much anything that repeatedly walks a tree or linked list of the same kind of records is going to be slower rather than faster this way, including abstract syntax trees and database query plan execution.

Self-modifying code

The 8080 has no instruction cache, so there is no extra cost to self-modifying code, except your sanity. By inserting some instruction bytes between the data fields in a record, you can make the record executable. For example, this subroutine loads B, C, D,

and E with four bytes in 38 cycles (plus 17 in the CALL instruction or 5 in the PCHL instruction to access it, for a total of 55), and occupies 9 bytes of RAM:

```
MVI B, 33h    ; 7 cycles each
MVI C, 31h
MVI D, 12h
MVI E, E8h
RET           ; 10 cycles
```

By poking new bytes into the appropriate locations (overwriting the immediate operands, not the MVI opcodes) you can update the data structure.

55 cycles ÷ 4 8-bit variable reads = 13.75 cycles per 8-bit variable read, dramatically less than the 27 cycles each you'd need for an indexed-offset read. However, an indexed-offset read followed by three 12-cycle sequential reads totals only 63 cycles, so the improvement is less dramatic than it would seem at first.

In some cases, the data can be paired with a more useful operation than merely loading into a register; here we have a bitmask and a bitfield that set the low three bits of A to 5:

```
ANI F8H       ; A &= 0xf8; 7 cycles
ORI 05H       ; A |= 0x05; 7 cycles
```

For function-local variables in nonrecursive functions that are only read in one place, storing the variable value as immediate data reduces the cost to read it from 17 cycles to 10 for 8-bit variables, or from 16 cycles to 10 for 16-bit variables, while adding no extra update cost. If the variable is read in more than one place, the other places can use LDA or LHLD or the LXI/MOV sequences mentioned earlier to read it from within the instruction where it's an immediate operand; alternatively, if it's read more often than it's written, the write operation can update multiple immediate operands.

This seems like a quite significant performance advantage, although it does require whole-program analysis during compilation to be used in a language like C; and this "field padding" in the records can be expensive when you only have a 64-KiB address space. For local variables, though, storing variables inline reduces space usage rather than increasing it.

Earlier I pointed out that chasing a 16-bit pointer chain costs 23 cycles per pointer, or 37 cycles to swizzle SP plus 15 cycles per pointer. But chasing a pointer represented as a JMP instruction costs only 10 cycles; a CALL/RET pair, however, costs 27 cycles.

Avoiding 16-bit variables

16-bit variables are pretty expensive on the 8080, not just to store but also to manipulate, so it's worth avoiding them as much as possible.

The 8080 has some limited 16-bit ALU operations; as noted above, it can do 16-bit addition, fetch, and store, but it can also do 16-bit increment and decrement. However, these operations are

much slower than the 8-bit variety, and its 8-bit repertoire also includes subtraction, addition and subtraction with carries and borrows, bit rotations, and bitwise AND, OR, XOR, and NOT. If you want 16-bit AND, you need to synthesize it out of two 8-bit ANDs, taking 28 cycles:

```
MOV A, D  ; 5 cycles
ANA B     ; A &= B; 4 cycles
MOV D, A
MOV A, E
ANA C
MOV E, A
```

The 8080 also has very limited register space — 88 bits of architecturally accessible registers, not counting the PSW, 16 of which are the PC. (Compare to the 16 32-bit general-purpose registers in most modern CPUs: 512 bits.) So handling a 16-bit value adds a significant amount of register pressure.

This means that in most cases you should avoid having large arrays; limit them to 256 items. If you can 256-byte-align the arrays, you can avoid doing any arithmetic to index them:

```
MVI B, 28H      ; array base address; 7 cycles
MOV C, A        ; index array with A; 5 cycles
LDAX B          ; chase pointer; 7 cycles
MOV C, A        ; index array again
LDAX B
MOV C, A        ; and again
LDAX B
```

This takes 12 cycles to follow each 8-bit pointer after the initial 7-cycle setup. For an additional 7 cycles, you can load a second array base address into D and alternate between them. And by loading C (or E) with a field offset and chucking A into B (or D), you can make the pointers point to 256-byte "memory pages".

If your arrays aren't 256-byte-aligned but don't cross 256-byte page boundaries, you can do an indexed-offset thing:

```
LXI B, 2821H    ; array base address; 10 cycles
ADD C           ; A += C; 4 cycles?
MOV C, A        ; set up address in BC; 5 cycles
LDAX B          ; load from array; 7 cycles
MVI C, 21H      ; fix base address; 7 cycles
ADD C
MOV C, A
LDAX B
```

On the first iteration, though, this is 26 cycles, barely any faster than the more flexible 27-cycle sequence I started with. Subsequent iterations get down to 23.

Givens's qe in particular uses 16-bit pointers fairly extensively so that it can treat the editor buffer as an undifferentiated, flat sequence

of bytes, which simplifies the description of editing operations and file access, and would especially simplify search if he implemented it.

Notes on the STM32 microcontroller family

Kragen Javier Sitaker, 2018-06-30 (updated 2018-11-12) (42 minutes)

I think I am switching from AVRs to STM32s for seven principal reasons.

• Speed: STM32s are much faster, from almost twice the clock speed to over ten times the clock speed, with registers that are four times as wide, including a single-cycle 32×32→32 multiply — which would be 10 8-bit multiplies and 7 8-bit adds. And AVRs without an external crystal are limited to 8 MHz, while STM32s can run at full speed on their internal ±1% RC oscillators.
• Power: With an STM32, you can run 32 32-bit instructions on the energy the AVR needs to run a single 8-bit instruction. AVRs, despite their "picoPower" marketing, use about 7500 picojoules per instruction (pJ/insn), and those are 8-bit instructions. The STM32F0 uses about 1500 pJ/insn, and the STM32L0 uses about 230 pJ/insn.
• Cost: The STM32 costs more than the AVR, but only slightly, and less per pin or per MIPS. The 48MHz STM32F031x4, with 39 GPIOs, costs US$1.30 in quantity 1 on Digi-Key. The cheapest reasonable† AVR is the 20MHz ATtiny13A, which costs US$0.40 and has 6 GPIOs.
• Size: The STM32L is *tiny*, 2.133 mm × 2.070 mm in the WLCSP package, with 21 GPIOs (two of which you can run I²C on). The AVR ATtiny4/5/9/10 is physically the same size, but only has 8 total pins and 4 GPIOs.
• Scalability: STM32s have a much higher ceiling; AVRs top out at 20 MHz with a limited range of peripherals, while STM32F7s run at 216MHz and have all kinds of crazy things.
• ADC: STM32s' ADCs are 12-bit and run at 1Msps and up, while AVRs' ADCs are 10-bit and run up to 15ksps at maximum resolution.

• Debugging: AVRs' DebugWIRE protocol, in a big FUCK YOU to users of free software, is undocumented, while STM32s have a debugging interface called "serial wire debug" which is supported in OpenOCD.

† The ATtiny4/5/9/10 are cheaper at 17¢ but are almost useless.

Introduction

I think the STM32F031 is going to be my new favorite microcontroller, replacing the AVR. It's a 32-bit 48MHz Cortex-M0, it costs US$1.30 in quantity 1 on Digi-Key, and there is already Arduino support for it, which should make it easy to get started. Like the ATMega328, it has 32 (or 16) kilobytes of Flash and 4 kilobytes of SRAM. And, in addition to easier-to-handle sizes with shitloads of pins (up to 39 GPIOs!), it comes in a 2.4-mm-square WLCSP25 form factor. And it uses one fifth the power of the AVR at the same clock speed!

(Hmm, the above mostly refers to the STM32F031x4/6, but I might have gotten some details from the STM32F030x4/6/8/C

mixed in there. The 4/6 is 16 or 32K; 8 and C are 64 and 256 K, and more interestingly, up to 32K of SRAM. These larger chips also come with up to 55 GPIOs. There are also STM32F3 and STM32F4 families, which are progressively more awesome; the F4 runs at 168MHz and has three 5Msps DACs, and both have floating-point.)

On the bad side, it still doesn't have a radio (unlike the ESP32) and it only runs up to 3.6 volts — 5 volts is right out.

There's an overview by Satoshi NM.

Instruction set

ARMv6-M with Thumb-2, ONLY. RAWK. Nothing comes close for machine code density. And it has a 1-cycle 32×32 → 32 (☹) multiply, which is pretty astounding even if it does discard half the result.

The STM32Foxxx Cortex-M0 Programming Manual (PM0215) doesn't include instruction timings at all except to say that the multiplier takes a single cycle, actually.

There's a separate stack pointer for interrupt handlers if you enable it, so that the interrupt handlers (I think there can be up to 7 on the stack at once) don't eat into the worst-case stack space of every thread.

Software support

OpenOCD even supports the "serial wire debug" interface, which apparently allows you to turn the microcontroller into the puppet of your workstation using two pins.

GPIOs and 5V

It does have 5V-*tolerant* I/O pins, though not all of them. Also, its GPIOs *can* be configured as open-drain rather than push-pull, which has two huge benefits:

• They can communicate with 5-V systems if there's an external 5V pullup;
• Perhaps they can switch somewhat heftier loads?

Supposedly the pins can source or sink 20 mA each, and up to 80 mA over the whole chip, which I think is inferior to the AVR's 200; still, if I could hook a 12V 100mA motor directly to four open-drain GPIO pins, that would be pretty awesome. I don't think I can because they get configured as input pins during and after reset, and those aren't supposed to be subjected to more than 4 volts.

Some other STM32s have a special pin for sinking a lot of current from an infrared LED.

The GPIO pins can also be configured with internal pullups, pulldowns, or neither.

Hmm, wait, it says the 5V-tolerant pins can be subjected to V_{DDIOx} + 4.0 volts as long as the pullups and pulldowns are disabled. What's V_{DDIOx}? Oh, I guess that's the 2.0V to 3.6V Vdd. So 7.6V is reasonable. But anything over 5.5V is outside "general operating conditions".

The smallest and cheapest ones only have 15 GPIOs, which is still pretty decent; that's under 9¢ per GPIO!

The massive number of GPIOs can toggle at up to half the clock

speed, i.e. 24MHz, supposedly. I don't quite understand how this works; do you just run a sequence of instructions that loads immediate 16-bit values into some CPU register and then writes them to the memory-mapped I/O register `GPIOx_ODR`, I guess? Or is there some way to feed the GPIOs with the DMA controller?

Analog

Its ADC is 12-bit rather than the AVR's 10-bit, and it's supposedly 1µs! Does that really mean 1Msps? It apparently does… and it has 9 or 10 external input channels. And it supports DMA, and there's a "DMA circular mode" (`DMACFG`=1) to just dump stuff into a ring buffer — ideal for seeing pre-trigger data!

It doesn't seem to have an analog comparator input, unfortunately. You have to fake it by configuring the ADC to do conversions constantly and fire an interrupt when they hit a threshold.

Another drawback compared to the AVR is that the ADC's full-scale reading is always Vdda, which must be at least as high as the power supply — at least 2.4 V. It has a calibrated internal bandgap voltage reference to measure against, but it can't set that as the ADC reference voltage directly. This means that the 4096 counts in the output are spaced at least 580 µV apart, and 880 µV at 3.6 V, while the AVR's 1024 counts can be spaced 1.07 mV apart. Some other STM32 chips support a separate VREF+ (alluded to in ST AN2834), but the STM32F031x4/6 does not. Only STM32s with 100 or 144 pins do. ST suggests solving the problem with a preamplifier.

The ADC requires at least 2.4 V, although most of the rest of the chip will run down to 2.0 V. And it uses 1 mA at its normal speed.

It's possible to configure the ADC for lower bit depth (10, 8, or 6 bits) to speed it up (to 928, 785, or 643 ns, respectively), which suggests you could crudely digitize signals up to 780 kHz with one STM32. The sample-and-hold is 1.5 cycles of the 14MHz ADC clock, so about 107 ns. This seems like it is likely to sharply attenuate frequency components above about 10MHz even if you can get several chips sampling them at once.

The Vdda pin is supposed to draw only about 0.9 mA, so putting it on a separate regulator might improve precision.

Like the AVR, it has an inaccurate temperature sensor: ±5°, better than the ±10° on the AVR. (Hmm, at least on the STM32L, the Vsense linearity with temperature is at worst ±2°, and at least 1.48 mV/°, which you would think would give you 1° accuracy? Maybe it's just `TS_CAL2` that is ±5°?)

In terms of PWM, well, it has 9 timers and 11 (?) PWM channels, which can run off 16-bit timers instead of an 8-bit one, which should give a lot more dynamic range. It even has a 32-bit timer!

Some of the timer counters can be run off an external quadrature input instead, which should enable quadrature feedback up to fairly high pulse rates.

The PWM counters have an adjustable "auto-reload value" and can count in either sawtooth, inverted sawtooth, or triangle form. I think you can run them off a 48 MHz clock, which ought to enable you to generate phase-correct PWM waves at 24 MHz and factors thereof (24 MHz, 12 MHz, 8 MHz, 6 MHz, 4800 kHz, 4 MHz, 3428 kHz, etc.) Or maybe 12 MHz.

They also have a dead-time mode specifically designed for

H-bridges.

Buses

It has I²C (including wakeup from Sleep, 10-bit addressing, multiple 7-bit slave addresses, and 1 Mbps "Fast Mode Plus") and an 18Mbps SPI interface. These, like the ADC, support DMA, so you don't have to handle interrupts after every byte like on the Arduino.

Its USART, which also supports DMA, can run at up to 6Mbps, which could be handy for RS-485.

The DMA support means that the CPU can sometimes be delayed in its access to memory, which seems like it could cause some problems for cycle-accurate bitbanging. The CPU doesn't seem to have a cache (why would you have a cache when all your RAM is zero-wait-state?), but it does have a 12-byte instruction prefetch buffer, which could also cause unpredictable timing; it can be disabled with `FLASH_ACR`.

The larger STM32F030x4/6/8/C has two I²C interfaces instead of one and two SPI interfaces instead of one. Other STM32 chips have a wide variety of peripherals available.

Clocks

In addition to an external crystal, in theory, like the AVR, it has an 8MHz internal oscillator — with an optional 6× PLL to bring it up to 48MHz.

A neat thing is that if the external crystal fails, it automatically switches to its internal oscillator. (But then it fires an NMI, and your ISR needs to clear the CSSC bit in `RCC_CIR` to escape the NMI loop, so it's not totally transparent.)

Power

Supposedly it normally uses like 20mA at 3.6 V and 48 MHz or more like 12mA if all the peripherals are turned off. This works out to something like 1.5 nJ per 32-bit instruction if we figure on 1 instruction per cycle. Strangely, the datasheet doesn't supply current consumption figures at 2 V.

This scales linearly down to about 3 mA at 8 MHz, then down to about 1mA as frequency approaches zero.

It has four modes: Run, Sleep, Stop (3.2–55 µA), and Standby (0.7–3 µA), which last is sort of turned off actually, losing all the memory contents. It can run down to 2V. Stop mode still has a bunch of possible interrupt sources as wake sources, though I'm not sure if timers are among them. (I think its RTC may be capable of doing this.) Presumably getting out of Standby involves rebooting, and it says the RTC can do this. Also the watchdog timer can wake it from Stop or even Standby.

The RTC has a separate supply and consumes 0.5–2.1 µA when enabled. It can continue working down to 1.65 V.

Wakeup from Stop mode takes 2.8 to 9 µs; wakeup from Standby takes like 50 or 60.

All of this would seem to imply that it is sensible to use Stop mode for duty cycles down to about 0.1% as long as the wakeups are for at least, say, 20 µs of execution — 1000 instructions or so. Which means that you can reasonably wake up every 25 ms for 1000 instructions,

using about 2 µJ while awake and another 1 µJ while asleep, for a total of 120 microwatts, 600 times lower than full power consumption of 72 mW.

72 milliwatts is about three red indicator LEDs.

(I'm not yet sure how clock speed depends on supply voltage.)

Standby mode might use 5 microwatts, and so makes sense for duty cycles down to 0.007%, but requires 100 µs or so (5000 instructions) of execution. I mean, you could do less execution, but then you would be spending way more energy on rebooting than on actually getting anything done. At this level you're waking up no more often than every 1.4 seconds or so. In this mode nearly all the GPIOs are tristated.

I think there may be some wrinkles around stabilization time of the system clock PLL I may be missing here. Like, if the PLL is disabled, you only get 8 MHz, not 48. But if the PLL is enabled, it might take a while to get sync (up to 200 µs, according to the datasheet). And the PLL automatically gets disabled whenever you enter Stop or Standby, though not Sleep, so you always wake up at 8MHz.

Note that erasing the Flash takes 20–40 MILLIseconds, during which time presumably the thing is using as much power as normally, or even more.

A 3-gram Energizer CR2032 lithium coin cell could power the STM32 directly, and its 240mAh down to 2 volts works out to 2.2 kJ. This would power the STM32 at full speed for 8 hours (if it can deliver a reasonable amount of current; its internal resistance is 20Ω until near the end, which in theory means it can deliver 150mA), in Stop mode 99.9% of the time waking up 40 times a second for 6 months, or in Standby mode waking up every 1.4 seconds for 14 years. (In either case you can use the IWDG independent watchdog or the RTC real-time clock to wake up at a scheduled time.)

To power the STM32 at full speed for a full second directly from a capacitor would require a 16000 microfarad capacitor. A 1-farad supercapacitor could theoretically run it for a full minute. If you had a buck converter and a boost converter, you could use a higher-voltage electrolytic. For example, the last inkjet printer I took apart has a 100µF 50V electrolytic on its main board, which is a bit smaller than my last pinky joint; this works out to ⅛J, or 1.74 seconds at full power.

The larger STM32F030 uses about 10% more power at the same high speeds.

1.5 nJ/insn is slightly higher than the 0.9 nJ/insn of the MSP430 family, but much higher than the 0.3 of an LPC1110 (see Keyboard-powered computers (p. 2220)). Atmel has a line of "picopower" ARM microcontrollers that are around 0.25 nJ/insn (see Low-power microcontrollers for a low-power computer (p. 2602)). Much-lower-power microcontrollers exist but are not widely used (see Keyboard-powered computers (p. 2220) and Low-power microcontrollers for a low-power computer (p. 2602).)

However, the most relevant comparison is the ATmega328, which (despite sharing the "picopower" moniker) gobbles 7.5 nJ/insn (see Low-power microcontrollers for a low-power computer (p. 2602)). So the STM32 family uses one fifth the power to process four times as many bits!

Relevant comparisons include: that an E-ink display uses about 3

mW during continuous reading at a comfortable rate; the ADC also uses 3 mW while running; and 3 mW from a 12%-efficient solar cell is about ¼ of a square centimeter.

Memory

It has a bootloader that can reprogram its own flash. Also it can somehow boot from its own SRAM. Erasing a 1KB page of the flash takes 20–40 ms, and programming a halfword takes 40–60 µs, which is like two or three thousand clock cycles.

Of course ARM is not Harvard, and so not only is C programming somewhat simplified, but also, it's possible to execute code from SRAM. In fact, that's mandatory if you want to keep executing code while erasing or even writing to the Flash, and the SRAM is zero-wait-state.

You don't get the full benefit of the implicit AND operation provided by NOR flash — the micro tries to protect you from yourself by refusing to program non-erased locations — except that you *can* overwrite arbitrary halfwords of the flash with 0x0000 without erasing entire pages. I feel like this could be useful.

Board support

The popular Blue Pill STMDuino is a Chinese design built around a STM32F103C8, which is a somewhat higher-end STM32: 72 MHz, 64 or usually 128 KB of Flash, and 20 KB of RAM. This is a Cortex-M3 rather than M0. (M4 is the one with the FPU, saturating arithmetic, and MAC.). I think it's the same size as an Arduino Micro or Nano, I'm not sure. It's 53.0 mm × 22.5 mm, just slightly larger than an Adafruit Feather.

The WLCSP25

The 2.4mm-square WLCSP25 that the STM32F031x4/6 can come in is particularly appealing to me. It's just so incredibly tiny; it's only 2.458 mm × 2.36 mm × 585 µm at most, and that includes its balls. It should weigh under 10 mg, since it occupies 3.4 µl. However, a few sacrifices are made to get it down to 25 pins, or rather solder balls. Port A has pins 0–10, 13, and 14, but is missing pins 11, 12, and 15. Port B has pins 0–1, 5–7, and that's it; port F has just pins 0 and 1, which are for the external oscillator. These 20 GPIOs, plus Vdd, Vss, Vdda, BOOT0, and NRST, suck up all the pins.

Port A and PB1 have the analog input channels, so it's fully supplied there. Port A also has the USART, the SPI interface, and the I²C interface, and most of these have alternate pins among those included from port B. PA13 and 14 have the SWD debugging interface.

It's missing the battery-backup pin for the real-time clock, it's missing the connections for a 32.768kHz watch crystal, and 8 of the pins aren't 5V-tolerant (namely, PA0–7), but it doesn't actually seem to be missing anything essential except moar GPIOs.

So, if you want to max out your GPIOs, you have 20 GPIOs, or if you want to preserve debuggability, you have 18 GPIOs and two SWD pins (PA13 and PA14). If you want to use it as a debuggable I²C slave to twiddle and maybe process GPIOs, you additionally dedicate either PA9–10 or PB6–7 to I²C, and you have 16 GPIOs. If

you need high timing precision, you put a crystal on PF0–1. If you want SPI, you can have it (at 3V) on PA4–7, sacrificing three or four analog pins. And you have PWM outputs on all the GPIO pins except PF0–1 (the oscillator pins) and PA13–14 (the SWD pins), except that I think a couple of those pins are actually just used as triggers for the PWM waveform (PA0 and PA5 are TIM1_CH1_ETR and TIM2_CH1_ETR, which I don't understand.)

Holy *SHIT*, the STM32L

I didn't realize this at first, but since 2015, there's *another* line in the STM32 lineup called the "access line ultra-low-power" STM32L, the low-power processors. And these are even *smaller* and also lower-power. And their ADC is *even faster* at 1.14 Msps, with DMA. *And* they have two analog comparators instead of zero. They still have SWD, I²C, and SPI ("only" 16Mbps, and then only above 2.7V; at 1.71V it can manage 12Mbps, and at 1.65V 8Mbps). They're a bit slower, though, at 32MHz, but they're still Cortex-M0+ with a single-cycle 32×32→32 multiplier.

The STM32L011x3/4 goes for US$1.50 on Digi-Key, and it has a WLCSP25 package (STM32L011ExY) that is 2.133 mm × 2.070 mm. Miraculously, it has *more* GPIOs than the larger STM32F0's WLCSP25: sort of 21 rather than 20, because the BOOT0 pin can be configured as PB9, though input only. It has less memory (the 3 has 8K of Flash, the 4 has 16K, both have 2K of SRAM) and it can operate down to 1.65 V, or 1.8 V if the brownout reset circuit is enabled.

The WLCSP25 pinout is gratuitously different from the STM32F031x4/6 WLCSP25 pinout, but since it's a different physical size, you couldn't use it in the same circuit board layout anyway. Almost the same set of pins is mapped: pins 0–10, 13, and 14 on port A, pins 0–1, 5–7, and 9 on port B, and pins 14 and 15 on port C, rather than 0 and 1 on port F, but those are still the external oscillator pins.

The friendliest way to get started with the STM32L might be using the LQFP32 package, which is 7 mm square and should be easy to hand-solder, since its pins are every 0.8 mm.

The GPIO currents are a bit lower: 16 mA sunk by three-volt pins, 22 mA sunk by five-volt pins, and 16 mA sourced by either.

STM32L ADC

The 12-bit ADC not only runs at 1.14 Msps down to 1.65V, it only uses 25µA at 10ksps and 200µA at 1Msps, and it supports up to 256× hardware oversampling in order to fake up to 16-bit sampling. So you could get 16-bit samples at 4.4 ksps.

STM32L power

The front page of the datasheet claims 0.95 DMIPS/MHz and "down to" 76 µA/MHz in Run mode. At 1.8V, if we ignore the "down to" clause, this would work out to 0.144 nJ/insn, 144 pJ/insn, dramatically lower than the STM32F0; even at its max of 3.6V it's only twice that, 290 pJ/insn. The aforementioned 3-gram Energizer CR2032 lithium coin cell with its 240mAh down to 2 volts (2.2 kJ) could thus power it for 3200 MHz-hours — 100 hours at 32 MHz, 200 hours (8 days) at 16 MHz, 400 hours (17 days) at 8 MHz, 3200 hours

(4 months) at 1 MHz.

Perhaps more interesting still, given a 1-farad 2.7-volt supercapacitor, which has 2 J and 0.9 coulombs down to 1.8 V, it could run for over 3 MHz-hours; with a 90%-efficient buck-boost regulator running the supercap down to 1.3 V (2.8 J), it could run 18 billion instructions, 4.9 MHz-hours. Such a capacitor as the 104µℓ 4Ω 1F Nichicon JUWT1105MCD (see Capacitors: some notes on tradeoffs (p. 134)) has a time constant of 4 seconds, so it can mostly recharge within 4 seconds and 95% charge within 12 seconds.

Digging in a bit more, above 16 MHz it needs at least 1.71 V, and there are two other "power consumption ranges" up to 16 MHz and 4.2 MHz, which apparently affect the number of wait states (perhaps to Flash only?). Power consumption is about 1 mA in sleep mode at 16 MHz with all peripherals off, and there are seven different low-power modes. In Standby mode, it consumes 180 nA without the RTC enabled or 410 nA with the RTC. It has a "low-power run" mode which can run at 32, 65, or 131 kHz, which, at 25°, runs at 5.7–17µA from RAM or 18–32µA from Flash, which works out to 210 pJ (1.65 V, 131 kHz, RAM) to 400 pJ (3.6 V, 32 kHz, Flash) per instruction; typical consumption for normal run mode ranges from 320 µA (4 MHz, running while(1) from RAM or with prefetch off) to 5.4 mA (32 MHz Dhrystone from Flash). Likely the most efficient is 1.95 mA for 16 MHz from RAM, which is further explained as "HSI16 clock source (16 MHz), Range 2, VOS[1:0] = 10, Vcore = 1.5 V, Flash switched OFF". If we figure that this is 15.2 MIPS and is being powered at 1.8 V, then that's 3.5 mW, 230 pJ/insn.

So I can't figure out where they get the "76 µA/MHz" claim from, because the best I can find in their measurements is 122 µA/MHz. Oh, wait, I think I see how to get partway there — the 1.95 mA is "code with data processing", which I think is Dhrystone, and `while(1)` uses about 30% less power. That gets you to 85 µA/MHz but not to 76.

This is still enormously better than, say, the 900pJ MSP430F2001.

A tricky bit here is what kind of suspend mode you can get away with using when there isn't stuff to do. You have Sleep (1 mA at 16 MHz), Stop (with or without RTC, retaining RAM contents), and Standby (with or without RTC, losing RAM contents). Aside from the wakeup time, the problem is that in Standby you can only be woken by the brown-out reset, power-on reset, RTC "tamper", something completely undocumented called "Auto WakeUp (AWU)", the independent watchdog, and two of the GPIO pins. By contrast, in Stop mode, you can also be woken up by the programmable voltage detector (PVD), the analog comparators, the LPTIM, all the GPIOs, the RTC (if it's running), the USART, the low-power UART, and I²C, though not SPI. And it only takes 5 µs to wake up instead of 65 µs.

In exchange for the wakeup limitations, you cut your power; at 1.8 V:

mode	µA	µW	time to drain	time to drain	duty
		1.8 V	CR2032 2.2 kJ	1F 2.8J	cycle
			coin cell	supercapacitor	
16MHz Run	1950	3500	175 hours	13 minutes	

16MHz Sleep	450	810	31 days	58 minutes	23%
131kHz Flash run	32	58	14 months	14 hours	1.66%
131kHz RAM run	17	31	27 months	25 hours	0.87%
Stop w/RTC	0.54	0.97	72 years	33 days	0.028%
Standby w/RTC	0.41	0.74	94 years	44 days	0.021%
Stop, no RTC	0.29	0.52	134 years	62 days	0.0149%
Standby, no RTC	0.18	0.32	220 years	101 days	0.0092%

The "duty cycle" column is the duty cycle at which the power used in low-power mode equals the power used in run mode at 16MHz. At greater than this duty cycle, the majority of power used is in run mode, so the low-power mode's power consumption is in the minority; at less than this duty cycle, run mode's power consumption is in the minority.

This makes me think that as long as your duty cycle is above 3% or so, you should just use low-power run mode instead of suspending, and above 0.1% or so, it isn't worth worrying about the differences between the different suspend modes, so you should just use stop with RTC; but below 0.03% or so, the differences between them could potentially give you a factor of three improvement in lifetime.

The Sleep mode doesn't give a huge improvement on power, but it's very cheap and only takes 7–10 clock cycles to wake up from.

The wakeup latency means that, above a certain frequency of wakeups, you no longer get the benefit of a low duty cycle. At the 5 µs wakeup time for Stop, for example, you get to the 0.028% duty cycle at 56 Hz, even if all you do after the wakeup is just go right back to Stop.

(The wakeup time even from Stop actually depends on the clock speed and the voltage regulator configuration and can range from 5.1 µs to 260 µs (!), and Standby wakeup can range from 65 µs to 3000 µs.)

Such a small device will probably have appreciable power usage in its communications with other devices. In "Range 2", the I²C interface uses 8.2 µA/MHz, GPIOA uses 6.3 µA/MHz, and GPIOB uses 4.1 µA/MHz. If all three are turned on, they total 18.6 µA/MHz, or 300 µA at 16 MHz, adding about 15% to run-mode power consumption, but increasing stop-mode power consumption by a factor of over 600. But maybe you could enable just I²C while stopped.

If it's communicating, though, in addition to running its own GPIO port, it needs to drive the input impedances of the other chip and the lines in between. Different input pins have different specified input leakage currents: ±50 nA, 200 nA, 500 nA, and they're specified as having a typical input capacitance of 5 pF, which means that charging them up to 1.8 V will cost you 9.0 picocoulombs, the same as you spend on the leakage current in 180 µs, 45 µs, or 18 µs, according to which leakage current you figure with.

9.0 picocoulombs on half the bits you transmit (the ones that differ from the previous bit) at 1.8 V gives you a cost of 8.1 pJ per bit, which triples to 24 pJ for separately-clocked serial protocols like I²C and SPI.

8 or 24 pJ per bit is relatively significant compared to 230 pJ/insn, since instructions generally produce 32 bits, which means 7.2 pJ per output bit. But it's far from the overwhelming cost I was fearing.

Local availability

I can get an STM32F103C8T6 here in Buenos Aires for AR$154 (US$5.39) or some kind of STM32F030 from */while1/* in Liniers for AR$99 (US$3.46). Arduinos based on the STM32F103C8T6 are even more common and cost from AR$200 to AR$300 (US$7–10.50). Large volumes would therefore seem to depend on importation.

The 103 has a Cortex-M3, USB, 72MHz, CAN, two 1Msps 12-bit ADCs, 20K of SRAM, 64K of Flash, three 16-bit timers, two I²C interfaces, JTAG, and 1.25 DMIPS/MHz. It runs down to 2.0V. It seems to come in LQFP100, LQFP64, and LQFP48 packages. The "C" in the part number means these are 48 pins, which means 37 GPIOs.

In particular "Arduino Arm Stm32 Cortex-m3 Stm32f103c8t6 Mona" is Monarca Electronica in Flores for $220, with male headers. Monday to Friday 10:00–13:00, 14:00–19:00. Gavilán 58, C1406AWA Buenos Aires, 011 4634-2407, info@monarcaelectronica.com, according to Gooble and Mercadoshops. Also WSAP 1162241486. I could go there TOMORROW.

Fun projects

You should totally be able to bitbang NTSC or PAL color from this bad mofo, or for that matter AM radio. You should even be able to do AM radio with their PWM outputs, since that's the 540 kHz to 1610 kHz range. The PWM waves unfortunately have relatively few power levels available, but the slightly lower frequencies actually within the AM radio spectrum have more; 545.5 kHz is subharmonic 44, so you should have 22 meaningfully different power levels available.

Given the 24MHz max GPIO toggle rate, a TV typewriter could in theory manage 400 kilopixels per 60Hz NTSC field, or 800 kilopixels on the screen. But NTSC is actually limited to about 6MHz of bandwidth, so it's more like 100 kilopixels per field or 200 kilopixels per frame — about 400 × 500. This is enough for 60 lines of 80 columns.

Rebraining a calculator with one of these bastards should give you access to virtually unlimited computational power.

The 8MHz HSI RC oscillator has an 8-bit HSITRIM register which adjusts its frequency up or down in steps of about 40kHz, about 0.5%. If scaled up into the FM radio range, these are steps of about 0.5 MHz — too big to get usable FM radio out of. But maybe there's another way to bend the HSI frequency by adjusting the voltage, current, or temperature of the chip. You're lacking about a factor of 4 in speed to do direct digital synthesis of FM radio waveforms without an analog front end, but maybe you could generate, say, a 14 MHz square wave and filter out its 7th harmonic. This would be about 3.4 CPU clock cycles per full oscillation, so it would be kind of tricky, but maybe you could do it.

All the trimming and calibration and precision in the ADC and clocks, plus the various push-pull/open-drain/pullup/pulldown optionson the GPIOs, should enable a much better version of the M328, especially if you use a crystal. And 3.6V or 2.4V should be a lot safer for the DUT than 5V. (Does the M328 run at 5V?)

The AVR could only sample from its ADC at very low sampling

rates. Even the cheapest STM32 can do 1 Msps and so you should be able to digitize 500 kHz waveforms. This gives you about 2.5% of a decent oscilloscope, which ought to be enough to debug slow circuits.

If you could gang up several STM32s, you could perhaps make 35% of a decent oscilloscope, or even a bit more. 14 STM32s adequate to the job should cost under US$10.

Alternatively, it ought to be feasible to build an SDR for broadcast AM or FM radio using that megasample of capture bandwidth.

Audio communication and touch detection should be easy.

The Magic Kazoo should definitely be built around one of these bad boys. So should lots of other musical instruments.

The 25-to-55-kΩ pullups and pulldowns should source or sink a few hundred μA. In theory you could use this to very dimly light an LED, or charge a capacitor or reverse-biased diode by a very small amount to measure light, heat, radioactivity, or vibration. Into 10 pF of capacitance you should get a few tens of mV/ns (MV/s), or a bit under a volt per 48 MHz cycle. According to the datasheet, a Vishay 1N4001 is about 15 pF and has a reverse leakage current that rises exponentially with temperature, from 0.2 μA at 50V at 25° up to 5 μA at 100° and 180 μA at 150°. Fortunately or unfortunately, it's also near exponential with voltage, being something like 0.03, 1.5, and 20 μA respectively at the 7% of peak reverse that 3.6 V represents. Unfortunately the input leakage current is given as up to ±0.2 μA in analog mode, which would overwhelm the smaller numbers in this list. 1.5 μA at 15 pF is 100 kV/s or 100 mV per 1μs ADC sample time. (The STM32 pins themselves weigh in at 5 pF.) A lower-voltage diode might be a better choice as a temperature sensor.

You should be able to use the hi-Z input state for detecting electrical fields, given this 0.2 μA number. Maybe a capacitive divider would be useful.

It should be feasible to do a pretty fast 16-bit-wide logic analyzer using one of the 16-bit GPIO ports. I don't know how often you can read them but it seems like it should be at least 10 million times a second, producing 20 megabytes per second. Probably you could stream such data out to an SPI peripheral at the much slower 18 megabits per second the SPI interface supports.

For parallel computing, it should be feasible to implement the PAPERS Beowulf barrier synchronization primitive on a cluster of these guys using their open-drain/pullup configuration. As each microcontroller reaches the barrier, it writes a 1 to its pin, but continues to read a 0 from it until the last open-drain output on the bus gets set to 1. Given the 20 mA sink current capability and the 25 kilohm minimal pullup resistance, it should be possible to synchronize over 100 microcontrollers within microseconds this way. If only a small number of microcontrollers enable their pullups, it should be feasible to scale to thousands. This approach is actually used in the Gestalt FABNET bus.

It should also be possible to compute a crude majority rule function in this way, by using the pullups and pulldowns to "vote".

Parallel computing is especially appealing given the STM32L0's six times lower cost per instruction, with the limitation to 16MHz. You could plausibly build a 3×3×3×3 81-processor hypercube with 162 kilobytes of RAM and 1.30 megabytes of Flash, capable of 1.2 billion

instructions per second, that weighed 100 milligrams and ran (for embarrassingly parallel problems) on 1.8 V, 160 mA, 280 mW, for a BOM cost of under US$100. It might measure 7 mm × 7 mm × 7 mm if the circuit boards and capacitors don't take up too much space. Without any external switches, it could scale its power usage down to 26 microwatts by moving all the processors to Standby; with one, it could power the unused processors off entirely, leaving a power of 0.32 μW for the one left in Standby.

It should be straightforward to do the DSP necessary for short-range ultrasonic communication even at hundreds of kHz, if you can find adequate transducers.

I think the key to inventing ubiquitous computation, if found in a literary genre, is going to be fantasy, not science fiction. Sterile tropes of human-like computers with voice interfaces do not help us to imagine how we might actually interact with these devices. If we can give the objects in our environment new rules — whatever new rules we want — what rules would we like to give them? If you can enchant the objects in your environment to act however you want, what would you have them do?

Perhaps you would have your possessions follow you around, put themselves away when you got home, and scream or fight back when they were being stolen. Your bullets and arrows would never miss, and your clothes would become hard as rock when the bullets of others were about to hit them. Your utensils would change color or cry out in pain if they recognized a poison in your food. Your clothes would always keep you dry and at a comfortable temperature, despite being thin and light, and would never rip or stain. You would know everything about whoever you met before they told you, and you would know whenever you were in danger. You could reach the top of the highest tree or through the narrowest keyhole, and hear a whisper across the city if it had your name in it. You could climb walls like Spider-Man, fly through the air like a bird, or run faster than a horse; you could send objects flying to wherever you wished. You could call down lightning and fire to destroy your enemies, or turn them to stone, mud, or pillars of salt. Your house would clean itself, and it would change its appearance as you wished.

The GD32

There's a similar line of ARM SoCs from a Chinese company called GigaSomething (GigaDynamics?) with part numbers that seem to mirror the STM32 line: GD32F107 and so on. I wouldn't be surprised if these were manufactured as drop-in STM32 compatibles with some competitive advantage: lower prices, being able to speak to the company only in Chinese, more predictable stocking, shorter lead times, or something.

Topics

Binate and KANREN

Kragen Javier Sitaker, 2018-12-02 (3 minutes)

You can construct the relation describing your desired program by composing it from binary relations.

I just woke up from a nightmare where I was scheduled to give a talk tonight at one of my two employers about some work I had just done, when the other employer informed me that they considered that work confidential to them and covered under my NDA to them, so I wasn't going to be able to give the talk. Since neither employer actually exists, this document briefly describes the work.

Binate is a particularly terse way of writing down relations by algebraically composing them from more primitive, binary relations. It can only express binary relations, but it can express binary relations among tuples, so that isn't actually a limitation.

In particular, you write relations in terms of more primitive relations using conjunction or intersection `,`, union `;`, converse or inverse `~`, composition (concatenation), transitive closure `*`, either negation `!` or set subtraction `-`, and a form of N-ary Cartesian product: `{x: a, y: b, ...}` produces a relation from the intersection of the domains of a and b etc. to a set of tuples which are the domain of the new relations x and y etc., whose codomains are the codomains of a and b etc. respectively, constructed in the only reasonable way. Literals are treated as relations from the entire universe to that literal. This turns out to be sufficient to express anything you can express in Codd's N-ary relational algebra or relational calculus.

Kanren is a family of relational programming languages in which you program not by constructing functions but by constructing more general relations, which is to say that when you invoke them on different occasions, you can change your mind about which arguments are inputs and which are outputs. This sounds like Prolog, but because Prolog contains a lot of extralogical operators, its ability to generalize is limited.

When using Prolog semantics, the major advantage of Binate over Prolog is that programs are dramatically terser because they are point-free. For example:

```
ancestor = parent parent*.
father = parent, "male" ~sex.
sibling = parent ~parent.
cousin = parent sibling ~parent.
```

The major advantage of Kanren and relational programming over functional programming is that, in cases where you need to use both a function and its inverse, you avoid having to write the inverse explicitly, which sort of doubles your programming power. Indeed, a function of multiple arguments may have many inverses, and you only have to write it once. Additionally, it's often much easier to describe a predicate you would like to find instances to satisfy than it is to describe an algorithm to generate them — this is the general virtue of constraint-oriented programming or programming with solvers — and at times you would like to change the search or solver

algorithm without changing the predicate you are trying to satisfy.

So, the trade-secret insight from my dream was this: by composing your program out of binary relations, you can describe the computation you want in a somewhat terser fashion than any previous language. You can beat APL for terseness.

wood and stone personal digital assistants

Kragen Javier Sitaker, 2007 to 2009 (6 minutes)

Polished-Stone Handheld Computers

So I've been thinking about making a handheld computer with the look and feel (shininess, irregularity, weight, seamlessness) of a polished semiprecious stone.

One way to do this would be to embed the electronics in polyester resin poured into a mold, with an embedded induction coil for charging, some embedded lead shot for weight, and a dark, but not quite opaque, surface layer to hide the interior except for when it was glowing. Input would probably be piezoelectric, localizing surface taps or using rhythm. (See earlier kragen-tol post magic boxes and secret knocks.) Output could be through embedded LEDs shining through the surface layer or through audio, especially if you held it against a window.

(How much lead shot would you need? Lead has a density of 11.3g/cc, against quartz's 2.6g/cc and the polyester resin's 1.11g/cc, so only 14.6% of the volume would need to be lead to equal quartz's density.)

It would be shockproof, waterproof, crushproof, not particularly prone to damage from ESD, and it would feel really good in your hand. Some hard silicone around the outside might improve its thermal conductivity. (There are hard silicone resins with high thermal conductivity, right?)

Beatrice suggested that you could use an actual polished semiprecious stone instead; cut out a circle from one side, drill out a cavity underneath, put the electronics inside, pot them with epoxy, replace the circle, wipe off the excess epoxy, and then polish the result.

Wood-Block Handheld Computers

Another "everyday object" kind of electronic device case: a block of wood. Some time ago I saw a web page about a wooden clock. It seems to be widely available now; for example, http://svp.co.uk/products-solo.php?pid=4989&ref=froogle&ci_src=o o18615224&ci_sku=8028 advertises it for £93.99. It explains:

> A totally minimal block of wood with digital numbers floating across the surface. These clever clocks have a very thin layer of real maple wood veneer that permits the LEDs to shine through.
> Each one is slightly different due to the natural variation in wood grain.
> Dimensions: 208 x 90 x 90mm Weight: 1.2kg

Another page says:

> TO:CA 'wood' LED clock designed by kouji iwasaki in 2002. this 'wooden' LED clock won top prize at the asahikawa international design fair in 2002.

A third page says they're actually made of MDF under the maple veneer, and has a photograph of the back that seems to confirm this, and a fourth page says the manufacturer is "Takumi of Japan".

I think a handheld computer that looks like a block of wood would

be pretty nice too. Something the size of a business card (3.5" x 2", or 89 x 51 mm) but fairly thick (say, 15mm), with veneer on at least one side. The resolution of the display would be limited by the light blurring on the way through the translucent veneer; each spot of light would have a radius on the order of the thickness of the veneer. Veneers are typically 0.8mm but are available as thin as 0.3mm.

If spaced 1.6mm apart, you could get almost 1800 pixels in a rectangular array into the business-card size. You could do a little better with a hexagonal array: if the distance from the center of a regular hexagon to the center of one of its sides is r, then the distance to one of its corners is about 1.15r, which is the same as the length of each side; and its area is 1½ * 1.15r * 2r = 3.45r², which is 14% smaller than a square circumscribed around the same size of circle. In the case of r=0.8mm, you'd have 2.2mm² per pixel instead of 2.56, so you'd get about 2000 pixels. But then you'd have to deal with the hexagonal array in your software.

1800 pixels is enough for about 45 letters in a traditional 5x8 single-bit-deep font, which is pretty cramped; my cheap two-year-old US$30 cellphone has something like 65 letters'worth of space on its display. But it's enough to be useful. It's a lot more than any of the under-US-$10 devices I picked up for the "cheap electronics dissection project" in 2006, and they are useful for some things.

I don't know how easy or hard it is to populate a PC board with 1800-2000 LEDs. I know I wouldn't want to do it by hand.

You could hollow out the middle of a block of wood with just a drill and jigsaw; a keyhole saw or wire saw might work in place of the jigsaw. Cutting all the way through it would be a lot easier than just chiseling out a hollow in one side of the block; then you'd need to put veneer on both sides instead of just one. To add strength and keep it from sounding hollow, you'd probably want to pot the whole interior with epoxy or something.

You could have a couple of finishing nails visible on one end if you wanted to charge it through actual electrical contacts rather than with induction.

Other Everyday Items

You could also embed handheld computers in the following: oyster shells; bricks; pens (I suggested this previously on kragen-tol); ceramic tiles; beanbags, pillows, and stuffed animals (like the Chumby and the Furby).

References

Eager Plastics, aka Eager Polymers, has an "EP4117 General Purpose Polyester Laminating Resin" with a density of 1.11 g/cc.

In April 2002, I posted "magic boxes and secret knocks" to kragen-tol.

The article Using Veneers describes the different kinds of wood veneers available today.

In 2006 I wrote a web page about my "cheap electronics dissection project", where I bought a bunch of cheap electronics and looked inside them.

The internet is probably not going to collapse for economic reasons

Kragen Javier Sitaker, 2016-09-06 (9 minutes)

Occasionally I run into articles about how the internet is doomed for economic reasons, even today, like this article by John Michael Greer. But they're wrong. Greer's basic argument is that internet services like Facebook are being heavily and unsustainably subsidized by money-losing venture capitalists and that the internet as a whole is heavily and unsustainably subsidized by fossil fuels.

Consumer monthly internet service pays the majority of internet costs

Every time I've mentioned the future of the internet on this blog, I've gotten comments and emails from readers who think that the price of their monthly internet service is a reasonable measure of the cost of the internet as a whole.

It actually is a reasonable measure, because the majority of the cost of operating the internet as a whole is the cost of operating the so-called "last mile" service. The total cost is maybe twice that.

For a useful corrective to this delusion, talk to people who work in data centers.

I do, all the time. They pay substantially less for their bandwidth and their computers than residential internet users do. This should be unsurprising, because they are able to drive bargains with equipment and bandwidth providers that residential users can't, and they can place their computers right next to the internet backbone instead of stringing cables through urban neighborhoods.

Amazon may be the biggest retailer on the planet, for example, and its cash flow has soared in recent years, but its expenses have risen just as fast, and it rarely makes a profit. Many other content provider firms, including fish as big as Twitter, rack up big losses year after year.

Twitter's current operating expenses are around two billion dollars a year, with 302 million active users. That's six dollars per user per year, or 50¢ per user per month. This is very small compared to the cost of the price of monthly residential internet service.

Facebook's operating expenses are around ten billion dollars a year, with which they serve 1.44 billion active monthly users, 936 million active each day. Again, that's about six dollars per user per year.

Wikipedia's operating expenses are only US$58.5 million, but of course that doesn't pay the editors, just the server infrastructure. Because of Wikipedia's privacy policy, they don't know how many people read Wikipedia every day, but comScore says it's about half a million. That means Wikipedia spends about 10¢ per user per year, or about 1¢ per user per month.

Now, it's true that getting some money from the users who benefit from an internet service into the pockets of a company who provides it is a pretty big problem, and one that Greer correctly points out many companies are all too happy to put off solving. But that doesn't imply that the total costs per user are high — as we've seen above, Twitter, Facebook, and Wikipedia (three of Alexa's top 10) are spending 50¢, 50¢, and 1¢ per user per month. Indeed, in all

likelihood, if Twitter and Facebook weren't desperately struggling to get more users, their operating expenses would probably be lower. But Twitter's only been able to put off profitability for so long because their cost per user is so low.

(If we extrapolate these costs down to a small three-person company, with each person costing US$100k per year and equipment costing a similar amount, we end up with US$600k / 50¢ ≈ 1.2 million users as the smallest viable online service these days.)

Once this happens, the companies that dominate the industry have to stay in business the old-fashioned way, by earning a profit, and that means charging as much as the market will bear, monetizing services that are currently free, and cutting service to the lowest level that customers will tolerate. That's business as usual, and it means the end of most of the noncommercial content that gives the internet so much of its current role in popular culture.

I often hear nonsense like this from people who are relatively new to the internet and therefore don't remember what it was like before privatization. Noncommercial "content" has a history on the internet far deeper than what is suggested here.

What we're seeing in practice is that, when you lower the cost of communication sufficiently, commercial "content" like Encarta or Encyclopedia Britannica or Microsoft Windows has a really hard time competing with noncommercial "content" like Wikipedia or FreeBSD (the free software MacOS is built from). The big websites like YouTube, Wikipedia, Facebook, and Twitter are not sources of content; they're just ways for people to talk to each other that happen to be more convenient and efficient, and no more expensive, than running peer-to-peer software on their own computers. The companies that currently "dominate the industry" (if by that we mean Facebook and Twitter and not Comcast and VSNL) are only able to do so because they are successfully able to deliver people to each other.

As long as some people can control the software running on their own computers and get those computers to talk to each other, companies like Facebook will have to compete with "free". (And as one of the commenters on Greer's post points out, BitTorrent already accounts for the majority of internet traffic.)

Non-fossil-fuel energy is abundant

the internet is simply a cheaper and more convenient way of doing things that people were doing long before the first website went live, and a big part of the reason why it's cheaper and more convenient right now is that internet users are being subsidized by the investors and venture capitalists who are funding the internet industry. That's not the only subsidy on which the internet depends, though. Along with the rest of industrial society, it's also subsidized by half a billion years of concentrated solar energy in the form of fossil fuels.

We've already shown above that the degree to which internet users are being subsidized by money-losing investors and venture capitalists is very small, but the energy subsidy question here is interesting, and Greer's position is spectacularly wrong.

It's true that our fossil fuels accumulated over half a billion years, but that does not mean that they are half a billion years of concentrated solar energy; the vast, vast majority of that solar energy was reflected or re-radiated into space and lost forever, not stored away in coal and oil to await humanity.

Current proven coal reserves are 861 billion tonnes, which at 24

GJ/tonne are about 21 zettajoules. Oil and gas reserves are somewhat less. The earth's radius is 6400 km, and it receives about 1000 W/m² of solar energy, which is about 128 petawatts over its circular cross-sectional area.

That means that current proven coal reserves are 45 hours of concentrated solar energy, not half a billion years, not a billion years, not a million years, not a thousand years, not a century, not a year, not even a week. Every two days, we receive from the sun as much energy as all of our currently-known coal reserves.

Historically, it has proven difficult to use solar energy — in part because, as Greer correctly notes, fossil fuels are more concentrated and therefore hard to compete with in an economic sense, but also because of our limited materials and fabrication technology, much as nitrate mined in Chile was a crucial strategic ingredient for explosives until the Haber process was invented.

But using solar energy is no longer particularly difficult, if we measure difficulty in dollars — Juan Cole collated several stories of recent utility-scale solar energy, among which is the news that Nawaz Sharif in Pakistan just inaugurated the hundred-megawatt Quaid-e-Azam Solar Plant in Punjab province built "by China's Tebian Electric Apparatus Stock Co Ltd (TBEA) [in] a year…at a cost of $190 million". That's US$1.90 per watt. Spain is already at 70% carbon-free electricity, mostly nuclear, hydroelectric, and wind.

Speaking of nuclear, the amount of energy available in easily fusible elements in seawater is comparable to the amount available in solar, if burned over a reasonable period of time; thorium is somewhat smaller, while uranium is substantially smaller. Fusion energy, hot-dry-rock geothermal (aka "enhanced geothermal systems"), and solar are each individually capable of getting human civilization to Kardashev Type 1.

An internet is a more energy-efficient way to communicate

Emacs22 annoyances

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

So I just upgraded to Emacs 22 in April, despite Debian Etch not supporting it. It solves several of my daily annoyances with Emacs 21: - It recognizes "Password: " as a password prompt, so ssh and sudo get the benefit of me not having to manually type M-x send-invisible. - I can paste Unicode text into it from a web browser, including asymmetrical quotes, real apostrophes, and em dashes, and have it save them to a UTF-8 file without fuss. (Although it still displays the quotes in an obnoxious double-width fashion until the file has been saved and reloaded.) - TRAMP works out of the box. - The documentation is included, unlike in Debian. (There's a licensing dispute over whether the GNU Free Documentation License is free enough to satisfy the Debian Free Software Definition.) - comment-region now asks what comment syntax to use if it doesn't know. - When I run e.g. "darcs" by itself in shell-mode, occasionally Emacs used to take quite a while to display its output usage message, because it was reading it one character at a time. This has been fixed.

I also anticipate joy using MuMaMo, but I haven't actually tried that yet.

There are some changelog/news entries that sounded pretty good:

...if you set `set-mark-command-repeat-pop' to t. I.e. C-u C-SPC C-SPC C-SPC C-SPC ... cycles through the mark ring. Use C-u C-u C-SPC to set the mark immediately after a jump. [Haven't tried this yet.]

```
...M-% typed in isearch mode invokes `query-replace' or
`query-replace-regexp' (depending on search mode) with the current
search string used as the string to replace.  [Haven't tried this
yet.]

You can now customize the use of window fringes.  To control this
for all frames, use M-x fringe-mode or the Show/Hide submenu
of... [so now I can have two 80-column windows on my screen at
once, which is awesome]

A new minor mode `next-error-follow-minor-mode' ... In this mode,
cursor motion in the buffer causes automatic display in another
window of the corresponding matches, compilation errors,
etc. [Haven't tried this.]

The new command `multi-occur' is just like `occur', except it can
search multiple buffers. [Useful. Also I didn't know about
`occur`.]

The grep commands provide highlighting support. Hits are fontified
in green, and hits in binary files in orange.  Grep buffers can be
saved and automatically revisited.  [This is in fact extremely
awesome.]

In addition, when ending or calling a macro with C-x e, the macro
can be repeated immediately by typing just the `e'. [This sounds
```

```
nice, but the F3 and F4 macro keybindings are better.]

The new package longlines.el provides ... "soft word wrap" [like
actual word processors have since the 1970s.  Turns out to be
fantastic.]

SES mode (ses-mode) is a new major mode for creating and editing
spreadsheet files.  [Haven't tried this yet.]

The new package table.el implements editable, WYSIWYG, embedded
`text tables' in Emacs buffers  [Haven't tried this yet.]

The new package flymake.el does on-the-fly syntax checking of
program source files.  [Haven't tried this yet.]

savehist saves minibuffer histories between sessions.  [Haven't
tried this yet.]

isearch in Info uses Info-search and searches through multiple
nodes.  [This is fantastic.]

Atomic change groups: To perform some changes in the current
buffer "atomically" so that they either all succeed or are all
undone, use `atomic-change-group' around the code that makes
changes.  [Sounds like a fantastic idea, but I haven't tried it
either.]
```

So far I've only noticed two new annoyances: one is that it uses its own python-mode that I don't like as well as the one that comes with Python, and the other is that C-x C-f RET no longer reverts the file to the version in the filesystem (assuming the buffer wasn't edited); now you actually have to type the filename.

The stuff in the NEWS file (C-h N) looks pretty innocuous. Nothing is terribly exciting, though.

ISAM designs for Tahoe-LAFS

Kragen Javier Sitaker, 2016-09-07 (2 minutes)

Tahoe-LAFS is, among other things, a content-hash-addressable store for use as a networked filesystem. https://www.tahoe-lafs.org/trac/tahoe-lafs/wiki/FAQ question 13 describes a "medium distributed mutable file" facility for storing mutable files as balanced Merkle trees of 128-kilobyte chunks. There's also a "large distributed mutable file" facility proposed but not yet implemented, which instead stores sequential logs of deltas like Mercurial's revlog file format.

In the Tahoe IR channel I wrote (edited for format):

https://tahoe-lafs.org/pipermail/tahoe-dev/2012-October/007750.html is a fairly different proposal from the "Mercurial revlog" proposal. It seems to me like B-trees might be a better fit for storage that has significant latency per random read, like disk or network filesystems, which I guess is how MDMF works. Has anybody tried running some kind of ISAM implementation on top of MDMF?

It seems like there might be a somewhat higher cost to running some kind of ISAM thing on top of something like MDMF than just journaling your ISAM updates directly onto a write-once block store, since journaling allows you to write just the updated records at first. Postponing the task of copying them together with the unchanged records into a single new block (to restore locality of reference) until less of the unchanged records are unchanged, but I don't have a good estimate for how large or small the cost of the extra abstraction layer (which also serves to implement regular mutable files) would be. A log-structured filesystem scavenger can choose to scavenge the segments with the smallest amount of surviving data, thus optimizing the cost/benefit ratio of segment scavenging.

MDMF could do that too, though! Is there more detailed performance data somewhere? The fact that SSD FTLs have a hard time with random writes, though, makes me think that the cost of hiding nonsequential writes at an MDMF-like low level is probably very significant. So what I'm suggesting is somewhere in between the "balanced Merkle tree" and "Mercurial revlog" approach, since balanced Merkle trees have potentially arbitrarily bad write performance, while Mercurial revlogs have potentially arbitrarily bad read performance.

Square wave synthesis

Kragen Javier Sitaker, 2014-02-24 (2 minutes)

An integral of a square wave is a spline approximation of a sine wave. The third integral is a cubic-spline approximation, which has very low harmonic distortion. The amplitude of the approximated sine wave is the amplitude of the square wave scaled by the Nth power of the period; for a third-order spline, it's scaled by the cube of the period.

This is interesting because the discrete analog of integral, running sum, is linear, time-invariant, and very cheap indeed to compute (one accumulator and one addition per sample), and sine waves are useful primitives for composing many signals.

In the case of audio synthesis, in particular, I'm thinking you can take some square waves (or envelope-shaped square waves), add them together, and take their running sum a few times, to get a mix of sinusoidal signals.

To be concrete, suppose you're synthesizing 16ksps audio, and you want to be able to cover the audible range down to 20Hz and up to the Nyquist frequency at 8kHz. A 20Hz square wave has a period of 16000/40 = 400 samples on both the top and bottom; this results in amplifying the original square wave by about 400^3 for a third-order spline, or 64 million. (This is not quite correct because of discretization; the actual number is 10.6 to 10.7 million.) This means you need 32-bit integer math for your accumulators (and for the amplitudes of your higher frequencies), but that 32-bit math gives you a dynamic range at 20Hz of 10dB $\log_{10}((2^{31}/10.6M)^2)$ = 46dB, which is quite respectable.

At higher frequencies, you have correspondingly more dynamic range; at Nyquist, you have 31 bits of dynamic range, since the square wave *is* the sine wave, or 187 dB.

So you have square waves, which are more or less cheap to compute (at least as long as you're far from Nyquist and can therefore disregard jitter), and which you sum; and then you integrate them (three times) to get a sum of (cubic) spline approximations of sine waves. You have to scale the amplitudes of the square waves as mentioned above, proportional to the Nth power of the frequency.

Wang tile addition

Kragen Javier Sitaker, 2017-02-16 (3 minutes)

Suppose you wanted to construct a set of Wang tiles that performed base-10 addition. Like, you would start with a row of interlocking puzzle-piece tiles that said " 3280+834 ", with a flat edge along the top, left, and right, but a ragged edge along the bottom, and all the possible ways to complete a smooth-edged shape would have the correct answer "4114" on the bottom row.

This involves four kinds of top-row tiles: digits, left boundary, right boundary, and "+". (Or 13 kinds, if we count each digit separately.) These can mostly all fit together in an arbitrary order, but the left and right boundary have smooth edges that won't interlock with anything else. And if you put more than one "+" sign in there, you will have created an unsolvable puzzle. (You could use two different kinds of digit tiles, one for the left addend and one for the right, in order to make this impossible.)

The first order of business is to get the corresponding digits lined up, so that you get some kind of representation of "(3+0), (2+8), (8+3), (0+4)". This involves introducing an extra "0" to the "834", and then shifting digits over, one per row, until they reach their final position. Then, once the corresponding digits are lined up, you need to reduce the pairs to sum digits, one by one, and finally once everything is a sum digit, you can finish off the bottom with a nice smooth-edged line.

Introducing extra leading zeroes

Here we're copying the original problem down, row by row; so we have "copy digits" whose tops interlock (only!) with the bottoms of the corresponding digits above them, and similarly a "copy left edge" and "copy right edge" and "copy plus sign". Except that there are 120 kinds of extra "digit insertion tiles" which allow you to, under the right circumstances, shift a number over by one tile to the right. Each of these kinds of digit insertion tiles has a digit printed on it that is determined by its left and bottom edges, which are the same, and a right edge that is the same as its top edge. There are top-edge versions for each of the possible digits that could be above, and also the "+" tile and the right-edge tile.

The "copy down +" and "copy left edge" tiles have a special right edge that allows an "insert leading 0", so you can add an extra-leading-zero tile to shift over either the left or the right operand by one. The "copy down" tiles are not "shift tiles", so you can only use them directly below the thing they're copying, so you can only insert one leading 0 per row.

Shifting corresponding digits left

Designing an archival virtual machine

Kragen Javier Sitaker, 2016-05-12 (6 minutes)

Software has a very variable lifetime. There are a few programs written in the 1970s that are still in use today, some 40 years later: many Unix utilities (including vi, now nvi), BRL-CAD, SPICE, Maxima, TeX, Smalltalk, and so on. There are many programs from the 1980s that are still in use today, 30 years later: much of X-Windows, MS-DOS, GNU Emacs, GCC, other GNU utilities, LaTeX, parts of Microsoft Windows, and so on.

In many of these cases, little of the original code remains; 30 or 40 years of maintenance have changed it considerably.

In order for our programming efforts to become part of the intellectual heritage of humanity, rather than be forgotten, they apparently need to be continually maintained. blah blah blah.

Urban Müller's BF, inspired by Wouter van Oortmerssen's False, is a virtual machine design with eight instructions that you can implement in half an hour in a page of code. It's probably close to the simplest virtual machine design that you can write real programs for; Linus Åkesson has written a Game of Life for it in a bit under four kilobytes. People have compiled text adventures and fractal renderers to it.

Unfortunately, BF is a terrible machine to program for. It has no subroutine-call mechanism, limited ability to index into memory, and limited arithmetic; straightforward implementations are exponentially inefficient, and even advanced implementations can be inefficient.

I'd like an archival virtual machine meeting the following requirements:

• within an order of magnitude of BF in difficulty to implement — which is to say, less than five hours and ten pages of code;
• within an order of magnitude of native code in performance when implemented in that way;
• within an order of magnitude of native code in programming difficulty, say, with an assembler;
• with high probability that a reimplementation from the specification will be compatible.

A simple reading of #1 suggests that the VM should have as few instructions as possible, and shouldn't have more than about 80 different instructions, but really it depends a great deal on how complex the instructions are. Some instructions can be implemented in a single line of code in the VM, while others might require a page of it.

A simple reading of #2 suggests that you need to keep your interpretation overhead down to no more than about, say, 9 instructions per virtual machine instruction. Unfortunately, this is really difficult! Threaded-code systems like Forths do manage to do it in about 5, at the expense of needing to compile to threaded code first, and of things like type-checking and bounds-checking.

We also need to ensure that the VM's instruction set is sufficiently expressive that you don't need three VM instructions to do what one native-code instruction could do. Forths often suffer from this; it's easy to need to do `OVER OVER -` where a single subtract instruction would suffice on a three-address machine.

The Chifir virtual machine, designed to run an emulator for the Smalltalk-72 virtual machine, has one register and 15 three-address instructions:

- jump (PC ← M[A])
- conditional jump (if M[B] = 0, then PC ← M[A])
- store program counter (M[A] ← PC)
- move (M[A] ← M[B])
- load (M[A] ← M[M[B]])
- store (M[M[B]] ← M[A])
- add (M[A] ← M[B] + M[C])
- sub (M[A] ← M[B] - M[C])
- mul (M[A] ← M[B] × M[C])
- div (M[A] ← M[B] ÷ M[C])
- mod (M[A] ← M[B] % M[C])
- cmp (M[A] ← M[B] < M[C] ? 1 : 0)
- nand (M[A] ← ~(M[B] & M[C]))
- refresh the screen
- block until a character is available from the keyboard and store it in M[A]

Requirement #3, that it not be too much of a pain to program, also exerts pressure in favor of a large, expressive instruction set.

Requirement #4, like #1, exerts substantial pressure on simplicity, but also runs strongly counter to including facilities like division (what do you do on division by zero?), floating-point arithmetic, signed integer arithmetic, and possibly other accesses to memory during the same instruction as a memory write (what order do they happen in?). All of these provide dangerous opportunities for implementations to diverge.

The Ethereum Virtual Machine has an interesting feature that could help to ameliorate some of these tensions: its registers (in its case, on a stack) are 256 bits, 32 bytes. You could imagine a virtual machine with similarly wide registers, but with SIMD instructions, like 3DNow, SSE and NEON; in some cases, not only would this allow a single instruction to do the work of several native instructions, it would allow the programmer to omit writing an explicit loop.

Another way to ameliorate these tensions somewhat is to combine several different operations into a single instruction. For example, if we have a register that always contains 0, another that always contains 1, and a third that always contains -1, then a single three-register A += B*C instruction (known as MAC or sometimes FMA) provides ADD, SUB, MUL, and clear-register as special cases; if the instruction works in complex cases, it is guaranteed to work in simple cases as well. Similarly, A ^= B&C provides AND, XOR, NAND, ANDNOT (BIC), and NOT as special cases.

A minimal-cost diet with adequate nutrition in Argentina in 2017 is US$0.67 per day

Kragen Javier Sitaker, 2017-06-15 (4 minutes)

In http://canonical.org/~kragen/comida.html I calculated the costs of some minimally adequate diets on 2012-08-16. So now I want to update the cost calculation for at least one of them to current prices.

The "minimal budget for balanced macronutrients", for 2482 kcal per day with 52% from carbohydrates, 18% from protein, and 30% from fat, consisted then of 200 grams per day of soybeans, 5 grams per day of salt, 33 grams per day of sunflower oil, and 430 grams per day of white flour. Coto Digital offers 500 g of soybeans for AR$14.99, 1 kg of Cañuelas 000 white flour for AR$7.72, 1 kg of salt for AR$41.65, 1 kg of medium-fine salt for AR$17.19, and 1.5 ℓ of sunflower oil for AR$49.75.

Food	size	AR$	price/g	g/day	AR$/day	% of cost
Soybeans	500	14.99	0.02998	200	5.996	56.055567
Flour	1000	7.72	7.72e-3	430	3.3196	31.034366
Salt	1000	41.65	0.04165	5	0.20825	1.9468932
Oil	1400	49.75	0.035535714	33	1.1726786	10.963169
Total			0/0		10.696529	100.

#+TBLFM: $4=$3/$2::$6=$4*$5::$7=100*$6/@6$6::@6$6=vsum(@2..@5)

So at supermarket prices, this diet would now cost you AR$10.70 per day. Maybe if you buy in bulk the prices would be lower; and on MercadoLibre, you can buy 30 kg of soybeans for AR$466, which works out to half the price of the supermarket.

However, this is 3¾× as much as it cost when I originally did the calculations, in Argentine pesos. (I don't have a good set of CPI figures to adjust the inflation with, because during the previous administration the integrity of the statistics bureau was destroyed, and they were forced to publish false numbers.) At the time, the dollar sold for AR$6.26, and this diet cost AR$2.86 per day, which works out to US$0.46 per day. Now, the dollar sells for AR$16.00, more or less, so this works out to US$0.67 per day. This represents a substantial loss of buying power in Argentine necessities for the dollar, and the popular feeling is that hours of labor have also lost substantial buying power.

With only three foods (not counting the salt), the proportions of the foods are set by the macronutrient balance requirements I've chosen; there is no wiggle room to reduce the price by changing the proportions slightly. But it might be the case that some other combination of foods is now the optimum — I doubt it, though, because the proportions are almost the same, except that now the oil

makes up a bit more of the cost (11% instead of 6%) and the flour correspondingly less. So probably none of these foodstuffs have increased in price proportional to the market as a whole, and I think the flour is maintained at an artificially low level by government subsidies paid to supermarkets, reducing malnutrition at the cost of encouraging people to eat too much flour.

This implies that a family of four will be malnourished if less than about AR$42.80 per day is spent on their nutritional needs, at supermarket prices; this works out to AR$1302 per month for the four.

For an actually healthy diet, you almost certainly need some fresh vegetables, even though the flour is supplemented with vitamins and minerals to prevent deficiency diseases. If bought retail, this adds substantially but not overwhelmingly to the cost; for example, carrots cost AR$17.90 per kg at Coto, so 100 g of carrots would add an additional AR$1.79.

Dehydrating processes and other interaction models

Kragen Javier Sitaker, 2018-12-28 (updated 2019-01-01) (36 minutes)

I was thinking about the problem of displaying graphical user interfaces and reacting to clicks and other user events in them, and I think I found an interesting unexplored design space, which seems more and more promising as I think about it.

To talk about this, I need to talk about a concept that I don't have a good name for. I guess I'll call it "interaction models". This is not exactly about user interface paradigms as conventionally understood — e.g., command-line software, graphical user interfaces, hypertext — although it's not entirely orthogonal to them. It's more about the model within which programs using those user-interface paradigms interact with not only the user, but also each other and the rest of the computing system. This document is about a new interaction model which I am exploring.

Background

Most existing programs fit fairly cleanly into one of several existing interaction models: "apps", "REST", "batch processing", "REPL", "notebook", and "open operating system", though of course there are gray areas.

Apps

The now-conventional ("apps") model for this is that, behind the window, there's a running program, typically on a multitasking operating system in which it runs in a "process" (a virtual computer), which has a thread of execution and a stack and a virtual memory space and whatnot; and, at times, it responds to user interface events, modifying its internal state and possibly its external appearance.

This works, and it can be extremely efficient, but it has some drawbacks:

• It's very difficult to return the process to a previous state ("undo"), for example because a user interface action had an effect you didn't like, or because you wanted to explore some other alternatives.
• It's very difficult to update the code of the process, because its internal memory state is entangled with the assignment of addresses to pieces of its code in a way that can be difficult to undo.
• Data tends to get "siloed" in particular programs, reducing users' control over the data and causing them to spend a substantial fraction of their time figuring out how to get data out of one program and into another.
• It uses a lot of memory space and, often, CPU time.
• It can be very difficult to migrate the process from one computer to another, which is a serious problem now that we're all carrying lots of computers around.

REST

Another approach is REST. In REST, the "window" is a

document sent to your user-agent by a server, containing your entire session state and including links to other resources that may be relevant. All applications use the same user-agent and the same resource link namespace. REST has a number of advantages over the apps model:

• The uniform link namespace enables a certain degree of interoperability;
• previous session states can be stored as "bookmarks" and returned to at will, or sent to other people as links;
• upgrading the code on the server is completely seamless in most cases.

However, because the server is physically far away and because the user-agents we are using are unbelievably inefficient, current software is shifting away from the REST model and toward the apps model.

Teletypes, typescripts, and the REPL model

"Apps" are actually somewhat older than graphical user interfaces — in a sense, an "app" is what you get as soon as you load a program onto a general-purpose computer and start it running, even if you don't have an operating system. The machine, in essence, starts to manifest in the physical world the behavior of the abstract machine embodied in the program — it becomes an avatar of the program, though perhaps likening programs to devas or gods is blasphemous. Traditionally, with or without timesharing, once the program starts running, barring the invocation of debugging features such as interrupt keys or single-step switches, your interaction is with the program, not the computer or the operating system — or, at least, that is the desired illusion.

In the app model, you launch a program, which puts your user interface to the machine into a special mode where it behaves differently until it exits — or, if you have a multitasking user interface, until you switch tasks. This is the same way Instagram interacts on your cellphone in 2018, the same way Sketchpad worked in 1962, and the same way Mel Kaye's Blackjack program worked on the LGP-30 in the 1950s.

The LGP-30 was a very simple computer indeed; it contained barely over a hundred vacuum tubes, and it ran far too slowly to produce a useful display on an oscilloscope screen. So the user interface on the LGP-30 was a Friden Flexowriter, a kind of teletype.

A Teletype™ (or, generically, a teletype) is an electric typewriter that could be driven either by the computer or by its operator. (Or, in its original application, by another teletype, perhaps in another city.) This meant that the user interface only needed enough electronic or electromechanical memory for the single byte currently being input or output, rather than the dozens of bytes required for the HP 9100's calculator display, the kilobyte or more required for character-cell terminals, or the many kilobytes to megabytes required for framebuffers. Some form of teletype was the primary form of user interface for BASIC, JOSS, and APL in the 1960s, and then Unix in the 1970s, and it remains with us today in the Unix terminal interface, which even today uses the abbreviation "tty".

On the teletype, many programs could produce their final permanent results just by showing them to the user, perhaps without

even storing them in the very limited memory of the time. For example, if you had a series of calculations you wanted to carry out in LISP, APL, JOSS, or BASIC, you could type the formulas into the computer, one after the other, and on the paper you would have the formulas, each followed by its result, for ease of future reference. This form of interactivity is known today as a REPL, for "read-eval[uate]-print loop", from its name in Lisp, and it remains nearly a sine qua non of new programming languages.

The REPL facility meant that you could write useful interactive programs in LISP or APL that, paradoxically, contained no code for processing user input; they merely provided a vocabulary of procedures for the user to invoke from the REPL, leaving the interaction to the REPL.

The teletype user interface is very limiting — you can't even erase a character once it's on the paper, and it was common to use baud rates as low as 110 baud, or 11 characters per second, because the mechanics couldn't print any faster anyway. But it does have some real advantages over framebuffers and character-cell terminals: you can get a large character repertoire and also boldface and underlining by overprinting multiple characters in the same position, and, most interestingly, the user is left with a complete and indelible record of their interaction, typically on continuous-feed fanfold paper, showing both everything they did and everything the computer typed — a record they could annotate with pencil or pen.

This made it possible to easily produce not only printed textual documents, but also banners, data tables, and data plots.

Batch processing

As an example of app-model glass-teletype interaction, Chapter 6 of the TeXbook (originally published in 1984 and documenting the 1983 version of TeX that supplanted the 1978 version) talks about how to start the TeX compiler and then interact with it once it's started:

log in; and start \TeX. \ (You may have to ask somebody how to do this on your local computer. Usually the operating system prompts you for a command and you type '`tex`' or '`run tex`' or something like that.)

When you're successful, \TeX\ will welcome you with a message such as

```
This is TeX, Version 3.141 (preloaded format=plain 89.7.15)
**
```

The '`**`' is \TeX's way of asking you for an input file name.
% Incidentally, 89.7.15 was Jill's 50th birthday.

…

Now you're ready for Experiment~2: Get \TeX\ going again. This time when the machine says '`**`' you should answer '`story`', since that is the name of the file where your input resides. \ (The file could also be called by its full name '`story.tex`', but \TeX\ automatically supplies the suffix '`.tex`' if no suffix has been specified.)

…(Previous \TeX\ systems required you to start by typing '`\input story`' instead of '`story`', and you can still do that; but most \TeX\ users prefer to put all of their commands into a file instead of typing them online, so \TeX\ now spares them the nuisance of starting out with `\input` each time.)…

You can see that TeX is interacting in the app model. However, it seems that for TeX users, app-mode interaction was often a nuisance that they wanted to minimize. They preferred to spend their time preparing the input file for TeX, then processing it as non-interactively as possible.

This leads us to the "batch-processing" interaction model, which is almost as old as the app model — or perhaps older, if you count running punched paper tape through a Teletype. In batch processing, you start a program, which runs for a while, reading input prepared ahead of time and producing output. Then the program terminates, without having interacted with you at all while it was running. Batch-processing operating systems predate interactive operating systems by a little bit.

Originally, in batch processing, you used a separate, non-computer machine to prepare your input, in the form of a deck of punched cards punched on a keypunch or of a reel of punched paper tape punched on a Teletype. Perhaps this was an incremental process where you gathered punched cards from different places, and even a non-mechanized process where you selected and ordered the punched cards by hand. (The equivalent with paper tape involved, as I understand it, knives and scotch tape.)

Why would you prefer batch processing to interactive processing?

For many years, a primary reason was economic; computers were very expensive compared to employees. A computing job that required one minute of computer time, if done interactively, might require the operator to go through ten minutes of machine setup and five minutes of teardown, during which time the computer spent all its time waiting on the operator, for a total of 16 minutes. If, instead of *operating* the machine manually, you used an *operating system*, you could do it in maybe a minute and a half, without requiring any multitasking. This approach was still occasionally used into the 2000s on supercomputers, because even though they run multitasking operating systems, you can sometimes run two jobs faster one after the other than if you divide the machine's resources between them.

The queue lengths were sometimes long, and programmers tell of needing to wait a day or more for their (printed) job output after submitting their job for processing, back in the 1970s. So if your one-minute job contained five bugs, each of which was hidden by the previous bug, it might take you a week and a half to get it to run in the batch system, while doing it interactively might have taken you 18 minutes. In such cases, the batch system would save computer time — it would consume perhaps 4 minutes in this case rather than 18 — at the expense of human time. So it paid off to be extremely cautious about correctness, and moreover, using a time-shared ("multitasking") system rather than a batch system could boost your productivity by an order of magnitude or more.

Time-shared operating systems got much the same computational efficiencies as batch operating systems — while you're sitting at your terminal thinking about what to do next, the computer is running someone else's job — and much the same human efficiencies as interactive operation without an operating system. But they required a terminal for each concurrent user, and when implemented with a virtual computer per user, they also required much more memory than a batch operating system.

However, even in the time-shared environment that Knuth took for granted in the above quote, batch processing was part of the picture — not just to use less terminals and memory, but also to simplify the programming and make the system easier to use.

The wonderful thing about batch processing — ignored for decades

in favor of mere economic considerations — is its *reproducibility*. A batch program starts up, accesses some input data, produces some output data, and exits. Normally, we have the guarantee that it will produce the same output data if given the same input data (a guarantee Knuth went to extreme lengths to provide in a cross-platform way in TeX, for reasons of preserving access to the scholarly record) and we can modify the input data incrementally to see what changes result.

Reproducibility is extremely valuable for testing and debugging, and it's also very useful for *caching*. A significant fraction of programming, perhaps the majority, consists of "optimizing" — not in the mathematical sense of finding the minimum of a function, but in the sense of making programs do the same thing in less time and/or memory. Caching — storing a previously obtained piece of data so that it's available again when needed — is the most important optimization in the world, and perhaps the majority of optimizing and even software design consists of tweaking what to cache, when, and how.

Reproducible computations can be cached. Irreproducible computations can't. By casting a computation into the batch-processing model, we make it reproducible and therefore cacheable. (Umut Acar's revolutionary "self-adjusting computation" work, as I understand it, is a matter of carrying this principle down to a microscopic level.)

The biggest change in mainstream programming practices over the last 20 years is the near-universal adoption of automated testing, which amounts to testing your software in batch mode, so that the test results are reproducible, rather than interactively.

Batch processing doesn't need "undo", because it just produces output data from input data. If you change the input data, you get new output data, but the old output data doesn't disappear. By incrementally changing input data, we can achieve a sort of "undo and redo" without burdening our program code with extra complexity — make a change to a part of the input that the program accesses early, and it's like undoing everything the program did after that, making the change, and then redoing all the other things in the new context. It's wonderful.

TeX users prefer to keep their interaction with TeX batch-mode because it becomes reproducible and thus gains these flexibilities. And TeX, despite unusually extensive interaction facilities for a compiler, depends on the batch-processing model — it cannot back up to a previous page and change it, for example, or save an editable form of a document so you can edit it again later, both of which would be core functionality for an app-model word-processing system. You can write a document entirely interactively in TeX — that was the Experiment~1 omitted from my TeXbook quote above — but it's impractical.

The Unix shell, and software tools

Shortly after the above quote from the TeXbook, there's a note about command lines:

\danger Incidentally, many systems allow you to invoke \TeX\ by typing a one-liner like '`tex story`' instead of waiting for the '`**`'; similarly, '`tex \relax`' works for Experiment~1, and '`tex &plain story`' loads the plain format before inputting the

`story` file. You might want to try this, to see if it works on your computer, or you might ask somebody if there's a similar shortcut.

This implies that, on some computers where people ran TeX, the only way to specify input files was through the app-model interaction described earlier, which meant that reproducing a TeX run required a human interaction.

This was an affliction suffered not just by TeX but by many systems of that time period, and indeed by many app-model programs nowadays. (For predatory companies such as Facebook, the owner of Instagram, this is an advantage, not a drawback, although internally they have systems for driving the Instagram app in batch mode for testing.)

Unix was a new operating system designed in the 1970s and late 1960s, using teletypes, based on a non-app, indeed anti-app, design — though Unix itself was unredeemably interactive, most of its programs were almost entirely batch-mode. A Unix user in the 1970s might use dozens of programs at different times during a session, but only *interact with* three of them — login, the "shell" (an interpreter for an ad-hoc programming language optimized for launching other programs) and ed, the editor.

In essence, the Unix shell user interface is a REPL for launching batch jobs, and the programs are designed to be composable in useful ways. Unix facilitates this by allowing programs to treat other programs' unfinished outputs as input files, as long as they only access them sequentially from beginning to end, a facility known as "pipes" — the reader process falls asleep until the writer process produces some data, just as with a disk or magnetic tape. The stream of input from the terminal can also be treated as an input file, and normally is, providing a certain degree of interactivity to normally-batch-mode programs and a certain degree of automatability to normally-interactive programs.

The power of the Unix "REPL" must be put in context in its place in the 1970s: it ran on a PDP-11, which might typically have a quarter-megabyte of RAM, of which each process could access no more than 64 KiB at a time. Nevertheless, in a few seconds, you could assemble a command line that strung together four or five processes to use the whole quarter-megabyte of RAM to process a file of a megabyte or more, fairly efficiently.

Some of the designers of Unix used the metaphor of "software tools" to explain the difference between Unix programs and traditional app-model programs: rather than climbing into a bulldozer to interact with it exclusively for a while, you could pick up a shovel in one hand while wrenches and hammers hung from your belt. The software-tools approach became popular with programmers on non-Unix systems as well, but without the Unix shell and pipes, it was much clumsier. Too, the heavy costs of launching new programs on non-Unix systems made the software-tools approach much less efficient than on Unix.

The `make` program added to Unix in the late 1970s provides an automatic caching system for such reproducible batch computations, the paradigmatic example being recompiling a file of source code and relinking an executable when that file has changed. With `make`, the invocations of the compiler are usually automatic. You can also use it to cache a wide variety of staged data processing.

The architecture of the Unix C compiler itself also took advantage of the pipe facility to separate a macro preprocessor, the compiler as such, and the assembler into separate concurrent processes, making C considerably more expressive than other minicomputer programming languages of the 1970s.

After a few years, the "C shell" from Berkeley added filename completion and command-line editing to the Unix "REPL", enabling incremental cut-and-try construction of command lines. As an example, in my shell history on this laptop, I have the following sequence as I incrementally excluded more types of files from my command-line listing:

```
ls
ls | grep -v 'mkv$|vtt$'
ls | egrep -v 'mkv$|vtt$'
ls | egrep -v 'mkv$|vtt$|webm$'
ls | egrep -v 'mkv$|vtt$|webm$|mp4$'
```

The `ls` and `egrep` programs need not be interactive to support this kind of incremental experimentation; they need only take their input from the Unix shell command line rather than interactively.

The C shell also added "job control", which allows a user using a teletype-emulating terminal to switch back and forth between one or more interactive apps and the shell, just as a GUI windowing system does.

The Unix shell, however, suffers some serious weaknesses. It's almost useless for anything involving graphics, although you can do things like this:

```
$ gnuplot -e 'set term dumb size 60,15; plot x**2'

  100 **+----------+-----------+------------+---------+**

    0 +-+----------+------***********-------+---------+-+
     -10          -5           0            5           10
```

Instead of drawing blocky ASCII art, gnuplot can write your plot to a file or open it in a window, but in neither case do you get the alternating list of queries and answers you normally get in a REPL typescript.

The shell is also useless for anything that requires feedback with latency under a second, like adjusting spline control points of a vector graphic.

Finally, the shell typescript session inevitably contains errors and false starts mixed in indiscriminately with the actual useful results, limiting the usefulness of the typescript without further editing. On a teletype this was inevitable, but not on a computer screen.

Notebooks

Like most fashionable programmers, I do a lot of my work nowadays in IPython notebooks (more recently renamed Jupyter notebooks). These are Python REPL transcripts enhanced with a few major features:

• As in the Unix shell or the Python REPL, you can edit previous command lines. Unlike those systems, by default, the edited version replaces the original, and its output also replaces the original output. If you want both versions in your notebook, you can copy and paste into a new "cell".
• The output from the command lines is not restricted to being text. It can include graphics, TeX markup for equations, and data tables, and often does. In fact, it can even support further graphical interaction through callbacks.
• Because the input and the output are distinguished — although they alternate, as in traditional REPL transcripts — it's possible to re-execute some or all of the cells with new input data, or to attempt to reproduce the results after an incremental change. You can think of the contents of each cell as the input to a batch job. Reproducibility is fairly limited, though, for a variety of reasons. First, the IPython session state is an additional, invisible, constantly-changing input to the "batch job". Second, the installed software and filesystem state are also potentially inputs, and they are also invisible and potentially changing.

You can also invoke other programming languages (including the Unix shell), include comments in Markdown with LaTeX equations, and a few other things, but those are not the most important advantages over the bare Unix shell in a terminal.

That is, the notebook is an alternative model for interacting with and integrating programs, different from apps, REST, batch processing, and teletype REPLs including the Unix shell.

The open operating system model

Before proceeding to talk about the new interaction model I'm exploring, I want to point out a few significant systems that don't fit into the above interaction models: Smalltalk, Emacs, Cedar, and Oberon. In these systems, many separately developed "programs" are loaded into the same memory space and can interact with one another using function calls, and the user can interact with them by invoking functions from any of them at any time, and can also load more programs.

In Smalltalk, the system developed at Xerox PARC in the 1970s in which object-orientation was invented, not only each window on the screen but each letter is an object, which is to say, a tiny virtual computer with its own code and state, and each window's code decides how to display it and how to react to events such as clicks. The difference from the apps model is that there's no separation between the windows — it's trivial to embed one "program" in another, call functions of one "program" from another, pass complex data objects from one "program" to another, and so on — like Windows OLE, but simple.

Cedar is a system developed at Xerox PARC in the late 1970s and early 1980s as a sort of improved alternative to Smalltalk and Interlisp,

but with strong static typing and separate compilation. Cedar is not as well known as Smalltalk, in part because the software was never published, but its successor language Oak is unfortunately extremely popular.

After spending a couple of sabbatical years at Xerox PARC working on Cedar and its predecessor Mesa, Wirth went back to Switzerland and, with Gutknecht and others, wrote his own version of it from scratch, starting in 1988, based on his language Modula-3; this system is called Oberon, and it is free software.

XXX Inferno?

Emacs also uses this interaction model. Emacs Lisp is not object-oriented, but it has the notions of "major modes", "minor modes", "keymaps", and "buffer-local variables", which permit different windows to respond differently to interaction; and there are a number of popular programs written in Emacs Lisp, including Org-mode, Gnus, Magit, Eshell, Ediff, and Hyperbole, in addition to the basic IDE functionality Emacs was written for. Although Emacs has been suffering substantially in popularity in recent years, some of these programs are, or once were, best-in-class applications.

Lampson and Sproull published a 1979 paper in which they called a version of this system architecture an "open operating system" or "open system", a term which has been reused for other purposes; they emphasized other aspects.

Mummified embedded apps

With that background out of the way, I've been hacking on Yeso, a simple framebuffer graphics input-output library, with the purpose of making it easy and direct to write graphical programs in any language that run pixel-identically on a variety of platforms. So far I only have X11 and Linux framebuffer console backends, but one of the next things I want to write for it is Wercam, a display server that uses Yeso itself, rather like Xnest, 8½, or Rio — it will allow Yeso apps to connect to it using a simple protocol and draw windows on its screen, and route events to them as appropriate.

This led me to ask: what kind of window management should it use? Should it use overlapping windows, like X, or alternate between giving different apps full control of the screen, like Android and IOS normally do?

And, of course, I'd been using notebooks for years, and Perry Lorier told me about a notebook-style shell he's writing using curses. Unlike Jupyter/IPython, in which only one cell can be evaluating at a time (except that they can respond to callbacks), in his notebook-shell, each process gets its own pseudo-terminal, and it can continue running freely while you're interacting with other processes.

So it occurred to me that maybe the window manager should be such a notebook-shell. If you start a program and it merely produces textual output and takes textual input, that would appear underneath your command, as per normal; but if a program opens a Yeso window, the window would be embedded in the notebook there, by default. Perry's notebook-shell takes a program full-screen when it issues a clear-screen escape sequence; perhaps some similar action would be useful.

The Yeso calling interface is in rapid flux, changing about once a

day for the last three weeks, but putting a colored rectangle on the screen can be done in C something like this:

```
#include <yeso.h>

int main()
{
  yeso w = yb_open("hola, mundo!", 64, 64, "");
  yi_fill(yb_framebuffer(w), 0xcc99cc);
  yb_flip(w);
  for (;;) yb_wait(w, 0);
}
```

On the Linux framebuffer console backend, that last line is somewhat unnecessary; it just makes the program hang until you kill it. On the X11 backend, it's kind of mandatory, because otherwise the window closes immediately as the program exits; it probably won't even be on the screen long enough for a screen refresh.

But preserving output from programs that are no longer running is sort of the sine qua non of REPLs and notebook interfaces. Maybe if Wercam uses a notebook interface for its window management, it should preserve the graphical output of the program, just as IPython preserves the graphical output of matplotlib plot commands that have plotted data. (Unless the user deletes them.) Wercam could actually do better than just save the last frame of output — because Yeso sends a sequence of full frames to the display, Wercam could record all the frames (up to some limit, by default) and allow you to fast-forward and rewind through the impromptu screencast.

Horcruxes or continuations

Having graphical output there in the notebook without a running process behind every scatterplot seems useful. But what if you want to zoom in on one of those plots later? How can you supply event-handling callbacks without a running IPython kernel or other process sitting there waiting to answer them?

Well, in the early days of the Web, clicking a link might launch a CGI program to generate the response document. Wercam could do something similar. What if the program left behind at its exit not only an image but also a sort of last will and testament, or perhaps a horcrux, giving a command to run to handle any new events, and perhaps a set of event types to ignore, such as mouse movements?

(Of course, for security reasons, that command should run only with the authority of the original program.)

At one point it would have been absurd to spawn a new Unix process for each mouse movement — it just took far too long. But my forkovh test on my laptop takes about 130 µs to fork a child process, written in C, which immediately dies, and then reap it. And httpdito takes about 30–50 µs to accept a connection, fork a child process, and then reap it. (The children handle HTTP requests, but that mostly happens on other cores.) Httpdito is faster probably because it's not linked with the C library, so its memory map is much smaller. Linking forkovh with glibc boosts its latency to 670 µs.

Exec is significantly more expensive, although possibly a better operating system would help. Forking, executing, and waiting for a hello-world C program takes about 3 ms with glibc on my laptop

(whether statically or dynamically linked), or 2 ms with dietlibc. On the Linux framebuffer, the Yeso PNG viewer takes 4 ms on small images. (Pentium N3700 1.6GHz at probably 500 MHz, Linux debian 4.4.0-21-generic #37-Ubuntu.)

These latency numbers are not insignificant, but on a 60fps display like the one on my laptop, 2 milliseconds out of a 16.7 ms frame is not immediately fatal. I mean, USB mice are normally polled every 10 milliseconds, and 1 millisecond is the shortest polling interval USB supports.

But suppose respawning the program when there's an input event, or maybe even after a specified timeout, is fast enough at the kernel level. Now the program needs to know the "session state" — if it's redrawing a scatterplot in response to a zoom, for example, it needs to know the data points and plot colors. If it's an interpreter, it needs the parsed program. If it's a PDF viewer that renders nearby pages in the background to avoid delays, it needs access to the prerendered cache. And it needs all of this without having to redo precious milliseconds of deserialization every time.

It turns out that arrays of binary integers or floating-point numbers, written to files in native byte order, and memory-mapped, works really well for this kind of thing. On my laptop, mmap() on an already-open file takes about 4–6 µs. For more elaborately structured data, something like FlatBuffers, CapnProto, or SBE enables you to get similarly zippy speeds without having to pay a startup deserialization tax.

So perhaps the "session state" or "horcrux" in the notebook cell should be a filesystem directory with the crucial state saved in files that the program knows to open and map into its memory when restarted; essentially they are a mummified version of the live program's non-ephemeral memory state, ready for instant rehydration and return to life. This is pretty similar to how Android saves the state of an Activity (an app, in Androidese) in a "bundle" in onSaveInstanceState and then passes that bundle to onCreate when it restarts the Activity; but Android "flattens" whatever you put into the bundle into a "parcel", which is extra overhead that should probably be avoided in this context.

links to programs rehydrating with new versions of code declaring which UI events to handle delegating to other programs file managers publishing outputs in formats usable by other programs Launching transactions that may fail editing text files reducers, replay, and distribution

Kerr snow display

Kragen Javier Sitaker, 2019-11-12 (3 minutes)

Snow, like titanium dioxide paint, is brilliant white because it's full of randomly oriented interfaces between transparent media of different refractive indices. This causes entering light rays to execute a low-loss random walk which ultimately comes back out of one side or the other of the metamaterial.

Kerr cells are, as I understand it, normally used to slightly retard the phase of light beams passing through a medium with a strong Kerr effect by applying a few thousand volts across a thin layer of it, thus slightly altering its refractive index.

A much more visible effect of the Kerr effect would result if the Kerr medium were mixed with transparent particles of a different phase, no Kerr effect, and a slightly lower refractive index. By matching the indices of the two materials, the cell would vary between transparency and translucency; when the Kerr effect caused their indices to match perfectly, the phase boundaries would cease to refract or cause total internal reflection, becoming perfectly invisible. This amounts to a sunlight-readable display, like a super-fast high-contrast reflective LCD.

Ideally the two media would have the same permittivity to prevent the electrical field from varying according to the local concentration of Kerr medium, but I don't know if that's possible.

In a variant of this approach, instead of particles, the other transparent medium occupies a triangular section of the Kerr cell, while the Kerr medium occupies a different triangular section, and light travels through the Kerr cell lengthwise, entering and exiting at the edge rather than parallel to the electric field. A time-varying electrical field will produce a time-varying refraction angle where the light beam strikes the oblique interface between the two materials, thus deflecting the beam through varying angles, perhaps including total internal reflection (at which point the angle becomes insensitive to further voltage changes). Possibly many different "pixels" can be obtained, each deflecting a different part of the same beam through an independent angle, with bandwidths up into the tens of MHz or more. In this case there is no particular requirement for their indices to be very close. If feasible, this is a better solution to the problem described in Lenticular deflector (p. 2612). Heck, this is probably a product that already exists.

This device as described can also provide amplification; like a MOSFET, its switching action is voltage-controlled and nondissipative, so it can shunt around much larger amounts of power than those needed to control it.

Term rewriting

Kragen Javier Sitaker, 2017-07-19 (3 minutes)

Typical term-rewriting patterns are of the form

```
x(?y, z) -> foo(?y, ?y)
```

where the "?" identifies the `y` as a variable (or, we might say, a metavariable). This poses a certain amount of difficulty for metacircularity, such as a program to determine whether a set of rewrite rules is confluent (normalizing); you might want to look for the literal pattern `?y` or especially `??y` for any `?y` in some rewrite rule you are trying to manipulate.

Prolog, where all this originally came from, is even trickier along this axis, since it spells `foo` and `?foo` as `foo` and `Foo`, respectively.

One possible solution to this problem is to declare the metavariables out-of-line:

```
(rewrite (y) (x y z) (foo y y))
```

or

```
metavariable y;
x(y, z) -> foo(y, y)
```

Another aspect of term-rewriting languages is that they don't accommodate extensible data structures very easily. Suppose you have a bunch of rules of the following form:

```
?x + constant(0) -> ?x
```

Now, you decide that constants should additionally include the line and column number where they were found, thus improving your debugging information. This forces you to modify the above rule as follows:

```
?x + constant(0, ?_) -> ?x
```

And you must do the same thing for all similar rules.

Suppose instead that the nodes of your graph instead have arbitrary sets of named properties, perhaps namespaced to avoid unfortunate property collisions, and with the proviso that extra properties not mentioned never cause a match failure. Then we can write the above instead as follows:

```
{addend1: ?x, addend2: {constant_value: 0}} -> ?x
```

This version will survive such an augmentation without modification.

This is the same data model as Binate, and suggests that you should be able to write such rewrite systems as Binate relations, making them point-free (and solving the above problem of metacircularity in a different way): the transitive closure of some rewrite relation,

perhaps. That is, the above algebraic rewrite rule would be part of a relation called something like `algebraically_simplifies_to`, so we could ask whether

```
(4 + 0) algebraically_simplifies_to 4.
```

or indeed what a given expression simplifies to. The `algebraically_simplifies_to` arc or arcs from that expression would be in some sense on equal standing with the `addend1` node from it to 4. We can take the transitive closure of that relation and subtract a version of its own converse from it to exclude results that can be algebraically simplified further.

I am not sure if this is in practice a feasible thing to do with Binate, or what would be needed to make it feasible, or whether it would be practical, but it is a very appealing simplification and unification!

It also avoids the ugly ad-hoc extension to term-rewriting pattern-matching in Leler's Bertrand (p.53 of his book) where `aNumber` matches any number, etc.

I think one big problem here is that in Binate, equality is (I think) necessarily defined by identity rather than content: two point objects with the same `x` and `y` properties are not equal, because one of them might have some other property (such as `z`) which is not supposed to affect the behavior of queries that don't mention that property.

Comparison of the PCO-1810 and PCO-1881 plastic bottlecap standards

Kragen Javier Sitaker, 2014-05-25 (updated 2016-07-27) (2 minutes)

Plastic bottlecaps are mostly compatible with each other because their threads conform to a standard called PCO 1810, or occasionally PCO 28, which is being gradually replaced by a newer standard called PCO 1881. These threads are formed into the bottleneck (called a "finish") before the shape of the rest of the bottle is formed; companies like Jesper PET Preform will sell you the bottle "preform", with the thread formed but the rest of the bottle uninflated; then it's up to you to blow-mold the bottle into the shape you want.

The bottle caps (called "closures") are sold separately, and they're usually made of polypropylene ("PP").

PCO 1881 has a slightly shorter neck (17mm instead of 21mm) and was finalized in 2009 by the International Society of Beverage Technologists. It apparently implies no loss in performance compared to the PCO-1810 standard, despite the steeper thread pitch and the threads going around only twice instead of the three times you see on PCO-1810 bottles.

Because the bottle neck and cap are so much thicker than the rest of the plastic bottle, they account for a substantial fraction of the material use in the bottle, so the 1.4 gram reduction due to the 4mm-shorter PCO-1881 standard amounts to 27% of the total weight of the PET bottle, not counting the cap.

ISBT has put the PCO-1810 standard and the PCO-1881 standard engineering drawings online along with their other standards, and "ippe" posted an STL file on Thingiverse that prints to a working PCO-1810 bottle closure at least in PLA on the Prusa Mendel I have access to. (You may want to turn that file upside down for printing if you want it to seal, though; the top was too long a horizontal span to cohere properly.)

In addition to the preforms, you can buy entire preblown bottles if you don't have blow molding ("pressure molding") equipment; a 43-gram 1ℓ bottle costs around €0.36–€0.69 without the cap.

Supervisor children for fault-tolerant Unix command-line programs

Kragen Javier Sitaker, 2019-01-04 (3 minutes)

It's straightforward for a Unix process to spawn a child and then clean up when the child exits — it can use the wait(2) system call to sleep until the child is done. For things like changing the video mode, turning off cursor display and character echo in a Unix terminal, turning on power to a heating element, and so on, this is an improvement over the usual approach of doing the cleanup in the same process, because it happens even if the supervised process crashes, for example because of an OOM kill or a segfault. This requires that the supervisor process be less likely to crash, but that is often easy to arrange; an effective supervisor for particular scenarios can be written in ten or twenty lines of C.

This is such an effective way to handle errors that systems designed for high-reliability applications, such as Erlang, often use it as their only way to handle errors.

However, it's a problem for the adoptability of a C library if using it requires its users to launch their programs in a special way. So another possible approach is to spawn a supervisor *child* which waits for the parent to die. Unix doesn't have a general way to wait for non-child processes to die, but this can be taken care of easily with a pipe from the supervised parent to the supervisor child — the parent can trigger a cleanup either by writing a byte to the child or by exiting, including by way of an OOM kill.

The supervisor child is not entirely transparent to the application, for two reasons.

First, if you have no children, wait(2) or waitpid(2) with a -1 PID will return immediately with ECHILD; the supervisor child would convert this into a deadlock, as each of the child and the parent are waiting for the other to exit. This can be fixed with the double-fork trick usually used to spawn daemons.

Second, and more seriously, POSIX threads are pretty aggressively incompatible with fork(); it's unsafe, at least in theory, to call things like ioctl() in the forked child if the parent is multithreaded, presumably because ioctl() might try to acquire a lock that was held by another thread at fork time, a thread which doesn't exist in the child and which therefore can't unlock its lock. To work around this — and also perhaps to reduce memory consumption and the likelihood of OOM kills — the supervisor child could exec() a special-purpose supervisor executable.

Graph construction

Kragen Javier Sitaker, 2016-09-08 (updated 2017-07-19) (23 minutes)

(See also Circuit notation (p. 1161) and A stack of stacks for simple modular electronics (p. 1779).)

I think I have a new approach to concisely and responsively describing directed graph structures that is useful in many different creative endeavors that can be undertaken with computers. I don't yet have a working implementation; this article is only an exploration.

Here's an overview of different possible notations for edge-labeled directed graphs (and related structures), including some new applications.

As an example application, in one variant of the notation, this is a schematic for an energy-harvesting power supply circuit taken from a paper on the subject. Here , represents parallel connection, concatenation represents serial connection, and <> represents reversal, among other things:

```
{{<d> {{ac i, c}}=q <d>, {<d> q <d>, c}} s {<d>, l {c, {<v>, r} r}}}
```

However, this approach is not limited to circuit design. All of the following can be conveniently represented as edge-labeled directed graphs:

- regular expressions
- finite state machines
- bubble-and-arrow diagrams (although the bubbles are more commonly labeled than the edges)
- database queries
- database contents
- dataflow pipelines (or more generally dataflow graphs)
- circuit schematics
- control-flow graphs in programs
- networks of constraints

These techniques should be applicable to user interaction and generative programming in all of these areas.

Netlists

You can write these things as netlists or 3-tuples; an abbreviated example of a bubble-and-arrow diagram from the dot man page:

```
digraph test123 {
        a -> z [label="hi", weight=100];
        x -> z [label="multi-line\nlabel"];
        b -> x;
}
```

Or, here's a circuit netlist in Spice:

```
Multiple dc sources
v1 1 0 dc 24
v2 3 0 dc 15
```

```
r1 1 2 10k
r2 2 3 8.1k
r3 2 0 4.7k
.end
```

This requires naming every node; the nodes are named `a`, `b`, `x`, and `z` in the dot example, and 0, 1, 2, and 3 in the Spice example.

Here's a dataflow example by zahorjan@cs.washington.edu in MIPS assembly, which is at the same level of abstraction, although it reuses the "dataflow node labels" `$t0` and `$t1` — each time they are the first operand of an instruction, their previous value is overwritten:

```
srl   $t0, $t0, 1      # i/2
addi  $t1, $gp, 28     # &A[0]
sll   $t0, $t0, 2      # turn i/2 into a byte offset (*4)
add   $t1, $t1, $t0    # &A[i/2]
```

If we were to rewrite that with SSA-style subscripts (what Ada Lovelace use prefixed superscripts for) we get:

```
srl   $t0₁, $t0₀, 1
addi  $t1₀, $gp₀, 28
sll   $t0₂, $t0₁, 2
add   $t1₁, $t1₀, $t0₂
```

There are better alternatives, though.

Infix

The traditional solution for the arithmetic dataflow case, of course, is to divide the computation into unary and binary operations and write them in infix notation; the above MIPS assembly then renders as follows:

```
($t0₀ >>> 1 << 2) + ($gp₀ + 28)
```

This is considerably easier to follow, bringing related things closer together and eliminating most of the accidental names, ending up about three times shorter.

By itself, it only covers a very restricted range of cases: tree-shaped digraphs, in which, if interpreted as dataflow graphs, each value is used only once, producing a single output. But it isn't immediately obvious how to apply that to get more general kinds of graphs.

Kleene's Theorem

Stephen Kleene (whose name I mispronounced for 21 years as [klin], but TIL it's actually [kleɪni]) showed that any regular language, and thus the possible paths through a finite state automaton, can be generated by a regular expression. As I understand it, a regular expression on some alphabet Γ is recursively defined as the smallest language L such that

```
L = Γ ∪ ({"concat", "alt"} × L × L) ∪ (L × {"*"}) ∪ {∅, ε}
```

Hmm, that definition is shitty, I'll try again. A regular expression `Γre` over Γ is defined as the sum type

```
Γ re = Lit of Γ
     | Concat of (Γ re × Γ re)
     | Alt of (Γ re × Γ re)
     | Closure of Γ re
     | Impossible
     | Emptystring
```

The language generated by a regular expression is defined as follows:

```
lang(Lit(x)) = {x}
lang(Concat(a, b)) = {wa || wb for wa in lang(a) for b in lang(b)}
lang(Alt(a, b)) = lang(a) ∪ lang(b)
lang(Closure(a)) = {ε} ∪ lang(Concat(a, Closure(a)))
lang(Impossible) = ∅
lang(Emptystring) = {ε}
```

Here || is string concatenation. (Or word concatenation, as combinatorists apparently like to say. And who can argue? A C program as little resembles a piece of twine as it does an entry in the dictionary.)

So the nifty thing here is that this gives you a way to generate all possible finite-state-machine languages by building up a finite-state machine from simpler single-entry single-exit finite-state machines, which is to say, building up a directed graph from simpler two-terminal directed graphs. You can't express every possible graph in this way; in particular, there are a set of "irreducible control flow structures" which, if present, require duplication of nodes. (McCabe's 1976 paper "A Complexity Measure" explains in more detail in the context of program control flow.)

Traditionally in regular expressions we write Concat, Alt, and Closure as mere juxtaposition, infix |, and postfix *, respectively, although, in the context of Kleene algebras, alternation is traditionally written with infix + instead.

And this is somewhat more expressive; it can express any series-parallel circuit. This includes trees as a subset. If we use the traditional |* notation, we can express the above MIPS-assembly arithmetic graph as follows:

XXX try , instead of |?

```
(($t0₀ | 1) >>> | 2) << | ($gp₀ | 28) +) +
```

Here we are supposing that constants and variables obliterate whatever data was present on their branch of the dataflow digraph, that rejoining dataflows creates a node where both pieces of data are available (with the left and right branches distinguished!), and that the operators then reduce the two pieces of data available at their node to 1.

But now we can also represent the SPICE circuit I gave above, for example. One possible representation is as follows:

```
(v⁻¹[dc 24] r[10k] (r[8.1k] v[dc 15] | r[4.7k]))*
```

This contains all the useful information in the original netlist, but it is both much easier to write and, I would argue, even much easier to

read; it's easy to see what is in series and what is in parallel. Interpreted as a regular expression, it yields all of the possible traversals through the circuit in a certain direction (which could be the direction current is flowing, but happens not to be).

It's common to be able to express the majority of an electrical circuit in terms of such series-parallel circuits, with the occasional deviation from series-parallel constructions; the same is true for control flow in programs.

Postfix

The arithmetic expression above may look suspicious:

```
(($t0₀ | 1) >>> | 2) << | ($gp₀ | 28) +) +
```

It happens to be exactly equivalent to how you'd express this expression in postfix (RPN), but with stack relationships explicitly called out — every time some value produced by `b` is on top of some value produced by `a` on the stack, we have written `(a|b)` rather than just `a b`. If we adopt the more usual convention, this expression reduces to the following:

```
$t0₀ 1 >>> 2 << $gp₀ 28 + +
```

Can we apply this to the circuit diagram as well? It's simple:

```
{ 24 dc v⁻¹ 10 k r { 8.1 k r 15 dc v | 4.7 k r } }
```

Consider the expression as an RPN program to construct a circuit diagram, with a stack consisting of node identifiers and numbers. It begins with a single node identifier on the stack, and it uses the following operations:

- `{` duplicates the top item on the stack
- `dc` pushes some number on the stack used to indicate DC
- `v⁻¹` pops a voltage type and parameters from the stack, allocates a new node, connects the positive side of a newly created voltage source to the new node, connects the negative side to the node on the stack, which it pops, and pushes the new node on the stack
- `k` multiplies the number on top of the stack by 1000
- `r` is analogous to `v⁻¹` but creates a resistor instead
- `v` is exactly the same as `v⁻¹` but connects its items in the opposite order.
- `|` exchanges the top two items on the stack
- `}` shorts together the two nodes on top of the stack, causing them to become equivalent

It turns out that, in this context, this semantics for `{ }` makes them adequate both for Kleene closure `*` and to enclose a binary alternation `|` in the context of circuit schematic capture, because a wire forward from the beginning of a part of a circuit to its end is the same as a wire backward from its end to its beginning. In other contexts, like regular expressions, these two are not equivalent.

`v⁻¹` is a bit suspiciously ad-hoc; really we might prefer this operation of flipping a bit of circuitry around before connecting it to be an orthogonal operation, rather than separately defining `v⁻¹`, `d⁻¹`,

`electrolytic_capacitor⁻¹`, and so on. You could instead define `v` to allocate two fresh nodes and push them both on the stack, then use a separate `forward` or `reverse` operation to short two of them together and remove them from the stack. Alternatively, you could have < and > operations that enclose a piece of circuitry to be reversed — the first allocating a fresh node and pushing two references to it onto the stack, the second performing the equivalent of `rot }`. But really this is the converse relationship on binary relations, about which more later.

In general, I find postfix less readable and more error-prone than infix, so I'm not sure it's really the right thing, but it has a few advantages which might be relevant in this context:

• Its semantics are ruthlessly simple and thus easy to implement correctly.
• It's very clear to see how to extend it to define new parametric components or macros — pseudo-arcs that are really an entire subgraph — simply by attaching a name to a sequence of graph-construction operations and invoking them as if by copy-paste later on.
• It smoothly handles three-terminal and multiple-output devices; three-terminal devices can, for example, consume two items from the stack and produce a third (ideal for things like logic gates) or push fresh nodes for all of their terminals onto the stack. If you can define new component macros, you could define a bridge-rectifier macro that consumes two AC terminals and returns two DC terminals.
• For interactive graph construction and editing, not only does it require fewer UI actions than other means of schematic capture, it can also provide immediate simulation feedback while the circuit is being constructed, because almost everything is already connected when it's constructed.

I'm not sure that "edge-labeled directed graphs" are quite the right abstraction for electrical circuits. Yes, a battery or a diode is a directed relationship between two wire nodes/nets, so representing it as a labeled directed edge in a graph makes some sense. But a bipolar transistor is a relationship between three wire nodes/nets, each of which has a unique relationship to it, and a microcontroller is in some sense a relationship between dozens of nodes. These are more like hypergraphs, but the existing work on *directed* hypergraphs is pretty slim.

This mirrors the state of relational databases and logic programming, where most of the work is with some arbitrary number of finitary (N-ary) relations, rather than binary relations.

A bipartite directed graph, where wire nodes/nets are one part and components are the other part, would be an adequate model. In dataflow, the parts would instead be values and operations.

Despite all this stuff and despite being quite compact, postfix, even augmented with the { | } operations above, can't construct arbitrary edge-labeled directed graphs, just directed graphs whose traversals are equivalent to traversals of any given directed graph, and that only at the cost of a potentially exponential expansion in graph size. In particular, they can't construct any nonplanar graphs, and not even all planar graphs.

Variables/Labels

The usual solution for this in dataflow is to use (possibly immutable) named variables, and in control flow to use labels and `goto` — essentially escaping back to netlists, where connection is indicated by coincidence of names rather than proximity. Labels or variables are "wormholes" in the otherwise planar and recursive graph construction; they can connect anywhere. Usually you don't need very many of them.

The above discussion of regular expressions leads us to speculate on whether we should be labeling nodes, as is normally almost universal, or entire subgraphs. Consider the following SPICE model, from the same textbook page as the example I gave earlier:

```
fullwave bridge rectifier
v1 1 0 sin(0 15 60 0 0)
rload 1 0 10k
d1 1 2 mod1
d2 0 2 mod1
d3 3 1 mod1
d4 3 0 mod1
.model mod1 d
.tran .5m 25m
.plot tran v(1,0) v(2,3)
.end
```

Like bridge circuits in general, this is not a series-parallel circuit; you need a label. You can represent most of it as a series-parallel circuit; let's use the postfix form, and suppose we have the direction-reversing brackets < and > suggested earlier:

```
{ 15 60 ac v  { d < d > | < d > d } }
```

This expresses the entire circuit above except for the load resistance. If we add the new operation }= to define a label for a subgraph, defining the word following it to hook up the two nodes on the stack as if they were an arc, then we can write it as follows:

```
{ 10 k r }= rload  { 15 60 ac v  { d rload d | < d rload d > } }
```

This defines exactly the same circuit as the SPICE model in a third less text, although it doesn't specify the simulation parameters. Each time `rload` is invoked, it connects its environment to the *same* component, unlike things like `d`, which generate a new component each time they're invoked.

Alternatively, and more traditionally, we could define }= to simply define a name for the node on top of the stack, removing it from the stack; when invoked, the name shorts that saved node to whatever is on top of the stack at the time. Then we can define the circuit as follows:

```
{ 15 60 ac v  { d { 10 k r }= rload < d > | < d > rload d } }
```

Explicit series connection

Another alternative, which I mention here more for completeness rather than because I think it's necessarily better than the others

mentioned, is to make the series connection explicit rather than implicit. In an infix syntax, for example, using the hyphen for the series connection, perhaps R-C is a series connection of a resistor and a capacitor, while R|C is a parallel connection. Then we can do things like L-(C|L-(C|R)). Here, as in the notation at the beginning, the values being combined are not circuit nodes or nets but rather subcircuits with a beginning and end.

We can, of course, use a stack notation for this as well; for example, instead of L-(C|L-(C|R)), we could write LCLCR|-|-. A stack-notation expression can represent any number of subcircuits rather than just one, because it can end with any number of items on the stack; similarly, it can represent a transformation of a circuit or set of circuits, rather than just a circuit. (Hmm, this is a digression; perhaps it belongs elsewhere.)

Without the explicit series combination operator, we can get the same amount of power in a stack-language context by having an explicit "push new disconnected node" operator. I think.

Other arities of edge creation

You could also create an edge between the top two nodes on the stack, consuming both and returning neither. In this model, you must explicitly create each node, then explicitly duplicate any node that will be connected to more than one edge; in a sense, the expected degree of a node is 1. (So to get three resistors in series, you would say NODE DUP NODE R NODE OVER R NODE OVER R. I think.) The other approaches I've been describing all have, in some sense, an expected degree of 2 for each node — the operation of adding each new edge to the graph consumes a node and produces a node, which then can be merged with some other node in the (implicitly exceptional) case where that is desired.

You could also imagine leaving all the nodes on the stack, not consuming any of them, so NODE NODE R R R would give you three resistors in parallel.

What's the best default node degree?

Eyeballing a couple of small schematics, I have:

- 8 nets, 8 2-terminal components, 2 3-terminal components, average degree of `(/ (+ (* 8 2) (* 2 3)) 8.0)` = 2.75.
- 12 nets, 8 2-terminal components, 6 3-terminal components, average degree of `(/ (+ (* 8 2) (* 6 3)) 12.0)` = $2.8\bar{3}$.
- 4 nets, 4 2-terminal components, 1 3-terminal component, average degree of `(/ (+ (* 4 2) (* 1 3)) 4.0)` = 2.75.
- 9 nets, 2 2-terminal components, 1 3-terminal component, 1 5-terminal component, average degree of `(/ (+ (* 2 2) (* 1 3) (* 1 5)) 9.0)` = $1.\bar{3}$.
- 12 nets, 12 2-terminal components, 5 3-terminal components, average degree of `(/ (+ (* 12 2) (* 5 3)) 12.0)` = 3.25.

In some sense, this suggests that the "average" degree of a circuit net (i.e. wire) is somewhere around 3.

However, that's including the power rails and ground as nets, which commonly have lots of connections. For example, in the last circuit above (Figure 12.67 from Horowitz & Hill 3ed., a simple laser drive circuit), ground has 7 connections and the positive power rail has 3. If we discount those, the average goes down to 2.416. The first

circuit, figure 5.56, has three ground connections; discounting those gives us 2.375.

Consequently, I think that the most likely optimum is not 1 or ∞ or even somehow 3 but 2.

Binary relations and the relational product

A few years back I spent some time on a database query language based on binary relations called Binate. It has several things in common with the work I'm describing here.

One of the things I never resolved properly in Binate was the status of constants; I treated them as relations from anything whatsoever to the constant value, like the transformation of a register state produced by a load-immediate instruction. This introduces potentially awkward infinities if you take its converse.

Binate uses a really-infix grammar whose expressions all evaluate to binary relations, so it handles non-binary finitary relations with an N-ary relational-product operation, which produces nodes that participate in a bunch of fresh binary relations.

Labels, dynamic scope, and linking

Earlier I mentioned NAND gates as an example of a three-terminal circuit element for which it's natural to consume two input nets from the stack and produce an output net, but in reality a two-input NAND gate has five terminals: power and ground. Usually in a big part of the circuit you use the same power and ground for all the NAND gates, but maybe not in the entire design. Flip-flops additionally have a clock, and it's very common to hook lots of them up to the same clock, but to have more than one clock domain in a design.

An analogous phenomenon pops up in graphics programming: it's common to do a bunch of drawing operations with the same color, the same font, the same line joins, and so on. It's annoying to have to specify this in every drawing operation.

Dynamically-scoped variables — accessible to lots of things, but set during particular dynamic scopes and restored afterwards — are one possible solution for this. In a stack machine, you could use a PostScript-style `load` operation to save the current binding of a label on the stack, then run a bunch of graph-constructing code, then restore it at the end. This requires that invoking the label connect you to its current value, like a DEFERred word in Forth or like an operator in PostScript, not like a regular word in Forth.

Another way of looking at this is that it's like what a linker does with an object file: it resolves the relocations for a given label to point to a given label definition from its environment at link time.

In some cases it may make sense to provide default arguments for things like pullup resistors and bypass capacitors, and those could be provided in a similar way, rather than taken from the stack.

Dropping brackets for parallel construction

In a sense the above uses series combination as the default operation, which can be sort of overridden by providing a different context, like the { } or < > contexts. In algebra, we also have a default operation, which is multiplication, but we don't have to write { $3x^2$ + {

`2x + 5 } }` conventionally; instead we just write $3x^2 + 2x + 5$. You could implement this by beginning with an empty sum (consisting of, say, 0) and an empty term (consisting of 1) "on the stack" and having the `+` separator sum the top two terms and push a new empty term "on the stack"; then all the other things can just implicitly multiply. This does require a final summing action on termination of input, and it can't handle infix division (it needs brackets), but that's not so relevant to graph construction.

You could insist on a single outermost set of parentheses, with these stack effects:

- `(` pushes 0 1
- `)` adds the top two items on the stack
- `+`, as before, adds the top two items on the stack and pushes 1

These rules give the right answer for nested expressions like `( ( 3 x + 2 ) x + 4 )`.

Coolants

Kragen Javier Sitaker, 2017-07-04 (updated 2017-07-12) (11 minutes)

This weekend Carolina had a terrible problem in her apartment: the building's radiator sprung a steam leak, and she doesn't have a valve that can cut off the leak, so she's having to depend on the building staff to not turn the boiler on. Whenever they forget and turn the boiler on, her bedroom fills with steam until her frantic phone calls succeed in getting it turned back off.

This led me to think about the problem of fluids for heat transfer in domestic life, and in particular problems of safety in the case of pipe failure. Water has the advantages of being nontoxic, inexpensive, having a large specific heat, and having enormous enthalpies of vaporization and fusion (at accessible equilibrium temperatures). However, it is somewhat corrosive, as a vapor it is somewhat dangerously overeffective (leading to explosions and burn hazards), and its limited temperature range and expansive freezing can cause problems.

Controlling heat flow is one of the major issues in quotidian human life. It gives us hot showers, cold refrigerators, dehumidification, warm houses in winter, cool houses in summer, fired pottery, cooked food, dried fruit, hot tea, warm beds, chilled sprains, and cool foreheads when we have fevers. Lack of air can kill you in minutes, lack of water can kill you in days, lack of food can kill you in weeks, and lack of sanitation can spread your diarrhea to your whole town, but lack of cool can kill you in an arbitrarily short period of time: milliseconds or less.

The major ways we control heat flow are through insulation, thermal mass, glazing, active heating, and convection. Convection is the one I'm focusing on here, because it allows the control of arbitrarily large amounts of power with arbitrarily small ones, given adequate available thermal mass and insulation. Small electric fans are a common way that we control enormous amounts of thermal power using very small amounts of mechanical power.

Candidate convection fluids as alternatives to water include air, glycerin, vegetable oil, propylene glycol, propane, mineral oil, sulfur hexafluoride, dimethyl sulfoxide, eutectic lead-tin mix, methyl ethyl ketone, d-limonene, Fluorinert, acetone, ammonia, turpentine, carbon dioxide, ethanol, difluoromethane, R-410A, tetrafluoromethane, fluoromethane (HFC-41), fluoroform, low-molecular-weight polyethylene glycols, and non-glycerin sugar alcohols (such as sorbitol, mannitol, maltitol, xylitol, erythritol, isomalt).

Air

Air is nonflammable, among the least toxic alternatives, and has the widest working temperature range. It has very low viscosity, allowing it to be pumped easily, and has the lowest cost of any alternative, being free if you aren't too picky about purity. Its major disadvantage is its very low density (1.2 kg/m³ = 1.2 g/ℓ = 1.2 mg/cc), which, combined with its fairly low specific heat (1.01 kJ/kg/K), requires torrential flow rates, large ducts (despite its

low viscosity), and correspondingly high insulation costs.

Air works down to oxygen's condensation point of -183°. It doesn't have a sharply defined upper temperature limit; rather, its upper usable temperature limit is usually set by the corrosive effects of its oxygen on materials in the environment, which themselves do not have a sharply defined transition point but rather an Arrhenius relation. It becomes intolerably corrosive to carbon around 600° (anthracite's glow point) or 700° (coke's glow point) and to most metals in the range from 800° to 1500°, but does not corrode fully oxidized materials such as quicklime, silica, and zirconia, nor fluorinated materials.

Needless to say, air is used constantly as a heat transfer fluid.

Glycerin

Glycerin is very nontoxic — perhaps less toxic even than water and air — and has a fairly wide temperature range, in liquid form from 18° to 290°. It is fairly nonreactive, less corrosive than water. If used alone for domestic climate control, it would be likely to freeze in the pipes in normal use, so you'd probably need either a preheating system to liquefy it or a mixture with some other substance to lower its freezing point. Even at normal temperatures, it is fairly viscous, and a solvent might help with that too.

Glycerin's autoignition temperature is 370°, and because its vapor pressure is very low, its flashpoint is 160°, so a glycerin spill is not a fire hazard under normal circumstances. It's a byproduct of biodiesel production, resulting in a low price for non-food-grade glycerin of 2¢–5¢/kg. Here in Buenos Aires current prices seem to be about AR$76/kg = US$4.75/kg for drug-grade glycerin.

Ethanol

Ethanol is sufficiently nontoxic that people drink it recreationally (7000 mg/kg ORL-RAT LD_{50}), but this also makes it expensive, about US$4 per liter here in Buenos Aires. It's considerably less corrosive than water, although it does dissolve many plastics, including some varnishes. It has an unremarkable heat capacity (0.11 kJ/mol/K, which at 46 g/mol works out to 2.4 kJ/kg/K) and water-like viscosity. It has an anomalously high thermal coefficient of expansion, leading to its use as a less-toxic substitute for mercury in thermometers.

Aside from the cost issue, fire hazards are probably prohibitive for wide domestic coolant use of ethanol by itself. Its autoignition temperature is 365°, but it is considerably more inflammable than this suggests because of its very high vapor pressure — 6 kPa at 20°, which leads to about a 6% concentration in air; its flashpoint is 16°, so a large ethanol spill in an inhabited area is almost certain to explode unless rapidly remediated. Unlike most organic solvents, it's miscible with water, so remediation is possible just by dumping water on it.

Vegetable oil

Vegetable oils vary considerably depending on source, but the commonly-available ones are so nontoxic that they are used as macronutrients for cooking, although they are not quite as nontoxic as glycerin (which, incidentally, is easily prepared from them by

transesterification or saponification). Sunflower oil is currently the cheapest I can find here in Buenos Aires, at AR$190/10ℓ = AR$19/ℓ ≈ US$1.20/ℓ ≈ US$1.40/kg; perhaps this is because Argentina is the world's third biggest producer of it. Historically, soybean oil was usually cheaper (Argentina is also a major world producer of it) but I can't find cheap soy oil here now.

Vegetable oils function over a relatively wide temperature range. Rather than boiling like most of the other chemicals discussed here, they begin to thermally decompose; because of its high saturated-fat content, sunflower oil is typically stable up to 230°, although refined forms can survive to 250°, nearly as high as soybean oil. It remains liquid down to -17°, and soybean oil down to -16°.

They are not inflammable (they will not support flames until well above the smokepoints mentioned above) and they are extremely noncorrosive, protecting metals, woods, and leathers from other kinds of corrosion. Because they are relatively poor solvents, they generally will not dissolve plastics, although they can plasticize some of the softer plastics such as polyethylene and polypropylene. If there is a pipe leak, however, cleaning the oil from the things that it has soaked would often be tricky, requiring detergents or even organic solvents (dry-cleaning).

Vegetable oil fires are definitely not to be extinguished with water — they won't burn until they are hot enough to instantly flash the water into steam, which would aerosolize the burning oil and convert a mere fire into a huge explosion.

Propylene glycol

Propylene glycol is a very nontoxic† (33700 mg/kg LD_{50}) alcohol commonly used as antifreeze, as a solvent for drugs, and as a food additive; in the US it's legal as up to 5% of an alcoholic beverage or 24% of a confection or frosting. Among its medical uses are direct application to human corneas to reduce edema. Cases of toxicity exist in the medical literature but generally result from continuous intravenous use. At about 50 centipoise, it's not as viscous as glycerin, but it's more viscous than water and ethanol. (Chemically, you get either of the propanols by hydroxylating propane, to propylene glycol by hydroxylating either of the propanols, and to glycerin by hydroxylating propylene glycol.)

It is antimicrobial. (Because hey, it's only *so* nontoxic.)

It has an unremarkable specific heat of 2.5 kJ/kg/K and is commonly used as a heat transfer fluid, both alone and mixed with water.

It has a wide temperature range, not boiling until 188° and solidifying into a glass at -60°. It's not much of a fire hazard, with a flashpoint of 220° due to its low vapor pressure (10.6 Pa at 20°) and an auto-ignition temperature of 700°, a higher temperature than anthracite. In fact, I think I've heard that it's used as an antifreeze in industrial fire suppression sprinkler systems.

If exposed to air at high temperatures, it can oxidize over time.

Propylene glycol currently runs about AR$130/kg (US$8/kg) here in Buenos Aires; the most popular use seems to be mixed with glycerin to promote evaporation for vaping in e-cigarettes.

Like glycerin and ethanol, propylene glycol could, if it caught fire, be extinguished with water, because it's miscible with water.

Propylene glycol is a relatively good organic solvent, so a spill of it might cause damage to plastics and varnishes; it's commonly used as a "permanent" plasticizer. It can dissolve about 1% of its own weight in most vegetable oils, but is immiscible with hydrocarbons.

† Except to cats. Propylene glycol is toxic to cats.

Propane

Liquefied propane gas is commonly used as a refrigerant, mixed with butane; unlike most of the other heat transfer fluids surveyed here, we can take advantage of its enthalpy of vaporization, which allows the use of a much smaller amount of heat transfer fluid. However, propane is ridiculously inflammable.

Mineral oil

Mineral oil, or paraffin oil, is a mix of alkanes of a relatively consistent chain length and low vapor pressure; it is relatively nontoxic, but indigestible, and is commonly used as a laxative. It is used as a heat transfer fluid in electric radiators, for high-voltage electric transformers, and in computers. Different grades have different freezing and melting points with different degrees of definiteness, but a typical melting point is -4°; it can survive slightly higher temperatures than vegetable oil, up to

Extending heckballs

Kragen Javier Sitaker, 2019-11-26 (6 minutes)

In Heckballs: a laser-cuttable MDF set of building blocks (p. 2782) I wrote a bit about Heckballs (Jecvals), although that dates to before I had done a bunch of the work I actually did on them.

Since then I've messed around quite a bit more with sheet cutting design (see for example Cardboard furniture (p. 742)) and come up with some other ideas.

Locking tabs in slits for sprung snap joints

One of the biggest improvements I haven't yet tested solves the problem of Heckballs falling apart once assembled due to the imprecision of the press fit. I saw this solution in a discarded liquor-box partition cardboard on the sidewalk one day. By extending the insertion bevel or chamfer or divot on one side of the mouth of a slit further down the slit, between one third and halfway down, it becomes possible to flex the inserted sheet significantly to one side after it's already inserted in the slit; the non-mouth end of the bevel becomes a fulcrum for this bending. Then, we add a roughly triangular projection to the opposite side of the slit, at the mouth; one side of it forms an insertion bevel at around 45°, while the other side is at right angles to the slit, forming a retaining clip. A corresponding hole is added to the sheet for it to insert into.

I've done this with cardboard and a scalpel, and in that medium it works beautifully, but MDF is quite a bit more rigid; will it work in Jecvals?

To be concrete about the dimensions, the octagon width in Heckballs is 100 mm, so the shallow slits are 25 mm. (There are also deep slits for joining two octagons into a ball.) I was cutting in 3 mm MDF with 2-mm chamfers (i.e., the chamfer forms a 2mm, 2mm, $2^{1½}$ mm right triangle) and 3.03 mm slit width. Extending the chamfer to 12.5 mm down the slit and 3 mm of extra slit width gives 12.5 mm of bendable span. We'd like to use a tab that presses on the full thickness of the inside surface of the hole, which would make it 3 mm tall, 3 mm deep, and a $3\sqrt{2}$ diagonal if it uses 45°.

But how much can we bend without stress-relief cuts? We only have 12.5 mm - 3 mm = 9.5 mm of bend length to work with! According to Heckballs: a laser-cuttable MDF set of building blocks (p. 2782), MDF has elongation at break of 0.45%; if we use 0.3% to be safe, the inner part of a circular bend can be 0.3% shorter and the outer part 0.3% longer, so the bend radius must be 150 times the material thickness or more: 450 mm. $450\text{ mm} - \sqrt{((450\text{ mm})^2 - (9.5\text{ mm})^2)}$ is, unfortunately, only 0.1 mm, which is so small that it might just slip out. If we extend the chamfer depth to 20 mm, leaving only 5 mm at the bottom of the slit to hold things in place, we might have 19 mm of bend; $450\text{ mm} - \sqrt{((450\text{ mm})^2 - (19\text{ mm})^2)} = 0.4\text{ mm}$, and an 0.4 mm tab is enough for some energy barrier to retention, but at a heavy cost to rigidity, and only about 10% of the crush strength of the material.

Also you'd probably want to chamfer the end of the retention tab triangle to keep it from breaking off, fillet the base one way or

another to prevent a stress riser, and angle the retention tab contact surface so that it always makes contact over at least some of its surface despite manufacturing variations.

Three perhaps more viable approaches:

• Have a full 3-mm-thickness tab that engages and disengages the hole without any elastic deformation directly, using a rigid-body relative motion, and some other much smaller normally-zero-load latching tab using elastic deformation to prevent that rigid motion. I'm not sure exactly how this would work yet.
• Instead of relying on sheet flexion to provide the elastic engagement motion, cut an in-plane flexure to allow the *latching tab* to move, perhaps like an injection-molded plastic clip. This can easily achieve much thinner bending sections (200 microns is feasible) and thus much smaller bending radii, and tabs can grab from both sides of the hole, cutting the distance of flexion in half, and avoiding accidental disengagement from structure loading. This might require more complex cuts.
• Use acrylic or cardboard or something instead of inflexible MDF.

Such clipping approaches would provide Jecvals structures with much-needed tensile strength and dimensional precision.

Panels and beam holes

The Jecvals beams form a lattice of the balls 400 mm center to center; this lattice can contain 400-mm squares and 400-mm equilateral triangles. If we add some holes along the centerlines of the beams, we can make panels with tabs that slot into these holes, thus enabling the construction of things like shelves, screens (*biombos*), and tables. To keep adjacent panels from trying to fill up the same hole from opposite sides, there should be at least four different hole positions, none of which are at the center point of the beam, so that flipping a panel over will move it into a different hole in the beams.

In the case of the triangles, there will definitely be non-right angles between the panels and the beams, which means that the holes need to be wider than the panel material thicknes.

In some cases the panels can be made of other materials, such as 1.5-mm MDF, acrylic, or colored paper.

It would be desirable for the holes for the panels to permit the engagement of other parts as well, such as beam ends, but I'm not sure how to make that possible.

Topics

Solar-cell Geiger counters

Kragen Javier Sitaker, 2016-07-30 (1 minute)

Photovoltaic cells are generally made with a PIN structure, with a large undoped intrinsic region between the P and N doped regions. I think that such a PIN diode, when back-biased (the normal case with a photovoltaic cell) will conduct like the avalanche tube of a Geiger counter when exposed to gamma rays or some other kinds of radioactivity.

There are cheaper PIN diodes available than solar cells, but for detecting radioactivity, a large total area is advantageous.

opengeiger.de has an open design for a PIN-diode-based Geiger counter using a low-capacitance PIN diode.

Probably the most practical radioactivity sources for testing such a Geiger counter are radioactive fluorescent light starters (now, thankfully, becoming obsolete) and supermarket potassium chloride, which emits mostly β particles and some gamma rays.

A one-operand stack machine

Kragen Javier Sitaker, 2016-07-24 (updated 2016-07-25) (12 minutes)

Zero-operand stack machines pack lots of operations per byte, since each instruction is only five or six bits, but typically they need close to twice as many fundamental operations as register machines. This makes register "bytecode" like that of Lua less memory-dense, but it has lower interpretive overhead. The Mill CPU architecture uses a "belt", a fixed-size random-access history of the last few instructions' results, to eliminate the need for register machines to specify destination registers in most instructions, but source registers are still necessary.

Register machines have much better code density than pure memory-to-memory machines like Chifir. They don't need a lot of registers to get much better code density; at eight registers you occasionally spill to memory, and at sixteen (like amd64) you almost never do.

The reason stack machines use more operations is that they have to use extra operations to get the operands into place to operate on them. In the common case, the things you want to operate on are right on top of the stack and are only used once, but often enough, they are not.

Implementations of stack machines often use registers — physical bits of silicon, unless you're doing this in software on top of a hardware substrate that does register renaming — for the top item or two of the stack. You have a "TOS" register, "top of stack", and maybe a "NOS" register, for "next on stack". Then, at RTL, the effect of an operation like + is something like this:

```
TOS ← TOS + NOS
NOS ← pop_overflow_stack()
```

The operation OVER, which pushes a copy of NOS, becomes:

```
push_overflow_stack(NOS)
TOS ← NOS
```

In i386 assembly, if you use %eax as TOS, %edx as NOS, and %esp to point to the overflow stack, these become:

```
plus: add %edx, %eas
      pop %edx
      NEXT
over: push %edx
      xchg %eax, %edx
      NEXT
```

In a hardware implementation, the TOS and NOS registers can be directly wired to the ALU, avoiding propagation delays from the multiplexers that would otherwise be needed.

The basic idea

As an alternative to pure stack or register machines, you could

imagine having several alternate TOS registers, each selected for the duration of a single instruction. If you had four possible TOS registers, you would need two bits in the instruction. Maybe that would eliminate a sufficiently large fraction of the five-bit stack operations that it would be a win.

The circle midpoint algorithm as example code to try designs with

Consider this Python implementation of (some variant of) the midpoint algorithm for drawing circles:

```
def mid(r):
    # `e` is always x² + y² - r²
    x, y, e = r, 0, 0
    while x > y:
        if e > 0:
            e -= x + x - 1
            assert e <= 0
            x -= 1

        yield x, y

        # For efficiency you could fold this into the above update of
        # `e` in the decrementing-`x` case.
        e += y + y + 1
        y += 1
```

On a stack machine

If rendered more or less directly into ANS Forth, I think this comes out as follows:

```
\ `e` is always x² + y² - r²
variable x  variable y  variable e  variable r
: mid
    dup r ! x !  0 y !  0 e !
    begin x @ y @ > while
        e @ 0> if
            x @ dup + 1- negate e +!
            e @ 0 <= assert
            x @ 1- x !
        then

        x @ y @ yield

        \ For efficiency you could fold this into the above update of
        \ `e` in the decrementing-`x` case.
        y @ dup + 1+ e +!
        y @ 1+ y !
    repeat
;
```

Now, aside from `yield` and `assert` not existing normally, and aside from the question of whether you should maybe refactor this into

smaller functions and maybe store the variables in a struct or something, this Forth is a bit more memory-access-heavy than it needs to be. It leaves both stacks empty at the end of each line. This is the easiest way to write Forth, because it completely avoids the temptation to get tricky with what you have on the stacks.

But let's see if we can maybe make it a bit more compact by storing *one* of its four variables on the stack. `e`, say. Also, we can get rid of `r`, because we never use it except to initialize `x`.

```
variable x  variable y
: mid
    x !  0 y !  0
    begin x @ y @ > while
        dup 0> if
            x @ dup + 1- -
            dup 0 <= assert
            x @ 1- x !
        then

        x @ y @ yield

        y @ dup + 1+ +
        y @ 1+ y !
    repeat
;
```

This is a little more compact and less memory-intense. We can go further and store `x` on the stack underneath `e`, compacting further:

```
variable y
: mid4
    0 y !  0
    begin over y @ > while
        dup 0> if
            over dup + 1- -
            dup 0 <= assert
            swap 1- swap
        then

        over y @ yield

        y @ dup + 1+ +
        y @ 1+ y !
    repeat
;
```

This is a little opaque for my taste, but it's not too unrealistic. In Forth itself, we could go further and store `y` on the return stack, but in this case I'm just using Forth as an example stack machine that I can conveniently test code on.

The above subroutine contains 39 instructions:

- 9 immediate constants, 6 of which are `y` and the other 3 of which are `0`;
- 6 memory accesses, which are 2 stores to `y` and 4 fetches from `y`;

• 2 calls to other functions (`assert` and `yield`);
• 9 stack manipulations, which are 3 `over`s, 2 `swap`s, and 4 `dup`s;
• 9 ALU operations, which are 2 comparisons, 4 `+`s and `-`s, and 3 `1+`s and `1-`s.
• 4 control-flow instructions, consisting of two conditional jumps (`if` and `while`), one unconditional jump (`repeat`), and one subroutine return (`;`).

How big is this?

If we figure that the base instruction opcodes cost 5 bits each, the function calls and immediate constants cost another 16 bits each, and the jumps cost another 5 bits for the jump offset, then the total is (+ (* 39 5) (* (+ 9 2) 16) (* 3 5)) = 386 bits, or 49 bytes. (We could probably tweak that a bit, but it's easy for that to amount to overfitting to this function; instead I would argue that this is a reasonable, if imperfect, estimate.)

On a two-operand register machine

Let's consider what it would look like in a two-operand register machine instead. Suppose we have registers A, B, C, D, E, F, G, and H, so that we need three bits to specify a register operand; and let's say that registers A and B hold the first two arguments to a function. Then it might look like this.

```
mid:    B ^= B      ; Y; sets Y to 0 with XOR
        E ^= E
 loop:    C := B
          C -= A    ; X
          JPZ done  ; jump if positive or zero
          C ^= C
          C -= E
          JPZ else  ; skip the following if E > 0
            E -= A
            E -= A
            E++
            C ^= C
            C -= E
            C := ispz(C)  ; an instruction like i386 LAHF
            call assert
            A--
 else:    C := A      ; Let's say our VM autosaves registers; it still needs
          call yield2 ; space for yield to maybe return at least one value!
          A := C      ; So we manually restore A.
          E += B
          E += B
          E++
          B++
        JMP loop
done:   return
```

This is only 25 instructions, which is a lot less interpretive overhead (although of course what matters in that case is not how many instructions are in memory but how many are executed), but each of them is bigger. We're down to only two immediate constants, we still have three 5-bit jump offsets, and let's suppose that our opcodes still need 5 bits even though we don't need stack manipulation

operations any more, and that the 3-bit register-number fields are present even in instructions like ++ and jumps that don't need them. So we're down to (+ (* 25 (+ 5 3 3)) (* 3 5) (* 2 16)) = 322 bits, or 41 bytes.

(This is clashing somewhat with my experience that stack machines in general and Forth in particular usually have very compact code, but...)

On a hybrid one-operand stack machine with four TOS registers

Now let's suppose we have four alternate TOS registers A, B, C, and D, and each of the machine's primitive operations is suffixed with the name of the register it uses for the top of stack. We can assign A to X, B to Y, and C to E, and suppose that our argument is passed in A.

To get a value onto the stack lower down, which is "shared" in the sense that all the levels below the top use the same stack, we can use dupA, dupB, and so on.

I'm supposing here that yield2 takes A and an argument from the stack below it, and consumes them both, leaving in A whatever was below that, and that it is careful to preserve the other registers. To preserve all those registers itself, it explicitly saves them onto the stack at entry.

```
: mid
    dupB dupB -B  dupC dupC -C  dupD
    begin dupA dupB dropD >D while
        dupC 0>C if
            dupA dropD dupD +D 1-D swapC -C
            dupC dupC dupC -C <=C call(assert)
            1-A
        then

        dupA dupB call(yield2)

        dupB dupB +C +C 1+C
        1+B
    repeat
    dropD dropC dropB dropA
;
```

That's 44 instructions, up from 39, and way bigger than 25, which is kind of terrible. This is not what I expected. But there are no more immediate constants, except for the call destinations. Now it's 44 7-bit instructions, plus two (let's say) 16-bit call destinations and three five-bit jump offsets: (+ (* 44 7) (* 2 16) (* 3 5)) = 355 bits. Intermediate in density (though maybe that's only because of not using immediate zeroes this time), but unnecessarily slow.

But the code is actually kind of fucking terrible and awkward. It's easy to inadvertently clobber and super awkward to bring together two values in two different registers.

What if we invert the idea?

On a hybrid one-operand stack machine with 1 TOS

register and 4 stacks

Let's suppose that instead of registers A, B, C, and D, we have *stacks* A, B, C, and D (very vaguely similar to Bernd Paysan's 4stack processor), which share a common TOS register. Then we can store `x` in, say, the TOS register (saving it to A when necessary), `y` in the NOS of B, and `e` in the NOS of C. Is that better?

Now we can use overB or overC to access the value at the top of stacks B or C, or alternatively dropB or dropC if we want to discard the value in TOS at the same time. dupB or dupC pushes a new value onto those stacks.

To make our lives easier, let's store a 0 on D.

Here's an almost certainly buggy but probably roughly correctly sized implementation:

```
: mid
    dupA  dupA -A  dupC  dupD  dropA
    begin  dupA overB >B while
        dupC 0>C if
            dupA dupA +A 1-A -C
            dupC dupD <=C call(assert)
            1-A
        then

        dupA dupB call(yield2)

        dupB dupB +C 1+C
        1+B
    repeat
    dropD dropC dropB dropA
;
```

That's 37 instructions, all of which are 7 bits, except for the two calls and three jump offsets; (+ (* 37 7) (* 3 5) (* 2 16)) = 306 bits, or 39 bytes.

It still feels super bug-prone, since I'm trying to figure out at which moments X is in TOS and when it's on stack A.

This is better than the register machine, but only by 16 bits.

Implementing flatMap in terms of call/cc, as in Raph Levien's Io

Kragen Javier Sitaker, 2015-09-03 (3 minutes)

I think you can write `flatMap` and thus `map` and `filter` as higher-order functions in the backtracking monad if you have `call/cc`. The iterator just takes a next-continuation and a fail-continuation (or end-continuation) as arguments. `flatMap` then takes a function f and an iterator i and invokes the iterator i with a next-continuation it makes up, and the same end-continuation. The new next-continuation invokes f with the item to get an iterator j and then invokes j with the original next-continuation and a new end-continuation it makes up, which returns from the made-up next-continuation. Then `map` and `filter` are simply invocations of this `flatMap` with slightly modified functions.

This structure allows you to do flatMap (and Python generator expressions) without arbitrary intermediate storage and therefore without a heap. In fact, I suspect you can do it quite easily without a heap in assembly language, piling up the various stack frames of the dynamic nesting structure of iterators by pushing the stack pointer lower and lower, resuming back and forth between the various coroutines by storing and restoring PC and BP and whatever other callee-saved registers your ABI requires.

Normally, I suppose, the fail continuation would just be the regular return path.

This idea turns out to be central to Raph Levien's Io language; although `flatMap` is not in the Io material I've seen (which does not include the original paper) it is very short to define, though to my mind somewhat tricky:

```
flat-map: -> f items k1;
    k1 -> return yield;
    items return -> item next;
    f item -> transformed-items;
    transformed-items next -> transformed-item next-transformed-item;
    yield transformed-item;
    next-transformed-item.
```

Here I have omitted as extraneous (and possibly ambiguous) the parens around action-valued variables as arguments that are used in the original paper; and I am using the convention from the paper that streams take as arguments first the return-continuation and then the yield-continuation. So, for example, the return-continuation for transformed-items is the resumption continuation for the items stream.

You can write `map` and `filter` in terms of `flat-map`, but you can also write them from scratch; we can use Levien's convention that a boolean function takes if-true and if-false continuation parameters.

```
map: -> f items k1;
    k1 -> return yield;
    items return -> item next;
```

```
    f item -> transformed-item;
    yield item;
    next.

filter: -> f items k1;
    k1 -> return yield;
    items return -> item next;
    f item (yield item; next) next.
```

(Oh dude! Raph put the paper online at http://www.levien.com/pubs/io_a_new_programming_notation.pdf ! That clears up a couple of my confusions.)

A bag of candidate techniques for sparse filter design

Kragen Javier Sitaker, 2019-09-01 (18 minutes)

Here I want to talk about some things to try for sparse filter design that might extend its range considerably.

What I mean by "sparse filters"

Sparse filters (p. 834) outlines some basic techniques for designing digital filters that require only a few inexpensive operations per sample, Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) demonstrates how to get an almost arbitrary approximate 2-D Gabor wavelet from under 30 additions and subtractions. Real-time bokeh algorithms, and other convolution tricks (p. 2661) describes some ways to do precise flat convolution filters in 2-D sparsely, and The miraculous low-rank SVD approximate convolution algorithm (p. 747) describes some once-well-known ways to do very inexpensive approximate convolution using a singular-value decomposition of the desired convolution kernel — approaches that do require multiplications, but fewer.

The conventional wisdom, as I understand it, is to use direct-form FIR filters, with their non-sparse array of coefficients which gains nothing from cascading (you might as well just convolve the two arrays of coefficients and get a single-stage FIR kernel with one fewer multiplication per sample to do), and IIR filters without any delay elements in them, ideally realized as a cascade of second-order sections, applied bidirectionally if you need linear phase delay. The Hogenauer filter, Karplus-Strong string synthesis, and PLLs hint that it's possible to do dramatically better, especially on computers and FPGAs where delay memory is nearly free but multiplication is expensive; but we still lack a theory of how to design such things.

If you convolve two FIR filters whose impulse responses are m and n samples long, the resulting impulse responses is $m + n - 1$ samples long. But, even without resorting to non-LTI filters, if you convolve two FIR filters whose impulse responses contain m and n nonzero elements, possibly with zero elements between them, the resulting impulse response may have as many as mn nonzero elements. So if you convolve n FIR filters each containing only two nonzero samples, you can get a FIR filter with 2^n nonzero samples, if there is never any overlap. This allows you to get a 2^n-tap FIR filter with only n multiplications — but not *any* 2^n-tap FIR filter, only certain special ones, ones which are as far as I know not very interesting. Still, the possibility is open that we can do exponentially better than we have done so far.

More interestingly, there are certain convolutions of FIR and IIR filters which produce FIR rather than IIR filters; this allows you to get, say, a zero-phase bandpass filter at any frequency with a selectable and arbitrarily high Q — perhaps 1000 or 100'000 — with six to ten additions and subtractions per sample.

Basics

The basic techniques I'm using are CIC or Hogenauer filters; comb filters, especially negative-feedback comb filters; linear filter composition, convolving their time-domain responses; filter addition, adding their time-domain responses; and zero-phase filter inversion.

(The notes in this section probably are not an adequate introduction to the subject, but hopefully are sufficient to tell if I have something basic wrong with my understanding; The Scientist's and Engineer's guide to DSP is a much better introduction.)

The basic Hogenauer filter is a boxcar low-pass filter built from a marginally stable recursive integrator and a feedforward comb filter; its response in the time domain is a pulse, which is of course finite, and in the frequency domain it's a sinc. Most commonly they're used for sample rate downconversion — you cascade two to four of them to get a Gaussian response in both domains, rearrange the order of the stages to put the integrators first, and decimate in between to reduce the memory requirement on the comb filters. Then, typically, you use a direct-form FIR filter at the lower rate to flatten out the passband.

Feedforward comb filters amount to adding the input signal to a delayed and possibly inverted version of itself; by destructive interference, this perfectly cancels frequencies for whom the delay is an odd number of half-cycles, or a whole number of cycles if inverted. Nearby frequencies are attenuated, but the notch is pretty sharp. They also amplify broad ranges of frequencies in between the notches by as much as 6 dB, those for which the interference is constructive. Negative-feedforward comb filters eliminate DC bias, and more generally they have a high-pass effect up to half of their first null frequency; positive-feedforward comb filters double DC bias. Feedforward comb filters' impulse responses consist of pairs of impulses.

Unity-gain *feedback* comb filters are marginally stable: their impulse response is an infinite impulse train, alternating in sign if gain is negative. Instead of sharp nulls, they have sharp resonances, with infinite gain in fact; the positive-feedback ones have resonances at the period of their lag and all its harmonics (including zero), while the negative-feedback ones have resonances at twice the period of their lag and its odd harmonics. So negative-feedback comb filters resonate at the frequencies that a positive-feedforward comb filter with the same lag would cancel, and positive-feedback comb filters resonate at the frequencies that a negative-feedforward comb filter with the same lag would cancel.

If you replace the marginally-stable integrator in a Hogenauer filter with a marginally-stable unity-feedback comb filter — positive or negative — then instead of integrating the DC component of the input, it starts integrating a pulse-train component of the input. (You need to make sure that the following stabilizing feedforward comb filter is canceling in-phase components of that pulse train.) This transforms the Hogenauer filter from a low-pass filter into a bandpass filter, one that responds equally at a fundamental frequency and either all its harmonics, including DC (if the feedback comb uses positive feedback) or just its odd harmonics (if it uses negative feedback). Its window is a boxcar and so its frequency-domain response is just a sinc, or rather a periodic, infinite sequence of sincs, so usually you

need to cascade this one too. A cascade of three or more provides a quite good approximation to a Gabor wavelet.

Cascading or composing filters convolves their time-domain impulse response and multiplies their frequency response; in particular this means that if a filter has zero response at some frequency, then so will any cascade of linear filters including it.

Given two or more filters, you can connect them to the same input and add together their outputs. The time-domain impulse response will be the sum of their individual responses, which is straightforward, and so will the frequency-domain impulse response, which is not straightforward, because the frequency-domain response is in general complex. So if two filters both amplify a certain frequency by 3 dB, their sum might amplify it by 3 dB, or by 9 dB, or they might cancel it out completely, or anything in between, depending on their relative phase.

For this reason it's often convenient to design with linear-phase filters, those whose impulse response is time-reversal-symmetric†, like the boxcar or an equal pair of impulses. By delaying your other signals relative to a linear-phase filter, you can make it a *zero-phase filter*, whose impulse response is time-reversal-symmetric *around zero time*. Linear-phase filters include boxcars, Gaussians, unity-gain positive-feedforward comb filters, and the bandpass variant of the Hogenauer filter described above — as long as its time-domain response has an *odd number* of half-wavelengths in it. They also include arbitrary convolutions of linear-phase filters and arbitrary sums of zero-phase filters.

Inversion is subtracting the null filter — the input signal — from a zero-phase, appropriately-scaled low-pass filter, converting it into a high-pass filter. This is very demanding of the low-pass filter, though: 1 dB of passband droop in the low-pass part is going to limit stopband attenuation to a miserable -10 dB!

† These have *even* time-domain response. Filters with *odd* time-domain response are *also* linear-phase but I don't know how to make them zero-phase other than, I guess, convolving them with another filter with odd time-domain response to get a filter with even time-domain response. There are other linear-phase filters which are weighted sums of odd and even filters with the same frequency response, but I have no idea how to take advantage of that.

Flattening out the passband without a direct-form FIR filter

As I said above, it's common to use a direct-form FIR filter to flatten out the passband of a CIC filter when you use it for rate downconversion. The idea is that you can run just the integrators, which just do an addition per sample, at the high sample rate, to get a kind of floppy low-pass-filtered signal that anyway doesn't have any significant signal left up at the top end to alias when you decimate it; then you can clean up that droopy passband at the lower sample rate where you have time for lots of computation per sample.

But what if you aren't using the Hogenauer filter for downconversion? What if you want a bandpass filter (using the variant I described above) or, God forbid, you want to invert the filter and get a high-pass filter out of it?

Well, it occurs to me that if you want your bandpass filter to have a somewhat flatter top, you have several alternatives. First, instead of cascading several sinc-frequency-response bandpass filters at the *same* frequency, you could *cascade* several at *different* but similar frequencies. The droop in the various frequency responses will compensate somewhat for the amplification that comes from the "integrators". Second, by using zero-phase bandpass filters — windowing their pulse-train time-domain response so that it's symmetric — you can *add* several of them in parallel.

Another alternative is to start with a much wider passband than you need — using a very short window in the time domain — and then *subtract* narrower bandpass filters above and below. Or maybe use feedforward comb filters to notch out frequencies above and below your desired passband.

Similarly, I think you can use a broad zero-phase bandpass filter of the kind described above — maybe with a Q of 2 or so — to shore up the droopy high end of an orthodox Hogenauer filter's passband.

Reducing harmonics of bandpass filters with frequency diversity

Windowing a feedback comb doesn't get you just one passband; it gets you as many passbands as will fit in your sample rate, since either all the harmonics of the baseband or all the odd harmonics will also be passbands. Since you need to cascade a few windowed combs to get acceptable stopband suppression anyway, you might try detuning them from each other a bit not only to flatten the desired passband but also so they mutually weaken one another's harmonics. This works because all the passbands of a feedback comb are equally wide (in cycles per sample) at, say, their half-power points, but harmonics are further apart (in cycles per sample) than the fundamental.

This may not be very important since you probably just want to use a low-pass filter to attenuate those harmonics.

Low-Q bandpass filters

Above I pointed out that you can get a Hogenauer-like bandpass filter with a cascade of a feedback comb like

$$y[t] = x[t] - y[t - 8]$$

and a feedforward comb like

$$y[t] = x[t] + x[t - 24]$$

to get a finite-time impulse response. This is very frugal if you want a lot of oscillations in your window and thus a high Q — you can get an arbitrarily large number of oscillations with just two adds or subtracts. But if you only want a small number of oscillations, for a filter for a broad range of frequencies, you might as well use a direct-form FIR filter:

$$y[t] = x[t] - 2x[t - 8] + x[t - 16]$$

You can see that these are equivalent by plotting the results of the following Numpy code:

```
def feedback_comb(sig, lag, gain):
    rv = sig.copy()
    for i in range(lag, len(rv)):
        rv[i] += gain * rv[i - lag]
```

```
    return rv

def feedforward_comb(sig, lag, gain):
    rv = sig.copy()
    rv[lag:] += gain * sig[:-lag]
    return rv

x = zeros(100)
x[2] = 5
y = feedback_comb(x, 8, -1)
z = feedforward_comb(y, 24, 1)
```

Various pulse sizes

If you have a single integrator connected to your input signal, you can use several negative-feedforward combs on it to get various sizes of boxcars out of it. The same boxcar can be added to itself with multiple different delays to build the overall shape of a filter kernel; indeed, going beyond series-parallel combinations, boxcars of a small number of different sizes can be used, then melted together with a low-pass filter.

Splines

If you convolve two boxcars of the same size you get a triangle function. If you convolve that triangle function with a signal sampled at intervals of the boxcar size — one impulse every boxcar length, with zeroes in between — you get a linear interpolation of the signal. This gives you an easy and fairly sparse way to generate a filter with piecewise-linear time-domain response, requiring one multiply per knot in the kernel, per sample.

If you convolve the triangle with itself, you get a piecewise-cubic approximation of the Gaussian. This is not a basis spline, but it's not far from one; it is a simple linear algebra exercise to express an arbitrary piecewise-cubic signal with knots at one-boxcar intervals in the basis of this kernel, shifted by one-boxcar intervals. (You convolve the signal at the knots with the representation of the basis spline in terms of the approximate Gaussian.) This gives you an only slightly less easy, and very nearly as sparse, way to generate a filter with a piecewise-cubic time-domain response, again, requiring one multiply per knot in the kernel, per sample.

In some cases it might make sense to sum a few different such spline kernels at different scales to different levels of detail at different times during the kernel.

A factitious sinc

A sinc looks like a Gaussian lump in the middle, a sine wave on the left that gets smaller on the left, and a sine wave on the right (180° out of phase with the left one) that gets smaller on the right. What if we add together a Gaussian and a few differently delayed copies of a shortish triangle-windowed oscillation kernel, made out of the bandpass thing described above? Could we get a frequency-domain bandpass response that looks more like sinc's ideal pulse?

Other candidates

• Recognizing a square wave, or in 2-D a zebra pattern, by convolving an impulse train (finite-length, windowed, or otherwise) with a pulse
• Combining filters by multiplication, min, or softmin rather than addition to recognize "templates"
• Measuring the ac energy along lines at different angles to identify the angles which contain most information, before running a more expensive operation (perhaps the humans do this when they tilt their heads)
• Maybe take the FFT of the signal along a line at some angle through an image to identify one or two dominant frequencies; the relative phases of those dominant frequencies in a nearby parallel line (obtainable with Goertzel or with the delay-line techniques discussed above) then give you an estimate of the dominant angle of lines running across the region between them — maybe cheaper than running a cross-correlation on the two lines
• Exponential filtering from a recursive non-unity-gain feedback comb filter (in any spatial direction, e.g. coma from lens aberration) is linear and "sparse" though it requires a multiplication; can you cut it down to a finite impulse response in the same way as its special cases above, the integrator and the unity-gain feedback comb? Even if not perfectly (e.g., due to rounding error), can you do it well enough to make useful IIR approximations of FIR filters?
• More generally, piecewise-complex-exponential approximations of filter responses
• Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) laments not having a way to rotate the phase of a given frequency 90 degrees without phase-shifting much lower frequencies detectably. Can it be as simple as a unity-negative-feedback comb?
• Spectral inversion is of course not linear, but it can be applied to a signal very cheaply. If you invert the spectrum of a signal on the way in and out of a linear filter, you have inverted the frequency response of that filter, though be careful of the delay so that you don't inadvertently invert the signal amplitude. In addition to doing this around $\frac{1}{2}f_s$ by alternating signs on every sample, you can do it around $\frac{1}{4}f_s$ by alternating signs every other sample, offering the potential of inverting either the signal amplitude or frequency if you get the phase delay wrong

Topics

Passive dehumidifier

Kragen Javier Sitaker, 2017-03-20 (14 minutes)

I was watching Thunderfoot's self-congratulatory video about the failure of the Fontus self-filling water bottle, and it occurred to me to do some calculations.

Looking at a psychrometric chart we can see that under the 21° 32% relative humidity conditions the dude was testing the dehumidifier under, the dewpoint is about 4°; this means you need to cool the air by 17 K before you start getting any water out. To a great extent, you could do this with a heat exchanger such as a recuperator or regenerator which cools the air on the way into the condensing chamber and warms it back up on the way out; the total energy involved is the 1.012 J/g/K specific heat of air times 17 K, or about 17 J/g. That's because the humidity ratio horizontal line on the psychrometric chart shows us that we have about 0.005 g of water per g of dry air under these conditions, which doesn't change as we cool the air down to saturation; this 0.005 ratio means this is about 3.4 kJ per g of water contained in the air, which we hope to conserve in the heat exchanger.

Water's enthalpy of vaporization is about 44 kJ/mol, 2.4 MJ/kg, or 2.4 kJ/g, and that's the energy we have to remove in order to condense the water. You also have to remove more energy to cool the air (and, less significantly, the water) further. It probably isn't practical to cool it below 0°, because then you have to waste more cold on forming ice, but (as you can see on the psychrometric chart) at 0° the saturation concentration is still .0037 grams of water per gram of air, so at that point you've only gotten about a quarter of the water out.

So in summary, you cool a gram of air down from 21° to 0°, spending 21.3 J to cool it down and another 3.1 J to extract 1.3 mg of water from it. Then you use this 0° air to cool down the incoming air through a heat exchanger as much as possible, getting back most of that 21.3 J. To quantify, I think a typical energy recovery heat exchanger can recover 85% of the "lost heat", so we probably only "lose" 3.2 J in this scenario — that is, have to actively remove 3.2 J of heat from each gram of input air in addition to the 3.1 J spent on condensation.

Thermoelectric coolers like those used in the Fontus are unfortunately rather inefficient, with typical coefficients of performance of around 0.5, though perhaps as high as 1.5 for the small 20 K temperature difference we're talking about here, according to Meerstetter's chart. But there are other refrigeration technologies with better coefficients of performance.

So, we have to remove about 3.2 J + 3.1 J = 6.3 J of energy per gram of air, and we may have to spend 12.6 J to do that with a Peltier cooler. And we get 1.3 mg of water. This works out to about 9.7 megajoules per kilogram or liter of water produced. This is higher than Thunderfoot's number of 2.3 MJ/ℓ, which was merely an approximation of the enthalpy of vaporization of water.

(Thunderfoot's original video was working from the "energy factors" of dehumidifiers, which are required to be at least 1.2 ℓ/kWh

to 1.6 ℓ/kWh to qualify for an "ENERGY STAR" label. These work out to 2.25 to 3 MJ/ℓ, but maybe that's measured on a more humid or hotter day.)

To support one person with four liters of water per day, then, we would need about 39 MJ, which is an average of about 450 watts. This is feasible for a person to carry a solar panel for, but not to exert.

Avenues of improvement

But that isn't all we can do.

Greenhouse evaporation probably works

There's supposedly a wilderness survival trick for distilling water using a sheet of clear plastic. You dig a hole in the ground, put a bowl in the center of the hole, cover the hole with plastic, weight it down with rocks around the edge, and put another rock in the center to make a dimple over the bowl. In the sun, the air under the plastic heats up like a greenhouse, evaporating water from the dug surface of the soil, until its dewpoint rises above the temperature of the plastic. Water then condenses on the plastic and runs down the slope to the dimple in the center, where it drips into the bowl.

To keep the air under the plastic saturated with moisture, it is often recommended to pile foliage in the hole, perhaps smashed up a bit in order to allow faster evaporation.

That is:

- Harness solar thermal energy to evaporate water and warm air so it can hold more water.
- Condense water from 100% saturated air instead of 30% saturated air by bringing the air into contact with moist matter.

If you can raise the air temperature to 30° in your greenhouse, which is fairly easy, and get the air to 100% saturation by blowing it through smashed-up leaves or moist dirt or whatever, then you have about 27 mg of water per gram of air. If you can cool that back down to 20° — a purely passive process, and again one that can be facilitated with a recuperative heat exchanger — you can recover about 12 mg per g of it.

Not only is this almost an order of magnitude more humidity per volume of air, reducing the problems associated with device size, the bigger deal is that it's powered almost entirely by low-grade thermal energy, like what you can get from sunlight. Some fans would be useful to circulate air between the condenser and the evaporator, and maybe some water pumps, but the mechanical power needed will be orders of magnitude smaller — less than 10 W, probably less than 1 W.

The thermal power still needs to be adequate to evaporate the water; if the thermal collector is 50% efficient (a common figure for inexpensive glazed solar thermal collectors, much better than the 16% of photovoltaic panels) then you need 4 kg/day · 2.4 MJ/kg / 50% = 220W on average. You probably need 660W during the day to average 220W for all 24 hours, so at 1000 W/m² you need almost a square meter of thermal collector per person.

Purely passive condensation probably isn't practical

You might think that you could avoid this solar evaporation

nonsense, since temperature changes between day and night are often sufficiently large to cross the dewpoint by themselves. And that's true, but even in moist climates, that is not dependable every day, and in dry climates it never happens.

Here in Buenos Aires, it's currently 21°, and the dewpoint is 18°; we should hit 18° for a couple of hours at about 4 AM. This should happen again on Thursday, where the dewpoint will rise to 19° during the day (with a temperature of 22° to 24°) and then the temperature will fall to 19° during the night and morning.

At a dewpoint of 18°, the air holds about 0.013 grams of moisture per gram of air, of which you can condense about 0.001 g/g per kelvin of cooling. So to condense 4 kg of water by cooling the humid Rioplatense air by a single degree below its dewpoint, you need to slightly cool 4 tonnes of air, extracting about 4 megajoules of heat from it, plus the 9.6 megajoules (4 kg · 2.4 MJ/kg) for condensing the water. The most reasonable way to do this is probably to cool down a cold reservoir at night by some 15 megajoules. If your cold reservoir is just water, this is going to require minimally 3.5 tonnes of water and probably 7 or 10 tonnes. On the bright side, 10 tonnes of water can be stored a lot more easily than 4 tonnes of air.

Phase-change materials, like the recently-discussed saturated aqueous solution of sodium hydroxide, probably allow you to do this with only a few hundred kg of mass.

However, all of this is overlooking the fact that it wouldn't work very well this week, because in both cases the low temperature comes *after* the high dewpoint. You'd have to store the cold from now until Thursday afternoon, four days. Doable, but a major undertaking.

Consider, by contrast, Albuquerque. Currently the temperature there is 17° and the dewpoint is -8°. Despite its 15° temperature swing from day to night, you are just not going to have any luck condensing water out of that air with a passive cool reservoir stored on a timescale of less than months; the highest the dewpoint gets is -1°.

Purely passive condensation with weather balloons

If you send a balloon up, it gets cold. The environmental lapse rate of the lower troposphere, up to about 11 km, is about -6.5 K / km, so at 11 km the temperature is usually about 70 K colder than at sea level. In almost all cases, that brings it below the dewpoint at ground level.

If a balloon goes up and then comes back down, it has done no net work, so need not necessarily have dissipated any energy. By bringing heat from the ground up, or bringing cold from the upper atmosphere down, it has not done any work yet either — the thermodynamic free energy there comes from the sun heating the earth's surface, energy which is eventually dissipated by winds forming convection cells. It's just speeding up the convection a bit locally.

In practice, you need *some* energy difference to induce the balloon-atmosphere system into motion in the desired direction, but it could be very small compared to the heat you harvest. A net force of 1 N should be enough to induce a 100 kg phase-change reservoir payload to rise at an acceptable rate. If you let it rise 3200 meters, dissipating that 1 N in drag, it will have dissipated 3.2 kJ. Having cooled the payload to below 0° and dropping a little gas at that altitude so as to reduce lift by 2 N (about 170 liters at 1.2 kg/m³), it

will then return to the ground dissipating another 3.2 kJ. A payload of 100 kg of water ice at 333 kJ/kg will have lost 33.3 MJ of enthalpy of fusion, which was bought with 6.4 kJ, about 0.02% of the total. You could probably even afford 10 N or 100 N.

That said, it is nontrivial to construct and fly a balloon of the 83 m^3, 5.4 m in diameter, needed to lift 100 kg. (I'm disregarding the weight of the hydrogen or helium within as smaller than my margin of error.)

Your 100 kg of ice is enough to condense almost 14 ℓ of water at 2.4 MJ/kg.

Compressor-based heat pumps reach much higher efficiencies

Typical vapor-compression heat pumps like residential air conditioners and normal electric refrigerators have coefficients of performance around 2, which is largely a result of having to pump heat against a large heat gradient, typically 15° to 25° of difference. (Note, however, that this is already several times better than Peltier coolers typically reach.)

(Thunderfoot implicitly claims that it would violate thermodynamic law for a refrigerator to have a CoP over 1, but he is mistaken.)

We can't do much about the ΔT (we have to pump heat from the water-condensing chamber into the surrounding environment) but if we can reach that COP of 2, then instead of spending 12.6 J per gram of air to remove 6.3 J of heat, we can spend 3.2 J, which works out to 2.4 MJ/kg of water, coincidentally exactly the same as the enthalpy of vaporization of water.

If it so happens that your air is already at 100% humidity, a heat pump could in theory condense water with an arbitrarily small ΔT, just by replacing the air very rapidly. With an arbitrarily small ΔT, a heat pump could theoretically have an arbitrarily high coefficient of performance. In practice, water-source heat pumps used in Japan for residential climate control often reach a CoP of 6, which would allow you to condense water at 2.4 MJ/kg ÷ 6 = 0.4 MJ/kg.

However, as Thunderfoot points out, under those circumstances, water is probably already abundant.

Ideal language syntax

Kragen Javier Sitaker, 2017-07-19 (1 minute)

What would make a language syntax ideal for my tastes?

• Short keywords. `my` or `=` instead of `var`, `to` or underlines, instead of `function`, `for` or a vertical line instead of `while`, maybe even `do` instead of `while` or `for`.
• Little punctuation. Python-style `:` instead of `{}`. `.` instead of `->`. `:` instead of `=>`.
• Punctuation and keywords that follow existing prose use; `--` is far better for comments than `;` or `#`, which mean something totally different in everyday life.
• Not fucking monospace.
• Infix syntax with either traditional precedence or required full parenthesization in cases where it would change the meaning. Because I don't want to puzzle over why `a + b * c` is giving the wrong answer, only to find that it means `(a + b) * c`.
• By the same token, operator overloading; I certainly don't want to have to write `a.plus(b.times(c))` as in JS.
• Some kind of aspect weaving so that a particular piece of code can be focused on only the things that are relevant to a particular task — for example, dataflow, types, proofs, resource limits, escape-analysis annotations.
• Lightweight lambdas.
• Extensibility, because sometimes lightweight lambdas aren't enough.

Of course there are other aspects of programming languages that are more important than the syntax, but the syntax is important.

ASCIIbetically homomorphic encodings of general data structures

Kragen Javier Sitaker, 2017-06-15 (2 minutes)

I thought I had written some notes about this previously, but I can't find them right now. I want a serialization for relatively general data structures (say, at least the S-expression or JSON data model) that possesses a useful homomorphism between some kind of natural ordering on the original data structures and the lexicographical ordering of the byte strings they serialize to. That is, if E is the serialization encoding, I want E(X) < E(Y) iff X < Y.

This is for five reasons:

• LevelDB: LevelDB can iterate over the keys that are ASCIIbetically within a certain range. In fact, that's the *only* kind of iteration it supports.
• oMQ: ZeroMQ and Nanomsg can efficiently filter messages from a pub-sub topic that begin with a given substring.
• Compressed indexing: Patricia and related trie structures, as well as FM-indices and related data structures, can efficiently retrieve and even compress data — but they only support retrieval by lexicographical prefixes, not by other arbitrary orderings.
• Suffix arrays: suffix arrays can efficiently find all the occurrences of a substring in a large file, and now there are simple O(N) suffix-array construction algorithms.
• Radix sorting: while comparison sorting is O(N log N), radix sorting is O(N).

To take advantage of these properties, I often end up writing some kind of simple ad-hoc serialization code for the data at hand, which often turns out to have bugs in it, and almost never generalizes to other kinds of data that aren't in the data I'm looking at. (For example, if I separate fields with spaces, I run into ordering errors once I have data containing ASCII control characters or spaces.)

Nonconductive relays

Kragen Javier Sitaker, 2019-11-12 (3 minutes)

Electromechanical relays have some lovely features: they can provide galvanic isolation, very high crosstalk immunity, enormous gain, very low on-impedance, and, in locking designs, bistability even when the power goes out.

However, they have some big problems: they're power-hungry and their operating speed is limited to the kHz to tens of kHz and their operating life is limited to thousands to millions of operations, which usually limits them to *average* operating speeds in the millihertz or less.

The reason for the short operating life is contact oxidation. (In theory elastic metal fatigue or creep could play a role too, but those are easy enough to avoid.) Mercury-wetted relays are a common design to lengthen this life, and Paper/foil relays (p. 3273) discusses the possibility of using contacts of carbon (like keyboard dome switches), silver, or gold instead.

In other sense-switch applications, a common approach to avoiding the oxidation problem is to use phenomena other than conduction to transfer the energy. The TRS-80 keyboard, for example, was capacitive (though using springs made of polyurethane foam, which degraded rapidly), as are modern touchscreens, touchpads, and some touch panels in embedded devices. And there are numerous inductive sensors for position, orientation, and so on.

It occurs to me that relays can work through these media as well.

For example, if you have two ferrite rods with one winding around each of them, you can make them into a transformer that efficiently transfers AC power from one to the other, from dozens of Hz up to several kHz, by completing the magnetic circuit with more ferrite. By moving this additional ferrite under the control of a solenoid, you have a relay, one that will never suffer contact oxidation, because the contacts are magnetic rather than electrical.

Similarly, although the circuits described in Paper/foil relays (p. 3273) are the usual kind of dc-coupled contact circuits, you could use a similar design to bring one of the plates of a variable capacitor into contact with the dielectric from a distance far enough to drop the capacitance by orders of magnitude. This could easily have enough capacitance to efficiently transmit power at frequencies of 100 MHz and up, again without any electrical contact and thus no oxidation. Such capacitive relays could move smaller amounts of mass, and over shorter distances, than the inductive relays described above, and so they should be able to operate much faster.

Frustration

Kragen Javier Sitaker, 2018-04-27 (2 minutes)

I am constantly frustrated with the inadequacies of the computer systems we have so far achieved, and I am unconvinced that our current approaches to designing them will get us to a better situation. Yet I am devoting almost none of my time to improving the situation — even on the most personal level of coming up with a reasonable individual email system.

I want to fix this. I want to write a computing system that provides a reasonable self-hosted development environment for the kinds of things I want to work on, allowing me to use the unbelievably huge existing free software ecosystem without being limited by it. I found out two days ago that not one but two of my coworkers at Satellogic have already done this, to one extent or another, with Smalltalk. Juan reports that his system, Cuis, is only about eighty thousand lines of code. Richie's system, Bee, may be bigger or smaller, but it's more to my taste.

It seems clear that the issue is that I'm not treating the self-sufficient computing environment project as a priority, in part because of Satellogic. If I'm going to make progress on it, I need to spend time on it each day, probably instead of Twitter or some shit like that.

A thing that would really help a lot with that would be some kind of ability to use the iPhone to make progress on it while I'm in transit — a little ratchet of progress.

I think a reasonable target might be the "100,000 words" of a 300-page novel, say, 600 kilobytes or so. At five "words" per "line", that would be the same "20,000 lines" of the STEPS project.

APL with typed indices

Kragen Javier Sitaker, 2013-05-17 (11 minutes)

Parallel arrays are bad because array indices are untyped, and sometimes because of storage management and locality of reference. But what if each array had its own ⎕IO (APL's name for OPTION BASE)? This could put each type of object ID into its own namespace, so that you'd get an index error if you tried to index an array with the wrong kind of object ID. It's like how in a spreadsheet, maybe rows 1–40 are the employees, and rows 101–120 are the products, and so if you have an index between 101 and 120, you know it identifies a product and not an employee. (Too bad that in an actual spreadsheet the column names will be the same in both cases.)

You could actually index arrays using an (object type, zero-based-index) pair rather than combining the two into a single number. This would give you many of the same type-safety and index-safety benefits of structs, aka records, without sacrificing the dubious benefits of aggregate operations. (And if you can verify all the type stuff at compile time, you could drop them at runtime!)

Element-by-element scalar functions should only work on arrays representing, in some sense, attributes of the same object. Operations like "grade up" and "compress" would create new index namespaces.

"Interesting" functions from APL (not element-by-element) include monadic ⍴⍳,⌹⌽⊖⍋⍒⍉, dyadic ∈⍴↑↓⊥⊤,⌿/⍳⌹⌽⊖⍉ and indexing [], plus the operators (scan, reduce, and inner and outer product).

The details I've been able to work out follow.

Since much of this is sort of about types, I'm going to write types in a Haskelly way: `a->b` means that something (a vector) takes as an argument (index) things of type `a`, and returns (has as elements) things of type `b`; and `X: T` is an expression which has the value of `X`, but asserts that that value is of type `T`.

Multidimensional arrays

I'm going to try to work out the cases of zero and one dimensions first, before attempting to handle multiple dimensions. An N-dimensional array for N>0 can be considered as either a homogeneous 1-dimensional array of N-1-dimensional arrays, an array indexed by N-tuples, or an N-1-dimensional array of 1-dimensional arrays; both of the first two interpretations are common in APL. Changing the nature of indexing is likely to interact with them in unpredictable ways.

Indexing []

Indexing `A[B]` (also `.` or simple juxtaposition in K, or `A@B` for another variant) should produce a value with the shape of B by indexing the elements of A. That is,

```
((A: c->d)[B: e->c]): e->d
```

It's like function composition. So the elements of B need to be valid indices for A.

Compress /

Dyadic `A/B`, "compress", gives you one element of output for every nonzero element in A. Its two arguments must have the same set of indices, and the left one must be boolean. If you compress two vectors `B` and `C` with the same vector `A`, the resulting vectors need to be conformable, so you can write `(A/B) + (A/C)`, for example.

In q/k/kdb+, I think this is written `B[where A]`, helpfully decomposing the operation into two steps, the first of which is constructing a vector of the positions where `A` is nonzero. I think this is the right way to analyze this operation, because it constructs a *new index namespace*:

```
(where (A: b->c)): d->b
```

(This is a rather remarkable type, creating a new type out of whole cloth!)

Indeed, this is such a common operation in APL that the Dyalog APL tutorial gives the APL spelling of it, `(V∈D)/⍳⍴V`, as their first example of an idiomatic APL expression.

It's probably more accurate to write `(where (A: b->bool)): d->b`, since the

Expand \

I haven't written enough APL to know what the dyadic expand function is good for. In a sense, it's the inverse of the compress function, but the compress function is lossy — it leaves out chunks of its right input, which the expand function will fill with zeroes. It's guaranteed that `A/A\B` is the same as `B`, but not `A\A/B`.

It seems rather difficult to type-check in a sane fashion: `A` needs to have exactly as many `1`s set as there are valid indices in `B`.

Dyalog APL's expand function extends this to the case where `A` may contain things beyond just booleans, interpreting them as a repeat count (or, if negative, a zero count).

The Dyalog APL tutorial gives the following common uses of expand:

• to add blank or zero rows in between the rows of a matrix (for example, to separate text output into paragraphs);
• to repeat a scalar some number of times.

It also gives as an exercise the problem of replacing a given letter globally with spaces: `'a' Whiten 'Panama is a canal between Atlantic and Pacific'` should return `'P n m is c n l between tl ntic nd P cific'`. The solution, I suppose, is the `A\A/B` above, where `A` is just `~Letter = Phrase`.

http://aplwiki.com/AplIn20Minutes may have some information.

Grade-up and grade-down ⍋⍒

These are used for sorting. `⍋X` (`>X` in K) is a vector such that `X[⍋X]` is sorted ascending; `⍒X` does the reverse. This is more useful than simply giving you the sorted results because, if you have another vector `Y` that can be indexed with the same indices as `X`, you can sort the elements of `Y` according to `X` with `Y[⍋X]`.

It does not generally make sense to index `X[⍋X]` with indices that are valid for `X`, with the exception of things that are sort of coincidental; for example, `1` is probably a valid index for both of them. But it

doesn't make sense to say, for example, `(X > 3)/X[⍋X]`; that's almost certainly a bug.

So grade-up and grade-down, like compress, creates a new index namespace:

```
(⍋(X: a->b)): d->a
(⍒(X: a->b)): d->a
```

This is maybe the point at which array indices might begin to have an advantage as object IDs over raw memory addresses: once you can start taking advantage of the sequence of the array indices.

Reversal and rotation, monadic and dyadic ⌽⊖

`⌽X` is just `X` with the indices of its last axis in reverse order; `⊖X` is the equivalent for the first axis. Analogously, rotation `3⌽X` rotates `X` three items to the right, which can be achieved by reversing `X`, reversing its first three items, and then reversing the remaining items. On the face of it, it seems that these should also create a new index namespace; it doesn't make sense to write `(X > 3)/⌽X`.

However, I think this is not actually true. The valid *range* of values is the same. `1⌽X` gives you the `X` property of the (cyclically) following object in `X`'s index sequence; this is a useful kind of thing to be able to do!

```
⌽(X: a->b): a->b
⊖(X: a->b): a->b
(N: int)⌽(X: a->b): a->b
(N: int)⊖(X: a->b): a->b
```

Shape and index generation: monadic ⍴ and monadic ⍳

`⍳`, aka "iota" or "index generator" (in K, `!` or `til`) counts from 1 (0 in K) to a given number; but its primary use is to generate the valid indices of a vector given its size. The size of a vector is generated with `⍴`, the "shape" operator (in K, `count`), so `⍳⍴V` gives you the indices of `V`.

This use of `⍳` is so important that Dyalog APL's `⍳` applied to a vector generates a sequence of multidimensional indices, such that `V[⍳V]` is equivalent to V for any shape of V (which is impossible in traditional APL), and the "index origin" variable `⎕IO`, equivalent to BASIC's `OPTION BASE` can affect `⍳`'s operation.

Although this form of `⍳` takes only one argument, it's straightforward to use it to generate values starting from any starting point, increasing by every step: `start + step * (⍳N)-1`, although of course the `-1` is a result of the default `⎕IO` being 1 rather than 0.

It seems to me that it's probably worthwhile to preserve the invariant that `⍳⍴V` produces the indices of a vector `V`. If this is to work with `⍴V` producing a scalar or 1-vector in this case, which seems desirable to avoid complication for multidimensional cases, then it needs to be possible to extract both the length and the object type from that scalar; that is, `employees[301]` needs to be a single scalar object from which you can extract `employees` and 301. If we represent `employees`

as `employees[0]`, then it's sufficient to provide a function for extracting either of the two; ordinary subtraction suffices to produce the other, and ordinary addition is sufficient to recombine the two.

So produces a single-element vector:

```
⍴(X: a->b): {0}->a
⍳(X: a): int->a
```

element-of ∈ and index-of, dyadic ⍳

`A∈B` produces a boolean array of the shape of `A` indicating whether each item of `A` occurs in the vector `B`; that is,

```
((A: c->d) ∈ (B: e->d)): c->bool
```

The index type of `B` disappears entirely, because we don't care *where* the elements of `A` occurred in `B`; we're just using it as a set. If we wanted their positions, we'd use the dyadic ⍳ function:

```
((A: c->d) ⍳ (B: e->d)): c->e
```

This is a little bit tricky, because for the elements of `A` that didn't occur at all in `B`, this function produces `1+⍴B` (or `⍴B` in the `⎕IO=0` case), which is not a valid index into `B`. You could say it's not a member of `B`'s index type `e` at all.

In K, the dyadic ⍳ function is written `B?A` instead.

The things I haven't figured out how to handle yet

How do you get literal vectors in your program to have a reasonable type?

What about take, drop, and catenate? Some uses of take and drop can be reasonably handled by rotation, but others can't.

Git learnings

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

Here are the top few things I learned about Git, mostly in the first few hours I used it. This is the document I wished I had had, on top of the various introductions floating around. Maybe it will be useful to somebody else.

• Git handles 400MB of HTML crawl data less gracefully than it handles 700K of Python. But it handles that data more gracefully than `cp` and `rsync` do.
• Don't `git push` to a repository that actually has a work area. Always use `git pull` instead. `git push` doesn't update the associated working area, or the index either, so if you try to `git commit` in that repository, you will commit a patch that undoes all the stuff you just did. See http://utsl.gen.nz/talks/git-svn/intro.html section "Push changes and the working copy". You can solve this with `git reset --mixed HEAD`, or eventually `git reset --hard HEAD` to throw away any changes in the working area.

```
23:05 < johnw> $ rsync -av .git/ server:/tmp/foo.git/ ; cd /tmp ; git clone ssh:/o
o/server/tmp/foo.git

23:06 < johnw> that's all you need to setup a remote repository, and to start usi o
ng it right away
```

• `git repack -a -d -f` can achieve some truly astonishing compression ratios. This is how you make git checkouts faster than `cp -a` or `rsync`. In my case, three times faster than `rsync` over a slow network, due to a 7:1 compression ratio.
• You have to `git add` changed files before you can `git commit` them, or use `git commit -a`, because `git commit` commits things from the index, not your work area. In older versions of Git, you used `git update-index` instead of `git add` on changed files.
• `git commit` takes an option `--amend` which lets you amend the previous commit. `git rebase --interactive` lets you amend previous commits in general. Both of these don't really work if you've shared the commits with someone else.
• `git clone -l` makes a hardlinked clone. (This is default in newer versions of Git. It's another factor in making git checkouts fast.)
• git has early-stage support for something called "submodules" in recent versions, similar to `svn:externals`. And there's an in-development `git hunk-commit` command that might end up in git someday that should add most of Darcs's UI niceness to git, although `git gui` or `git add --interactive` get you partway there already. http://raphael.slinckx.net/files/git-darcs-record

02:38 < twb> I found git commit --interactive pretty confusing.
02:39 < andreaja> twb: I prefer to use git add -p

• If you try to `git pull` when you have un-checked-in changes, `git` will complain with an unhelpful error message. Check in the changes or `git stash` them before you pull.

I took the first 125 563 056 bytes of my mailbox and compressed them into 59M with git. However, git (1.4) doesn't seem to work very well with multi-gigabyte quantities.

If you're using the Git 1.4 from Debian Stable, you'll want to know to use `init-db` instead of `init`, `repo-config` instead of `config`, and often `update-index` instead of `add`.

Why is there so much anti-plastic sentiment? Visibility, Arcadian primitivism, conspicuous consumption, and profit.

Kragen Javier Sitaker, 2018-06-21 (7 minutes)

Posted to https://news.ycombinator.com/item?id=17369521

The biggest problem with making statements about "plastic" is that it's such a broad category of materials that you almost invariably doom yourself to talking nonsense.

Most plastic (particularly PET, PP, HDPE, and LDPE) is not poisonous, even when decomposed, and does not bioaccumulate in the conventional sense. Perhaps by "poison sponge" you don't mean that it's poisonous; you mean that it absorbs poisons. Well, isn't that what you would want to do with poisons? Clay and activated charcoal absorb and adsorb poisons too. That's why you feed them to poisoning victims. The problem is the poisons, not the plastics.

Using alternatives where they exist may or may not be an improvement. Usually you can use glass bottles instead of plastic bottles, for example. But a PET 2-ℓ bottle might be 27 grams of extremely nontoxic PET. The corresponding glass bottle weighs nearly a kilogram, 30 times as much. This means that most kinds of environmental damage associated with it increase by one and a half orders of magnitude; you need 30 trucks instead of one to transport the bottles to the bottling facility, 30 tons of raw material instead of one to make 30,000 bottles, and so on. The glass also needs higher processing temperatures, using more energy, and produces broken glass when discarded, so the disparity is actually somewhat larger.

Similarly, a traditional plastic shopping bag is entirely nontoxic, weighs 100 milligrams, and can be reused three or four times, but is sterile the first time you use it. If you replace it with a canvas bag that weighs 65 grams and can be reused hundreds of times, you're using 650 times more material in exchange for only 100 times more uses, and you dramatically increase your risk of food poisoning from raw vegetables. Washing the canvas bag once will typically use both more energy than the plastic bag used during its entire lifecycle and also more material — it's hard to get it clean with only 100 milligrams of soap!

A better tradeoff is to use slightly thicker plastic bags which can survive dozens of uses, use new plastic bags for your raw vegetables, and bury the plastic safely when you're done with it. (A common pathological effect of regulations against plastic shopping bags is that people have to replace them with plastic garbage bags.)

Being able to use 30 or 100 times less material, and common, nontoxic materials like carbon and hydrogen instead of rare, toxic materials like boron and chromium, are major environmental advantages of *many* plastics in *many uses*. There are *some uses* of plastics which are environmentally harmful, and there are *some plastics* which do generate toxic products if they are allowed to break

down — most notably PVC.

Car fuel consumption is, generally speaking, closely proportional to weight; and, for a given emissions control system, harmful emissions are closely proportional to fuel consumption. Individual car weight has diminished enormously during the last 50 years primarily due to greatly increased use of plastics, though improved metals have also played a role. You can build cars almost entirely from metals, with only a few crucial components such as gaskets and hoses made from plastics, but doing so is environmentally harmful.

So why is there so much anti-plastic sentiment? I think there are four main reasons, aside from the actual environmental damage from some uses of plastics.

• Plastic is very visible, and renouncing plastic is a low-cost, high-visibility way to advertise your virtue as an Environmentally Conscious Person. Doing things that would actually have a significant benefit to the environment, such as not having children, not eating meat, not financially supporting the US military through taxes, carefully weighing the costs and benefits of possible actions, and using passive solar climate control in your house, is costly and therefore unpopular.

• I'm a hippie, and the horror at what industrial civilization is doing to our beautiful planet leads many hippies to reject industrial civilization entirely. This kind of anarcho-primitivism, which I do not agree with, considers products of industry and especially petroleum and chemistry to be undesirable, at times even ritually impure, like cannibalism. Thus canvas bags are preferable to plastic bags, wool (such as actual fleece) is preferable to microfiber polyester ("polar fleece"), and brass is preferable to plastic, entirely independent of their actual environmental impact. This creates a sort of coincidental association between environmentalism and the rejection of plastic which provides fertile ground for anti-plastics arguments and barren ground for pro-plastics arguments.

• At least in the US, the upper class considers wool preferable to microfiber polyester and brass preferable to plastic for an entirely different reason from anarcho-primitivists: they consider innovation and cheap goods to be déclassé, deriving much of their social value from a traditionalist, Romanticist value system. Cynics might also point out that using expensive goods where cheap ones would do serves as a form of conspicuous consumption, reliably signaling the wealth of the consumer to observers. Either way, the upper class — which still controls much of the press in the US, and thus has a powerful role as tastemakers, despite the rise of lower-class celebrities like the Kardashians and Trump — is also fertile ground for anti-plastics arguments and barren ground for pro-plastics arguments.

• Selling alternatives to disposable plastics is very profitable. As a simple example, a supermarket can sell cloth bags instead of giving away plastic bags for free. Many times, its customers will forget to bring cloth bags with them, and will buy more bags than they need, so in practice a single cloth bag will replace 10 plastic bags instead of 100. This works as a form of price discrimination, since customers on tighter budgets will be more careful to bring bags to avoid the artificially imposed cost. Finally, this makes the supermarket appear

upscale, both because it's advertising its hip environmental consciousness, and because it is less associated with déclassé things like plastic bags. This enables it to charge higher profit margins on its other merchandise.

Paper/foil relays

Kragen Javier Sitaker, 2019-04-02 (updated 2019-10-23) (13 minutes)

Preliminary calculations suggest it's feasible to build electrostatic relays out of paper and graphite that operate reliably for millions of cycles at frequencies from DC up to medium-wave RF, at voltages of dozens to hundreds of volts, with individual devices that can be clearly seen with the naked eye. Actually this is so absurdly good on paper that surely someone has tried it and the scheme has some hidden fatal flaw I'm not seeing. Details follow.

MEMS electrostatic relays

I was reading about electrostatic relays the other day. MEMS relays are made using nanophotolithography techniques, just like CMOS, but have significantly different performance characteristics; they turn on and off more slowly than MOSFETs do, but once they're active, they pass signals with lower resistance and thus higher speed; and they don't have a linear region the way MOSFETs do, having near-infinite gain at their transition point. Careful circuit design can get circuits with comparable performance.

The idea of an electrostatic relay might seem paradoxical: wouldn't you need a higher "gate voltage" to turn it on and off than what it can switch? The solution taken by the MEMS designs is very simple: the contact area is small, and the signal conductor is narrow, while the gate area is large. (They are insulated from one another with a layer of amorphous silicon dioxide.) Because the contact area is small, the electrostatic force generated by the signal being switched is proportionally small, perhaps two orders of magnitude smaller than the force generated by the larger-area gate.

Other solutions are possible, involving things like leverage to allow a smaller electrostatic force to outwrestle a larger one, but just using larger and smaller plate areas is simple enough.

Macroscopic paper foil electrostatic relays

It occurred to me that you could build such devices macroscopically, or mesoscopically (with, say, a characteristic dimension of 100μm to 1mm rather than 10mm or 1μm) out of paper and foil. The most obvious conductors to use, aluminum and copper, are not very suitable for relay contacts for operation in air — sparks at the contacts will produce hard, nonconductive oxide layers which will make the relays unreliable in short order. Reasonable alternative contact materials include gold (reduces its oxide), silver (has a conductive oxide), graphite (has gaseous oxide), tin (has a semiconducting oxide), and lead (has conductive metallic dioxide).

Typical electromagnetic relays are good to only about 10k to 100k operations, although high-reliability mercury-wetted reed relays sometimes advertise a million. These electrostatic relays should be able to last many times longer through the use of more appropriate materials, much lower circuit inductance, and much lower currents. But this is speculative.

Spring materials might be trickier. Paper might work okay at least for prototypes, but ideally you'd like something that doesn't creep or

fatigue over time, such as glass foil or foils of other metal oxides. Alternatively, instead of relying on the insulator to provide a spring force, we could rely on the conductor — metallic conductors such as copper, silver, gold, or even iron should be immune to creep and fatigue at these temperatures, deformations, and thicknesses, and a thin film of some insulator could be deposited onto the surface of the gate conductor to separate the gate from a later-deposited channel.

A 3mm×3mm paper foil relay might consist of a 100μm-thick square of aluminum foil on the gate side (this is conservative; common household foil is 22μm, while ribbon-microphone aluminum-leaf is 0.6–2μm), attracted toward a 100-μm-thick square on a substrate paper, which has a 100-μm-thick insulating paper layer (again, conservative; ordinary 80 g/m² office paper is this thick, but 80-μm 60 g/m² paper is easily available) separating it from the traces being bridged, which might each have a 1mm×1mm contact area. Actually you probably only need one such area, but let's keep it simple. The moving gate might move by 100μm to bring the contacts into contact.

Our 3mm × 3mm sheet works out to be more like 5mm × 5mm including quiet zones around it:

```
EE EE EE EE EE
EE AA AA AA EE
DD BB CC BB DD
EE AA AA AA EE
EE EE EE EE EE
```

Here the different pixels have stacked-up contents as follows when the contacts are open, with "G" being the gate electrode, "." being air, "I" being insulating paper, "C" being the contact material, "N" being the channel conductor (for example, copper), and "S" being the substrate electrode, which can be aluminum or copper or whatever.

```
AA:   BB:   CC:   DD:   EE:

GGGG  GGGG  GGGG  ....  ....
IIII  IIII  IIII  ....  ....
....  CCCC  NNNN  ....  ....
....  ....  ....  ....  ....
....  CCCC  ....  NNNN  ....
IIII  IIII  IIII  IIII  IIII
SSSS  SSSS  SSSS  ....  ....
```

If each of these layers is 100μm thick, which seems plausible, we have 500μm between the gate and the substrate at the point where we want to activate the thing. The total moving mass is about 0.9 mm³ of aluminum gate (about 2.4 mg) plus a similar volume of paper (about 0.9 mg) plus 0.3 mm³ of channel (say, another 1 mg, depending on what you make it from) for a total of 4.3 mg. You want to somehow hinge or spring it so that the paper spring restoring force is large comparable to the weight of the 4.3 mg (so it won't fail from being upside down) but not too enormous. How much electrostatic force can we expect?

Say we run the thing on 200V, since it's an electrostatic device and those have always required a fair amount of EMF to do anything.

Coulomb's law $F = k(q_1q_2)/r^2$ tells us that two 1-nanocoulomb point charges 500 μm apart will generate a 36-millinewton force. But how much charge do we have at 200 volts? If our capacitance $C = \varepsilon A/d$ and our ε is ε_0 — probably a good approximation for paper, and an excellent one for air — our capacitance is 0.160 pF, so we have about 32 picocoulombs on each foil, giving about 1.12 mN, under whose influence the relay will snap shut at initially 259 m/s², about 26 times the acceleration of gravity, which is in the right ballpark. It might even be possible to use lower voltages like 48V or 24V.

https://www.hindawi.com/journals/jchem/2017/4909327/ may be relevant; on a single sheet of notebook paper (probably 80 μm?) the dude got 53 pF/cm², so 0.53 pF/mm² (?), which is in pretty close agreement with what I calculated above for the larger plate separation encountered in an electrostatic relay.

(I think we can neglect the electrostatic force of the channel since, as I said above, we can make it almost arbitrarily narrow.)

Neglecting the spring force, which I think can be substantially smaller than the electrical force, we have in theory an operational speed of around 2 μs, which in theory requires about a 16 μA charging current — though the capacitance will increase by 20% by the time the contacts come into contact, generating additional charging current and electrostatic force.

At currents and voltages like these, resistances below a few hundred kilohms will have no effect, so you might as well use graphite for all the conductors, rather than trickier and heavier metal foils. (Silver's resistivity ρ is 1.59×10^{-8} Ωm, copper's 1.68×10^{-8}, gold's 2.44×10^{-8}, aluminum's 2.82×10^{-8}, lead's 2.2×10^{-7}, amorphous carbon's $5–8\times10^{-4}$, and graphite's $2.5–5.0\times10^{-6}$ perpendicular to the basal plane. So a 100μm×1mm×3mm trace of randomly oriented graphite particles in good contact might contribute as much as 10^{-5}Ωm×3mm/1mm/.1mm = 0.3Ω, six orders of magnitude too small to matter. This suggests in some sense that you could narrow the channel by six orders of magnitude, down to 1nm, before its resistance became important, but that is of course impractical.) Also, you probably want to avoid sharp corners to avoid ionizing the air or the paper.

Actually reaching such high frequencies might require you to extensively perforate the paper (without bridging the contacts on the two sides) or operate the whole device in a vacuum to avoid air resistance.

Dynamic deformation

Andrea Shepard points out that at high frequencies the paper will not behave as a rigid or quasi-rigid object; applying a force to one part of the paper will cause displacement to ripple out from that place as shear waves at a speed of sound in the paper, on the order of 1 km/s, which is to say 1 mm/μs. This would cause great slowness if the gate electrode did not overlap the "channel" and "contact" material, as it does in the above design sketch. Even in the above sketch, there is a distance of some 100 μm between them, and the compressive deformation will take on the order of 100 ns to propagate through it and 1 μs to approximate the behavior of a rigid object again. I hazard a guess that this will not be the limiting factor in the performance of these hypothetical devices.

The perfectly overlapping electrodes are somewhat questionable, though, for a different reason: electric fields can't normally penetrate

conductive masses such as the channel and contact material, because statically speaking the field induces a surface charge sufficient to cancel it. (This also creates a MOSFET-like "charge injection" problem.) So there might be no net force from the overlapping part of the gate, and the shear waves described above might carry almost all of the opening or closing force.

Scaling laws

If you scale the device down by a factor N, its area diminishes by N^2 while its plate separation diminishes by N, so the capacitance, the charge per volt, decreases by N. At the same time, though, the Coulomb force per nanocoulomb increases by N^2, so the force per volt *increases* by N. The mass that must be moved decreases by N^3, so the acceleration per volt increases by N^4, so the time to cover a given distance at a given voltage decreases by N^2. And the contact separation distance also decreases by N, which, with the same acceleration, would give you a $\sqrt{N}$ speedup. So you actually get an $N^2\sqrt{N}$ speedup, in a vacuum, at a constant voltage. Maybe more in the real world. Or less.

This suggests that, with crepe paper or Mylar or glass foil or something, you should be able to reach well into the megahertz with devices that are still individually visible to the naked eye, although perhaps a bit tricky to construct by hand.

In the limit you might have to diminish the voltage as the plate separation and radii of corners decrease to keep corona discharge and avalanche breakdown under control. If you decrease the voltage, you get proportionally less force, and need proportionally less charge. This means that the characteristic resistances stay the same, but in some sense the amplification factor drops. Like CMOS, these devices are capacitive loads, though very small ones; they have gain limited only by the leakage current, in this case further potentiated by the additional extremely high factor of gain at the threshold voltage between barely contacting and barely not contacting.

Multipole relays

In the above diagram, the vast majority of the area is occupied by the gate electrode; the channel occupies only a small part of the device. It might be worthwhile to run two or three channels across it to amortize the expense of the large gate over more channels. As calculated above, the channel itself doesn't reach a significant resistance at these voltages and currents until it's only 1nm wide (and 100µm tall, making it more like a graphite wall than a graphite trace, so maybe reducing it to 30µm × 30µm would be more reasonable). So you could run many channels across, controlling them all with a single gate voltage, and thus get many bits of switching out of a single device.

Shaped hammer face giant pressure

Kragen Javier Sitaker, 2019-11-10 (21 minutes)

As explained in Electric hammer (p. 1865) and Hammering toolhead (p. 3297), a hammer is a simple machine, although Archimedes and Galileo were unaware of this because they lacked the modern concept of kinetic energy; its mechanical advantage is limited only by the fact that its impact is not instantaneous.

It turns out that it is possible to substantially improve this mechanical advantage.

Basic hammering physics

As impact time approaches zero, the force and pressure of the impact approach infinity. Moreover, even during the impact, the deceleration of the hammer varies; as the deceleration approaches infinity, so does the force and pressure.

Thus you can beat an ice cube with a massive broomstick without damaging it, but a light whack with the bowl of a metal spoon can shatter it; and the tempered glass of a car window can withstand a baseball bat impact, but not a crackhead throwing a piece of sintered-aluminum-oxide spark plug at it.

Once the impact begins, the resulting deceleration does not affect the entire hammer at once, nor does the force affect the entire workpiece at once; instead, they travel through these bodies as sound waves. These waves reflect from other surfaces of the bodies in the same way that electrical waves reflect from the ends of transmission lines or sound waves reflect from the open ends of pipes, and may be focused or scattered in different parts of the solids. As a rule of thumb, the transmission line or hammer behaves like a rigid object or lumped-element node only over timescales about ten times the round-trip time of waves through it.

These sound waves are somewhat more complex than everyday sound waves. First, they involve both shear waves and compression waves, which travel at different speeds, each of which can produce the other under some circumstances. Second, their magnitude is often large enough to cause the usual linear approximations to break down; in particular, if there is a region within which the material stiffens with increased deformation, this can cause higher-amplitude waves to travel faster than, and overtake, lower-amplitude waves, and this can result in the propagation of self-sustaining discontinuous wavefronts through the material — in sound waves in air we call this a “shock wave” or a “detonation”, and a similar phenomenon in water channels is a “flash flood” or, on the beach, a “breaker”. Except when playing a percussion instrument, normally the point of using a hammer is to provoke some kind of nonlinear response from the thing you are hammering on, such as breaking or deforming plastically, so these phenomena are actually quite common in hammering.

Additionally, unless the impact is deep inside a hole in the workpiece, surface acoustic waves represent additional modes of vibration that may or may not carry significant energy dissipation.

Paddles

One obvious approach to shortening the impact time and thus increasing the force is to shorten the distance from the impact side of the hammer head to the back side, shortening the timescale over which it behaves like a rigid object. Taken to the logical extreme, this suggests using a hammer that is just a thin, flat sheet of material, which is brought into contact with the workpiece at the same time over its whole surface.

One use of this approach is the "slapper foil" detonator, which does in fact work, but other examples include flat paddles, slappers, or leather spanking straps used to punish children or excite masochists. These enable the development of sufficiently high impact forces to cause localized tissue damage despite low energies (typically on the order of a joule) distributed over large areas (typically on the order of 100 J/m^2). Even more prosaically, the same strategy is used for open-hand slapping, which the humans commonly use as a form of symbolic aggression to induce pain without any danger of more serious damage; and it is a factor in the effectiveness of spoon shattering of ice as well.

One difficulty of slapping things with paddles is that, in air, the large surface area of the paddle tends to accumulate an area of high-pressure air in front of it, soaking up most of the input energy. This can be desirable if the objective is merely to make a loud noise, but if maximal impact force is the objective, it is a drawback. Strategies to reduce this problem include putting air holes in the paddle, dividing the paddle into many strands (a "flogger"), or using a whip rather than a paddle.

Workpiece waveform propagation

During the impact, wavefronts of deformation are traveling through the workpiece as well as the hammer, and if the materials have reasonably similar acoustic impedances, they can even pass back and forth across the hammer-workpiece interface rather than being entirely reflected. Their particular behavior in the workpiece material depends on the properties of that material; for example, when a human is being slapped, I think much of the slap energy is dissipated by viscous and plastic behavior in the immediate neighborhood of the impact, so there is no tissue damage even millimeters away, while when using a bent wire to tap glass that has been scored on the other side, the stresses induced by the propagating wave are high enough to provoke the formation of a crack from the score.

(I don't really know if that's the reason slapping humans causes no damage except at submillimeter distances from the impact. Possibly dispersion also plays a role.)

Sensitivity to impact conditions

The direction in which each wavefront travels through the workpiece depends on the speed of each sound in the workpiece material and on the relative phase of the impact at each part of the workpiece surface; since the speeds of sound in solids are typically around 1km/s and the speeds of movement of hammers are typically around 1m/s, even fairly small rotations between mated hammer and workpiece surfaces can result in fairly large differences in propagation directions. Consider a flat hammer face that is 10mm across striking a

flat workpiece at 1 m/s with a compression-wave speed of sound of 1km/s with one milliradian of deviation from parallelism. So, when one side of the hammer face strikes, the other is still 10 microns away from striking; the contact area spreads across the hammer face gradually, as the hammer and workpiece deform, until reaching the opposite edge of the face 10 microseconds later. In those 10 microseconds, the waves from the initial impact have propagated 10 mm into the material, resulting in a planar wavefront propagating at a 60-degree angle from the surface normal, rather than in a nearly normal direction, as you might expect. The shear (or transverse or S) waves will propagate in a more nearly normal direction, since they propagate typically about 40% slower.

Since the "propagation time" of the contact area across the material is on the order of the speed of sound in either material, we should not expect the initial impact to alter the conditions much for later parts of the impact.

Shaped hammers

By shaping the hammer face to time different parts of the impact relative to one another, we can change the propagation characteristics of the wave in the material. For example, a convex hammer face, like the bowl of a spoon, or the traditional spherical blacksmithing hammers of Dablo, Burkina Faso, shown in Christopher Roy's documentary "From Iron Ore to Iron Hoe", will tend to produce a spherical wave that propagates outwards in all directions in the workpiece from a common center, and inwards toward a focus inside the hammer, like the convergent ultrasound waves used in sonoluminescence. A concave hammer face will tend to produce a convergent wave *within the workpiece*, but as noted above, small misalignments in the hammer angle will produce large deviations in the direction in which the wave propagates.

You might think that a potentially more predictable way to focus waves within the workpiece might be to shape the workpiece surface to be concave instead, but that just makes matters worse; the same small angles of hammer misalignments will still produce the same large angles of deviation, and additionally now lateral translation of the hammer blow by similar amounts will also produce those same deviation angles.

Outriggers

A better approach is to use three or more small "outriggers" sticking out of the sides of the hammer face to rotate it into submicron alignment with the workpiece surface by elastically deforming over hundreds of microseconds before the main impact. This approach can also compensate for some degree of imperfection in the workpiece surface itself, but not for micron-scale concavity or convexity over the impact area.

Phased arrays

Given a precise depth map of the workpiece surface, you could use a phased array of hammers in, for example, a hexagonal grid, each launched toward the surface to arrive at a time scheduled with submicrosecond jitter; this should enable the formation of a precisely customized wavefront within the workpiece material.

I had thought that perhaps you could use independent outriggers on a swarm of independent hammers (perhaps swung together using some kind of compliant coupling) to do this depth-mapping and timing mechanically rather than in software; the idea was that the outriggers would come into contact with the surface first, with the microsecond-scale jitter imposed by micron-scale surface roughness and milliradian-scale alignment imprecision, and would act to retard the subhammers that would otherwise make contact first and/or advance the subhammers that would otherwise make contact late, all by a few microseconds. But I don't see how to make that work mechanically.

Focusing hammers

Given a known hammer geometry, it should be possible to arrange for focusing of deformation waves at or near the hammer surface as well. For example, a convex hammer surface can produce an expanding spherical pressure wave inside the hammer upon the initial impact, with minimal dependence on the precise angle and position of the impact; if the back surface of the hammer is an ellipsoid with one focus at the virtual source of this wave, it can then reflect this spherical wave into a convergent spherical wave focused on a particular point or points. (See Caustics (p. 1619) for notes on designing light-reflective surfaces to form chosen focused patterns of intense light; this approach is also applicable to these sound waves.) The material at or near this focus point will experience stresses enormously greater than the stresses it would normally experience from an ordinary hammer blow, perhaps by two orders of magnitude or more. This point can be chosen to be within the hammer, at the interface with the workpiece, and probably most usefully, some distance inside the workpiece, thus limiting the damage to the hammer.

To be concrete, suppose we are using a steel hammer with a Young's modulus of 200 GPa (which Plastic cutters (p. 1074) and Wikipedia claim is typical of steels), weighing 1 kg, swung at 10 m/s, striking a flat piece of steel, and the hammer's circular striking surface is shaped to be precisely 20 microns higher in the center than at its edges, which are 40 mm apart. (At 7.9 g/cc, the hammer head then must average 101 mm long to weigh 10 kg.) If the hammer strikes straight on, the center of its face will strike 2 microseconds earlier than its edges do. Supposing the speed of sound in steel is 6 km/s, that means the center of the wave will have a phase advance of 2 microseconds and 12 mm relative to the edges. The 12 mm of steel compressed by 20 microns amounts to 1.7 millistrains and thus is under some 300 MPa of pressure. (XXX this is wrong but I don't know how to correct it yet; see below.)

A naive, untutored hammer of these dimensions used in this way will convert its 50 J of kinetic energy in a relatively straightforward fashion into 50 J of elastic deformation, with the pressure wave and other waves bouncing back and forth through the hammer and workpiece, augmenting the pressure by some 300 MPa on each bounce, over a timescale of a millisecond or two, during which time the hammer has come to a stop and begun to rebound violently — an average deceleration of about 5 km/s/s with a peak of about 10 km/s/s, producing about 10 kN of peak force. However, this only

amounts to about 8 MPa of pressure, so clearly I have miscalculated in a very significant way above; ASTM A36 steel actually has a yield stress of only 250 MPa, so 8 MPa is a lot more plausible than 250 MPa.

(This 10 kN amounts to a mechanical advantage of about 1000, depending on how much space you have to swing the hammer in: a constant 10 N accelerates the 1 kg hammer up to 10 m/s in one second, requiring 5 meters of swing.)

Suppose our super-hammer, with its ellipsoidal back face, can focus the initial impact wave to two orders of magnitude higher strains within the workpiece, or some 800 MPa. This is enough to provoke cold steel into plasticity, which will prevent the 800 MPa figure from actually being reached. A significant fraction of the impact energy will then be converted into heat within about a gram of steel inside the workpiece, heating it by some tens of degrees.

Applications

If it is possible to provoke fracture in the workpiece by this approach, which should be easily feasible for brittle materials, the available concentration factors should increase dramatically: the bubble of vacuum thus formed inside the workpiece would experience very large forces and temperatures as its walls crashed together on the following oscillation, again similar to sonoluminescence or to the collapse of the void when a stone falls into water or fluidized sand.

A particularly interesting situation is when the focus is at or near the opposite face of a flat workpiece, because it seems plausible that this mechanism could be used to pit it, eject material from it, heat-treat it, or cold-weld it to something else. This is a particularly appealing prospect for heat-treating inaccessible places like the interior surfaces of structural tubing after welding, although it might turn out to be impractical to achieve high enough concentration factors in ductile metals to reach the necessary temperatures.

Hammer materials

Better hammer materials might include things like copper and tungsten, with their lower speeds of sound, or even some kind of lead-filled steel foam. Graded-acoustic-impedance metamaterials should make it possible to reflectionlessly couple sonic energy into the workpiece even from a hammer (or other transducer) with a quite different acoustic impedance.

Multilayer slappers

Above I mentioned that one use of paddles is for exciting masochists. A device popular in this connection is a thing known as a "slapper": a double-layered paddle similar to the slapstick used in vaudeville or by Arlecchino. Shortly after the initial impact, the second layer of the paddle slaps into the first, producing an additional painful impact (as well as a much louder noise).

A potential advantage of this construction is that energy is not lost during the hammer swing to the air resistance of the second layer; the air between the layers moves along with the hammer, so it only absorbs any energy during the impact, when it is compressed between the layers to some degree, which is what gives the slapstick its loud

slap.

This could be extended to many layers, but without further elaboration, the layers will produce many separate impacts as they pile up on a pile on the workpiece, starting with the ones closest to the workpiece. This may be useful for producing some sort of vibration or recorded-sound reproduction, but by itself it will not produce any kind of unusual impact; dead-blow hammers filled with shot already do something similar.

What is needed for giant pressure is for the layers to collide very nearly simultaneously, but in the *reverse* order, starting with the layers furthest from the workpiece, with the compression wave propagating through each layer just in time for the layer to hit the next layer. For 1-mm-thick layers of steel, the ideal timing should be about 170 ns apart; with 100 such layers the overall sequence would total about 17 microseconds.

However, even if the impacts are simultaneous, this would only broaden the peak of the shock wave traveling through the stack of layers by those 17 microseconds, which is already about a factor of 50 to 100 better than a standard hammer, exceeding the physical limits of steel, though perhaps not those of some technical ceramics.

A variety of well-known pantograph-like linkages could be pressed into service for getting the stack of layers to uniformly expand and contract; moreover, they could be activated by the contact of "outriggers" with the workpiece surface, thus completing the stackup as the frontmost layer slams into the surface. The difficulty will be to get them to perform with enough precision to significantly exceed the impact force of an ordinary hammer.

By slightly thinning the sheets in their centers, the impact shock wave can be produced as a convergent spherical shock wave, focused as before on a chosen position within the workpiece. In this case, however, the precision of the hammer's positioning and angle are no longer so important, because the focusing of the shock wave does not depend on them, but only on the relative positioning of the layers in the stackup.

How much would you need to thin them? With the 40-mm-diameter, 101-mm-long geometry suggested above, and 6 km/s propagation velocity, the rearmost sheet would need a phase advance of about 2 mm and thus 333 ns at its outermost edge, if the focus is near the front of the hammer. If a 10 m/s impact velocity were split up evenly among 100 inter-sheet gaps, it would strike the sheet in front of it with a relative velocity of 0.1 m/s, so we're talking about etching it 33 nanometers deep in the middle to get a 330-ns phase difference. Other sheets would be etched progressively deeper, but we're still talking about a very difficult level of precision to reach any meaningful kind of focus.

By perforating the sheets it should be possible to provide low-resistance air paths from the center of the stack to outside of it, thus reducing the loss of potential impact energy to air compression. Simple aligned round perforations would provide lengthwise channels, but elongated and partly-aligned perforations could provide diagonal and radial air channels, which would be shorter and thus lower-resistance for many hammer geometries.

Lithium fission energy

Kragen Javier Sitaker, 2016-09-06 (updated 2019-09-16) (6 minutes)

From the WP article about Castle Bravo:

> a theoretical error made by designers... They considered only the lithium-6 isotope in the lithium deuteride secondary to be reactive; the lithium-7 isotope, accounting for 60% of the lithium content, was assumed to be inert. ... It was assumed that the lithium-7 would absorb one neutron, producing lithium-8 which decays (via beryllium-8) to a pair of alpha particles on a timescale of seconds—vastly longer than the timescale of nuclear detonation. However, when lithium-7 is bombarded with energetic neutrons, rather than simply absorbing a neutron, it captures the neutron and decays almost instantly into an alpha particle, a tritium nucleus, and another neutron.

The result was an extra 10 megatons of yield (4.2e16 joules, i.e. 42 petajoules) from the 10.7 tonnes of the device, most of which was presumably the lithium; this is about 6 or 7 petajoules per kg.

This reaction is remarkably similar to the "energy amplification" reaction used in thorium reactors: a neutron entering a mass of lithium-7 will stimulate a decay, which emits another neutron, which is either lost or stimulates another decay, and so on. We can infer that this does not produce a self-sustaining chain reaction because natural lithium still contains 92.5% lithium-7, and there is apparently no critical mass of lithium which results in a uranium-like or plutonium-like chain reaction.

(Presumably this is because in fact the decay to two helium nuclei via ^{8}Be mentioned above does happen even at high energies and consumes some or most of the neutrons. This was in fact the first artificial "splitting of the atom", carried out by Cockcroft and Walton in 1932 with a 700kV tube to accelerate protons — the cyclotron, necessary to reach energies per charge higher than your voltage, was only invented that same year in Berkeley.)

Lithium, however, is more appealing than thorium for a variety of reasons, occurs at 17 ppm in the crust, compared to thorium's 6 ppm, and there is an existing industry extracting over half a million tonnes of it from the crust per year, while thorium only has a few uses and is somewhat dangerous to refine because of its natural radioactivity. Thorium is imported into the US at a few tens of tonnes per year, and costs around US$100 per kilogram, while lithium is imported at a rate of some 3000 tonnes per year and costs around US$6000 per tonne, or US$6 per kilogram.

Lithium-6 also produces tritium when irradiated with a neutron, yielding 4.8 MeV (about 40 times less than the energy of an actinide fission), which works out to 77 TJ/kg, about 1% of the energy density inferred above for the Castle Bravo excess energy.

(The World Nuclear Association says that lithium-7 constitutes 92.5% of natural lithium and has a very low neutron cross section of 0.045 barns, and that on proton bombardment it fissions to 2He-4 yielding 17 MeV.)

US$6/kg and 6 PJ/kg conveniently give a fuel cost of US$1/PJ. By comparison, a common wholesale price for electrical energy is US$60/MWh (though this fluctuates minute by minute and goes negative most nights). This electrical price works out to US$16.67 per gigajoule, and thus US$16'666'667 per petajoule, some three

million times the price of the lithium fast fission energy. Even the lower energy of the ^{6}Li decay would be some thirty thousand times cheaper than grid power.

The tritium produced also decays energetically with a half-life of some 12 years; while this is too slow to be useful for a nuclear weapon, it could be useful for a nuclear reactor.

There's still an engineering question about how difficult it is to generate the neutrons to initiate the reaction; fusing lithium deuteride to generate the neutrons is clearly not an option in most cases, and you need to take into account the energy consumed by the particle accelerator. I suspect that the slow fission reaction by way of ^{8}Be mentioned above would also work, in which case the neutrons need not be energetic. Quite likely the usual approach of neutron spallation from a mercury target impacted by a proton beam would be adequate.

Lithium is particularly troublesome here because of its small cross-section — while ^{238}U has a thermal neutron capture cross-section of about 2 barns, I'm guessing both ^{6}Li and ^{7}Li have capture and fission cross-sections in the neighborhood of the capture cross section of hydrogen (0.2 barns), deuterium (0.0003 barns), or carbon (0.002 barns), which are another two to four orders of magnitude lower for fast neutrons. This means you might need 10 or 100 or 1000 times as much thickness of lithium absorbing the neutrons as you would for an actinide, or, alternatively, 10 or 100 or 1000 times as many neutrons.

The fission produces helium, a gas, and tritium, which can be gaseous if it reacts with other tritium rather than something else in the area; this suggests that the fuel should be kept liquid, perhaps as a molten salt, to allow the gas to bubble out instead of building up inside a solid.

Given the uniquely prominent position of ^{7}Li/^{8}Be fission in the history of nuclear physics research, it is inconceivable that this idea is original, so there is probably an obvious, well-known reason why it doesn't work; Szilárd surely tried it in the early 1930s, ten years before he and Fermi got a successful chain reaction going in uranium in 1942, but of course Szilárd didn't have access to modern fast electronics or even a cyclotron at the time.

Hot oil cutter

Kragen Javier Sitaker, 2016-08-16 (updated 2016-08-17) (8 minutes)

Some plastics, such as 6/6 nylon, are so resistant to abrasion that it is very difficult to machine them, but have very low viscosity once melted. You can cut nylon with an abrasive wheel, for example, but it destroys the wheel. Acetal (that is, polyoxymethylene or POM, aka Delrin) is popular not primarily because of its material properties — although they are quite good — but because it can be cut much more easily than most other thermoplastics.

Plastic foams such as Styrofoam can be cut using a hot wire, typically stainless steel, but this approach doesn't work for solid plastics; the molten plastic closes up the kerf behind the wire. Hot-wire cutting also typically suffers from poor temperature control, vaporizing and burning some of the plastic, which increases the risk of hazardous fumes.

Suppose that instead you had a narrow steel or aluminum pipe, for example 8 mm diameter with 0.5-mm-thick walls, heated to a precisely controlled temperature by pumping heated oil through it. The oil could, for example, be heated to 290° and pumped around a closed loop past an electrically heated aluminum heatsink, with the heat applied to the heatsink controlled by a thermostat measuring the temperature of the output oil. With this approach, most of the molten nylon can be made to run out of the kerf as the pipe advances through it, particularly if the nylon material is in a sheet of only a few millimeters thickness.

If we take 45–45 cal/g (188 kJ/kg) to be the heat of fusion — a bit less than that of paraffin — 271° to be the final melting point, and 1.21 g/cc to be the density of 6/6 nylon, from Starkweather, Noller, and Jones 1984 then melting a 9 mm kerf through a 20 mm thickness of nylon would require 41 J/mm to do just the melting. If we believe Engineering Toolbox's specific heat table, the heat capacity is 1.7 kJ/kg/K, so heating by 250 K is another 425 kJ/kg, for a total of 613 kJ/kg. This means that same 9 mm kerf at 20 mm thickness requires 135 J/mm. So cutting at a reasonable speed of 10 mm/s, neglecting conduction, requires 1300 W. Cutting at higher powers is more efficient, because you'll get a smaller error from neglecting conduction.

Polyvinyl chloride is another example of a plastic that can be easily cut with a hot object, but is hazardous with poor temperature control. If we believe the Polymer Science Learning Center's decomposition temperature table, PVC decomposes in the 200°–300° range but doesn't melt until 265°, and nylon 6,6 decomposes in the 310°–380° range, while PET melts at 268° and decomposes in the 283°–306° range.

Transferring 1500 W to oil through a heatsink probably requires a heatsink of some 100 mℓ capacity, so the total amount of oil needed for this tool is probably around 150 mℓ.

Avocado oil has a smoke point of 270°, which is probably high enough to melt nylon, but more normal cooking oils like soybean oil smoke at much lower temperatures like 238°. This suggests that if a nontoxic oil is to be used in this tool, it has to be medical-grade

paraffin or polydimethylsiloxane rather than any actually edible oil. I'm not certain that either of these, but especially medical-grade paraffin, will withstand such high temperatures; Engineering Toolbox suggests a limit of 149° for mineral oil and 260° for PDMS or other silicones, but I suspect that may just be the point where the oil ceases to lubricate. Some companies do sell high-temperature lubricants capable of lubricant use up to 270° and more; the fluorinated Krytox XHT supposedly doesn't degrade until 350° and doesn't corrode metals until 288°.

If the oil is heated to 290° and must not cool below 271°, we only have 19 K of sensible heat in which to store all the heat to be delivered to the nylon. If the oil has a heat capacity of 1.67 kJ/kg/K (according to Engineering Toolbox's table), that's only 32 kJ/kg, so we need 47 g/s of flow. At 0.8 g/cc, that's 59 mℓ/s. If a single-acting piston pump driven at 1500 rpm is driving this, the pump's displacement needs to be 2.35 cc.

In a 7-mm-diameter pipe, that's a rather shocking 1.5 m/s average linear speed. The Reynolds number is almost 11000. But according to an anonymous online calculator, the pressure drop from 200 mm of such a flow with .01 mm pipe roughness, if the fluid were water, would be only 11 mbar (1.1 kPa). This implies that only 65 mW of pumping power is needed, which seems surprisingly small to me, suggesting that maybe my pipe resistance calculation is wrong. Another random online calculator suggests that the head loss will be 294 mm, which would be 2.9 kPa, which is a little higher but still in the ballpark.

These high powers suggest that it might be desirable to power the tool directly with fire rather than electrically.

Alternative heat transfer fluids might include perfluorocarbons (like the Krytox XHT mentioned earlier), molten salts, and molten metals.

In particular, ordinary tin-lead 63/37 solder melts at 183°, doesn't boil until 1500°, and doesn't suffer chemical breakdown.

It does tend to dissolve metals — tin quite rapidly, of course, but also gold, silver, and copper at significant speeds, and even nickel some 25 times slower than copper. In the case of copper, the dissolution diminishes rapidly once the solder is saturated with dissolved copper (at a fairly low level), as is done in SAVBIT solder. Presumably this also applies to other metals it can dissolve, too. People add nickel to solder to keep it from dissolving iron. Phosphorus counteracts this effect and increases stainless steel erosion — in lead-free tin-copper solder.

There's debate about whether tin-lead solder is capable of even *joining* steel, which I thought might imply that it has a very hard time *dissolving* steel as well. Other alloys (lead-silver, cadmium- silver, tin-silver, and maybe tin-bismuth) supposedly work well for joining steel. But apparently tin-lead solder does work with steel if you use acid flux.

Molten solder in wave-soldering equipment is normally contained in stainless-steel equipment, which suffers erosion over a period of months, but this is at lower temperatures than what I'm discussing here. One study I found, though, found about 0.25 mm erosion depth on stainless steel 304 (and a bit less on 316) after 384 hours in a 350° lead-free solder, which seems slow enough that the tool could

still be useful.

Type metal is a variant that has the desirable property that it doesn't have a sudden change in volume when it melts. It's a tin-lead solder that also includes antimony; the traditional composition is 18% tin, 28% antimony, 54% lead, while the eutectic is 4% tin, 12% antimony, 84% lead, which melts at 240°. (Elemental antimony is fairly nontoxic, although its compounds are deadly, and its fumes are bad for you too.) Legend has it that type metal is very poor at dissolving iron.

Scrap type metal from Linotypes and the like is available on MercadoLibre at AR$55/kg (US$3.60/kg).

If using a coolant that melts above room temperature, then to keep the machine from freezing solid permanently the first time you turn it off, you could thread a resistance heating element all the way through the pipe, probably with insulation around it. That way, when you turn the element on, it will melt a path around it through the tube, allowing the coolant to begin to flow.

Mail reader

Kragen Javier Sitaker, 2018-04-27 (updated 2018-06-18) (7 minutes)

Several times I've started writing a mail reader. More than once I've gotten something I used for a while, then stopped.

Shape of the problem

I currently have 4.8 gigabytes of incoming email on adjuvant, which goes back to 2014, and a 1-gibibyte sample on my laptop. My laptop's SSD is capable of 77 MB/s, or 13 seconds per gigabyte.

Compression for faster access

lz4 can fail to compress 300 MB/s on its CPU, or compress a gibibyte of this mail by about 40% in about 20.0 seconds, of which only 3.1 are user time (suggesting the other 16.9 were waiting on the SSD). The 818-megabyte compressed file decompressed in 2.0 user seconds and 12.2 wallclock seconds. This suggests using LZ4 is capable of getting a modest storage speedup and saving about a gigabyte.

gzip -1 gets it down to 638 megabytes, and can decompress it in 18.3 seconds (16 seconds user, 2.5 seconds kernel). This suggests that gzip is actually nearly as fast as the SSD! pigz actually gets the time down to 11.6 seconds, suggesting that gzip -1 is actually *faster* than lz4 -1 here, because it gets substantially better compression and so can more effectively use the disk bandwidth.

lz4 -9 takes 78" to compress the file down to 779 megabytes; the resulting file can be decompressed in 3.1 seconds from warm cache, but reading it from the disk still takes 14 seconds.

pigz -9 compresses the file to 610 megabytes in 35", and the resulting file decompresses (with pigz) in 13.4" (10.6" user, 1.4" system).

In sum, compression might be some kind of a win, but probably not much of one, and it's easy for it to be a loss. lz4 -1 is probably pretty reasonable, but it's still slower than memcpy.

Linear access speeds

I'd like to be able to do full-text search on the mailbox in a reasonable amount of time. `grep ajgwio` takes 1.0 user seconds and 1.0 system seconds (and 14.4 wallclock seconds) to read through the gibibyte (already in memory!) and find no matches.

`grep '^From '` takes 110 milliseconds and finds 5838 messages, giving a mean message size of a bit under 200K. However, this is wrong; `grep -a '^From '` gives 41630 messages and takes 870 ms wallclock, 500 ms user and 480 ms kernel, providing a more reasonable message size of 26K.

`grep -a ajgw` yields some 25 random hits in 1300 ms wallclock, 820 ms user, 430 ms system. These are entirely in base64 data. `grep -a 'zines de villa urquiza'`, a literal string that occurs in four subject lines, takes 730 ms wallclock, 260 ms user, 450 ms system. It seems to be reading with read(), initially in 32768-byte chunks and eventually in half-mebibyte chunks, with some 17000 system calls, which seems like an inefficient approach in this case, but it does seem to be taking

substantially less time with the longer search string. And it avoids the problems of mmap(). Even `LANG=C fgrep -Ua 'We still need more volunteers to watch the Tor community and report'` still takes 620 ms wallclock, 230 ms user, 400 ms system.

Previous experiments on this laptop suggest 300 ns per system call plus 171 ps per byte, or 171 ns per kilobyte. This suggests copying the data takes 184 milliseconds, and doing the system call entries and exits should take about another 5 milliseconds. This is about half of the actual kernel time alone observed, so perhaps part of the problem is mere cache misses.

Previous experiments on this laptop have found a memcpy speed of about 3 gigabytes/second for files of a few kilobytes and 1.9 gigabytes/second for larger files, which seems like it could easily account for the extra runtime.

Probably this indicates that we could scan through data already in RAM at 6 gigabytes per second, but the laptop only has 4 gigabytes of RAM, so the mailbox won't fit in RAM. And reading it into RAM would take nearly a minute! Even with pigz, it would take 45 seconds. That's not an acceptable keystroke response time.

Storing an index in LevelDB

It's clear that I can't get by with just linear scans for searching, not with almost five gigabytes of email.

LevelDB on my laptop can insert 62 million small records into a LevelDB in 3'24". The result is 516 megabytes, or 8.3 bytes per record. I haven't measured how many queries per second it can handle but I assume it's pretty adequate.

I think this is probably inadequate performance for insertion, though, even assuming it remains constant for larger datasets. A somewhat typical message contains 250 words of body text (more or less 250 unique, too) in 5 kilobytes of message; perhaps a mean message contains 1000 unique words. Then LevelDB will be able to handle the insertion of only about 300 messages per second. The 41630 messages in my sample gibibyte would take a bit over two minutes; the whole mailbox would take about ten minutes.

Actually, you know what? Ten minutes to index my last three years of mail doesn't sound unusably slow. I should give it a try.

Syncing

I need to be able to get the mail from the server, which means running some kind of code on the server. I could upload a separate Python program, or I could send a bunch of shell commands, including over a pipe to an ssh process or something. Or I could do something really weird like upload bytecode for some kind of immutable virtual machine.

I also need some way to limit the amount of disk space I use locally.

Languages

For writing workflow stuff I probably want Python, or maybe JS or something. But for handling large volumes of data quickly, or for that matter for guaranteed UI responsiveness, I probably don't. Certainly not Python, not even PyPy I think.

I don't know how much of a hassle it would be to call LevelDB via ctypes or cffi. It's pretty easy in C++, and writing a little C-callable

C++ API that does what I need should be pretty easy, too. And then calling it from ctypes should be pretty easy.

...there's already a LevelDB binding for Python!

Topics

Simplifying code with concurrent iteration

Kragen Javier Sitaker, 2014-04-24 (2 minutes)

An observation from Unix is that it's often more convenient to structure a computation as a set of concurrent processes, each applying some simple transformation to one or more data streams, than to force everything into a single thread.

I'm observing this right now in a $work project that is scraping data from a server, respecting API rate limits, where the explicit state machine that handles API errors is gradually getting more and more complicated. In a well-structured program, this state machine would be written as a composition of primitive actions using sequences, conditionals, and iteration, with the state of the state machine encoded in the program counter; but since each API response from the server is handled by a callback function, this is not straightforward.

A simple way to handle this is to spawn off a separate thread that has a blocking proxy object for the API. When it calls a method on the blocking proxy object, this sends a message to the server (via the callback thread if necessary) and waits until the callback thread gets a response, either success, error, or if necessary, a timeout. Then I can write my retry and looping logic in this other thread using normal structured control flow and block-structured local variables, instead of a passel of boolean variables and suchlike.

This would work well on this project, where I have just one thread — although I'm probably not going to do it, because I don't expect to modify that code enough more to justify such a rewrite — but there are some practical memory difficulties with large numbers of threads.

Hash feature detection

Kragen Javier Sitaker, 2015-09-17 (5 minutes)

Thinking about image registration and feature extraction, I thought: what about hashing?

In particular, think about a record player playing a scratched-up record, full of random crackles and pops, each due to a pit in the record surface left by the needle being shoved into it by long-ago dust. If you're looking for a particular location on the record, you can cross-correlate the audio stream with the specific sequence of crackles and pops at that location, and you are nearly sure to have a sharp peak at exactly the right point. This, in theory, allows you to determine the position of the turntable disc at that moment to within a fraction of a micron.

This won't work in its simple form if the playback speed is a little bit off — the distance between the pops in the pattern you're looking for will be off by more than the width of a pop, and so the correlation won't have a clear peak. But this can be remedied inexpensively, and save you the expense of running the full cross-correlation to boot.

Suppose our sample pattern is one second of audio. Take the strongest, say, five pops in that second. Typically, they'll be a decibel or so louder than the sixth-loudest pop, which is a decibel or so louder than the seventh-loudest, and so on. Now, take the last 1.5 seconds of audio and find the loudest eight pops in it, and try matching all 56 three-pop subsequences of those eight against all 10 three-pop subsequences of those five you're looking for, 560 comparisons in all. The candidate pops might not be in exactly the same order of loudness, because some of them might be very similar to the same level, and there is noise in the playback, but because the pops are so much louder than the rest of the recording, it's almost certain that there will be a match. And because you're matching a three-pop sequence, you have a ratio of intervals that have to match pretty closely between the pattern and the signal, according to some kind of time stretch. And that gives you a probably-unique candidate alignment on which to try the whole correlation.

You can adjust the values of 8, 5, 3, and 1.5, of course. Increasing 8 and 5 will increase the number of candidate alignments to try, thus increasing the chances of finding the correct alignment; increasing the value of 3 will increase the number at first and then decrease it. Increasing 1.5 will increase the amount of scale variation that can be tolerated, but at the risk of missing a match unless you increase 8, 5, 3, or all three.

(Of course, you can do much better if you have a pretty good idea where you are in the record groove to start with, because then you just need to adjust your estimate of the velocity up or down a bit as each pop or crackle goes by.)

In a sense, image feature detection algorithms are an attempt to superimpose crackles and pops onto images in such a way that their position, relative to the underlying image, remains precise in the face of a panoply of insults: from noise to 2-D rotation to scaling to 3-D rotation obscuring part of an object.

But in some sense, at least in the one-dimensional world where we

don't need to worry about rotations in two or three dimensions, it seems like it should be trivial to develop a robust feature-detection algorithm. Nearly any function should work as long as it's local, not totally disrupted by noise, and positions itself relatively precisely. For example, if we apply a couple of noise-reduction filters (maybe a median filter, if speckle noise is not actually signal as in the above example, and a Gaussian convolution) the last few peaks or zero-crossings should often be pretty stable; perhaps we can hash the distances between them, or the ratios of distances between them, perhaps quantized a bit. Then we can apply a filter to this stream of hash values: for example, ignore the hash unless its last 10 bits are zeroes. This should make our "pops" sufficiently sparse to be useful.

If we're trying to apply such an approach to images, it might be useful to do it by tracing paths in the image, using some kind of convergent approach, like maybe ascending the gradient of the absolute value of the gradient, thus seeking to walk along edges.

Reconstructing a 3-D Lambertian surface from video with a moving light source

Kragen Javier Sitaker, 2016-09-16 (1 minute)

Lambertian surface reconstruction

To 3-d scan a Lambertian surface with a plain video camera and a light:

Move a point source of light near a Lambertian surface as you capture video from a camera stationary relative to the surface. Pixelwise differences between frames show the effect of removing the source from one frame and adding it to another. Hypothetically, ambient diffusion from other reflectors contributes negligibly to this difference, since the source is close to the surface being scanned. Given an estimated depth for each pixel and per-frame estimated light locations in 3-space, you can compute a simulated frame difference, which you can compare to the real frame difference to get an error. Each pixel of this error is a nonlinear (?) function of ten unknowns: the two x, y, z of the light locations, the estimated depth to that pixel, the surface gradient depth at that object point, and the estimated reflectance at that point. Given just one such error image, we can optimize the two light locations to minimize the error using gradient descent, holding the estimated depths fixed, or we can optimize the depths

Hammering toolhead

Kragen Javier Sitaker, 2017-08-18 (6 minutes)

Using a hammer-and-chisel approach should enable new kinds of lightweight, portable, but slow CNC machine tools, by way of eliminating toolhead side forces during positioning.

One of the greatest challenges in precision machining is toolhead side forces. A 3-D printer can get by with a low-rigidity frame, open-loop control with stepper motors, and triangular-thread (V-thread) leadscrews in large part because the forces at its toolhead are so small. But cutting metal with edged tools or abrasives, even very sharp edged tools, produces substantial side forces, and these forces change rapidly and even unpredictably as contact is established or contact angles change. Consequently, precision machining invariably uses closed-loop control and massive structural members to achieve the desired stiffness, and usually also uses ballscrews or acme-thread leadscrews.

I've speculated previously that it with sufficiently rapid control systems, it will be possible to provide such stiffness "virtually", by countering a detected displacement with a larger opposing displacement in some actuator, effectively multiplying the rigidity of the frame by the ratio of displacements. But here I want to discuss a different approach, that of hammering.

A hammer or karate chop is a kind of simple machine: you apply a small force to the hammer over a large distance, and the hammer applies a large force to the work over a proportionally small distance. (Stevin and Galileo did not include the hammer in their list of simple machines, as they lacked, I think, the concept of kinetic energy.) Sufficiently rapid and precise feedback about the hammer's path allows you to control the point of impact precisely with low energy, but an alternative mechanism is the hammer-and-chisel mechanism used by an automatic center punch; this allows you to position the chisel as slowly and precisely as you like, then transmitting a hammer strike anywhere on the chisel head precisely to the chisel tip.

The hammer-and-chisel mechanism has been used for this purpose since the Paleolithic, when it enabled soft, squishy human hands to precisely shape rocks harder than steel.

At one point I was pretty skeptical of hammering on things to precisely shape or fix them, since there's inevitably a shock produced at the time of impact, and that shock can damage things as it propagates through the rest of the structure. But eventually I learned that hammering is, in many cases, safer and more precise than applying a large force more slowly through an elastic frame; applying a force F through a mechanism with stiffness k requires building up an energy $\frac{1}{2}F^2/k$. If the resistance diminishes once initial resistance is overcome, as in solid friction and many kinds of material fracture, this energy is released all at once in an uncontrolled fashion. By contrast, a hammer blow can have an arbitrarily small energy, and the energy *at a given force* is limited only by the stiffness of the chisel and hammer head themselves, which can be made orders of magnitude smaller than the stiffness of an entire frame.

This very feature is one of the reasons for the use of automatic

center punches: their hammer energy is the same on every stroke, so every divot has fairly precisely the same depth.

You could imagine a CNC machine that precisely repositioned a chisel several times a second under very low toolhead forces, striking the chisel with a hammer separately moved with higher, but still fairly low, forces, in order to cut or form a piece of material by applying a precisely controlled amount of energy with a very large force at a precisely controlled location. Wood chisels have been used with this technique by carpenters to make precise cuts in wood since the paleolithic.

As the hammer approaches the chisel, it must of course be held in some kind of mechanism to apply force to it, which means that it needs some non-negligible stiffness to the chisel and workpiece. However, at the point that it actually strikes the chisel, it is not necessary for it to be held with any stiffness in the axis in which it strikes the chisel. It could, for example, be sliding down a tube under its own momentum, or held with a negative-stiffness cancelation mechanism like that used to isolate the LIGO from vibration. Such an expedient could prevent the shock of impact from being transmitted back into the struture holding the hammer, which would introduce a vibrational impulse into the machine frame.

For metal cutting, it probably is not possible to reach the optimal cutting speed with this approach; recall, as cutting speeds go up, up to a point, tool life goes up too, because the machine is cutting hot metal which applies less force to the cutting edge, wearing it less. (I think it also is more efective at producing a built-up edge, which worsens cutting precision but decreases wear.) So we should expect that cutting tools used in this way will not last as long as cutting tools used in the traditional cutting mode on a lathe with continuous movement. Milling-machine cutting points (whether inserts or just flute edges) are typically used in a similar discontinuous-cutting mode, but the metal of the workpiece does not have time to cool completely between strokes.

- Magic sinewave filter (p. 200) 2019-12-17 (6 minutes)
- Sorting in logic (p. 498) 2019-12-28 (2 minutes)

Notes concerning “Aliasing”

• Randomizing delta-sigma conversion to eliminate aliasing (p. 2834) 2014-04-24 (7 minutes)
• Accelerating convolution and correlation with short periodic waveforms using OLAP marginal prefix sums (p. 895) 2018-06-05 (4 minutes)
• Time domain analog chaos (p. 2198) 2018-10-28 (4 minutes)
• Antialiased line drawing (p. 1803) 2018-11-13 (updated 2019-09-01) (4 minutes)

Notes concerning “Alternate history”

• Steampunk spintronics: magnetoresistive relay logic? (p. 1315) 2013-05-17 (15 minutes)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• Saturation detector (p. 1588) 2013-05-17 (3 minutes)
• An extremely simple electromechanical state machine (p. 50) 2014-04-24 (16 minutes)
• Alien game challenge (p. 2313) 2015-09-03 (6 minutes)
• Vitruvius could have taken photographs (p. 992) 2016-07-30 (1 minute)
• A plotter language of 9-bit bytes (p. 2154) 2017-05-29 (updated 2017-06-01) (11 minutes)
• Wang tile font (p. 1463) 2018-08-16 (5 minutes)
• Gradient pixels (p. 2202) 2018-08-16 (updated 2018-10-28) (9 minutes)
• Hall-effect Wheatstone bridges for impractical steampunk electronic logic gates (p. 2351) 2019-04-24 (2 minutes)

Notes concerning “Anatomy”

- Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) 2014-07-16 (updated 2019-08-21) (14 minutes)
- Intermittent fluid flow for heat transport (p. 521) 2019-07-10 (4 minutes)

Notes concerning “Android”

- Fast geographical maps on Android (p. 455) 2015-10-16 (9 minutes)
- Notes on local file browsing (p. 484) 2019-09-15 (updated 2019-09-28) (4 minutes)

Notes concerning “Anytime algorithms”

• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Anytime realtime (p. 803) 2016-04-22 (4 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Affine arithmetic optimization (p. 2801) 2017-07-19 (updated 2019-09-15) (3 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• Using the method of secants for general optimization (p. 1773) 2019-07-22 (updated 2019-11-26) (13 minutes)

Notes concerning “APL”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• A stack of coordinate contexts (p. 2987) 2007 to 2009 (9 minutes)
• Index set inference or domain inference for programming with indexed families (p. 1434) 2007 to 2009 (updated 2019-05-05) (27 minutes)
• APL with typed indices (p. 3264) 2013-05-17 (11 minutes)
• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• Relational modeling and APL (p. 1217) 2019-05-20 (updated 2019-05-21) (5 minutes)
• Observable transaction possibilities (p. 2086) 2019-06-15 (10 minutes)
• Reducing the cost of self-verifying arithmetic with array operations (p. 2205) 2019-06-23 (15 minutes)
• A formal language for defining implicitly parameterized functions (p. 144) 2019-09-05 (updated 2019-09-30) (29 minutes)

Notes concerning "Approximation"

• Differentiable neighborhood regression (p. 2944) 2019-08-31 (15 minutes)
• Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) 2019-08-31 (updated 2019-09-08) (28 minutes)

Notes concerning "Archival"

• Copyright status of the Oxford English Dictionary: relevant data (p. 82) 2007 to 2009 (3 minutes)
• Instant hypertext (p. 630) 2013-05-17 (updated 2013-05-20) (14 minutes)
• Holographic archival (p. 766) 2014-04-24 (10 minutes)
• Offline datasets (p. 599) 2014-04-24 (15 minutes)
• Archival transparencies (p. 1345) 2014-06-05 (updated 2014-06-29) (7 minutes)
• The Dontmove archival virtual machine (p. 2113) 2014-06-29 (5 minutes)
• Archival with a universal virtual computer (UVC) (p. 399) 2014-06-29 (17 minutes)
• XCHG: An Archival Swap Machine (p. 2997) 2014-06-29 (7 minutes)
• A mechano-optical vector display for animation archival (p. 3047) 2014-12-28 (updated 2015-09-03) (28 minutes)
• Quadratic opacity holograms (p. 3073) 2015-09-03 (7 minutes)
• Can you read the lunar lander's plaque from Earth? Or write a new one? (p. 125) 2015-09-03 (9 minutes)
• Viral wiki (p. 1024) 2015-10-15 (3 minutes)
• Designing an archival virtual machine (p. 3203) 2016-05-12 (6 minutes)
• Wikipedia people (p. 948) 2016-06-01 (6 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• Algorithm time capsule (p. 2263) 2016-08-11 (1 minute)
• Executable scholarship, or algorithmic scholarly communication (p. 2137) 2016-08-11 (13 minutes)
• Rosetta opacity hologram (p. 98) 2016-09-05 (8 minutes)
• Distributed computing environment (p. 776) 2017-07-19 (8 minutes)
• Piezoelectric engraving (p. 1070) 2017-07-19 (4 minutes)
• Notes on scraping the Codex Arundel to preserve it (p. 330) 2017-08-22 (1 minute)
• Data archival on gold leaf or Mylar with DVD-writer lasers or sparks (p. 1455) 2018-04-27 (5 minutes)
• Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952) 2018-04-27 (4 minutes)
• Caustics (p. 1619) 2018-08-18 (updated 2019-11-08) (8 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• Bootstrapping instruction set (p. 459) 2018-11-06 (updated 2019-05-03) (19 minutes)
• Archival of hypertext with arbitrary interactive programs: a design outline (p. 2472) 2018-11-09 (3 minutes)
• Atmospheric pressure harvesting phoenix egg (p. 2081) 2018-11-23 (14 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)

• Raid zim (p. 253) 2019-01-17 (updated 2019-02-08) (1 minute)
• Progressive revealment crypto (p. 2068) 2019-04-10 (2 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)
• Some extensions of William Beaty's scratch holograms (p. 2536) 2019-07-11 (9 minutes)

Notes concerning “Arduino”

• Randomizing delta-sigma conversion to eliminate aliasing (p. 2834) 2014-04-24 (7 minutes)
• Arduino radio (p. 169) 2016-07-30 (4 minutes)
• Could you do DDS of comprehensible radio signals with an Arduino? (p. 1829) 2017-03-31 (4 minutes)
• Urban autarkic network (p. 1026) 2018-04-27 (1 minute)
• Arduino curve tracer (p. 591) 2018-06-17 (10 minutes)
• Arduino safety (p. 3015) 2018-12-10 (4 minutes)

Notes concerning “Argentina”

• Smoky day (p. 3010) 2008-04-19 (4 minutes)
• Personal notes from 2013-06-06 (p. 2673) 2013-06-06 (updated 2014-04-24) (11 minutes)
• Some personal notes from February 2014 (p. 2134) 2014-02-13 (8 minutes)
• A Sunday in 2014 (p. 1089) 2014-02-24 (3 minutes)
• Jim Weirich’s death and my daily life (p. 829) 2014-04-24 (5 minutes)
• Notes from a Buenos Aires blackout, summer 2013-2014 (p. 267) 2014-04-24 (15 minutes)
• Building a resilient network out of litter (p. 2107) 2014-04-24 (4 minutes)
• Ostinatto (p. 2780) 2014-04-24 (4 minutes)
• José, the Galician mover (p. 3076) 2015-11-09 (2 minutes)
• Phase-change heat reservoirs for household climate control (p. 2257) 2016-06-14 (updated 2016-06-17) (13 minutes)
• A minimal-cost diet with adequate nutrition in Argentina in 2017 is US$0.67 per day (p. 3206) 2017-06-15 (4 minutes)
• Categorical zero sum prohibition (p. 2553) 2019-05-27 (updated 2019-06-01) (23 minutes)

Notes concerning “Arrays”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• A stack of coordinate contexts (p. 2987) 2007 to 2009 (9 minutes)
• Designing a Scheme for APL-like array computations, like Lush (p. 661) 2007 to 2009 (4 minutes)
• Index set inference or domain inference for programming with indexed families (p. 1434) 2007 to 2009 (updated 2019-05-05) (27 minutes)
• APL with typed indices (p. 3264) 2013-05-17 (11 minutes)
• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• Ndarray java (p. 2261) 2015-05-28 (1 minute)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Raggedcolumns (p. 2703) 2015-08-28 (3 minutes)
• Counting the number of spaces to the left in parallel (p. 1067) 2016-10-11 (5 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• JIT-compiling array computation graphs in JS (p. 155) 2017-07-19 (1 minute)
• A minimal window system (p. 1545) 2018-04-27 (updated 2018-10-26) (12 minutes)
• Composing code gobbets with implicit dependencies (p. 2437) 2018-04-27 (updated 2019-05-21) (3 minutes)
• Relational modeling and APL (p. 1217) 2019-05-20 (updated 2019-05-21) (5 minutes)
• Observable transaction possibilities (p. 2086) 2019-06-15 (10 minutes)
• Reducing the cost of self-verifying arithmetic with array operations (p. 2205) 2019-06-23 (15 minutes)

Notes concerning “Asciibetical homomorphism”

- String tuple encoding (p. 2419) 2017-04-28 (2 minutes)
- ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)

Notes concerning "Assembly language"

• Notes on reading eForth 1.0 for the 8086 (p. 541) 2007 to 2009 (5 minutes)
• Forth looping (p. 2025) 2007 to 2009 (16 minutes)
• Interesting features of the GNU assembler Gas (p. 3000) 2007 to 2009 (2 minutes)
• Maybe Counting Characters in UTF-8 Strings Isn't Fast After All! (p. 2992) 2007 to 2009 (15 minutes)
• Optimizing the Visitor pattern on the DOM using Quaject-style dynamic code generation (p. 1508) 2013-05-17 (updated 2013-05-20) (21 minutes)
• Distinguishing natural languages with 3-grams of characters (p. 2953) 2013-05-17 (updated 2013-05-20) (7 minutes)
• The Dontmove archival virtual machine (p. 2113) 2014-06-29 (5 minutes)
• Implementing flatMap in terms of call/cc, as in Raph Levien's Io (p. 3248) 2015-09-03 (3 minutes)
• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• What's the dumbest register allocator that might give you reasonable performance? (p. 2596) 2016-10-11 (15 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Golomb-coding operands as belt offsets likely won't increase code density much (p. 1605) 2017-06-15 (updated 2017-06-20) (6 minutes)

• Bit difference array (p. 1748) 2018-10-28 (10 minutes)
• A two-operand calculator supporting programming by demonstration (p. 2387) 2018-12-11 (22 minutes)
• Evaluating DSP operations in minimal buffer space by pipelining (p. 321) 2018-12-18 (updated 2018-12-19) (20 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)
• Assembler bootstrapping (p. 2922) 2019-07-18 (updated 2019-12-08) (16 minutes)
• Techniques for, e.g., avoiding indexed-offset addressing on the 8080 (p. 3166) 2019-07-20 (updated 2019-07-24) (27 minutes)
• An 8080 opcode map in octal (p. 1059) 2019-08-28 (updated 2019-11-24) (11 minutes)
• Notes on Óscar Toledo G.'s bootOS (p. 277) 2019-10-07 (updated 2019-10-08) (28 minutes)
• Forth assembling (p. 940) 2019-12-08 (updated 2019-12-11) (18 minutes)
• Immediate-mode PEG parsers in assembly language (p. 365) 2019-12-10 (updated 2019-12-11) (21 minutes)
• My very first toddling steps in ARM assembly language (p. 1684)

2019-12-10 (updated 2019-12-13) (46 minutes)
• Can you eliminate backpatching? (p. 1769) 2019-12-17 (8 minutes)

Notes concerning “Astronomy”

• Solar system scale model (p. 2678) 2017-04-18 (1 minute)
• Seeing the Apollo flags from Earth would require a telescope 27× the size of the Gran Telescopio Canarias (p. 309) 2019-04-10 (updated 2019-04-16) (2 minutes)

Notes concerning “Audio”

• Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
• Alastair thesis review (p. 1784) 2013-05-17 (1 minute)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• A unicast phased-array ultrasonic “radio” (p. 3077) 2013-05-17 (4 minutes)
• Square wave synthesis (p. 3200) 2014-02-24 (2 minutes)
• Randomizing delta-sigma conversion to eliminate aliasing (p. 2834) 2014-04-24 (7 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• Rhythm codes (p. 2375) 2015-09-03 (4 minutes)
• Would Synthgramelodia make a good base for livecoding music? (p. 2540) 2015-09-03 (8 minutes)
• Convolution applications (p. 2930) 2015-09-07 (updated 2019-08-14) (9 minutes)
• Hash feature detection (p. 3294) 2015-09-17 (5 minutes)
• Piano synthesis (p. 1655) 2015-09-17 (updated 2017-07-19) (6 minutes)
• Virtual instruments (p. 658) 2015-11-09 (3 minutes)
• How can we build an efficient microcontroller-based amplifier? (p. 2821) 2016-07-13 (5 minutes)
• What’s the dumbest register allocator that might give you reasonable performance? (p. 2596) 2016-10-11 (15 minutes)
• The Magic Kazoo: a synthesizer you stick in your mouth (p. 1873) 2017-04-04 (updated 2019-05-12) (6 minutes)

• Wang tile addition (p. 3201) 2017-02-16 (3 minutes)
• Tagging parsers (p. 208) 2018-11-23 (updated 2018-12-10) (9 minutes)
• What can you build out of 256-byte ROMs? (p. 1468) 2018-12-02 (1 minute)
• Turning a delay line into a counter with a FSM (p. 1680) 2018-12-10 (1 minute)
• Profile-guided parser optimization should enable parsing of gigabytes per second (p. 2283) 2019-05-23 (8 minutes)

Notes concerning “Automatic differentiation”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Affine arithmetic has quadratic convergence when interval arithmetic has linear convergence (p. 1029) 2016-08-24 (updated 2017-01-18) (10 minutes)
• $1 recognizer diagrams (p. 1264) 2019-08-11 (updated 2019-10-24) (15 minutes)
• Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) 2019-08-17 (updated 2019-09-15) (15 minutes)
• Fast mathematical optimization with affine arithmetic (p. 3163) 2019-09-15 (5 minutes)
• Some thoughts on SDF raymarching (p. 312) 2019-11-11 (updated 2019-12-10) (31 minutes)

Notes concerning “AVR microcontrollers”

• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• You’re pretty much fucked if you want to build an oscilloscope on the AVR’s ADC (p. 1269) 2013-05-17 (3 minutes)
• A resistive-capacitive trackpad made from garbage and three ADC microcontroller pins (p. 852) 2013-05-17 (updated 2013-05-20) (17 minutes)
• The Tinkerer’s Tricorder (p. 72) 2013-05-17 (updated 2014-04-24) (27 minutes)
• Arduino radio (p. 169) 2016-07-30 (4 minutes)
• Low-power microcontrollers for a low-power computer (p. 2602) 2016-09-06 (updated 2018-10-28) (18 minutes)
• Augmenting a slow precise ADC with a sloppy fast high-pass filtered parallel ADC (p. 1469) 2017-03-20 (2 minutes)
• Loading new firmware on an AVR (p. 88) 2017-03-31 (3 minutes)
• Could you do DDS of comprehensible radio signals with an Arduino? (p. 1829) 2017-03-31 (4 minutes)
• Can you bitbang USB with an ATMega’s RC oscillator? (p. 1990) 2017-04-04 (1 minute)
• Minimum hardware and software to get a flexible notetaking device running (p. 535) 2017-04-28 (4 minutes)
• An RPN CPU instruction set doubling as user interface (p. 177) 2017-07-19 (updated 2019-07-10) (21 minutes)
• Bench trash power supply (p. 1457) 2018-04-27 (9 minutes)
• Arduino curve tracer (p. 591) 2018-06-17 (10 minutes)
• Turning off the power supply for every sample to reduce noise (p. 239) 2018-06-18 (2 minutes)
• The TWI and I²C buses and better alternatives like CAN and RS-485 (p. 1638) 2018-06-28 (updated 2018-07-05) (24 minutes)
• The Adafruit Feather (p. 2966) 2018-06-30 (1 minute)
• Notes on the STM32 microcontroller family (p. 3176) 2018-06-30 (updated 2018-11-12) (42 minutes)
• Arduino safety (p. 3015) 2018-12-10 (4 minutes)
• Really simple lab power supply (p. 240) 2019-12-10 (7 minutes)

Notes concerning “Backtracking”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• Immediate-mode PEG parsers in assembly language (p. 365) 2019-12-10 (updated 2019-12-11) (21 minutes)

Notes concerning “Barcode”

- Barcode receipts (p. 2359) 2007 to 2009 (6 minutes)
- A 2007 overview of matrix barcodes (p. 1094) 2007 to 2009 (2 minutes)

Notes concerning “Batteries”

• Bike charger (p. 2099) 2014-04-24 (2 minutes)
• Zombie contingency plan (p. 2656) 2017-07-19 (9 minutes)
• Lithium battery welder (p. 2846) 2018-06-21 (updated 2019-01-22) (2 minutes)
• Balcony battery (p. 2377) 2019-02-11 (updated 2019-12-06) (6 minutes)
• Terrestrial lithium supplies provide adequate energy storage to reach Kardashev Type 1 (p. 2123) 2019-07-25 (6 minutes)
• Energy storage efficiency (p. 1300) 2019-07-30 (4 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Bicicleta”

• Bicicleta maps (p. 582) 2007 to 2009 (2 minutes)
• Nested inheritance (p. 340) 2007 to 2009 (2 minutes)
• OMeta contains Wadler's "Views" (p. 842) 2007 to 2009 (updated 2019-05-20) (13 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)

Notes concerning “Binary relations”

• Twingler (p. 2547) 2014-02-24 (7 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Time series data type (p. 304) 2016-08-26 (3 minutes)
• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• Binate and KANREN (p. 3189) 2018-12-02 (3 minutes)

Notes concerning “Binate”

- Efficiently querying a log of everything that ever happened (p. 2506) 2015-09-03 (7 minutes)
- Term rewriting (p. 3221) 2017-07-19 (3 minutes)
- Binate and KANREN (p. 3189) 2018-12-02 (3 minutes)

Notes concerning “Bitcoin”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• State of the world 2016 (p. 2973) 2016-09-05 (10 minutes)
• What are Bitcoin’s uses other than sidestepping the law? (p. 2159) 2019-03-11 (updated 2019-07-05) (6 minutes)
• Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333) 2019-07-03 (6 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)

Notes concerning “BitTorrent”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Hash gossip exchange (p. 1470) 2015-11-19 (4 minutes)

Notes concerning “Bokeh”

• Real-time bokeh algorithms, and other convolution tricks (p. 2661) 2018-12-18 (updated 2019-08-15) (23 minutes)
• Debokehfication (p. 473) 2019-09-01 (updated 2019-09-12) (4 minutes)
• Bokeh pointcasting (p. 92) 2019-09-08 (updated 2019-09-09) (16 minutes)

Notes concerning “Book reviews”

• Alastair thesis review (p. 1784) 2013-05-17 (1 minute)
• Review notes for Chris Anderson’s “Makers” (p. 1072) 2013-05-17 (5 minutes)
• The Stretch book is truly alien (p. 1888) 2018-11-27 (6 minutes)
• Commentaries on reading Engelbart’s “Augmenting Human Intellect” (p. 2091) 2018-12-24 (updated 2018-12-25) (25 minutes)
• A review of Wirth’s Project Oberon book (p. 431) 2019-02-04 (updated 2019-03-19) (63 minutes)

Notes concerning “Bootstrapping”

• IRC bots with object-oriented equational rewrite rules (p. 838) 2007 to 2009 (6 minutes)
• Making the CPU instruction set a usable interactive user interface (p. 59) 2015-09-17 (8 minutes)
• Exponential technology and capital (p. 406) 2016-02-18 (updated 2017-07-19) (8 minutes)
• The book written in itself (p. 2400) 2016-06-12 (updated 2016-06-14) (18 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• An RPN CPU instruction set doubling as user interface (p. 177) 2017-07-19 (updated 2019-07-10) (21 minutes)
• Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952) 2018-04-27 (4 minutes)
• Some notes on FullPliant and Pliant (p. 866) 2018-04-27 (9 minutes)
• Hand drawn font compositing (p. 1810) 2018-10-28 (2 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)
• Assembler bootstrapping (p. 2922) 2019-07-18 (updated 2019-12-08) (16 minutes)
• A homoiconic language with a finite-map-based data model rather than lists? (p. 2630) 2019-09-25 (updated 2019-09-28) (46 minutes)

Notes concerning “Bottles”

• Storing dry bulk foods in used Coke bottles (p. 2145) 2012-10-15 (updated 2012-10-21) (5 minutes)
• Food storage (p. 2706) 2013-05-11 (updated 2013-05-17) (54 minutes)
• Bottle washing (p. 921) 2014-04-24 (7 minutes)
• Comparison of the PCO-1810 and PCO-1881 plastic bottlecap standards (p. 3223) 2014-05-25 (updated 2016-07-27) (2 minutes)
• Zombie contingency plan (p. 2656) 2017-07-19 (9 minutes)
• Hot water bottles (p. 3066) 2018-07-14 (4 minutes)
• Mayonnaise (p. 1320) 2019-03-19 (updated 2019-06-10) (10 minutes)

Notes concerning “The Brainfuck esolang”

• Archival with a universal virtual computer (UVC) (p. 399) 2014-06-29 (17 minutes)
• XCHG: An Archival Swap Machine (p. 2997) 2014-06-29 (7 minutes)
• Designing an archival virtual machine (p. 3203) 2016-05-12 (6 minutes)
• Options for bootstrapping a compiler from a tiny compiler using Brainfuck (p. 2958) 2017-07-19 (2 minutes)
• Bootstrapping instruction set (p. 459) 2018-11-06 (updated 2019-05-03) (19 minutes)

Notes concerning “Browsers”

• What’s wrong with ../../? (p. 2304) 2007 to 2009 (2 minutes)
• Web prefetch (p. 3046) 2017-06-15 (1 minute)
• Minimal distributed streams (p. 1844) 2018-04-27 (5 minutes)
• Dercuano search (p. 1532) 2019-05-16 (2 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)
• Notes on local file browsing (p. 484) 2019-09-15 (updated 2019-09-28) (4 minutes)

Notes concerning “BubbleOS”

• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Minimal GUI libraries (p. 663) 2015-11-14 (updated 2015-11-15) (5 minutes)
• The book written in itself (p. 2400) 2016-06-12 (updated 2016-06-14) (18 minutes)
• MiniOS (p. 1091) 2016-12-28 (updated 2017-01-03) (6 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• A nonscriptable design for the Wercam windowing system (p. 3092) 2018-10-26 (updated 2018-11-13) (6 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• Hand drawn font compositing (p. 1810) 2018-10-28 (2 minutes)
• Speculative plans for BubbleOS (p. 2128) 2018-10-28 (updated 2019-02-24) (12 minutes)
• Dilating letterforms (p. 651) 2018-11-04 (15 minutes)
• Leconscrip: a family of JS subsets for BubbleOS (p. 2126) 2018-11-23 (2 minutes)
• IMGUI programming compared to Tcl/Tk (p. 2333) 2018-12-24 (updated 2018-12-31) (8 minutes)
• Yeso notes (p. 2585) 2018-12-25 (updated 2019-01-01) (11 minutes)
• IMGUI programming language (p. 103) 2019-01-01 (updated 2019-07-30) (21 minutes)
• A review of Wirth’s Project Oberon book (p. 431) 2019-02-04 (updated 2019-03-19) (63 minutes)

Notes concerning “Buddhism”

Notes concerning “Building blocks”

• Heckballs: a laser-cuttable MDF set of building blocks (p. 2782) 2016-08-17 (updated 2016-08-30) (24 minutes)
• Maximal-flexibility designs for printable building blocks (p. 1839) 2019-04-20 (18 minutes)
• Extending Heckballs (p. 3239) 2019-11-26 (6 minutes)

Notes concerning “Business cards”

Notes concerning “Bytecode”

• Using bytecode won’t make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Thredsnek: a tiny Python-flavored programming language (p. 1172) 2017-03-20 (7 minutes)
• A sketch of a minimalist bytecode for object-oriented languages (p. 1790) 2017-03-20 (updated 2017-06-20) (13 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• Bootstrapping instruction set (p. 459) 2018-11-06 (updated 2019-05-03) (19 minutes)

Notes concerning “Bytestrings”

• String tuple encoding (p. 2419) 2017-04-28 (2 minutes)
• ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)
• Byte prefix tuple space (p. 427) 2018-07-14 (updated 2018-07-15) (4 minutes)

Notes concerning “C ”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• Embedding objects inside other objects in memory, versus by-reference fields (p. 3112) 2014-02-24 (13 minutes)
• Linear trees (p. 1811) 2016-05-19 (updated 2016-05-20) (6 minutes)

Notes concerning “C”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• I think I understand how to use libart's antialiased rendering API now (p. 409) 2007 to 2009 (10 minutes)
• C bad (p. 2832) 2007 to 2009 (4 minutes)
• Error Reporting is Part of the Programmer's User Interface (p. 2323) 2007 to 2009 (18 minutes)
• Developing Win32 programs on Debian (p. 609) 2007 to 2009 (12 minutes)
• Win32 startup (p. 2439) 2007 to 2009 (2 minutes)
• Optimizing the Visitor pattern on the DOM using Quaject-style dynamic code generation (p. 1508) 2013-05-17 (updated 2013-05-20) (21 minutes)
• Distinguishing natural languages with 3-grams of characters (p. 2953) 2013-05-17 (updated 2013-05-20) (7 minutes)
• Embedding objects inside other objects in memory, versus by-reference fields (p. 3112) 2014-02-24 (13 minutes)
• How to generate unique IDs for IMGUI object persistence? (p. 2035) 2014-09-02 (3 minutes)

• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• Cobstrings (p. 1312) 2015-08-21 (updated 2015-08-31) (5 minutes)
• An IMGUI-style drawing API isn't necessarily just immediate-mode graphics (p. 2671) 2015-09-03 (3 minutes)
• Linear trees (p. 1811) 2016-05-19 (updated 2016-05-20) (6 minutes)
• Quicklayout (p. 2189) 2017-01-10 (updated 2017-01-18) (3 minutes)

• The history of NoSQL and dbm (p. 45) 2017-04-10 (16 minutes)
• Byte-stream pipe and antipipe façade objects for editor buffers (p. 950) 2017-04-10 (3 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)
• A minimal window system (p. 1545) 2018-04-27 (updated 2018-10-26) (12 minutes)
• Whistle detection (p. 357) 2018-06-06 (updated 2018-12-02) (18 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• Evaluating DSP operations in minimal buffer space by pipelining (p. 321) 2018-12-18 (updated 2018-12-19) (20 minutes)
• Yeso notes (p. 2585) 2018-12-25 (updated 2019-01-01) (11 minutes)
• IMGUI programming language (p. 103) 2019-01-01 (updated 2019-07-30) (21 minutes)
• Honk development (p. 1188) 2019-03-21 (2 minutes)
• Reducing the cost of self-verifying arithmetic with array operations

(p. 2205) 2019-06-23 (15 minutes)

Notes concerning “Caching”

• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• How can we usefully cache screen images for incrementalization? (p. 1077) 2013-05-17 (18 minutes)
• Simple dependencies in software (p. 2447) 2014-06-05 (9 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• Automatic dependency management (p. 881) 2015-05-28 (updated 2015-09-03) (5 minutes)
• Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870) 2015-05-28 (updated 2016-06-22) (16 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Memoize the stack (p. 2021) 2015-09-03 (5 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Amnesic hash tables for stochastically LRU memoization (p. 502) 2017-04-03 (1 minute)
• Parallel DFA execution (p. 2337) 2017-04-18 (9 minutes)
• Caching screen contents (p. 2362) 2017-06-14 (2 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)
• Cached SOA desktop (p. 2229) 2017-08-03 (updated 2018-10-26) (6 minutes)
• A minimal dependency processing system (p. 911) 2017-09-21 (3 minutes)
• Incremental recomputation (p. 1184) 2018-04-27 (12 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• Archival of hypertext with arbitrary interactive programs: a design outline (p. 2472) 2018-11-09 (3 minutes)
• Dehydrating processes and other interaction models (p. 3208) 2018-12-28 (updated 2019-01-01) (36 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)
• Dercuano backlinks (p. 475) 2019-05-22 (7 minutes)
• Profile-guided parser optimization should enable parsing of gigabytes per second (p. 2283) 2019-05-23 (8 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)

Notes concerning “Calculators”

• drag-and-drop calculator for touch devices (p. 1045) 2015-09-03 (5 minutes)
• Interactive calculator 0 (p. 1453) 2015-09-17 (2 minutes)
• Solar-powered portable computers (p. 2959) 2016-09-17 (updated 2018-10-28) (15 minutes)
• Usability of scientific calculators (p. 2379) 2016-09-29 (19 minutes)
• Notations for defining dynamical systems (p. 2872) 2016-10-03 (updated 2016-10-06) (6 minutes)
• Reflections on rebraining calculators with this RPN calculator code I just wrote (p. 1717) 2017-04-11 (4 minutes)
• Relational modeling (p. 1102) 2017-05-17 (updated 2017-06-01) (6 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Interactive calculator (p. 2771) 2018-04-26 (16 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• First impressions on using the μMath+ calculator program for Android (p. 195) 2019-05-21 (13 minutes)

Notes concerning “Calculus vaporis”

• Making the CPU instruction set a usable interactive user interface (p. 59) 2015-09-17 (8 minutes)
• Clanking replicators (p. 171) 2016-11-30 (3 minutes)

Notes concerning “Cameras”

• Vitruvius could have taken photographs (p. 992) 2016-07-30 (1 minute)
• Reconstructing a 3-D Lambertian surface from video with a moving light source (p. 3296) 2016-09-16 (1 minute)
• Servoing a V-plotter with a webcam? (p. 62) 2017-02-16 (3 minutes)
• Flying spot reilluminatable stage (p. 2358) 2017-05-15 (1 minute)
• Paper editing (p. 1761) 2017-06-15 (3 minutes)
• Seeing the Apollo flags from Earth would require a telescope 27× the size of the Gran Telescopio Canarias (p. 309) 2019-04-10 (updated 2019-04-16) (2 minutes)
• Photodiode camera (p. 2265) 2019-09-04 (16 minutes)
• Camera flash extrapolation (p. 2792) 2019-11-12 (6 minutes)

Notes concerning “Carbon capture”

- House scrubber (p. 248) 2016-09-06 (updated 2019-11-25) (13 minutes)
- Scrubber mask (p. 90) 2019-05-08 (5 minutes)

Notes concerning “Cardboard”

• String cutting cardboard (p. 515) 2016-06-30 (5 minutes)
• Cardboard furniture (p. 742) 2019-08-01 (updated 2019-08-11) (15 minutes)
• Sandwich theory (p. 2450) 2019-08-05 (updated 2019-08-29) (31 minutes)

Notes concerning “Cellular automata”

• Archival with a universal virtual computer (UVC) (p. 399) 2014-06-29 (17 minutes)
• Transmission line computer (p. 509) 2016-07-11 (updated 2019-07-23) (7 minutes)

Notes concerning “Caustics”

• Caustics (p. 1619) 2018-08-18 (updated 2019-11-08) (8 minutes)
• You can’t construct optical systems with arbitrary light transfers, but you can do some awesome shit (p. 981) 2018-09-10 (11 minutes)
• Caustic simulation (p. 1454) 2018-09-10 (updated 2018-11-04) (2 minutes)
• Gauzy shit (p. 2985) 2018-11-04 (4 minutes)
• Caustic business card (p. 255) 2019-04-08 (3 minutes)
• Analemma sundial (p. 1955) 2019-07-05 (11 minutes)

Notes concerning “Cement”

• Approaches to 3-D printing in sandstone (p. 1095) 2017-08-03 (5 minutes)
• Pythagorean cement pipes for your shower singing (p. 156) 2019-09-08 (updated 2019-09-09) (7 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)
• Berlinite gel (p. 848) 2019-12-14 (updated 2019-12-15) (10 minutes)

Notes concerning “Censorship”

• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• Solving the incentive problem for censorship-resistant DHTs (p. 923) 2016-09-07 (updated 2019-05-21) (3 minutes)

Notes concerning “Ceramic”

• Improvising high-temperature refractory materials for pottery kilns (p. 2701) 2013-05-17 (4 minutes)
• Waterproofing (p. 429) 2015-09-03 (4 minutes)
• Flux deposition for 3-D printing in glass and metals (p. 1366) 2016-07-03 (15 minutes)
• Solar dehumidifier (p. 717) 2016-08-11 (5 minutes)
• Regenerator gas kiln (p. 2653) 2016-09-05 (updated 2017-04-10) (9 minutes)
• Clay fabrication objectives (p. 2111) 2017-01-16 (updated 2017-01-17) (3 minutes)
• Millikiln (p. 2581) 2017-01-17 (updated 2017-03-02) (4 minutes)
• 3-D printing by flux deposition (p. 466) 2017-02-24 (updated 2019-07-27) (21 minutes)
• Vibratory powder delivery (p. 1747) 2017-02-25 (2 minutes)
• An electric furnace the size of a sake cup (p. 666) 2017-02-25 (updated 2017-03-02) (10 minutes)
• Approaches to 3-D printing in sandstone (p. 1095) 2017-08-03 (5 minutes)
• A brief note on autonomous cyclic fabrication systems from inorganic raw materials (p. 2965) 2018-04-27 (1 minute)
• Plasma glazing (p. 71) 2019-04-24 (1 minute)
• Cold plasma oxidation (p. 2406) 2019-05-01 (updated 2019-08-21) (7 minutes)
• Induction kiln (p. 2352) 2019-06-02 (19 minutes)
• Measuring the moisture content of coffee and other things with dielectric spectroscopy (p. 1033) 2019-07-16 (updated 2019-07-17) (28 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)

Notes concerning “Chat”

- Gaim group chat (p. 2677) 2007 to 2009 (3 minutes)
- Minimal distributed streams (p. 1844) 2018-04-27 (5 minutes)
- Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)

Notes concerning “Chemistry”

• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Bottle washing (p. 921) 2014-04-24 (7 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) 2015-09-11 (updated 2019-12-20) (49 minutes)
• Electrodeposition 3d printing (p. 1115) 2016-02-19 (4 minutes)
• Vitruvius could have taken photographs (p. 992) 2016-07-30 (1 minute)
• House scrubber (p. 248) 2016-09-06 (updated 2019-11-25) (13 minutes)
• Immersion plating of copper on iron with blue vitriol (p. 1099) 2016-09-24 (8 minutes)
• Freeze distillation at 1 Hz (p. 2796) 2016-10-06 (5 minutes)
• Coolants (p. 3235) 2017-07-04 (updated 2017-07-12) (11 minutes)
• Copper plating furniture (p. 1460) 2017-07-19 (updated 2017-09-01) (4 minutes)
• Home dehumidifier (p. 3131) 2018-05-20 (updated 2019-04-02) (12 minutes)
• Cold plasma oxidation (p. 2406) 2019-05-01 (updated 2019-08-21) (7 minutes)
• Scrubber mask (p. 90) 2019-05-08 (5 minutes)
• Reducing nighttime bedroom CO_2 levels (p. 478) 2019-07-08 (updated 2019-07-09) (14 minutes)
• Needle binder injection printing (p. 1492) 2019-08-05 (12 minutes)
• Why you can't run a diesel engine on water and diesel fuel with electrolysis (p. 345) 2019-11-24 (2 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)
• Berlinite gel (p. 848) 2019-12-14 (updated 2019-12-15) (10 minutes)
• Sulfuric acid dehydration printing (p. 174) 2019-12-18 (updated 2019-12-19) (3 minutes)

Notes concerning “Chifir”

• Designing an archival virtual machine (p. 3203) 2016-05-12 (6 minutes)
• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• Bootstrapping instruction set (p. 459) 2018-11-06 (updated 2019-05-03) (19 minutes)

Notes concerning “China”

• What are Bitcoin’s uses other than sidestepping the law? (p. 2159) 2019-03-11 (updated 2019-07-05) (6 minutes)
• Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)

Notes concerning “CIC or Hogenauer filters”

• Can you make a vocoder simpler using CIC filters? (p. 2006) 2017-06-28 (updated 2018-06-17) (2 minutes)
• Sparse filters (p. 834) 2018-12-02 (4 minutes)
• Evaluating DSP operations in minimal buffer space by pipelining (p. 321) 2018-12-18 (updated 2018-12-19) (20 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)
• Isotropic nonlinear texture effects for letterforms from a scale-space representation (p. 1609) 2019-09-10 (16 minutes)

Notes concerning “Circle midpoint algorithm”

• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• Midpoint method texture mapping (p. 1837) 2019-06-01 (3 minutes)

Notes concerning “Clay”

- Waterproofing (p. 429) 2015-09-03 (4 minutes)
- A brief note on autonomous cyclic fabrication systems from inorganic raw materials (p. 2965) 2018-04-27 (1 minute)
- Plasma glazing (p. 71) 2019-04-24 (1 minute)
- Cold plasma oxidation (p. 2406) 2019-05-01 (updated 2019-08-21) (7 minutes)

Notes concerning “Computer-mediated communication systems”

• Desbarrerarme: a UI for speaking to people (p. 186) 2015-09-03 (5 minutes)
• DHT bulletin board (p. 3001) 2016-09-07 (7 minutes)

Notes concerning “CoAP”

• What’s wrong with CoAP (p. 560) 2017-06-15 (3 minutes)
• Micro pubsub (p. 1504) 2017-06-15 (8 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)
• Compressing REST transactions with per-connection state (p. 1117) 2018-04-27 (11 minutes)

Notes concerning “Code generation”

• Optimizing the Visitor pattern on the DOM using Quaject-style dynamic code generation (p. 1508) 2013-05-17 (updated 2013-05-20) (21 minutes)
• Kernel code generation (p. 2302) 2019-07-02 (6 minutes)

Notes concerning “Communication”

• Cheap shit ultrawideband (p. 2776) 2013-05-17 (10 minutes)
• Time domain lightning triggering (p. 2534) 2013-05-17 (4 minutes)
• A unicast phased-array ultrasonic “radio” (p. 3077) 2013-05-17 (4 minutes)
• Constructing error-correcting codes using Hadamard transforms (p. 1474) 2013-05-17 (updated 2013-05-20) (22 minutes)
• Ultraslow radio for resilient global communication (p. 2071) 2013-05-17 (updated 2013-05-20) (26 minutes)
• Building a resilient network out of litter (p. 2107) 2014-04-24 (4 minutes)
• Rhythm codes (p. 2375) 2015-09-03 (4 minutes)
• Arduino radio (p. 169) 2016-07-30 (4 minutes)
• License-free femtowatt UHF radio transceiver ICs under a μJ per bit (p. 162) 2016-09-19 (5 minutes)
• Could you do DDS of comprehensible radio signals with an Arduino? (p. 1829) 2017-03-31 (4 minutes)
• Dumb vocoder (p. 1391) 2017-05-10 (2 minutes)
• Interactive bandwidth (p. 779) 2017-08-03 (2 minutes)
• Cassette tape capacity (p. 2079) 2018-04-27 (1 minute)
• Urban autarkic network (p. 1026) 2018-04-27 (1 minute)
• The Bleep ultrasonic modem for local data communication (p. 966) 2018-12-10 (updated 2018-12-11) (8 minutes)
• Broadcast ECC with graceful degradation, or avoiding the cliff effect (p. 2045) 2018-12-18 (5 minutes)
• Free space optical coding gain (p. 1244) 2019-05-08 (updated 2019-05-09) (4 minutes)
• Can you bitbang wireless communication between AVRs? How about AM-radio energy harvesting? (p. 2509) 2019-08-27 (updated 2019-08-28) (37 minutes)
• Transmitting low-power TV signals around your house via RF modulation with an SDR (p. 1950) 2019-12-01 (6 minutes)

Notes concerning “Compilers”

• Using bytecode won’t make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)
• Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009 (13 minutes)
• Simple system language (p. 1659) 2013-05-17 (7 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Parallel NFA evaluation (p. 2967) 2015-09-03 (updated 2015-10-01) (8 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• Prototyping stuff (p. 176) 2016-08-11 (1 minute)
• What’s the dumbest register allocator that might give you reasonable performance? (p. 2596) 2016-10-11 (15 minutes)
• Binary translation register maps (p. 2080) 2017-07-19 (1 minute)
• Options for bootstrapping a compiler from a tiny compiler using Brainfuck (p. 2958) 2017-07-19 (2 minutes)
• JIT-compiling array computation graphs in JS (p. 155) 2017-07-19 (1 minute)
• A review of Wirth’s Project Oberon book (p. 431) 2019-02-04 (updated 2019-03-19) (63 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)
• Techniques for, e.g., avoiding indexed-offset addressing on the 8080 (p. 3166) 2019-07-20 (updated 2019-07-24) (27 minutes)
• A homoiconic language with a finite-map-based data model rather than lists? (p. 2630) 2019-09-25 (updated 2019-09-28) (46 minutes)
• Dercuano grinding (p. 2475) 2019-10-01 (12 minutes)

Notes concerning “Compression”

• Git data (p. 2823) 2007 to 2009 (5 minutes)
• Git learnings (p. 3268) 2007 to 2009 (3 minutes)
• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• Instant hypertext (p. 630) 2013-05-17 (updated 2013-05-20) (14 minutes)
• Compression with second-order diffs (p. 2152) 2014-04-24 (3 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• Improving LZ77 compression with a RET bytecode (p. 964) 2016-04-05 (updated 2016-04-06) (3 minutes)
• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• Compact namespace sharing (p. 237) 2016-07-25 (7 minutes)
• Improving lossless image compression with basic machine learning algorithms (p. 2546) 2016-07-27 (2 minutes)
• A sketch of a minimalist bytecode for object-oriented languages (p. 1790) 2017-03-20 (updated 2017-06-20) (13 minutes)
• Secure, self-describing, self-delimiting serialization for Python (p. 243) 2017-04-11 (8 minutes)
• ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)
• Golomb-coding operands as belt offsets likely won’t increase code density much (p. 1605) 2017-06-15 (updated 2017-06-20) (6 minutes)

• Compressing a screen update with a tree of dirty bits (p. 303) 2017-06-21 (1 minute)
• CIC-filter fonts (p. 1229) 2017-06-28 (1 minute)
• Compact code cpu (p. 397) 2017-07-19 (3 minutes)
• Cassette tape capacity (p. 2079) 2018-04-27 (1 minute)
• Compressing REST transactions with per-connection state (p. 1117) 2018-04-27 (11 minutes)
• Mail reader (p. 3290) 2018-04-27 (updated 2018-06-18) (7 minutes)

• Wang tile font (p. 1463) 2018-08-16 (5 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)
• Dercuano drawings (p. 64) 2019-04-30 (updated 2019-05-30) (18 minutes)
• Some musings on applying Fitts’s Law to user interface design and data compression (p. 1164) 2019-05-06 (updated 2019-05-09) (27 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)

• Dercuano plotting (p. 2885) 2019-09-03 (updated 2019-09-05) (34 minutes)

Notes concerning “Concurrency”

• Enumerating binary trees and their elements (p. 1445) 2007 to 2009 (4 minutes)
• Iterative string formatting (p. 1392) 2013-05-17 (9 minutes)
• Simplifying code with concurrent iteration (p. 3293) 2014-04-24 (2 minutes)
• Simple dependencies in software (p. 2447) 2014-06-05 (9 minutes)
• Low-cost green thread locks (p. 252) 2016-09-06 (2 minutes)
• Minimal transaction system (p. 2460) 2017-09-21 (5 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• Byte prefix tuple space (p. 427) 2018-07-14 (updated 2018-07-15) (4 minutes)
• Transactional event handlers (p. 139) 2019-01-24 (14 minutes)

Notes concerning “Constraint satisfaction”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Generalizing my RPN calculator to support refactoring (p. 969) 2016-10-17 (12 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Relational modeling (p. 1102) 2017-05-17 (updated 2017-06-01) (6 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• Binate and KANREN (p. 3189) 2018-12-02 (3 minutes)
• Dercuano drawings (p. 64) 2019-04-30 (updated 2019-05-30) (18 minutes)
• Designing a drawing editor for well-factored drawings (p. 2115) 2019-05-07 (9 minutes)
• Relational modeling and APL (p. 1217) 2019-05-20 (updated 2019-05-21) (5 minutes)

Notes concerning “Construction”

• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Improvising high-temperature refractory materials for pottery kilns (p. 2701) 2013-05-17 (4 minutes)
• Waterproofing (p. 429) 2015-09-03 (4 minutes)
• Subterranean glazing (p. 1126) 2016-09-06 (25 minutes)
• Pythagorean cement pipes for your shower singing (p. 156) 2019-09-08 (updated 2019-09-09) (7 minutes)

Notes concerning “Content addressable”

• Git data (p. 2823) 2007 to 2009 (5 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• A simple content-addressable storage-server protocol (p. 774) 2015-09-03 (3 minutes)
• ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
• Blob computation (p. 2214) 2017-07-19 (2 minutes)
• Distributed computing environment (p. 776) 2017-07-19 (8 minutes)
• Archival of hypertext with arbitrary interactive programs: a design outline (p. 2472) 2018-11-09 (3 minutes)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)

Notes concerning “Control”

• Charge transfer servo (p. 3017) 2013-05-17 (2 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• 2016 outlook for automated fabrication and 3-D printing (p. 2316) 2016-08-11 (20 minutes)
• Starfield servo (p. 1709) 2016-08-30 (updated 2018-11-07) (13 minutes)
• Jello printing (p. 2426) 2016-12-14 (8 minutes)
• Servoing a V-plotter with a webcam? (p. 62) 2017-02-16 (3 minutes)
• High-precision control of low-stiffness sytems with bounded-Q resonances (p. 1002) 2017-05-29 (updated 2017-06-01) (4 minutes)
• Sous vide (p. 2921) 2019-04-02 (2 minutes)
• Derivative based control (p. 2829) 2019-11-12 (6 minutes)

Notes concerning “Convolution”

• Some speculative thoughts on DSP algorithms (p. 2590) 2014-04-24 (20 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Very fast FIR filtering with time-domain zero stuffing and splines (p. 1146) 2015-09-03 (updated 2015-09-07) (13 minutes)
• Convolution surface plotting (p. 2264) 2015-09-03 (updated 2015-09-13) (2 minutes)
• Convolution with intervals (p. 1044) 2015-09-07 (1 minute)
• Convolution applications (p. 2930) 2015-09-07 (updated 2019-08-14) (9 minutes)
• Recurrent comb cascade (p. 483) 2018-11-09 (updated 2018-11-10) (2 minutes)
• Real-time bokeh algorithms, and other convolution tricks (p. 2661) 2018-12-18 (updated 2019-08-15) (23 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)
• The miraculous low-rank SVD approximate convolution algorithm (p. 747) 2019-08-14 (updated 2019-08-15) (31 minutes)
• Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) 2019-08-31 (updated 2019-09-08) (28 minutes)
• A bag of candidate techniques for sparse filter design (p. 3250) 2019-09-01 (18 minutes)
• Isotropic nonlinear texture effects for letterforms from a scale-space representation (p. 1609) 2019-09-10 (16 minutes)
• Sparse sinc (p. 1880) 2019-09-15 (10 minutes)
• Sparse filter optimization (p. 2610) 2019-11-01 (5 minutes)

Notes concerning “Cooking”

• Storing dry bulk foods in used Coke bottles (p. 2145) 2012-10-15 (updated 2012-10-21) (5 minutes)
• A minimal-cost diet with adequate nutrition in Argentina in 2017 is US$0.67 per day (p. 3206) 2017-06-15 (4 minutes)
• Zombie contingency plan (p. 2656) 2017-07-19 (9 minutes)
• Deep freeze (p. 1465) 2017-08-22 (updated 2019-01-22) (7 minutes)

• Low-carbohydrate diets are ecologically sustainable (p. 540) 2018-04-27 (2 minutes)
• Home dehumidifier (p. 3131) 2018-05-20 (updated 2019-04-02) (12 minutes)
• Household thermal stores (p. 1533) 2018-12-02 (updated 2018-08-19) (27 minutes)
• Mayonnaise (p. 1320) 2019-03-19 (updated 2019-06-10) (10 minutes)
• Sous vide (p. 2921) 2019-04-02 (2 minutes)
• Waterfryer (p. 1462) 2019-04-20 (1 minute)

Notes concerning “Cooling”

• Air conditioning (p. 1665) 2007 to 2009 (21 minutes)
• A design sketch of an air conditioner powered by solar thermal power (p. 2233) 2016-12-22 (updated 2017-01-04) (29 minutes)
• Passivhaus seasonal thermal store (p. 1723) 2017-03-02 (updated 2017-03-07) (2 minutes)
• Passive dehumidifier (p. 3256) 2017-03-20 (14 minutes)
• Ice pants (p. 298) 2017-04-04 (updated 2019-01-22) (17 minutes)
• Zombie contingency plan (p. 2656) 2017-07-19 (9 minutes)
• Deep freeze (p. 1465) 2017-08-22 (updated 2019-01-22) (7 minutes)

• Salt slush refrigeration (p. 1230) 2017-08-22 (updated 2019-10-08) (12 minutes)
• Household thermal stores (p. 1533) 2018-12-02 (updated 2018-08-19) (27 minutes)
• Drone cutting (p. 1106) 2019-06-11 (12 minutes)
• Reducing nighttime bedroom CO_2 levels (p. 478) 2019-07-08 (updated 2019-07-09) (14 minutes)
• Intermittent fluid flow for heat transport (p. 521) 2019-07-10 (4 minutes)
• Can artificially-lit vertical farming compete with greenhouses? (p. 2064) 2019-09-08 (12 minutes)
• Methods of pumping ice-vest coolant silently (p. 2415) 2019-09-28 (12 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Copper plating”

- Electrodeposition 3d printing (p. 1115) 2016-02-19 (4 minutes)
- Immersion plating of copper on iron with blue vitriol (p. 1099) 2016-09-24 (8 minutes)
- Copper plating furniture (p. 1460) 2017-07-19 (updated 2017-09-01) (4 minutes)
- Absurd household materials (p. 532) 2018-04-26 (updated 2018-05-18) (8 minutes)

Notes concerning “Copper”

- Electrodeposition 3d printing (p. 1115) 2016-02-19 (4 minutes)
- Immersion plating of copper on iron with blue vitriol (p. 1099) 2016-09-24 (8 minutes)
- Copper plating furniture (p. 1460) 2017-07-19 (updated 2017-09-01) (4 minutes)
- Absurd household materials (p. 532) 2018-04-26 (updated 2018-05-18) (8 minutes)

Notes concerning “Cross compiling”

• Developing Win32 programs on Debian (p. 609) 2007 to 2009 (12 minutes)
• Win32 startup (p. 2439) 2007 to 2009 (2 minutes)

Notes concerning “Cryptography”

• How to use “correct horse battery staple” as an encryption key, including a recommended 4096-word list (p. 2522) 2014-04-24 (44 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Further notes on algebras for dark silicon (p. 1753) 2016-09-17 (updated 2017-04-18) (23 minutes)
• What’s wrong with CoAP (p. 560) 2017-06-15 (3 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)
• Progressive revealment crypto (p. 2068) 2019-04-10 (2 minutes)
• Human memorable secret sharing (p. 426) 2019-08-10 (2 minutes)
• Resurrecting duckling hashing (p. 3128) 2019-10-26 (updated 2019-11-10) (8 minutes)

Notes concerning “CSS”

• Dercuano stylesheet notes (p. 374) 2019-04-28 (updated 2019-05-09) (72 minutes)
• Dercuano formula display (p. 495) 2019-04-30 (5 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)

Notes concerning “Comma-separated values (CSV)”

- Storing CSV records in minimal memory in Java (p. 524) 2015-09-03 (6 minutes)
- Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)

Notes concerning “Databases”

• The Problem: Writing With One Access Pattern, Reading With Another (p. 3004) 2007 to 2009 (19 minutes)
• lattices, powersets, bitstrings, and efficient OLAP (p. 2345) 2014-04-24 (17 minutes)
• Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870) 2015-05-28 (updated 2016-06-22) (16 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Efficiently querying a log of everything that ever happened (p. 2506) 2015-09-03 (7 minutes)
• Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)
• Prototyping stuff (p. 176) 2016-08-11 (1 minute)
• ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• The history of NoSQL and dbm (p. 45) 2017-04-10 (16 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Database explorer (p. 225) 2017-06-20 (2 minutes)
• Compressing REST transactions with per-connection state (p. 1117) 2018-04-27 (11 minutes)
• Speculative plans for BubbleOS (p. 2128) 2018-10-28 (updated 2019-02-24) (12 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)
• Prolog table outlining (p. 2837) 2019-07-05 (11 minutes)
• Text relational query (p. 1223) 2019-08-28 (10 minutes)
• Query evaluation with interval-annotated trees over sequences (p. 1423) 2019-08-30 (updated 2019-09-03) (30 minutes)
• An affine-arithmetic database index for rapid historical securities formula queries (p. 2275) 2019-09-15 (15 minutes)
• Bytecode pubsub (p. 205) 2019-12-04 (6 minutes)

Notes concerning “Dataflow”

- Tagged dataflow (p. 405) 2007 to 2009 (2 minutes)
- Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
- Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
- Incremental recomputation (p. 1184) 2018-04-27 (12 minutes)
- A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)

Notes concerning “Datasets”

• Distinguishing natural languages with 3-grams of characters (p. 2953) 2013-05-17 (updated 2013-05-20) (7 minutes)
• Handling Landsat 8 images in limited RAM with netpbm (p. 1884) 2014-04-24 (4 minutes)
• Offline datasets (p. 599) 2014-04-24 (15 minutes)
• Fast geographical maps on Android (p. 455) 2015-10-16 (9 minutes)
• Servoing a V-plotter with a webcam? (p. 62) 2017-02-16 (3 minutes)

Notes concerning “Death”

- High-risk behavior in context (p. 1485) 2007 to 2009 (5 minutes)
- Jim Weirich’s death and my daily life (p. 829) 2014-04-24 (5 minutes)

Notes concerning "Decentralization"

• Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
• Review notes for Chris Anderson's "Makers" (p. 1072) 2013-05-17 (5 minutes)
• Stuff I've posted to kragen-tol over the years about post-HTTP (p. 1815) 2014-02-24 (12 minutes)
• Building a resilient network out of litter (p. 2107) 2014-04-24 (4 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• DHT bulletin board (p. 3001) 2016-09-07 (7 minutes)
• ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
• Solving the incentive problem for censorship-resistant DHTs (p. 923) 2016-09-07 (updated 2019-05-21) (3 minutes)
• Distributed computing environment (p. 776) 2017-07-19 (8 minutes)
• Kafka-like feeds for offline-first browser apps (p. 903) 2017-08-03 (5 minutes)
• How inefficient is SNAT hole-punching via random port trials? (p. 1155) 2018-04-27 (2 minutes)
• What are Bitcoin's uses other than sidestepping the law? (p. 2159) 2019-03-11 (updated 2019-07-05) (6 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)

Notes concerning “Dependencies”

• Simple dependencies in software (p. 2447) 2014-06-05 (9 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• Automatic dependency management (p. 881) 2015-05-28 (updated 2015-09-03) (5 minutes)
• Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)
• Blob computation (p. 2214) 2017-07-19 (2 minutes)
• A minimal dependency processing system (p. 911) 2017-09-21 (3 minutes)
• Dercuano backlinks (p. 475) 2019-05-22 (7 minutes)

Notes concerning “Dercuano”

Notes concerning “Desalination”

• Calculations about desalination in Israel (p. 2827) 2016-08-11 (3 minutes)
• Fast sea salt evaporator (p. 1087) 2017-06-01 (3 minutes)
• A quintuple-acting vacuum cascade to recycle heat for more efficient distillation and desalination (p. 519) 2017-06-21 (updated 2019-12-27) (3 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)

Notes concerning “Deterministic builds”

• Automatic dependency management (p. 881) 2015-05-28 (updated 2015-09-03) (5 minutes)
• Blob computation (p. 2214) 2017-07-19 (2 minutes)

Notes concerning “Deterministic computation”

• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• Prototyping stuff (p. 176) 2016-08-11 (1 minute)
• Blob computation (p. 2214) 2017-07-19 (2 minutes)
• Archival of hypertext with arbitrary interactive programs: a design outline (p. 2472) 2018-11-09 (3 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)

Notes concerning “Distributed hash tables”

- DHT bulletin board (p. 3001) 2016-09-07 (7 minutes)
- Solving the incentive problem for censorship-resistant DHTs (p. 923) 2016-09-07 (updated 2019-05-21) (3 minutes)

Notes concerning "Digital fabrication"

• Polycaprolactone (p. 1813) 2007 to 2009 (3 minutes)
• Predictions for future technological development (2008) (p. 341) 2008-04-19 (11 minutes)
• Review notes for Chris Anderson's "Makers" (p. 1072) 2013-05-17 (5 minutes)
• Notes on 3-D printing a mechanical LUT (p. 1326) 2014-04-24 (3 minutes)
• Making a mechanical state machine via sheet cutting (p. 1013) 2014-04-24 (updated 2015-09-03) (7 minutes)
• Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) 2014-07-16 (updated 2019-08-21) (14 minutes)
• We should use end-to-end optimization algorithms for 3-D printing design (p. 1550) 2015-09-03 (14 minutes)
• A hand-powered computer? (p. 624) 2015-09-03 (updated 2017-07-19) (11 minutes)
• Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) 2015-09-11 (updated 2019-12-20) (49 minutes)
• Exponential technology and capital (p. 406) 2016-02-18 (updated 2017-07-19) (8 minutes)
• Electrodeposition 3d printing (p. 1115) 2016-02-19 (4 minutes)
• String cutting cardboard (p. 515) 2016-06-30 (5 minutes)
• Flux deposition for 3-D printing in glass and metals (p. 1366) 2016-07-03 (15 minutes)
• 2016 outlook for automated fabrication and 3-D printing (p. 2316) 2016-08-11 (20 minutes)
• Sun cutter (p. 56) 2016-09-06 (9 minutes)
• Filling hollow FDM things with other materials (p. 2119) 2016-09-07 (5 minutes)
• Laser ablation of zinc or pewter for printed circuit boards (p. 2799) 2016-09-19 (4 minutes)
• 3-D printing glass with continuously varying refractive indices for optics without internal surfaces (p. 1156) 2016-10-06 (3 minutes)
• Hot air ice shaping (p. 864) 2016-10-06 (4 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Servoing a V-plotter with a webcam? (p. 62) 2017-02-16 (3 minutes)
• Wang tile addition (p. 3201) 2017-02-16 (3 minutes)
• 3-D printing by flux deposition (p. 466) 2017-02-24 (updated 2019-07-27) (21 minutes)

Notes concerning “Egg of the Phoenix”

• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• Atmospheric pressure harvesting phoenix egg (p. 2081) 2018-11-23 (14 minutes)

Notes concerning “Epistemology”

- On hanging out with cranks (p. 1715) 2008-04 (4 minutes)
- Studies support authority (p. 1541) 2017-04-10 (2 minutes)

Notes concerning “Erlang”

- Using bytecode won’t make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)
- Erlang musings (p. 2789) 2007 to 2009 (3 minutes)

Notes concerning “Español”

• Pensamientos acerca de diseñar un calefón solar (p. 117) 2012-10-15 (2 minutes)
• Más pensamientos acerca de diseñar un calefón solar (p. 1713) 2012-10-15 (5 minutes)
• Cristina Fernández de Kirchner tweets about the attempt to kidnap Assange (p. 985) 2014-04-24 (3 minutes)
• ¿Qué necesito para relación de pareja? (p. 1298) 2016-03-09 (6 minutes)
• La vibración del hierro, ¿es de baja frecuencia o qué? (p. 2231) 2016-10-07 (3 minutes)
• ¿Se puede armar un colector solar de agua caliente que anda en invierno acá en Buenos Aires? (p. 2911) 2017-04-17 (2 minutes)

Notes concerning “Espeak”

- Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
- English diphones (p. 2061) 2019-12-03 (5 minutes)

Notes concerning “Etymology”

- The etymology of “tradeoff” (p. 165) 2016-08-11 (5 minutes)
- One-line thoughts that don’t merit separate notes (p. 80) 2017-01-04 (updated 2017-02-25) (4 minutes)
- Replicating education (p. 557) 2017-07-19 (7 minutes)

Notes concerning “Euler method”

• Matrix exponentiation linear circuits (p. 355) 2018-12-18 (4 minutes)
• Accelerating Euler’s Method on linear time-invariant systems by exponentiating matrices (p. 348) 2019-03-24 (updated 2019-04-02) (7 minutes)

Notes concerning “F-83”

• Forth looping (p. 2025) 2007 to 2009 (16 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)

Notes concerning “Facepalm”

• Barcode receipts (p. 2359) 2007 to 2009 (6 minutes)
• A stack of coordinate contexts (p. 2987) 2007 to 2009 (9 minutes)
• Food miles imply insignificant energy costs (p. 2187) 2007 to 2009 (4 minutes)
• Predictions for future technological development (2008) (p. 341) 2008-04-19 (11 minutes)
• Steampunk spintronics: magnetoresistive relay logic? (p. 1315) 2013-05-17 (15 minutes)
• Compression with second-order diffs (p. 2152) 2014-04-24 (3 minutes)
• Plato was not particularly democratic; ἄρχειν is not “participating in politics” (p. 1707) 2014-04-24 (5 minutes)
• Practically decodable random error correction codes with popcount (p. 606) 2015-07-01 (updated 2015-09-03) (6 minutes)
• Robust hashsplitting with sliding Range Minimum Query (p. 733) 2016-09-05 (7 minutes)
• Low-cost green thread locks (p. 252) 2016-09-06 (2 minutes)
• High academic achievement almost certainly depends more on tutoring than group averages by race or sex (p. 113) 2016-09-08 (3 minutes)
• La vibración del hierro, ¿es de baja frecuencia o qué? (p. 2231) 2016-10-07 (3 minutes)
• Analogies between spring–mass–dashpot systems, electrical systems, and fluidic systems (p. 1472) 2016-10-30 (4 minutes)
• The ultimate capacity of human memory if spaced-practice memorization works as advertised (p. 2442) 2017-01-04 (updated 2017-01-08) (14 minutes)
• What’s wrong with CoAP (p. 560) 2017-06-15 (3 minutes)
• Nova RDOS (p. 1724) 2017-06-15 (22 minutes)
• A quintuple-acting vacuum cascade to recycle heat for more efficient distillation and desalination (p. 519) 2017-06-21 (updated 2019-12-27) (3 minutes)
• Salt slush refrigeration (p. 1230) 2017-08-22 (updated 2019-10-08) (12 minutes)
• Accelerating convolution and correlation with short periodic waveforms using OLAP marginal prefix sums (p. 895) 2018-06-05 (4 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• What can you build out of 256-byte ROMs? (p. 1468) 2018-12-02 (1 minute)
• A failed attempt to make squares cheaper to compute (p. 1622) 2019-07-09 (updated 2019-07-11) (4 minutes)
• the oversold-as-low-power Renesas RL78 microcontroller line (p. 504) 2019-08-27 (10 minutes)
• What it means that HTML is “not a programming language”, and why the ignorant sometimes think otherwise (p. 1555) 2019-09-09 (updated 2019-10-01) (24 minutes)

Notes concerning “Factionalism”

- Notch scorn (p. 115) 2019-04-20 (5 minutes)
- Categorical zero sum prohibition (p. 2553) 2019-05-27 (updated 2019-06-01) (23 minutes)

Notes concerning “Failure-free computing”

• Constant-space grep (p. 296) 2014-02-24 (3 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Linear trees (p. 1811) 2016-05-19 (updated 2016-05-20) (6 minutes)
• Statically bounding runtime (p. 2398) 2016-07-19 (4 minutes)
• Generic programming with proofs, specification, refinement, and specialization (p. 958) 2017-05-10 (6 minutes)
• The Z-machine memory model (p. 2903) 2017-07-19 (4 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• Arduino safety (p. 3015) 2018-12-10 (4 minutes)
• Techniques for, e.g., avoiding indexed-offset addressing on the 8080 (p. 3166) 2019-07-20 (updated 2019-07-24) (27 minutes)

Notes concerning “Feedback”

• 2016 outlook for automated fabrication and 3-D printing (p. 2316) 2016-08-11 (20 minutes)
• Jello printing (p. 2426) 2016-12-14 (8 minutes)

Notes concerning “Fiction”

• He listened to the human intently (p. 2543) 2014-06-29 (4 minutes)

• Buenos Aires seen from behind the mirror (p. 809) 2014-09-02 (7 minutes)
• Statement from the Confederation of Teachers (p. 725) 2016-10-11 (updated 2016-10-12) (4 minutes)
• The imbalance inherent in copyright systems (p. 2158) 2017-07-19 (2 minutes)
• 2017 [Provisional English translation of intercepted transmission] (p. 2192) 2018-04-27 (updated 2018-07-14) (13 minutes)
• The fable of the specialized fox (p. 1076) 2019-08-17 (1 minute)
• GPT-2 sets the scene (p. 2978) 2019-11-22 (updated 2019-12-01) (22 minutes)

Notes concerning “Filesystems”

• Double ended log structured filesystem (p. 1653) 2007 to 2009 (4 minutes)
• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Robust hashsplitting with sliding Range Minimum Query (p. 733) 2016-09-05 (7 minutes)
• ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
• Speculative plans for BubbleOS (p. 2128) 2018-10-28 (updated 2019-02-24) (12 minutes)
• Raid zim (p. 253) 2019-01-17 (updated 2019-02-08) (1 minute)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)

Notes concerning “Flexures”

• Tapered thread (p. 363) 2015-09-03 (updated 2019-06-10) (4 minutes)
• Absurd household materials (p. 532) 2018-04-26 (updated 2018-05-18) (8 minutes)
• Foil origami robots (p. 2286) 2019-06-13 (updated 2019-06-14) (10 minutes)

Notes concerning “Flux deposition”

- Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) 2015-09-11 (updated 2019-12-20) (49 minutes)
- Flux deposition for 3-D printing in glass and metals (p. 1366) 2016-07-03 (15 minutes)
- 3-D printing by flux deposition (p. 466) 2017-02-24 (updated 2019-07-27) (21 minutes)
- Needle binder injection printing (p. 1492) 2019-08-05 (12 minutes)

Notes concerning “Fonts”

• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Convolution applications (p. 2930) 2015-09-07 (updated 2019-08-14) (9 minutes)
• CIC-filter fonts (p. 1229) 2017-06-28 (1 minute)
• Wang tile font (p. 1463) 2018-08-16 (5 minutes)
• Hand drawn font compositing (p. 1810) 2018-10-28 (2 minutes)
• Dilating letterforms (p. 651) 2018-11-04 (15 minutes)
• Dercuano stylesheet notes (p. 374) 2019-04-28 (updated 2019-05-09) (72 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)
• Isotropic nonlinear texture effects for letterforms from a scale-space representation (p. 1609) 2019-09-10 (16 minutes)

Notes concerning “Food storage”

• Storing dry bulk foods in used Coke bottles (p. 2145) 2012-10-15 (updated 2012-10-21) (5 minutes)
• Food storage (p. 2706) 2013-05-11 (updated 2013-05-17) (54 minutes)
• A minimal-cost diet with adequate nutrition in Argentina in 2017 is US$0.67 per day (p. 3206) 2017-06-15 (4 minutes)
• Zombie contingency plan (p. 2656) 2017-07-19 (9 minutes)

Notes concerning “Formal methods”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Statically bounding runtime (p. 2398) 2016-07-19 (4 minutes)
• Generic programming with proofs, specification, refinement, and specialization (p. 958) 2017-05-10 (6 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• Arduino safety (p. 3015) 2018-12-10 (4 minutes)
• Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)

Notes concerning “Forth”

• Notes on reading eForth (p. 1398) 2007 to 2009 (9 minutes)
• Notes on reading eForth 1.0 for the 8086 (p. 541) 2007 to 2009 (5 minutes)
• Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009 (13 minutes)
• Forth looping (p. 2025) 2007 to 2009 (16 minutes)
• Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Iterative string formatting (p. 1392) 2013-05-17 (9 minutes)
• Forth with named stacks (p. 2101) 2014-02-24 (7 minutes)
• Archival with a universal virtual computer (UVC) (p. 399) 2014-06-29 (17 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• Rarely are function-local variables in Forth justified (p. 1055) 2018-04-27 (10 minutes)
• Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952) 2018-04-27 (4 minutes)
• Assembler bootstrapping (p. 2922) 2019-07-18 (updated 2019-12-08) (16 minutes)
• 10tcl ui (p. 1823) 2019-12-06 (17 minutes)
• Introduction to closures (p. 1403) 2019-12-07 (5 minutes)
• Forth assembling (p. 940) 2019-12-08 (updated 2019-12-11) (18 minutes)
• Immediate-mode PEG parsers in assembly language (p. 365) 2019-12-10 (updated 2019-12-11) (21 minutes)
• Can you eliminate backpatching? (p. 1769) 2019-12-17 (8 minutes)

Notes concerning “Fractals”

• Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) 2014-07-16 (updated 2019-08-21) (14 minutes)
• Rendering iterated function systems (IFSes) with interval arithmetic (p. 2433) 2014-09-02 (6 minutes)
• Fractal palettes (p. 202) 2019-04-02 (7 minutes)

Notes concerning “Free software”

• Free software debugging (p. 136) 2007 to 2009 (2 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Better be weird (p. 1831) 2019-06-17 (updated 2019-06-24) (9 minutes)

Notes concerning “Frustration”

- Prototyping stuff (p. 176) 2016-08-11 (1 minute)
- Frustration (p. 3263) 2018-04-27 (2 minutes)

Notes concerning “Furniture”

- Inflatable stool (p. 1047) 2014-04-24 (6 minutes)
- Oval cam lock (p. 3060) 2019-11-26 (5 minutes)

Notes concerning “Games”

- Gaim group chat (p. 2677) 2007 to 2009 (3 minutes)
- Alien game challenge (p. 2313) 2015-09-03 (6 minutes)
- Text editor slow keys (p. 808) 2017-02-07 (2 minutes)
- An IDE modeled on video games (p. 1959) 2019-04-08 (5 minutes)
- Progressive revealment crypto (p. 2068) 2019-04-10 (2 minutes)
- Why Minetest is so addictive (p. 1781) 2019-04-20 (8 minutes)

Notes concerning “Garbage collection”

- Simple system language (p. 1659) 2013-05-17 (7 minutes)
- Linear trees (p. 1811) 2016-05-19 (updated 2016-05-20) (6 minutes)

Notes concerning “Garbage”

• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• A resistive-capacitive trackpad made from garbage and three ADC microcontroller pins (p. 852) 2013-05-17 (updated 2013-05-20) (17 minutes)
• US$10M for a new, much better McMurdo Base, or less (p. 2879) 2016-05-18 (updated 2016-05-19) (7 minutes)
• One-line thoughts that don’t merit separate notes (p. 80) 2017-01-04 (updated 2017-02-25) (4 minutes)
• Lab power supply (p. 2421) 2017-02-21 (updated 2018-06-18) (17 minutes)
• Home dehumidifier (p. 3131) 2018-05-20 (updated 2019-04-02) (12 minutes)
• Household thermal stores (p. 1533) 2018-12-02 (updated 2018-08-19) (27 minutes)
• Cardboard furniture (p. 742) 2019-08-01 (updated 2019-08-11) (15 minutes)
• Sandwich theory (p. 2450) 2019-08-05 (updated 2019-08-29) (31 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Gardening”

- Subterranean glazing (p. 1126) 2016-09-06 (25 minutes)
- Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)

Notes concerning “Gelbart”

• Optical lever thermometer (p. 2624) 2015-09-03 (1 minute)
• Tapered thread (p. 363) 2015-09-03 (updated 2019-06-10) (4 minutes)

Notes concerning “Gestures”

• $1 recognizer diagrams (p. 1264) 2019-08-11 (updated 2019-10-24) (15 minutes)
• Complex linear regression (in the field ℂ of complex numbers) (p. 3018) 2019-08-17 (updated 2019-08-18) (9 minutes)

Notes concerning “Ghettobotics”

• Charge transfer servo (p. 3017) 2013-05-17 (2 minutes)
• Cheap shit ultrawideband (p. 2776) 2013-05-17 (10 minutes)
• Ghettobotics: making robots out of trash (p. 2747) 2013-05-17 (41 minutes)
• You’re pretty much fucked if you want to build an oscilloscope on the AVR’s ADC (p. 1269) 2013-05-17 (3 minutes)
• A resistive-capacitive trackpad made from garbage and three ADC microcontroller pins (p. 852) 2013-05-17 (updated 2013-05-20) (17 minutes)
• Solar-cell Geiger counters (p. 3241) 2016-07-30 (1 minute)
• Soldering with a compound parabolic concentrator or even just an imaging lens (p. 101) 2016-09-07 (2 minutes)
• A 7-segment-display font with 68 glyphs (p. 1798) 2017-02-21 (4 minutes)
• Disk oscilloscope (p. 713) 2017-04-10 (updated 2017-06-20) (3 minutes)
• TV oscilloscope (p. 1253) 2017-04-10 (updated 2017-06-20) (4 minutes)
• Laser printer oscilloscope (p. 449) 2017-04-18 (updated 2017-06-20) (2 minutes)
• Can a simple nonlinear VCO enable super cheap oscilloscopes? (p. 1357) 2017-05-04 (updated 2017-05-10) (5 minutes)
• VCR oscilloscope (p. 213) 2017-05-10 (updated 2017-06-20) (2 minutes)
• CCD oscilloscope (p. 1861) 2017-06-20 (updated 2017-07-04) (7 minutes)
• Macroscopic capacitive DLP (p. 1834) 2019-04-08 (1 minute)
• Rubber wheel pinch drive (p. 2912) 2019-08-16 (updated 2019-08-18) (8 minutes)
• Examination of a shitty USB car charger (p. 286) 2019-10-24 (13 minutes)
• Audio logic analyzer (p. 1801) 2019-11-12 (3 minutes)

Notes concerning “Geographical information systems (GIS)”

- Full res globe (p. 1255) 2014-02-24 (1 minute)
- Fast geographical maps on Android (p. 455) 2015-10-16 (9 minutes)
- Stereographic map app (p. 1281) 2018-12-02 (2 minutes)

Notes concerning “Git”

• Git data (p. 2823) 2007 to 2009 (5 minutes)
• Git learnings (p. 3268) 2007 to 2009 (3 minutes)
• User-per-group (UPG), umask, and “Permission denied” on shared Git repos via ssh (p. 2481) 2007 to 2009 (4 minutes)
• Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)

Notes concerning “Glass”

• Flux deposition for 3-D printing in glass and metals (p. 1366) 2016-07-03 (15 minutes)
• 3-D printing glass with continuously varying refractive indices for optics without internal surfaces (p. 1156) 2016-10-06 (3 minutes)

Notes concerning “Goertzel”

• Notations for defining dynamical systems (p. 2872) 2016-10-03 (updated 2016-10-06) (6 minutes)
• Cheap frequency detection (p. 3026) 2017-06-29 (updated 2019-06-19) (50 minutes)
• The Bleep ultrasonic modem for local data communication (p. 966) 2018-12-10 (updated 2018-12-11) (8 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)

Notes concerning “Golang”

Notes concerning “Gossip”

• Gaim group chat (p. 2677) 2007 to 2009 (3 minutes)
• Viral wiki (p. 1024) 2015-10-15 (3 minutes)
• Hash gossip exchange (p. 1470) 2015-11-19 (4 minutes)
• Kafka-like feeds for offline-first browser apps (p. 903) 2017-08-03 (5 minutes)
• Minimal distributed streams (p. 1844) 2018-04-27 (5 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)

Notes concerning “GPGPU”

Notes concerning “Gradient descent”

• Modeling trees with slices containing metaballs (p. 2619) 2014-06-29 (updated 2014-07-02) (6 minutes)
• Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) 2019-08-17 (updated 2019-09-15) (15 minutes)
• Fast mathematical optimization with affine arithmetic (p. 3163) 2019-09-15 (5 minutes)

Notes concerning “Gradients”

• Achieving smooth curves in scanline image generation (p. 1507) 2013-05-17 (1 minute)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Affine arithmetic has quadratic convergence when interval arithmetic has linear convergence (p. 1029) 2016-08-24 (updated 2017-01-18) (10 minutes)
• Gradient rendering (p. 583) 2016-09-24 (11 minutes)
• 3-D printing glass with continuously varying refractive indices for optics without internal surfaces (p. 1156) 2016-10-06 (3 minutes)
• Reduced affine arithmetic raytracer (p. 2007) 2017-05-10 (1 minute)
• Gradient overlay (p. 1587) 2018-04-27 (2 minutes)
• Gradient pixels (p. 2202) 2018-08-16 (updated 2018-10-28) (9 minutes)

Notes concerning “Granular hypertext”

• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• A sentence-granularity hypertext editor (p. 2290) 2018-04-27 (4 minutes)
• Agenda hypertext (p. 1836) 2018-07-14 (updated 2018-07-15) (2 minutes)

Notes concerning “Graphics”

• I think I understand how to use libart’s antialiased rendering API now (p. 409) 2007 to 2009 (10 minutes)
• Index set inference or domain inference for programming with indexed families (p. 1434) 2007 to 2009 (updated 2019-05-05) (27 minutes)
• Worst-case-logarithmic-time reduction over arbitrary intervals over arbitrary semigroups (p. 1021) 2012-12-04 (5 minutes)
• a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees) (p. 1190) 2012-12-06 (updated 2013-05-17) (10 minutes)
• Achieving smooth curves in scanline image generation (p. 1507) 2013-05-17 (1 minute)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• Simple system language (p. 1659) 2013-05-17 (7 minutes)
• Full res globe (p. 1255) 2014-02-24 (1 minute)
• Embedding objects inside other objects in memory, versus by-reference fields (p. 3112) 2014-02-24 (13 minutes)
• Handling Landsat 8 images in limited RAM with netpbm (p. 1884) 2014-04-24 (4 minutes)
• Archival transparencies (p. 1345) 2014-06-05 (updated 2014-06-29) (7 minutes)
• Modeling trees with slices containing metaballs (p. 2619) 2014-06-29 (updated 2014-07-02) (6 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• Alien game challenge (p. 2313) 2015-09-03 (6 minutes)
• An IMGUI-style drawing API isn’t necessarily just immediate-mode graphics (p. 2671) 2015-09-03 (3 minutes)
• Convolution surface plotting (p. 2264) 2015-09-03 (updated 2015-09-13) (2 minutes)
• Convolution applications (p. 2930) 2015-09-07 (updated 2019-08-14) (9 minutes)
• Hash feature detection (p. 3294) 2015-09-17 (5 minutes)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Minimal GUI libraries (p. 663) 2015-11-14 (updated 2015-11-15) (5 minutes)
• Anytime realtime (p. 803) 2016-04-22 (4 minutes)
• Circle-portal GUI (p. 1151) 2016-06-03 (11 minutes)
• Improving lossless image compression with basic machine learning algorithms (p. 2546) 2016-07-27 (2 minutes)
• Interval radiosity (p. 1544) 2016-07-27 (1 minute)
• Kinect modeling (p. 164) 2016-09-16 (1 minute)
• Reconstructing a 3-D Lambertian surface from video with a moving light source (p. 3296) 2016-09-16 (1 minute)
• Further notes on algebras for dark silicon (p. 1753) 2016-09-17

(updated 2017-04-18) (23 minutes)
• Gradient rendering (p. 583) 2016-09-24 (11 minutes)
• Changing the basis to a more expressive one with better affordances (p. 1389) 2016-09-29 (5 minutes)
• Texture synthesis with spatial-domain particle filters (p. 857) 2016-10-06 (2 minutes)
• Current hardware trends tend toward raytracing (p. 1351) 2016-10-07 (4 minutes)
• Chintzy depth of field (p. 629) 2016-10-27 (1 minute)
• One-line thoughts that don't merit separate notes (p. 80) 2017-01-04 (updated 2017-02-25) (4 minutes)
• What is the type of lerp? (p. 1985) 2017-01-08 (5 minutes)
• Quicklayout (p. 2189) 2017-01-10 (updated 2017-01-18) (3 minutes)

• Constant time sets for pixel painting (p. 1484) 2017-02-07 (2 minutes)
• Reduced affine arithmetic raytracer (p. 2007) 2017-05-10 (1 minute)
• Relational modeling (p. 1102) 2017-05-17 (updated 2017-06-01) (6 minutes)
• A plotter language of 9-bit bytes (p. 2154) 2017-05-29 (updated 2017-06-01) (11 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Pixel stream (p. 617) 2017-06-15 (updated 2018-10-26) (4 minutes)
• Compressing a screen update with a tree of dirty bits (p. 303) 2017-06-21 (1 minute)
• CIC-filter fonts (p. 1229) 2017-06-28 (1 minute)
• Rasterizing polies (p. 2023) 2017-07-19 (3 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• General purpose layout syntax (p. 3117) 2017-11-10 (updated 2019-09-01) (34 minutes)
• Optimization-based painting software (p. 1158) 2018-04-27 (1 minute)
• Gradient overlay (p. 1587) 2018-04-27 (2 minutes)
• A minimal window system (p. 1545) 2018-04-27 (updated 2018-10-26) (12 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• Wang tile font (p. 1463) 2018-08-16 (5 minutes)
• Gradient pixels (p. 2202) 2018-08-16 (updated 2018-10-28) (9 minutes)
• Window systems (p. 1335) 2018-10-26 (1 minute)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• Bit difference array (p. 1748) 2018-10-28 (10 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)
• Hand drawn font compositing (p. 1810) 2018-10-28 (2 minutes)
• Cheap textures (p. 736) 2018-10-28 (updated 2019-05-05) (5 minutes)
• Dilating letterforms (p. 651) 2018-11-04 (15 minutes)
• Gauzy shit (p. 2985) 2018-11-04 (4 minutes)
• Antialiased line drawing (p. 1803) 2018-11-13 (updated 2019-09-01)

(4 minutes)
• Stereographic map app (p. 1281) 2018-12-02 (2 minutes)
• Evaluating DSP operations in minimal buffer space by pipelining (p. 321) 2018-12-18 (updated 2018-12-19) (20 minutes)
• Sample reversal (p. 1353) 2018-12-18 (updated 2019-01-17) (5 minutes)
• Real-time bokeh algorithms, and other convolution tricks (p. 2661) 2018-12-18 (updated 2019-08-15) (23 minutes)
• Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm (p. 216) 2019-01-04 (updated 2019-11-12) (26 minutes)
• Median filtering (p. 3155) 2019-01-17 (11 minutes)
• Fractal palettes (p. 202) 2019-04-02 (7 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)
• Dercuano drawings (p. 64) 2019-04-30 (updated 2019-05-30) (18 minutes)
• Some musings on applying Fitts's Law to user interface design and data compression (p. 1164) 2019-05-06 (updated 2019-05-09) (27 minutes)
• An algebra of textures for interactive composition (p. 1283) 2019-05-08 (4 minutes)
• Granite texture (p. 1991) 2019-05-08 (updated 2019-05-09) (5 minutes)
• Dercuano rendering (p. 2300) 2019-05-11 (updated 2019-05-12) (3 minutes)
• Image approximation (p. 2394) 2019-05-14 (10 minutes)
• Midpoint method texture mapping (p. 1837) 2019-06-01 (3 minutes)
• Recursive curves (p. 1948) 2019-06-10 (5 minutes)
• Using the method of secants for general optimization (p. 1773) 2019-07-22 (updated 2019-11-26) (13 minutes)
• $1 recognizer diagrams (p. 1264) 2019-08-11 (updated 2019-10-24) (15 minutes)
• The miraculous low-rank SVD approximate convolution algorithm (p. 747) 2019-08-14 (updated 2019-08-15) (31 minutes)
• Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) 2019-08-31 (updated 2019-09-08) (28 minutes)
• Cloth structure from shading (p. 84) 2019-09-01 (2 minutes)
• Processing halftoning (p. 915) 2019-09-01 (15 minutes)
• Debokehfication (p. 473) 2019-09-01 (updated 2019-09-12) (4 minutes)
• Dercuano plotting (p. 2885) 2019-09-03 (updated 2019-09-05) (34 minutes)
• Isotropic nonlinear texture effects for letterforms from a scale-space representation (p. 1609) 2019-09-10 (16 minutes)
• Interval raymarching (p. 1342) 2019-11-02 (updated 2019-11-10) (6 minutes)
• Some thoughts on SDF raymarching (p. 312) 2019-11-11 (updated 2019-12-10) (31 minutes)
• Camera flash extrapolation (p. 2792) 2019-11-12 (6 minutes)
• Byte stream gui applications (p. 128) 2019-11-29 (updated 2019-11-30) (17 minutes)

Notes concerning “Graphs”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Circuit notation (p. 1161) 2016-09-08 (updated 2017-04-18) (7 minutes)
• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• Incremental recomputation (p. 1184) 2018-04-27 (12 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)

Notes concerning “Greenarrays”

- Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
- Making the CPU instruction set a usable interactive user interface (p. 59) 2015-09-17 (8 minutes)
- An RPN CPU instruction set doubling as user interface (p. 177) 2017-07-19 (updated 2019-07-10) (21 minutes)

Notes concerning “Grt”

- String tuple encoding (p. 2419) 2017-04-28 (2 minutes)
- ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)

Notes concerning “Graphical user interfaces”

• Index set inference or domain inference for programming with indexed families (p. 1434) 2007 to 2009 (updated 2019-05-05) (27 minutes)
• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• Instant hypertext (p. 630) 2013-05-17 (updated 2013-05-20) (14 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• An IMGUI-style drawing API isn’t necessarily just immediate-mode graphics (p. 2671) 2015-09-03 (3 minutes)
• Minimal GUI libraries (p. 663) 2015-11-14 (updated 2015-11-15) (5 minutes)
• Circle-portal GUI (p. 1151) 2016-06-03 (11 minutes)
• Quicklayout (p. 2189) 2017-01-10 (updated 2017-01-18) (3 minutes)

• Caching screen contents (p. 2362) 2017-06-14 (2 minutes)
• Pixel stream (p. 617) 2017-06-15 (updated 2018-10-26) (4 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• Cached SOA desktop (p. 2229) 2017-08-03 (updated 2018-10-26) (6 minutes)
• What does a futuristic OS look like? (p. 2163) 2017-08-18 (updated 2019-05-05) (6 minutes)
• General purpose layout syntax (p. 3117) 2017-11-10 (updated 2019-09-01) (34 minutes)
• A minimal window system (p. 1545) 2018-04-27 (updated 2018-10-26) (12 minutes)
• Window systems (p. 1335) 2018-10-26 (1 minute)
• A nonscriptable design for the Wercam windowing system (p. 3092) 2018-10-26 (updated 2018-11-13) (6 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• Speculative plans for BubbleOS (p. 2128) 2018-10-28 (updated 2019-02-24) (12 minutes)
• IMGUI programming compared to Tcl/Tk (p. 2333) 2018-12-24 (updated 2018-12-31) (8 minutes)
• IMGUI programming language (p. 103) 2019-01-01 (updated 2019-07-30) (21 minutes)
• Byte stream gui applications (p. 128) 2019-11-29 (updated 2019-11-30) (17 minutes)

Notes concerning “Hadamard matrices”

• Constructing error-correcting codes using Hadamard transforms (p. 1474) 2013-05-17 (updated 2013-05-20) (22 minutes)
• Hadamard rhythms (p. 831) 2019-11-01 (6 minutes)

Notes concerning “Hammers”

• Hammering toolhead (p. 3297) 2017-08-18 (6 minutes)
• Electric hammer (p. 1865) 2018-07-02 (updated 2018-07-05) (14 minutes)
• Shaped hammer face giant pressure (p. 3278) 2019-11-10 (21 minutes)

Notes concerning “Hand computers”

Notes concerning “Human–computer interaction”

• Error Reporting is Part of the Programmer's User Interface (p. 2323) 2007 to 2009 (18 minutes)
• Running your regular desktop in QEMU? (p. 292) 2007 to 2009 (3 minutes)
• Why Thunderbird is inadequate for opening a 7-gigabyte mbox (p. 980) 2007 to 2009 (2 minutes)
• wood and stone personal digital assistants (p. 3191) 2007 to 2009 (6 minutes)
• Writing math in Unicode with the Compose key (p. 1863) 2007 to 2009 (2 minutes)
• Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• In what sense is e the optimal branching factor, and what does it mean for menu tree design? (p. 2483) 2012-12-04 (3 minutes)
• How can we take advantage of 16:9 screens for programming? (p. 1982) 2012-12-17 (2 minutes)
• Clickable terminal patterns (p. 859) 2013-05-17 (2 minutes)
• Instant hypertext (p. 630) 2013-05-17 (updated 2013-05-20) (14 minutes)
• Precisely how is 3 “optimal” for one-hot state machines, sparse FIR kernels, etc.? (p. 450) 2014-04-24 (8 minutes)
• How to use “correct horse battery staple” as an encryption key, including a recommended 4096-word list (p. 2522) 2014-04-24 (44 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)

• Image approximation (p. 2394) 2019-05-14 (10 minutes)
• Using the method of secants for general optimization (p. 1773) 2019-07-22 (updated 2019-11-26) (13 minutes)

Notes concerning “Immediate-mode GUIs”

• How to generate unique IDs for IMGUI object persistence? (p. 2035) 2014-09-02 (3 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• An IMGUI-style drawing API isn’t necessarily just immediate-mode graphics (p. 2671) 2015-09-03 (3 minutes)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Trees as code (p. 2488) 2016-05-10 (4 minutes)
• IMGUI programming compared to Tcl/Tk (p. 2333) 2018-12-24 (updated 2018-12-31) (8 minutes)
• IMGUI programming language (p. 103) 2019-01-01 (updated 2019-07-30) (21 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)

Notes concerning “Incentive design”

- Barcode receipts (p. 2359) 2007 to 2009 (6 minutes)
- Free software debugging (p. 136) 2007 to 2009 (2 minutes)
- Microfinance (p. 2875) 2007 to 2009 (6 minutes)
- Dollar auctions and tournaments in human society (p. 884) 2013-05-17 (7 minutes)
- Dutch auction raffle (p. 2474) 2018-06-05 (3 minutes)

Notes concerning "Incremental computation"

• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• Worst-case-logarithmic-time reduction over arbitrary intervals over arbitrary semigroups (p. 1021) 2012-12-04 (5 minutes)
• a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees) (p. 1190) 2012-12-06 (updated 2013-05-17) (10 minutes)
• How can we usefully cache screen images for incrementalization? (p. 1077) 2013-05-17 (18 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• Simple dependencies in software (p. 2447) 2014-06-05 (9 minutes)
• A reactive crawler using Amygdala (p. 2492) 2014-09-02 (updated 2014-09-19) (4 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870) 2015-05-28 (updated 2016-06-22) (16 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Incremental MapReduce for Abelian-group reduction functions (p. 331) 2015-09-03 (4 minutes)
• Efficiently querying a log of everything that ever happened (p. 2506) 2015-09-03 (7 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Parallel DFA execution (p. 2337) 2017-04-18 (9 minutes)
• Caching screen contents (p. 2362) 2017-06-14 (2 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)
• Cached SOA desktop (p. 2229) 2017-08-03 (updated 2018-10-26) (6 minutes)
• Incremental recomputation (p. 1184) 2018-04-27 (12 minutes)
• Composing code gobbets with implicit dependencies (p. 2437) 2018-04-27 (updated 2019-05-21) (3 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)
• Robust local search in vector spaces using adaptive step sizes, and

thoughts on extending quasi-Newton methods (p. 1138) 2019-08-17 (updated 2019-09-15) (15 minutes)

Notes concerning “Incremental search”

• Text editor slow keys (p. 808) 2017-02-07 (2 minutes)
• Quasimode keyboard (p. 2693) 2018-07-14 (24 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)
• Fencepost cognitive interface errors in text editing (p. 993) 2019-04-24 (24 minutes)

Notes concerning “Independence”

• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Food storage (p. 2706) 2013-05-11 (updated 2013-05-17) (54 minutes)
• Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
• Ghettobotics: making robots out of trash (p. 2747) 2013-05-17 (41 minutes)
• Ultraslow radio for resilient global communication (p. 2071) 2013-05-17 (updated 2013-05-20) (26 minutes)
• The Tinkerer’s Tricorder (p. 72) 2013-05-17 (updated 2014-04-24) (27 minutes)
• Bike charger (p. 2099) 2014-04-24 (2 minutes)
• Offline datasets (p. 599) 2014-04-24 (15 minutes)
• Keyboard-powered computers (p. 2220) 2014-10-25 (updated 2018-10-28) (26 minutes)
• A hand-powered computer? (p. 624) 2015-09-03 (updated 2017-07-19) (11 minutes)
• The book written in itself (p. 2400) 2016-06-12 (updated 2016-06-14) (18 minutes)
• Thermodynamic systems in housing (p. 2804) 2016-06-28 (24 minutes)
• Solar dehumidifier (p. 717) 2016-08-11 (5 minutes)
• Regenerative fuel air cutting (p. 2622) 2016-09-06 (4 minutes)
• House scrubber (p. 248) 2016-09-06 (updated 2019-11-25) (13 minutes)
• Solar-powered portable computers (p. 2959) 2016-09-17 (updated 2018-10-28) (15 minutes)
• License-free femtowatt UHF radio transceiver ICs under a μJ per bit (p. 162) 2016-09-19 (5 minutes)
• MiniOS (p. 1091) 2016-12-28 (updated 2017-01-03) (6 minutes)
• Lab power supply (p. 2421) 2017-02-21 (updated 2018-06-18) (17 minutes)
• Thredsnek: a tiny Python-flavored programming language (p. 1172) 2017-03-20 (7 minutes)
• Minimum hardware and software to get a flexible notetaking device running (p. 535) 2017-04-28 (4 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)

Notes concerning "Interval and affine arithmetic"

• An algebraic approach to 3D geometry (p. 669) 2014-06-03 (updated 2014-06-29) (22 minutes)
• Modeling trees with slices containing metaballs (p. 2619) 2014-06-29 (updated 2014-07-02) (6 minutes)
• Rendering iterated function systems (IFSes) with interval arithmetic (p. 2433) 2014-09-02 (6 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Bayesian and Gricean programming (p. 711) 2015-08-20 (3 minutes)

• Convolution with intervals (p. 1044) 2015-09-07 (1 minute)
• Interactive calculator 0 (p. 1453) 2015-09-17 (2 minutes)
• Interval filters (p. 1282) 2015-09-17 (2 minutes)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Interval radiosity (p. 1544) 2016-07-27 (1 minute)
• Affine arithmetic has quadratic convergence when interval arithmetic has linear convergence (p. 1029) 2016-08-24 (updated 2017-01-18) (10 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Reduced affine arithmetic raytracer (p. 2007) 2017-05-10 (1 minute)
• High-precision control of low-stiffness sytems with bounded-Q resonances (p. 1002) 2017-05-29 (updated 2017-06-01) (4 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Affine arithmetic optimization (p. 2801) 2017-07-19 (updated 2019-09-15) (3 minutes)
• Solving initial-value problems faster and with guaranteed error bounds with affine arithmetic (p. 836) 2019-04-02 (5 minutes)
• Relational modeling and APL (p. 1217) 2019-05-20 (updated 2019-05-21) (5 minutes)
• Reducing the cost of self-verifying arithmetic with array operations (p. 2205) 2019-06-23 (15 minutes)
• Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)
• Query evaluation with interval-annotated trees over sequences (p. 1423) 2019-08-30 (updated 2019-09-03) (30 minutes)
• Fast mathematical optimization with affine arithmetic (p. 3163) 2019-09-15 (5 minutes)
• An affine-arithmetic database index for rapid historical securities formula queries (p. 2275) 2019-09-15 (15 minutes)
• Interval raymarching (p. 1342) 2019-11-02 (updated 2019-11-10) (6 minutes)

Notes concerning “Io”

• Notes on Raph Levien's "Io" Programming Language (p. 1740) 2007 to 2009 (10 minutes)
• Implementing flatMap in terms of call/cc, as in Raph Levien’s Io (p. 3248) 2015-09-03 (3 minutes)

Notes concerning “The Jaquet-Droz automata”

• Making a mechanical state machine via sheet cutting (p. 1013) 2014-04-24 (updated 2015-09-03) (7 minutes)
• Differential spiral cam (p. 512) 2017-07-19 (9 minutes)
• An RPN CPU instruction set doubling as user interface (p. 177) 2017-07-19 (updated 2019-07-10) (21 minutes)

Notes concerning “Java”

• Embedding objects inside other objects in memory, versus by-reference fields (p. 3112) 2014-02-24 (13 minutes)
• A reactive crawler using Amygdala (p. 2492) 2014-09-02 (updated 2014-09-19) (4 minutes)
• Ndarray java (p. 2261) 2015-05-28 (1 minute)
• Storing CSV records in minimal memory in Java (p. 524) 2015-09-03 (6 minutes)
• Notes on higher-order programming on the JVM (p. 1355) 2016-09-06 (6 minutes)

Notes concerning “Journal”

• Vanagon mail (p. 2032) 2007 to 2009 (3 minutes)
• Smoky day (p. 3010) 2008-04-19 (4 minutes)
• Personal notes from 2013-06-06 (p. 2673) 2013-06-06 (updated 2014-04-24) (11 minutes)
• Some personal notes from February 2014 (p. 2134) 2014-02-13 (8 minutes)
• A Sunday in 2014 (p. 1089) 2014-02-24 (3 minutes)
• Jim Weirich’s death and my daily life (p. 829) 2014-04-24 (5 minutes)
• Notes from a Buenos Aires blackout, summer 2013-2014 (p. 267) 2014-04-24 (15 minutes)
• Ostinatto (p. 2780) 2014-04-24 (4 minutes)
• José, the Galician mover (p. 3076) 2015-11-09 (2 minutes)
• ¿Qué necesito para relación de pareja? (p. 1298) 2016-03-09 (6 minutes)
• Phase-change heat reservoirs for household climate control (p. 2257) 2016-06-14 (updated 2016-06-17) (13 minutes)

Notes concerning “JS”

• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• Automatic dependency management (p. 881) 2015-05-28 (updated 2015-09-03) (5 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• A type-inferred dialect of JS (p. 265) 2016-04-22 (4 minutes)
• Hipster stack 2017 (p. 2242) 2017-04-28 (updated 2017-05-04) (26 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• JIT-compiling array computation graphs in JS (p. 155) 2017-07-19 (1 minute)
• Minimal distributed streams (p. 1844) 2018-04-27 (5 minutes)
• How small can we make a comfortable subset of JS? (p. 1348) 2018-11-27 (updated 2018-12-02) (3 minutes)
• Dercuano drawings (p. 64) 2019-04-30 (updated 2019-05-30) (18 minutes)
• A homoiconic language with a finite-map-based data model rather than lists? (p. 2630) 2019-09-25 (updated 2019-09-28) (46 minutes)
• Introduction to closures (p. 1403) 2019-12-07 (5 minutes)

Notes concerning “JSON”

- Twingler (p. 2547) 2014-02-24 (7 minutes)
- Tagging parsers (p. 208) 2018-11-23 (updated 2018-12-10) (9 minutes)

Notes concerning “Jupyter”

• Quasicard: a hypothetical reimagining of HyperCard and TiddlyWiki (p. 416) 2017-04-18 (updated 2017-06-09) (18 minutes)
• Literate programs should include example output, like Jupyter, but Jupyter is imperfect (p. 1308) 2018-04-27 (3 minutes)
• Dehydrating processes and other interaction models (p. 3208) 2018-12-28 (updated 2019-01-01) (36 minutes)

Notes concerning “Kanthal”

- Millikiln (p. 2581) 2017-01-17 (updated 2017-03-02) (4 minutes)
- An electric furnace the size of a sake cup (p. 666) 2017-02-25 (updated 2017-03-02) (10 minutes)
- Radiant heating (p. 493) 2018-05-20 (3 minutes)

Notes concerning “Keyboards”

- Writing math in Unicode with the Compose key (p. 1863) 2007 to 2009 (2 minutes)
- Trellis-coded buttons to run a whole keyboard off two microcontroller pins (p. 2011) 2013-05-17 (updated 2019-06-13) (30 minutes)
- Keyboard-powered computers (p. 2220) 2014-10-25 (updated 2018-10-28) (26 minutes)
- Coinductive keyboard (p. 1893) 2016-07-30 (4 minutes)
- Quasimode keyboard (p. 2693) 2018-07-14 (24 minutes)

Notes concerning “Kilns”

• Improvising high-temperature refractory materials for pottery kilns (p. 2701) 2013-05-17 (4 minutes)
• Regenerator gas kiln (p. 2653) 2016-09-05 (updated 2017-04-10) (9 minutes)
• A design sketch of an air conditioner powered by solar thermal power (p. 2233) 2016-12-22 (updated 2017-01-04) (29 minutes)
• Millikiln (p. 2581) 2017-01-17 (updated 2017-03-02) (4 minutes)
• An electric furnace the size of a sake cup (p. 666) 2017-02-25 (updated 2017-03-02) (10 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Inductor thermocouple sensing (p. 2037) 2019-06-01 (21 minutes)
• Induction kiln (p. 2352) 2019-06-02 (19 minutes)

Notes concerning “Kogluktualuk”

• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• Blob computation (p. 2214) 2017-07-19 (2 minutes)

Notes concerning “Laser cutters”

Notes concerning “Lasers”

• Phosphorescent laser display (p. 1987) 2016-08-16 (8 minutes)
• Digital logic with lasers, induced X-ray emission, and neutron-induced fission, for femtosecond switching times? (p. 1027) 2016-09-06 (3 minutes)
• Data archival on gold leaf or Mylar with DVD-writer lasers or sparks (p. 1455) 2018-04-27 (5 minutes)

Notes concerning “Latency”

• Why Thunderbird is inadequate for opening a 7-gigabyte mbox (p. 980) 2007 to 2009 (2 minutes)
• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• Instant hypertext (p. 630) 2013-05-17 (updated 2013-05-20) (14 minutes)
• Interactive calculator 0 (p. 1453) 2015-09-17 (2 minutes)
• Anytime realtime (p. 803) 2016-04-22 (4 minutes)
• Circle-portal GUI (p. 1151) 2016-06-03 (11 minutes)
• Quicklayout (p. 2189) 2017-01-10 (updated 2017-01-18) (3 minutes)

• Text editor slow keys (p. 808) 2017-02-07 (2 minutes)
• Reflections on rebraining calculators with this RPN calculator code I just wrote (p. 1717) 2017-04-11 (4 minutes)
• Caching screen contents (p. 2362) 2017-06-14 (2 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• A minimal window system (p. 1545) 2018-04-27 (updated 2018-10-26) (12 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• A nonscriptable design for the Wercam windowing system (p. 3092) 2018-10-26 (updated 2018-11-13) (6 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)
• Cheap textures (p. 736) 2018-10-28 (updated 2019-05-05) (5 minutes)
• Transactional event handlers (p. 139) 2019-01-24 (14 minutes)

Notes concerning “Law”

• Copyright status of the Oxford English Dictionary: relevant data (p. 82) 2007 to 2009 (3 minutes)
• What might Diamond-Age-like phyles look like in the real 21st century? (p. 1599) 2014-04-24 (9 minutes)

Notes concerning “Layout”

• Instant hypertext (p. 630) 2013-05-17 (updated 2013-05-20) (14 minutes)
• Quicklayout (p. 2189) 2017-01-10 (updated 2017-01-18) (3 minutes)

• General purpose layout syntax (p. 3117) 2017-11-10 (updated 2019-09-01) (34 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)

Notes concerning “Laziness”

- Iterative string formatting (p. 1392) 2013-05-17 (9 minutes)
- Simple dependencies in software (p. 2447) 2014-06-05 (9 minutes)
- Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)

Notes concerning “LevelDB”

• ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)
• Mail reader (p. 3290) 2018-04-27 (updated 2018-06-18) (7 minutes)

• Byte prefix tuple space (p. 427) 2018-07-14 (updated 2018-07-15) (4 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)

Notes concerning “The LGP-30 computer”

• Transmission line computer (p. 509) 2016-07-11 (updated 2019-07-23) (7 minutes)
• Non-inverting logic (p. 861) 2017-02-18 (updated 2019-07-20) (8 minutes)
• Dehydrating processes and other interaction models (p. 3208) 2018-12-28 (updated 2019-01-01) (36 minutes)

Notes concerning “Li ion”

• Lithium battery welder (p. 2846) 2018-06-21 (updated 2019-01-22) (2 minutes)
• Terrestrial lithium supplies provide adequate energy storage to reach Kardashev Type 1 (p. 2123) 2019-07-25 (6 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Light deflection”

• Lenticular deflector (p. 2612) 2019-09-08 (updated 2019-09-09) (9 minutes)
• Kerr snow display (p. 3220) 2019-11-12 (3 minutes)

Notes concerning “Lighting”

Notes concerning “Linear algebra”

• Matrix exponentiation linear circuits (p. 355) 2018-12-18 (4 minutes)
• The miraculous low-rank SVD approximate convolution algorithm (p. 747) 2019-08-14 (updated 2019-08-15) (31 minutes)
• Complex linear regression (in the field $\mathbb{C}$ of complex numbers) (p. 3018) 2019-08-17 (updated 2019-08-18) (9 minutes)
• Differentiable neighborhood regression (p. 2944) 2019-08-31 (15 minutes)

Notes concerning “Lisp”

• Enumerating binary trees and their elements (p. 1445) 2007 to 2009 (4 minutes)
• Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009 (13 minutes)
• Designing a Scheme for APL-like array computations, like Lush (p. 661) 2007 to 2009 (4 minutes)
• Quasiquote patterns (p. 3021) 2007 to 2009 (9 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Linear trees (p. 1811) 2016-05-19 (updated 2016-05-20) (6 minutes)
• Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952) 2018-04-27 (4 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• A homoiconic language with a finite-map-based data model rather than lists? (p. 2630) 2019-09-25 (updated 2019-09-28) (46 minutes)

Notes concerning “Lithium”

• Lithium fission energy (p. 3285) 2016-09-06 (updated 2019-09-16) (6 minutes)
• Terrestrial lithium supplies provide adequate energy storage to reach Kardashev Type 1 (p. 2123) 2019-07-25 (6 minutes)

Notes concerning “Logging”

• Desbarrerarme: a UI for speaking to people (p. 186) 2015-09-03 (5 minutes)
• Efficiently querying a log of everything that ever happened (p. 2506) 2015-09-03 (7 minutes)
• Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)
• Notations for defining dynamical systems (p. 2872) 2016-10-03 (updated 2016-10-06) (6 minutes)
• A language whose memory model is a bunch of temporally-indexed logs (p. 1359) 2019-05-12 (updated 2018-05-21) (20 minutes)

Notes concerning “Log-structured merge trees (LSM-trees)”

• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
• Set hashing (p. 2485) 2017-03-09 (9 minutes)
• Incremental persistent binary array sets (p. 1008) 2017-04-10 (4 minutes)

Notes concerning “Lua”

• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)
• Improving Lua #L with incremental prefix sum in the ∧ monoid (p. 2008) 2018-12-18 (7 minutes)
• B-Tree ropes (p. 2762) 2019-09-24 (updated 2019-09-25) (19 minutes)
• A homoiconic language with a finite-map-based data model rather than lists? (p. 2630) 2019-09-25 (updated 2019-09-28) (46 minutes)

Notes concerning “Magic kazoo”

• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Another candidate lightweight frequency tracking algorithm (p. 2069) 2017-08-18 (4 minutes)
• How can we do online pitch detection? (p. 1869) 2018-04-27 (updated 2018-04-30) (6 minutes)

Notes concerning "Manufacturing"

• Polycaprolactone (p. 1813) 2007 to 2009 (3 minutes)
• Review notes for Chris Anderson's "Makers" (p. 1072) 2013-05-17 (5 minutes)
• Notes on 3-D printing a mechanical LUT (p. 1326) 2014-04-24 (3 minutes)
• 2025 manufacturing and economics scenario (p. 699) 2014-04-24 (24 minutes)
• Comparison of the PCO-1810 and PCO-1881 plastic bottlecap standards (p. 3223) 2014-05-25 (updated 2016-07-27) (2 minutes)
• We should use end-to-end optimization algorithms for 3-D printing design (p. 1550) 2015-09-03 (14 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• A hand-powered computer? (p. 624) 2015-09-03 (updated 2017-07-19) (11 minutes)
• Hot wire saw (p. 3159) 2015-12-28 (updated 2019-06-02) (10 minutes)
• 2016 outlook for automated fabrication and 3-D printing (p. 2316) 2016-08-11 (20 minutes)
• Prototyping stuff (p. 176) 2016-08-11 (1 minute)
• Regenerative fuel air cutting (p. 2622) 2016-09-06 (4 minutes)
• Soldering with a compound parabolic concentrator or even just an imaging lens (p. 101) 2016-09-07 (2 minutes)
• Filling hollow FDM things with other materials (p. 2119) 2016-09-07 (5 minutes)
• Laser ablation of zinc or pewter for printed circuit boards (p. 2799) 2016-09-19 (4 minutes)
• Spark particulate sieve (p. 2047) 2016-10-06 (updated 2016-10-11) (7 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Self replication changes (p. 2842) 2017-01-16 (5 minutes)
• Servoing a V-plotter with a webcam? (p. 62) 2017-02-16 (3 minutes)
• 3-D printing by flux deposition (p. 466) 2017-02-24 (updated 2019-07-27) (21 minutes)
• Vibratory powder delivery (p. 1747) 2017-02-25 (2 minutes)
• How cheap can laser-cut boxes be? (p. 2545) 2017-06-01 (2 minutes)
• Approaches to 3-D printing in sandstone (p. 1095) 2017-08-03 (5 minutes)
• Hammering toolhead (p. 3297) 2017-08-18 (6 minutes)
• A brief note on autonomous cyclic fabrication systems from inorganic raw materials (p. 2965) 2018-04-27 (1 minute)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• UHMWPE clothes could be lightweight and sturdy (p. 3071)

2018-06-05 (3 minutes)
• Electrolytic anodizing, with a small movable electrode (p. 3059) 2018-10-28 (2 minutes)
• Single-point incremental forming of aluminum foil (p. 769) 2019-03-11 (updated 2019-06-10) (14 minutes)
• Elastic metamaterials (p. 719) 2019-03-19 (17 minutes)
• Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)
• Caustic business card (p. 255) 2019-04-08 (3 minutes)
• Maximal-flexibility designs for printable building blocks (p. 1839) 2019-04-20 (18 minutes)
• Cold plasma oxidation (p. 2406) 2019-05-01 (updated 2019-08-21) (7 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)
• Induction kiln (p. 2352) 2019-06-02 (19 minutes)
• Drone cutting (p. 1106) 2019-06-11 (12 minutes)
• Cardboard furniture (p. 742) 2019-08-01 (updated 2019-08-11) (15 minutes)
• Needle binder injection printing (p. 1492) 2019-08-05 (12 minutes)
• Printed circuits on fired-clay ceramic (p. 960) 2019-08-13 (11 minutes)
• Harmonic motion chain robot (p. 2197) 2019-08-16 (2 minutes)
• Gold leaf trusses (p. 3055) 2019-08-31 (11 minutes)
• Expanded mineral beads (p. 2166) 2019-10-01 (12 minutes)
• Bistable magnetic electromechanical display (p. 1016) 2019-10-24 (16 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)
• Hot lye granite cutting (p. 581) 2019-11-01 (2 minutes)
• Shaped hammer face giant pressure (p. 3278) 2019-11-10 (21 minutes)
• Incremental roller comb forming (p. 3146) 2019-11-27 (4 minutes)
• Berlinite gel (p. 848) 2019-12-14 (updated 2019-12-15) (10 minutes)
• Nomadic furniture optimization (p. 1658) 2019-12-15 (2 minutes)

Notes concerning “Materials”

• Air conditioning (p. 1665) 2007 to 2009 (21 minutes)
• Polycaprolactone (p. 1813) 2007 to 2009 (3 minutes)
• The economics of solar energy (p. 1175) 2008 (27 minutes)
• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Improvising high-temperature refractory materials for pottery kilns (p. 2701) 2013-05-17 (4 minutes)
• A resistive-capacitive trackpad made from garbage and three ADC microcontroller pins (p. 852) 2013-05-17 (updated 2013-05-20) (17 minutes)
• Holographic archival (p. 766) 2014-04-24 (10 minutes)
• Inflatable stool (p. 1047) 2014-04-24 (6 minutes)
• An extremely simple electromechanical state machine (p. 50) 2014-04-24 (16 minutes)
• Archival transparencies (p. 1345) 2014-06-05 (updated 2014-06-29) (7 minutes)
• A mechano-optical vector display for animation archival (p. 3047) 2014-12-28 (updated 2015-09-03) (28 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Waterproofing (p. 429) 2015-09-03 (4 minutes)
• Tapered thread (p. 363) 2015-09-03 (updated 2019-06-10) (4 minutes)
• Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) 2015-09-11 (updated 2019-12-20) (49 minutes)
• Hot wire saw (p. 3159) 2015-12-28 (updated 2019-06-02) (10 minutes)
• Material merits (p. 1496) 2016-05-08 (6 minutes)
• US$10M for a new, much better McMurdo Base, or less (p. 2879) 2016-05-18 (updated 2016-05-19) (7 minutes)
• Spring energy density (p. 3106) 2016-05-28 (updated 2016-06-06) (13 minutes)
• Phase-change heat reservoirs for household climate control (p. 2257) 2016-06-14 (updated 2016-06-17) (13 minutes)
• Thermodynamic systems in housing (p. 2804) 2016-06-28 (24 minutes)
• String cutting cardboard (p. 515) 2016-06-30 (5 minutes)
• Flux deposition for 3-D printing in glass and metals (p. 1366) 2016-07-03 (15 minutes)
• How would you maximize the energy density of a capacitor? (p. 42) 2016-07-27 (5 minutes)
• Electroluminescent matrix (p. 974) 2016-07-27 (2 minutes)
• Vitruvius could have taken photographs (p. 992) 2016-07-30 (1 minute)
• Executable scholarship, or algorithmic scholarly communication (p. 2137) 2016-08-11 (13 minutes)
• Solar dehumidifier (p. 717) 2016-08-11 (5 minutes)
• Hot oil cutter (p. 3287) 2016-08-16 (updated 2016-08-17)

(8 minutes)

• Computation with strain (p. 2812) 2019-06-13 (17 minutes)

• Foil origami robots (p. 2286) 2019-06-13 (updated 2019-06-14) (10 minutes)
• Spiral chinese windlass (p. 2915) 2019-07-23 (updated 2019-07-24) (7 minutes)
• Sandwich theory (p. 2450) 2019-08-05 (updated 2019-08-29) (31 minutes)
• Harmonic motion chain robot (p. 2197) 2019-08-16 (2 minutes)
• Rubber wheel pinch drive (p. 2912) 2019-08-16 (updated 2019-08-18) (8 minutes)
• Gold leaf trusses (p. 3055) 2019-08-31 (11 minutes)
• Photodiode camera (p. 2265) 2019-09-04 (16 minutes)
• Lenticular deflector (p. 2612) 2019-09-08 (updated 2019-09-09) (9 minutes)
• Methods of pumping ice-vest coolant silently (p. 2415) 2019-09-28 (12 minutes)
• Bistable magnetic electromechanical display (p. 1016) 2019-10-24 (16 minutes)
• Shaped hammer face giant pressure (p. 3278) 2019-11-10 (21 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)
• Oval cam lock (p. 3060) 2019-11-26 (5 minutes)

Notes concerning “Memex”

• Writing hypertext is still a pain (p. 715) 2016-02-18 (6 minutes)
• Quasicard: a hypothetical reimagining of HyperCard and TiddlyWiki (p. 416) 2017-04-18 (updated 2017-06-09) (18 minutes)

Notes concerning “Memory models”

• Simple system language (p. 1659) 2013-05-17 (7 minutes)
• Constant-space grep (p. 296) 2014-02-24 (3 minutes)
• Embedding objects inside other objects in memory, versus by-reference fields (p. 3112) 2014-02-24 (13 minutes)
• Linear trees (p. 1811) 2016-05-19 (updated 2016-05-20) (6 minutes)
• Similarities between Golang and Rust (p. 1523) 2017-01-11 (updated 2017-01-17) (7 minutes)
• Cartesian product storage (p. 3012) 2017-03-20 (3 minutes)
• Parametric polymorphism and columns (p. 1835) 2017-07-19 (2 minutes)
• The Z-machine memory model (p. 2903) 2017-07-19 (4 minutes)
• Constant space flexible data (p. 352) 2018-04-27 (5 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• Constant space lists (p. 3062) 2018-12-10 (10 minutes)
• India rubber memory (p. 579) 2019-03-19 (4 minutes)
• A language whose memory model is a bunch of temporally-indexed logs (p. 1359) 2019-05-12 (updated 2018-05-21) (20 minutes)

Notes concerning “Merkle DAGs”

• ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
• Distributed computing environment (p. 776) 2017-07-19 (8 minutes)

Notes concerning “Messaging”

• Queueing messages to amortize dynamic dispatch and take advantage of hardware heterogeneity (p. 586) 2016-09-17 (13 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)

Notes concerning “Metaballs”

• Modeling trees with slices containing metaballs (p. 2619) 2014-06-29 (updated 2014-07-02) (6 minutes)
• Convolution surface plotting (p. 2264) 2015-09-03 (updated 2015-09-13) (2 minutes)

Notes concerning “Metallurgy”

• Flux deposition for 3-D printing in glass and metals (p. 1366) 2016-07-03 (15 minutes)
• Vitruvius could have taken photographs (p. 992) 2016-07-30 (1 minute)
• Immersion plating of copper on iron with blue vitriol (p. 1099) 2016-09-24 (8 minutes)
• Copper plating furniture (p. 1460) 2017-07-19 (updated 2017-09-01) (4 minutes)

Notes concerning “Metamaterials”

- Elastic metamaterials (p. 719) 2019-03-19 (17 minutes)
- Gold leaf trusses (p. 3055) 2019-08-31 (11 minutes)
- Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)

Notes concerning “Method of secants”

• Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)
• Using the method of secants for general optimization (p. 1773) 2019-07-22 (updated 2019-11-26) (13 minutes)
• Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) 2019-08-17 (updated 2019-09-15) (15 minutes)
• Rediscovering successive parabolic interpolation: derivative-free optimization of scalar functions by fitting a parabola (p. 727) 2019-11-26 (updated 2019-11-27) (8 minutes)

Notes concerning “Metrology”

• Charge transfer servo (p. 3017) 2013-05-17 (2 minutes)
• The Tinkerer’s Tricorder (p. 72) 2013-05-17 (updated 2014-04-24) (27 minutes)
• Optical lever thermometer (p. 2624) 2015-09-03 (1 minute)
• A hand-powered computer? (p. 624) 2015-09-03 (updated 2017-07-19) (11 minutes)
• Solar-cell Geiger counters (p. 3241) 2016-07-30 (1 minute)
• Augmenting a slow precise ADC with a sloppy fast high-pass filtered parallel ADC (p. 1469) 2017-03-20 (2 minutes)
• Disk oscilloscope (p. 713) 2017-04-10 (updated 2017-06-20) (3 minutes)
• TV oscilloscope (p. 1253) 2017-04-10 (updated 2017-06-20) (4 minutes)
• Laser printer oscilloscope (p. 449) 2017-04-18 (updated 2017-06-20) (2 minutes)
• Can a simple nonlinear VCO enable super cheap oscilloscopes? (p. 1357) 2017-05-04 (updated 2017-05-10) (5 minutes)
• VCR oscilloscope (p. 213) 2017-05-10 (updated 2017-06-20) (2 minutes)
• CCD oscilloscope (p. 1861) 2017-06-20 (updated 2017-07-04) (7 minutes)
• Arduino curve tracer (p. 591) 2018-06-17 (10 minutes)
• Turning off the power supply for every sample to reduce noise (p. 239) 2018-06-18 (2 minutes)
• Measuring submicron displacements by pitch bending a slide guitar (p. 905) 2019-05-05 (18 minutes)
• Inductor thermocouple sensing (p. 2037) 2019-06-01 (21 minutes)
• Measuring the moisture content of coffee and other things with dielectric spectroscopy (p. 1033) 2019-07-16 (updated 2019-07-17) (28 minutes)
• Phase relations (p. 2200) 2019-07-23 (updated 2019-07-24) (4 minutes)

Notes concerning "Microcontrollers"

• Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
• Programming paradigms for tiny microcontrollers (p. 2104) 2007 to 2009 (6 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Ghettobotics: making robots out of trash (p. 2747) 2013-05-17 (41 minutes)
• A resistive-capacitive trackpad made from garbage and three ADC microcontroller pins (p. 852) 2013-05-17 (updated 2013-05-20) (17 minutes)
• The Tinkerer's Tricorder (p. 72) 2013-05-17 (updated 2014-04-24) (27 minutes)
• Trellis-coded buttons to run a whole keyboard off two microcontroller pins (p. 2011) 2013-05-17 (updated 2019-06-13) (30 minutes)
• Randomizing delta-sigma conversion to eliminate aliasing (p. 2834) 2014-04-24 (7 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• A hand-powered computer? (p. 624) 2015-09-03 (updated 2017-07-19) (11 minutes)
• How can we build an efficient microcontroller-based amplifier? (p. 2821) 2016-07-13 (5 minutes)
• Jellybean ICs 2016 (p. 817) 2016-07-14 (updated 2019-05-05) (17 minutes)
• Low-power microcontrollers for a low-power computer (p. 2602) 2016-09-06 (updated 2018-10-28) (18 minutes)
• Solar-powered portable computers (p. 2959) 2016-09-17 (updated 2018-10-28) (15 minutes)
• Current hardware trends tend toward raytracing (p. 1351) 2016-10-07 (4 minutes)
• The Magic Kazoo: a synthesizer you stick in your mouth (p. 1873) 2017-04-04 (updated 2019-05-12) (6 minutes)
• Minimum hardware and software to get a flexible notetaking device running (p. 535) 2017-04-28 (4 minutes)
• How can we do online pitch detection? (p. 1869) 2018-04-27 (updated 2018-04-30) (6 minutes)
• Arduino curve tracer (p. 591) 2018-06-17 (10 minutes)
• Transistors vs. Microcontrollers (p. 2918) 2018-06-17 (updated 2018-07-05) (8 minutes)
• The TWI and I²C buses and better alternatives like CAN and RS-485 (p. 1638) 2018-06-28 (updated 2018-07-05) (24 minutes)
• The Adafruit Feather (p. 2966) 2018-06-30 (1 minute)
• Notes on the STM32 microcontroller family (p. 3176) 2018-06-30 (updated 2018-11-12) (42 minutes)
• Byte prefix tuple space (p. 427) 2018-07-14 (updated 2018-07-15) (4 minutes)

• Microlens vibrating lightfield (p. 1219) 2018-07-14 (updated 2018-07-15) (11 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)
• The Bleep ultrasonic modem for local data communication (p. 966) 2018-12-10 (updated 2018-12-11) (8 minutes)
• the oversold-as-low-power Renesas RL78 microcontroller line (p. 504) 2019-08-27 (10 minutes)
• Audio logic analyzer (p. 1801) 2019-11-12 (3 minutes)

Notes concerning “Microprint”

• Full res globe (p. 1255) 2014-02-24 (1 minute)
• Holographic archival (p. 766) 2014-04-24 (10 minutes)
• Archival transparencies (p. 1345) 2014-06-05 (updated 2014-06-29) (7 minutes)
• Quadratic opacity holograms (p. 3073) 2015-09-03 (7 minutes)
• Rosetta opacity hologram (p. 98) 2016-09-05 (8 minutes)
• Microprint visor (p. 523) 2016-09-07 (2 minutes)
• Piezoelectric engraving (p. 1070) 2017-07-19 (4 minutes)
• Data archival on gold leaf or Mylar with DVD-writer lasers or sparks (p. 1455) 2018-04-27 (5 minutes)

Notes concerning “Microscopy”

- Compressed sensing microscope (p. 306) 2016-10-06 (7 minutes)
- Caustics (p. 1619) 2018-08-18 (updated 2019-11-08) (8 minutes)
- Debokehfication (p. 473) 2019-09-01 (updated 2019-09-12) (4 minutes)

Notes concerning “Mill”

• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• Notations for defining dynamical systems (p. 2872) 2016-10-03 (updated 2016-10-06) (6 minutes)
• Generalizing my RPN calculator to support refactoring (p. 969) 2016-10-17 (12 minutes)
• A sketch of a minimalist bytecode for object-oriented languages (p. 1790) 2017-03-20 (updated 2017-06-20) (13 minutes)
• Golomb-coding operands as belt offsets likely won’t increase code density much (p. 1605) 2017-06-15 (updated 2017-06-20) (6 minutes)

• Compact code cpu (p. 397) 2017-07-19 (3 minutes)
• A language whose memory model is a bunch of temporally-indexed logs (p. 1359) 2019-05-12 (updated 2018-05-21) (20 minutes)

Notes concerning "miniKANREN"

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• Binate and KANREN (p. 3189) 2018-12-02 (3 minutes)
• The uses of introspection, reflection, and personal supercomputers in software testing (p. 2306) 2019-02-04 (updated 2019-03-11) (12 minutes)
• Relational modeling and APL (p. 1217) 2019-05-20 (updated 2019-05-21) (5 minutes)

Notes concerning “Minsky algorithm”

• Notations for defining dynamical systems (p. 2872) 2016-10-03 (updated 2016-10-06) (6 minutes)
• Cheap frequency detection (p. 3026) 2017-06-29 (updated 2019-06-19) (50 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)

Notes concerning “Minimal Instruction Set Computing”

• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• A sketch of a minimalist bytecode for object-oriented languages (p. 1790) 2017-03-20 (updated 2017-06-20) (13 minutes)
• Golomb-coding operands as belt offsets likely won’t increase code density much (p. 1605) 2017-06-15 (updated 2017-06-20) (6 minutes)

Notes concerning “Moon”

• Can you read the lunar lander’s plaque from Earth? Or write a new one? (p. 125) 2015-09-03 (9 minutes)
• Seeing the Apollo flags from Earth would require a telescope 27× the size of the Gran Telescopio Canarias (p. 309) 2019-04-10 (updated 2019-04-16) (2 minutes)

Notes concerning “Morphology”

• Dilating letterforms (p. 651) 2018-11-04 (15 minutes)
• Some notes on morphology, including improvements on Urbach and Wilkinson’s erosion/dilation algorithm (p. 216) 2019-01-04 (updated 2019-11-12) (26 minutes)
• Median filtering (p. 3155) 2019-01-17 (11 minutes)
• Tabulating your top event of the month efficiently using RMQ algorithms (p. 619) 2019-03-19 (8 minutes)
• Isotropic nonlinear texture effects for letterforms from a scale-space representation (p. 1609) 2019-09-10 (16 minutes)

Notes concerning “Multiplication”

- Multiplication with squares (p. 1983) 2017-07-19 (updated 2019-07-09) (5 minutes)
- Hardware multiplication with square tables (p. 1886) 2019-02-08 (updated 2019-07-09) (4 minutes)
- Karatsuba (p. 2090) 2019-04-20 (2 minutes)

Notes concerning “Multitouch”

• drag-and-drop calculator for touch devices (p. 1045) 2015-09-03 (5 minutes)
• Interactive calculator (p. 2771) 2018-04-26 (16 minutes)
• Interactive geometry (p. 508) 2018-04-26 (1 minute)
• Two-thumb quasimodal multitouch interaction techniques (p. 1765) 2018-04-26 (11 minutes)
• Multitouch livecoding (p. 122) 2018-06-17 (1 minute)
• Quasimode keyboard (p. 2693) 2018-07-14 (24 minutes)
• Dercuano drawings (p. 64) 2019-04-30 (updated 2019-05-30) (18 minutes)
• First impressions on using the µMath+ calculator program for Android (p. 195) 2019-05-21 (13 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)
• $1 recognizer diagrams (p. 1264) 2019-08-11 (updated 2019-10-24) (15 minutes)
• Multitouch and accelerometer puppeteering (p. 1785) 2019-08-29 (updated 2019-09-01) (12 minutes)
• Audio tablet (p. 2178) 2019-09-28 (7 minutes)

Notes concerning “The MuP21 MISC microcontroller”

• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• mechanical computation: with Merkle gates, height fields, and thread (p. 2494) 2010-06-28 (36 minutes)

Notes concerning “Music”

• Alastair thesis review (p. 1784) 2013-05-17 (1 minute)
• Square wave synthesis (p. 3200) 2014-02-24 (2 minutes)
• Rhythm codes (p. 2375) 2015-09-03 (4 minutes)
• Would Synthgramelodia make a good base for livecoding music? (p. 2540) 2015-09-03 (8 minutes)
• Convolution applications (p. 2930) 2015-09-07 (updated 2019-08-14) (9 minutes)
• Virtual instruments (p. 658) 2015-11-09 (3 minutes)
• The Magic Kazoo: a synthesizer you stick in your mouth (p. 1873) 2017-04-04 (updated 2019-05-12) (6 minutes)
• Can you make a vocoder simpler using CIC filters? (p. 2006) 2017-06-28 (updated 2018-06-17) (2 minutes)
• Multitouch livecoding (p. 122) 2018-06-17 (1 minute)
• Sample reversal (p. 1353) 2018-12-18 (updated 2019-01-17) (5 minutes)
• Honk development (p. 1188) 2019-03-21 (2 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)
• Measuring submicron displacements by pitch bending a slide guitar (p. 905) 2019-05-05 (18 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)
• Pythagorean cement pipes for your shower singing (p. 156) 2019-09-08 (updated 2019-09-09) (7 minutes)
• Hadamard rhythms (p. 831) 2019-11-01 (6 minutes)
• Audio logic analyzer (p. 1801) 2019-11-12 (3 minutes)
• Applying FM synthesis to natural sounds such as voices (p. 596) 2019-11-12 (2 minutes)

Notes concerning “Networking”

• A survey of small TCP/IP implementations (p. 2616) 2007 to 2009 (4 minutes)
• The internet is probably not going to collapse for economic reasons (p. 3194) 2016-09-06 (9 minutes)
• Web prefetch (p. 3046) 2017-06-15 (1 minute)
• A REST interface to a software transactional memory (p. 3014) 2017-06-21 (2 minutes)
• Interactive bandwidth (p. 779) 2017-08-03 (2 minutes)
• How inefficient is SNAT hole-punching via random port trials? (p. 1155) 2018-04-27 (2 minutes)
• Notes on SIP VoIP in 2019 (p. 1064) 2019-06-07 (updated 2019-06-28) (8 minutes)

Notes concerning “Newton–Raphson iteration (“Newton’s method”)”

• Anytime realtime (p. 803) 2016-04-22 (4 minutes)
• Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)
• Using the method of secants for general optimization (p. 1773) 2019-07-22 (updated 2019-11-26) (13 minutes)
• Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) 2019-08-17 (updated 2019-09-15) (15 minutes)
• Fast mathematical optimization with affine arithmetic (p. 3163) 2019-09-15 (5 minutes)
• Rediscovering successive parabolic interpolation: derivative-free optimization of scalar functions by fitting a parabola (p. 727) 2019-11-26 (updated 2019-11-27) (8 minutes)

Notes concerning “Non-imaging optics”

• US$10M for a new, much better McMurdo Base, or less (p. 2879) 2016-05-18 (updated 2016-05-19) (7 minutes)
• Soldering with a compound parabolic concentrator or even just an imaging lens (p. 101) 2016-09-07 (2 minutes)

Notes concerning “Natural-language processing”

• Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
• Distinguishing natural languages with 3-grams of characters (p. 2953) 2013-05-17 (updated 2013-05-20) (7 minutes)
• Alphanumerenglish (p. 2882) 2015-04-06 (updated 2016-07-27) (6 minutes)
• Toward a language for hacking around with natural-language processing algorithms (p. 1681) 2016-09-08 (7 minutes)
• Surrealist code (p. 1325) 2016-10-11 (3 minutes)
• English diphones (p. 2061) 2019-12-03 (5 minutes)

Notes concerning “Noise”

- Digital noise generators (p. 1137) 2018-10-28 (2 minutes)
- Time domain analog chaos (p. 2198) 2018-10-28 (4 minutes)

Notes concerning “Nuclear”

• Solar-cell Geiger counters (p. 3241) 2016-07-30 (1 minute)
• Digital logic with lasers, induced X-ray emission, and neutron-induced fission, for femtosecond switching times? (p. 1027) 2016-09-06 (3 minutes)
• Lithium fission energy (p. 3285) 2016-09-06 (updated 2019-09-16) (6 minutes)

Notes concerning “Numpy”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)

• English diphones (p. 2061) 2019-12-03 (5 minutes)
• Nomadic furniture optimization (p. 1658) 2019-12-15 (2 minutes)

Notes concerning “Optimum trits”

• In what sense is e the optimal branching factor, and what does it mean for menu tree design? (p. 2483) 2012-12-04 (3 minutes)
• Precisely how is 3 “optimal” for one-hot state machines, sparse FIR kernels, etc.? (p. 450) 2014-04-24 (8 minutes)

Notes concerning “Oscilloscopes”

• Argentine oscilloscope pricing 2016 (p. 1965) 2016-08-16 (4 minutes)
• Augmenting a slow precise ADC with a sloppy fast high-pass filtered parallel ADC (p. 1469) 2017-03-20 (2 minutes)
• Disk oscilloscope (p. 713) 2017-04-10 (updated 2017-06-20) (3 minutes)
• TV oscilloscope (p. 1253) 2017-04-10 (updated 2017-06-20) (4 minutes)
• Laser printer oscilloscope (p. 449) 2017-04-18 (updated 2017-06-20) (2 minutes)
• Can a simple nonlinear VCO enable super cheap oscilloscopes? (p. 1357) 2017-05-04 (updated 2017-05-10) (5 minutes)
• VCR oscilloscope (p. 213) 2017-05-10 (updated 2017-06-20) (2 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• CCD oscilloscope (p. 1861) 2017-06-20 (updated 2017-07-04) (7 minutes)
• Oscilloscope screens (p. 578) 2018-06-05 (2 minutes)
• Can you turbocharge the STM32 ADC to build an oscilloscope? (p. 137) 2018-07-14 (5 minutes)
• Phase relations (p. 2200) 2019-07-23 (updated 2019-07-24) (4 minutes)

Notes concerning “OpenStreetMap”

- Full res globe (p. 1255) 2014-02-24 (1 minute)
- Fast geographical maps on Android (p. 455) 2015-10-16 (9 minutes)

Notes concerning “Parallelism”

• Schimmler parallelism asymptotic gain (p. 294) 2007 to 2009 (1 minute)
• Incremental MapReduce for Abelian-group reduction functions (p. 331) 2015-09-03 (4 minutes)
• Parallel NFA evaluation (p. 2967) 2015-09-03 (updated 2015-10-01) (8 minutes)
• Internal determinism (p. 2803) 2016-08-17 (2 minutes)
• Counting the number of spaces to the left in parallel (p. 1067) 2016-10-11 (5 minutes)
• Bitsliced operations with a hypercube of shuffle operations (p. 2363) 2016-11-30 (2 minutes)
• Parallel DFA execution (p. 2337) 2017-04-18 (9 minutes)
• Vectorized prefix sum (p. 529) 2017-07-19 (5 minutes)

Notes concerning “Parselov”

• Parsing a conservative approximation of a CFG with a FSM (p. 159) 2015-09-03 (7 minutes)
• Parallel NFA evaluation (p. 2967) 2015-09-03 (updated 2015-10-01) (8 minutes)
• Profile-guided parser optimization should enable parsing of gigabytes per second (p. 2283) 2019-05-23 (8 minutes)

Notes concerning “Parsing”

• OMeta contains Wadler's "Views" (p. 842) 2007 to 2009 (updated 2019-05-20) (13 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Parsing a conservative approximation of a CFG with a FSM (p. 159) 2015-09-03 (7 minutes)
• DReX and “regular string transformations”: would an RPN DSL work well? (p. 453) 2016-09-19 (3 minutes)
• Secure, self-describing, self-delimiting serialization for Python (p. 243) 2017-04-11 (8 minutes)
• Toward a minimal PEG parsing engine (p. 955) 2018-06-06 (4 minutes)
• Immediate mode productive grammars (p. 898) 2018-09-13 (8 minutes)
• Tagging parsers (p. 208) 2018-11-23 (updated 2018-12-10) (9 minutes)
• How small can we make a comfortable subset of JS? (p. 1348) 2018-11-27 (updated 2018-12-02) (3 minutes)
• Minimal imperative language (p. 2175) 2018-12-10 (7 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)
• Profile-guided parser optimization should enable parsing of gigabytes per second (p. 2283) 2019-05-23 (8 minutes)
• Dercuano grinding (p. 2475) 2019-10-01 (12 minutes)
• Immediate-mode PEG parsers in assembly language (p. 365) 2019-12-10 (updated 2019-12-11) (21 minutes)

Notes concerning “Particle filters”

• Interval filters (p. 1282) 2015-09-17 (2 minutes)
• Texture synthesis with spatial-domain particle filters (p. 857) 2016-10-06 (2 minutes)

Notes concerning “Parsing Expression Grammars (PEGs)”

- OMeta contains Wadler's "Views" (p. 842) 2007 to 2009 (updated 2019-05-20) (13 minutes)
- Toward a minimal PEG parsing engine (p. 955) 2018-06-06 (4 minutes)
- Tagging parsers (p. 208) 2018-11-23 (updated 2018-12-10) (9 minutes)
- How small can we make a comfortable subset of JS? (p. 1348) 2018-11-27 (updated 2018-12-02) (3 minutes)

Notes concerning “Performance”

• Bicicleta maps (p. 582) 2007 to 2009 (2 minutes)
• Using bytecode won’t make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)
• A cute algorithm for card-image templates (p. 1946) 2007 to 2009 (2 minutes)

• High temperature semiconductors (p. 2436) 2019-12-01 (2 minutes)

Notes concerning “Plaster”

• Approaches to 3-D printing in sandstone (p. 1095) 2017-08-03 (5 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)

Notes concerning “Plating”

- Electrodeposition 3d printing (p. 1115) 2016-02-19 (4 minutes)
- Immersion plating of copper on iron with blue vitriol (p. 1099) 2016-09-24 (8 minutes)
- Copper plating furniture (p. 1460) 2017-07-19 (updated 2017-09-01) (4 minutes)
- Absurd household materials (p. 532) 2018-04-26 (updated 2018-05-18) (8 minutes)

Notes concerning “Phase-locked loops”

• Karplus–Strong PLLs (p. 2100) 2017-06-09 (1 minute)
• Is a phase vocoder or a bunch of PLLs a more efficient way to listen to all FM radio stations at once? (p. 1405) 2018-06-17 (updated 2019-07-29) (7 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)

Notes concerning "Politics"

• Free software debugging (p. 136) 2007 to 2009 (2 minutes)
• Copyright status of the Oxford English Dictionary: relevant data (p. 82) 2007 to 2009 (3 minutes)
• Rich programmers (p. 805) 2007 to 2009 (4 minutes)
• Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
• Dollar auctions and tournaments in human society (p. 884) 2013-05-17 (7 minutes)
• Who is inventing the future in 2013? (p. 897) 2013-05-17 (1 minute)

• Review notes for Chris Anderson's "Makers" (p. 1072) 2013-05-17 (5 minutes)
• Some personal notes from February 2014 (p. 2134) 2014-02-13 (8 minutes)
• What would a basic income guarantee for Argentina cost? (p. 2409) 2014-04-24 (7 minutes)
• 2025 manufacturing and economics scenario (p. 699) 2014-04-24 (24 minutes)
• Ostinatto (p. 2780) 2014-04-24 (4 minutes)
• What might Diamond-Age-like phyles look like in the real 21st century? (p. 1599) 2014-04-24 (9 minutes)
• Plato was not particularly democratic; ἄρχειν is not "participating in politics" (p. 1707) 2014-04-24 (5 minutes)
• In a world with ubiquitous surveillance, what does politics look like? (p. 1615) 2014-04-24 (11 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• State of the world 2016 (p. 2973) 2016-09-05 (10 minutes)
• Solving the incentive problem for censorship-resistant DHTs (p. 923) 2016-09-07 (updated 2019-05-21) (3 minutes)
• High academic achievement almost certainly depends more on tutoring than group averages by race or sex (p. 113) 2016-09-08 (3 minutes)
• Statement from the Confederation of Teachers (p. 725) 2016-10-11 (updated 2016-10-12) (4 minutes)
• World War III is starting (?) (p. 346) 2016-10-17 (2 minutes)
• Selfish conformity (p. 622) 2016-11-15 (5 minutes)
• The problem is not that people are not turning to real journalism anymore (p. 2934) 2016-11-15 (8 minutes)
• Self replication changes (p. 2842) 2017-01-16 (5 minutes)
• The continuous-web press and the continuous press of the World-Wide Web (p. 1134) 2017-03-20 (6 minutes)
• Studies support authority (p. 1541) 2017-04-10 (2 minutes)
• Replicating education (p. 557) 2017-07-19 (7 minutes)
• 2017 [Provisional English translation of intercepted transmission] (p. 2192) 2018-04-27 (updated 2018-07-14) (13 minutes)
• Why is there so much anti-plastic sentiment? Visibility, Arcadian

primitivism, conspicuous consumption, and profit. (p. 3270) 2018-06-21 (7 minutes)
• Ultralight tunnel personal rapid transit (p. 706) 2019-03-11 (15 minutes)
• What are Bitcoin's uses other than sidestepping the law? (p. 2159) 2019-03-11 (updated 2019-07-05) (6 minutes)
• Weregild (p. 3149) 2019-03-24 (3 minutes)
• Notch scorn (p. 115) 2019-04-20 (5 minutes)
• On influencers (p. 660) 2019-05-16 (3 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)
• Categorical zero sum prohibition (p. 2553) 2019-05-27 (updated 2019-06-01) (23 minutes)
• Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333) 2019-07-03 (6 minutes)
• The fable of the specialized fox (p. 1076) 2019-08-17 (1 minute)
• Everything is money? (p. 1859) 2019-08-31 (4 minutes)

Notes concerning “Pompous”

• A Sunday in 2014 (p. 1089) 2014-02-24 (3 minutes)
• La vibración del hierro, ¿es de baja frecuencia o qué? (p. 2231) 2016-10-07 (3 minutes)
• Surrealist code (p. 1325) 2016-10-11 (3 minutes)
• Statement from the Confederation of Teachers (p. 725) 2016-10-11 (updated 2016-10-12) (4 minutes)
• Notch scorn (p. 115) 2019-04-20 (5 minutes)
• GPT-2 sets the scene (p. 2978) 2019-11-22 (updated 2019-12-01) (22 minutes)

Notes concerning “Post-scarcity things”

• What would a basic income guarantee for Argentina cost? (p. 2409) 2014-04-24 (7 minutes)
• 2025 manufacturing and economics scenario (p. 699) 2014-04-24 (24 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Exponential technology and capital (p. 406) 2016-02-18 (updated 2017-07-19) (8 minutes)
• Self replication changes (p. 2842) 2017-01-16 (5 minutes)
• Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)

Notes concerning “Power supplies”

- Lab power supply (p. 2421) 2017-02-21 (updated 2018-06-18) (17 minutes)
- Bench trash power supply (p. 1457) 2018-04-27 (9 minutes)
- Really simple lab power supply (p. 240) 2019-12-10 (7 minutes)

Notes concerning “Predicate logic”

• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• Bayesian and Gricean programming (p. 711) 2015-08-20 (3 minutes)

• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• Querying a pile of free-text strings with quasi-Prolog (p. 811) 2017-11-17 (6 minutes)
• Relational modeling and APL (p. 1217) 2019-05-20 (updated 2019-05-21) (5 minutes)

Notes concerning “Prefix sums”

• Worst-case-logarithmic-time reduction over arbitrary intervals over arbitrary semigroups (p. 1021) 2012-12-04 (5 minutes)
• a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees) (p. 1190) 2012-12-06 (updated 2013-05-17) (10 minutes)
• Square wave synthesis (p. 3200) 2014-02-24 (2 minutes)
• Compression with second-order diffs (p. 2152) 2014-04-24 (3 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Efficiently querying a log of everything that ever happened (p. 2506) 2015-09-03 (7 minutes)
• Parallel NFA evaluation (p. 2967) 2015-09-03 (updated 2015-10-01) (8 minutes)
• Counting the number of spaces to the left in parallel (p. 1067) 2016-10-11 (5 minutes)
• Parallel DFA execution (p. 2337) 2017-04-18 (9 minutes)
• Vectorized prefix sum (p. 529) 2017-07-19 (5 minutes)
• Accelerating convolution and correlation with short periodic waveforms using OLAP marginal prefix sums (p. 895) 2018-06-05 (4 minutes)
• Real-time bokeh algorithms, and other convolution tricks (p. 2661) 2018-12-18 (updated 2019-08-15) (23 minutes)
• Some notes on morphology, including improvements on Urbach and Wilkinson’s erosion/dilation algorithm (p. 216) 2019-01-04 (updated 2019-11-12) (26 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)
• The miraculous low-rank SVD approximate convolution algorithm (p. 747) 2019-08-14 (updated 2019-08-15) (31 minutes)
• Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) 2019-08-31 (updated 2019-09-08) (28 minutes)
• A bag of candidate techniques for sparse filter design (p. 3250) 2019-09-01 (18 minutes)
• Nonlinear bounded leaky integrator (p. 3150) 2019-09-11 (8 minutes)

Notes concerning "Pricing"

• Air conditioning (p. 1665) 2007 to 2009 (21 minutes)
• A comparison of prices for different forms of energy (p. 3097) 2007 to 2009 (2 minutes)
• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• Polycaprolactone (p. 1813) 2007 to 2009 (3 minutes)
• Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
• The economics of solar energy (p. 1175) 2008 (27 minutes)
• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Food storage (p. 2706) 2013-05-11 (updated 2013-05-17) (54 minutes)
• Illuminating yourself with 10 kilolux of LEDs to combat seasonal affective disorder (p. 527) 2013-05-17 (5 minutes)
• Only a constant factor worse (p. 1648) 2013-05-17 (16 minutes)
• Review notes for Chris Anderson's "Makers" (p. 1072) 2013-05-17 (5 minutes)
• Trellis-coded buttons to run a whole keyboard off two microcontroller pins (p. 2011) 2013-05-17 (updated 2019-06-13) (30 minutes)
• Some personal notes from February 2014 (p. 2134) 2014-02-13 (8 minutes)
• Jim Weirich's death and my daily life (p. 829) 2014-04-24 (5 minutes)
• What would a basic income guarantee for Argentina cost? (p. 2409) 2014-04-24 (7 minutes)
• The future of the human energy market (2014) (p. 1846) 2014-04-24 (19 minutes)
• Building a resilient network out of litter (p. 2107) 2014-04-24 (4 minutes)
• How to use "correct horse battery staple" as an encryption key, including a recommended 4096-word list (p. 2522) 2014-04-24 (44 minutes)
• Comparison of the PCO-1810 and PCO-1881 plastic bottlecap standards (p. 3223) 2014-05-25 (updated 2016-07-27) (2 minutes)
• Waterproofing (p. 429) 2015-09-03 (4 minutes)
• A hand-powered computer? (p. 624) 2015-09-03 (updated 2017-07-19) (11 minutes)
• Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) 2015-09-11 (updated 2019-12-20) (49 minutes)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Electrodeposition 3d printing (p. 1115) 2016-02-19 (4 minutes)
• Material merits (p. 1496) 2016-05-08 (6 minutes)
• US$10M for a new, much better McMurdo Base, or less (p. 2879) 2016-05-18 (updated 2016-05-19) (7 minutes)
• Wikipedia people (p. 948) 2016-06-01 (6 minutes)

• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)
• Speculative plans for BubbleOS (p. 2128) 2018-10-28 (updated 2019-02-24) (12 minutes)
• Notes on SIP VoIP in 2019 (p. 1064) 2019-06-07 (updated 2019-06-28) (8 minutes)
• Resurrecting duckling hashing (p. 3128) 2019-10-26 (updated 2019-11-10) (8 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)
• Byte stream gui applications (p. 128) 2019-11-29 (updated 2019-11-30) (17 minutes)

Notes concerning “Psychology”

• On hanging out with cranks (p. 1715) 2008-04 (4 minutes)
• Ostinatto (p. 2780) 2014-04-24 (4 minutes)
• How to use “correct horse battery staple” as an encryption key, including a recommended 4096-word list (p. 2522) 2014-04-24 (44 minutes)
• Ideas to ship in 2014 (p. 1409) 2014-04-24 (updated 2019-05-05) (35 minutes)
• He listened to the human intently (p. 2543) 2014-06-29 (4 minutes)

• Buenos Aires seen from behind the mirror (p. 809) 2014-09-02 (7 minutes)
• ¿Qué necesito para relación de pareja? (p. 1298) 2016-03-09 (6 minutes)
• Do visually expanding images evoke an orienting response, or the startle response, and what does that mean for ZUIs? (p. 1805) 2016-06-03 (14 minutes)
• Selfish conformity (p. 622) 2016-11-15 (5 minutes)
• The ultimate capacity of human memory if spaced-practice memorization works as advertised (p. 2442) 2017-01-04 (updated 2017-01-08) (14 minutes)
• A tournament to decide which notes to devote attention to polishing (p. 1195) 2017-07-19 (2 minutes)
• Frustration (p. 3263) 2018-04-27 (2 minutes)
• Life octaves (p. 173) 2018-10-28 (2 minutes)
• An IDE modeled on video games (p. 1959) 2019-04-08 (5 minutes)
• A note on meditation (p. 494) 2019-04-20 (1 minute)
• Categorical zero sum prohibition (p. 2553) 2019-05-27 (updated 2019-06-01) (23 minutes)
• Human memorable secret sharing (p. 426) 2019-08-10 (2 minutes)
• Autism is overfitting (p. 2692) 2019-08-31 (1 minute)

Notes concerning “Pubsub”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Micro pubsub (p. 1504) 2017-06-15 (8 minutes)
• Kafka-like feeds for offline-first browser apps (p. 903) 2017-08-03 (5 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• Fast secure pubsub (p. 545) 2019-02-04 (updated 2019-12-03) (2 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)
• Bytecode pubsub (p. 205) 2019-12-04 (6 minutes)

Notes concerning “Python”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• Using bytecode won't make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)
• A cute algorithm for card-image templates (p. 1946) 2007 to 2009 (2 minutes)
• Enumerating binary trees and their elements (p. 1445) 2007 to 2009 (4 minutes)
• Error Reporting is Part of the Programmer's User Interface (p. 2323) 2007 to 2009 (18 minutes)
• Index set inference or domain inference for programming with indexed families (p. 1434) 2007 to 2009 (updated 2019-05-05) (27 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Range literals (p. 1719) 2014-04-24 (6 minutes)
• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Toward a language for hacking around with natural-language processing algorithms (p. 1681) 2016-09-08 (7 minutes)
• Thredsnek: a tiny Python-flavored programming language (p. 1172) 2017-03-20 (7 minutes)
• A sketch of a minimalist bytecode for object-oriented languages (p. 1790) 2017-03-20 (updated 2017-06-20) (13 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• Vectorized prefix sum (p. 529) 2017-07-19 (5 minutes)
• Rarely are function-local variables in Forth justified (p. 1055) 2018-04-27 (10 minutes)
• A minimal window system (p. 1545) 2018-04-27 (updated 2018-10-26) (12 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• Yeso notes (p. 2585) 2018-12-25 (updated 2019-01-01) (11 minutes)
• Observable transaction possibilities (p. 2086) 2019-06-15 (10 minutes)
• Reducing the cost of self-verifying arithmetic with array operations (p. 2205) 2019-06-23 (15 minutes)
• Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)
• The miraculous low-rank SVD approximate convolution algorithm (p. 747) 2019-08-14 (updated 2019-08-15) (31 minutes)
• Robust local search in vector spaces using adaptive step sizes, and

Notes concerning “Qemu”

• Notes on running QEMU on Debian Etch (p. 1646) 2007 to 2009 (3 minutes)
• Running your regular desktop in QEMU? (p. 292) 2007 to 2009 (3 minutes)

Notes concerning “Quasimodal”

• Interactive geometry (p. 508) 2018-04-26 (1 minute)
• Two-thumb quasimodal multitouch interaction techniques (p. 1765) 2018-04-26 (11 minutes)

Notes concerning “Quasimodes”

- Interactive calculator (p. 2771) 2018-04-26 (16 minutes)
- Quasimode keyboard (p. 2693) 2018-07-14 (24 minutes)

Notes concerning “Radio”

• Arduino radio (p. 169) 2016-07-30 (4 minutes)
• Could you do DDS of comprehensible radio signals with an Arduino? (p. 1829) 2017-03-31 (4 minutes)
• Dumb vocoder (p. 1391) 2017-05-10 (2 minutes)
• Urban autarkic network (p. 1026) 2018-04-27 (1 minute)
• Is a phase vocoder or a bunch of PLLs a more efficient way to listen to all FM radio stations at once? (p. 1405) 2018-06-17 (updated 2019-07-29) (7 minutes)
• Can you bitbang wireless communication between AVRs? How about AM-radio energy harvesting? (p. 2509) 2019-08-27 (updated 2019-08-28) (37 minutes)
• Examination of a shitty USB car charger (p. 286) 2019-10-24 (13 minutes)
• Transmitting low-power TV signals around your house via RF modulation with an SDR (p. 1950) 2019-12-01 (6 minutes)

Notes concerning “Raytracing”

- Current hardware trends tend toward raytracing (p. 1351) 2016-10-07 (4 minutes)
- Reduced affine arithmetic raytracer (p. 2007) 2017-05-10 (1 minute)

Notes concerning “Refractories”

• Regenerator gas kiln (p. 2653) 2016-09-05 (updated 2017-04-10) (9 minutes)
• Millikiln (p. 2581) 2017-01-17 (updated 2017-03-02) (4 minutes)
• An electric furnace the size of a sake cup (p. 666) 2017-02-25 (updated 2017-03-02) (10 minutes)

Notes concerning “Regenerators”

• Regenerator gas kiln (p. 2653) 2016-09-05 (updated 2017-04-10) (9 minutes)
• Regenerative fuel air cutting (p. 2622) 2016-09-06 (4 minutes)
• Freeze distillation at 1 Hz (p. 2796) 2016-10-06 (5 minutes)
• Reducing nighttime bedroom CO_2 levels (p. 478) 2019-07-08 (updated 2019-07-09) (14 minutes)

Notes concerning “Regexps”

- Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
- Parallel DFA execution (p. 2337) 2017-04-18 (9 minutes)

Notes concerning “Relays”

• Paper/foil relays (p. 3273) 2019-04-02 (updated 2019-10-23) (13 minutes)
• Bistable magnetic electromechanical display (p. 1016) 2019-10-24 (16 minutes)
• Nonconductive relays (p. 3262) 2019-11-12 (3 minutes)

Notes concerning "Reproducibility"

• The book written in itself (p. 2400) 2016-06-12 (updated 2016-06-14) (18 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Dehydrating processes and other interaction models (p. 3208) 2018-12-28 (updated 2019-01-01) (36 minutes)

Notes concerning “Research”

• Low-power microcontrollers for a low-power computer (p. 2602) 2016-09-06 (updated 2018-10-28) (18 minutes)
• Academic lineage (p. 2292) 2016-10-30 (updated 2019-11-24) (15 minutes)
• Commentaries on reading Engelbart’s “Augmenting Human Intellect” (p. 2091) 2018-12-24 (updated 2018-12-25) (25 minutes)
• A review of Wirth’s Project Oberon book (p. 431) 2019-02-04 (updated 2019-03-19) (63 minutes)
• Some musings on applying Fitts’s Law to user interface design and data compression (p. 1164) 2019-05-06 (updated 2019-05-09) (27 minutes)

Notes concerning “REpresentational State Transfer”

• Stuff I’ve posted to kragen-tol over the years about post-HTTP (p. 1815) 2014-02-24 (12 minutes)
• A simple content-addressable storage-server protocol (p. 774) 2015-09-03 (3 minutes)
• Caching screen contents (p. 2362) 2017-06-14 (2 minutes)
• Micro pubsub (p. 1504) 2017-06-15 (8 minutes)
• Service-oriented email (p. 1302) 2017-06-20 (updated 2017-06-21) (15 minutes)
• A REST interface to a software transactional memory (p. 3014) 2017-06-21 (2 minutes)
• Cached SOA desktop (p. 2229) 2017-08-03 (updated 2018-10-26) (6 minutes)
• Compressing REST transactions with per-connection state (p. 1117) 2018-04-27 (11 minutes)

Notes concerning "Retrocomputing"

• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• mechanical computation: with Merkle gates, height fields, and thread (p. 2494) 2010-06-28 (36 minutes)
• Alien game challenge (p. 2313) 2015-09-03 (6 minutes)
• Changing the basis to a more expressive one with better affordances (p. 1389) 2016-09-29 (5 minutes)
• Nova RDOS (p. 1724) 2017-06-15 (22 minutes)
• Pixel stream (p. 617) 2017-06-15 (updated 2018-10-26) (4 minutes)
• Some notes on reverse-engineering The Wizard's Castle (p. 1970) 2018-04-26 (9 minutes)
• Oscilloscope screens (p. 578) 2018-06-05 (2 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)
• A review of Wirth's Project Oberon book (p. 431) 2019-02-04 (updated 2019-03-19) (63 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)
• Techniques for, e.g., avoiding indexed-offset addressing on the 8080 (p. 3166) 2019-07-20 (updated 2019-07-24) (27 minutes)
• An 8080 opcode map in octal (p. 1059) 2019-08-28 (updated 2019-11-24) (11 minutes)

Notes concerning “The range minimum query problem”

- Worst-case-logarithmic-time reduction over arbitrary intervals over arbitrary semigroups (p. 1021) 2012-12-04 (5 minutes)
- a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees) (p. 1190) 2012-12-06 (updated 2013-05-17) (10 minutes)
- Robust hashsplitting with sliding Range Minimum Query (p. 733) 2016-09-05 (7 minutes)
- Some notes on morphology, including improvements on Urbach and Wilkinson’s erosion/dilation algorithm (p. 216) 2019-01-04 (updated 2019-11-12) (26 minutes)
- Tabulating your top event of the month efficiently using RMQ algorithms (p. 619) 2019-03-19 (8 minutes)

Notes concerning “Robotics”

• Ghettobotics: making robots out of trash (p. 2747) 2013-05-17 (41 minutes)
• 2025 manufacturing and economics scenario (p. 699) 2014-04-24 (24 minutes)
• A one-motor robot (p. 118) 2015-09-03 (13 minutes)
• 2016 outlook for automated fabrication and 3-D printing (p. 2316) 2016-08-11 (20 minutes)

Notes concerning “Robots”

• Charge transfer servo (p. 3017) 2013-05-17 (2 minutes)
• Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
• Servoing a V-plotter with a webcam? (p. 62) 2017-02-16 (3 minutes)
• High-precision control of low-stiffness sytems with bounded-Q resonances (p. 1002) 2017-05-29 (updated 2017-06-01) (4 minutes)
• Ideas to pursue (p. 1084) 2018-05-05 (updated 2018-08-16) (6 minutes)
• Image approximation (p. 2394) 2019-05-14 (10 minutes)
• Harmonic motion chain robot (p. 2197) 2019-08-16 (2 minutes)
• Rubber wheel pinch drive (p. 2912) 2019-08-16 (updated 2019-08-18) (8 minutes)
• Derivative based control (p. 2829) 2019-11-12 (6 minutes)

Notes concerning “Rosetta project”

- Holographic archival (p. 766) 2014-04-24 (10 minutes)
- Rosetta opacity hologram (p. 98) 2016-09-05 (8 minutes)

Notes concerning “Rust”

- Simple system language (p. 1659) 2013-05-17 (7 minutes)
- Similarities between Golang and Rust (p. 1523) 2017-01-11 (updated 2017-01-17) (7 minutes)

Notes concerning "Systems architecture"

• Running your regular desktop in QEMU? (p. 292) 2007 to 2009 (3 minutes)
• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• When and why exactly should your code "tell, not ask"? That is, use CPS? (p. 1051) 2014-01-08 (4 minutes)
• Stuff I've posted to kragen-tol over the years about post-HTTP (p. 1815) 2014-02-24 (12 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870) 2015-05-28 (updated 2016-06-22) (16 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Incremental MapReduce for Abelian-group reduction functions (p. 331) 2015-09-03 (4 minutes)
• Viral wiki (p. 1024) 2015-10-15 (3 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• DHT bulletin board (p. 3001) 2016-09-07 (7 minutes)
• Queueing messages to amortize dynamic dispatch and take advantage of hardware heterogeneity (p. 586) 2016-09-17 (13 minutes)
• MiniOS (p. 1091) 2016-12-28 (updated 2017-01-03) (6 minutes)
• Quicklayout (p. 2189) 2017-01-10 (updated 2017-01-18) (3 minutes)

• Burst computation (p. 1500) 2017-03-20 (13 minutes)
• Caching screen contents (p. 2362) 2017-06-14 (2 minutes)
• Nova RDOS (p. 1724) 2017-06-15 (22 minutes)
• Pixel stream (p. 617) 2017-06-15 (updated 2018-10-26) (4 minutes)
• Fast message router (p. 1853) 2017-06-15 (updated 2019-07-23) (15 minutes)

• Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)
• Broken computer frustrations (p. 102) 2019-08-11 (2 minutes)
• Resurrecting duckling hashing (p. 3128) 2019-10-26 (updated 2019-11-10) (8 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)
• Byte stream gui applications (p. 128) 2019-11-29 (updated 2019-11-30) (17 minutes)
• Bytecode pubsub (p. 205) 2019-12-04 (6 minutes)
• Memory safe virtual machines (p. 975) 2019-12-04 (14 minutes)

Notes concerning “Safety”

• Passively safe solar hot water (p. 1333) 2012-10-15 (updated 2012-10-16) (6 minutes)
• Phosphorescent laser display (p. 1987) 2016-08-16 (8 minutes)
• Approaches to limiting self-replication (p. 1004) 2016-11-30 (7 minutes)
• Coolants (p. 3235) 2017-07-04 (updated 2017-07-12) (11 minutes)
• Notes on a possible household air filter (p. 1961) 2018-05-05 (updated 2018-05-15) (10 minutes)
• Barrel safety (p. 1097) 2018-07-14 (3 minutes)
• Arduino safety (p. 3015) 2018-12-10 (4 minutes)
• Cold plasma oxidation (p. 2406) 2019-05-01 (updated 2019-08-21) (7 minutes)
• Methods of pumping ice-vest coolant silently (p. 2415) 2019-09-28 (12 minutes)

Notes concerning “Scheme”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• Enumerating binary trees and their elements (p. 1445) 2007 to 2009 (4 minutes)
• Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009 (13 minutes)
• IRC bots with object-oriented equational rewrite rules (p. 838) 2007 to 2009 (6 minutes)
• Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
• Separating implementation, optimization, and proofs (p. 780) 2019-06-26 (updated 2019-07-22) (41 minutes)
• A homoiconic language with a finite-map-based data model rather than lists? (p. 2630) 2019-09-25 (updated 2019-09-28) (46 minutes)
• Immediate-mode PEG parsers in assembly language (p. 365) 2019-12-10 (updated 2019-12-11) (21 minutes)

Notes concerning “Scholarship”

- Executable scholarship, or algorithmic scholarly communication (p. 2137) 2016-08-11 (13 minutes)
- Notch scorn (p. 115) 2019-04-20 (5 minutes)

Notes concerning “Scrubbers”

• Thermodynamic systems in housing (p. 2804) 2016-06-28 (24 minutes)
• House scrubber (p. 248) 2016-09-06 (updated 2019-11-25) (13 minutes)
• Scrubber mask (p. 90) 2019-05-08 (5 minutes)
• Reducing nighttime bedroom CO_2 levels (p. 478) 2019-07-08 (updated 2019-07-09) (14 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Signed distance functions (SDFs)”

Notes concerning “Sdr”

• Is a phase vocoder or a bunch of PLLs a more efficient way to listen to all FM radio stations at once? (p. 1405) 2018-06-17 (updated 2019-07-29) (7 minutes)
• Transmitting low-power TV signals around your house via RF modulation with an SDR (p. 1950) 2019-12-01 (6 minutes)

Notes concerning “Search”

• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• Constant-space grep (p. 296) 2014-02-24 (3 minutes)
• ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)
• Quasimode keyboard (p. 2693) 2018-07-14 (24 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)
• Fencepost cognitive interface errors in text editing (p. 993) 2019-04-24 (24 minutes)
• Dercuano search (p. 1532) 2019-05-16 (2 minutes)

Notes concerning “The Secure Scuttlebutt protocol”

- Gaim group chat (p. 2677) 2007 to 2009 (3 minutes)
- Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)
- Kafka-like feeds for offline-first browser apps (p. 903) 2017-08-03 (5 minutes)
- Minimal distributed streams (p. 1844) 2018-04-27 (5 minutes)
- Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)

Notes concerning “Security”

• lattices, powersets, bitstrings, and efficient OLAP (p. 2345) 2014-04-24 (17 minutes)
• How to use “correct horse battery staple” as an encryption key, including a recommended 4096-word list (p. 2522) 2014-04-24 (44 minutes)
• A simple content-addressable storage-server protocol (p. 774) 2015-09-03 (3 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• What’s wrong with CoAP (p. 560) 2017-06-15 (3 minutes)
• Distributed computing environment (p. 776) 2017-07-19 (8 minutes)
• Obscurity platform (p. 2991) 2018-04-27 (1 minute)
• Bokeh pointcasting (p. 92) 2019-09-08 (updated 2019-09-09) (16 minutes)
• Resurrecting duckling hashing (p. 3128) 2019-10-26 (updated 2019-11-10) (8 minutes)

Notes concerning “Umut Acar’s “self-adjusting computation””

• Automatic dependency management (p. 881) 2015-05-28 (updated 2015-09-03) (5 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Dehydrating processes and other interaction models (p. 3208) 2018-12-28 (updated 2019-01-01) (36 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)
• Fast secure pubsub (p. 545) 2019-02-04 (updated 2019-12-03) (2 minutes)
• Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138) 2019-08-17 (updated 2019-09-15) (15 minutes)

Notes concerning "Self-replication"

• The economics of solar energy (p. 1175) 2008 (27 minutes)
• mechanical computation: with Merkle gates, height fields, and thread (p. 2494) 2010-06-28 (36 minutes)
• Ghettobotics: making robots out of trash (p. 2747) 2013-05-17 (41 minutes)
• 2025 manufacturing and economics scenario (p. 699) 2014-04-24 (24 minutes)
• Planar lookup tables (p. 3105) 2014-04-24 (2 minutes)
• Making a mechanical state machine via sheet cutting (p. 1013) 2014-04-24 (updated 2015-09-03) (7 minutes)
• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Exponential technology and capital (p. 406) 2016-02-18 (updated 2017-07-19) (8 minutes)
• The book written in itself (p. 2400) 2016-06-12 (updated 2016-06-14) (18 minutes)
• String cutting cardboard (p. 515) 2016-06-30 (5 minutes)
• 2016 outlook for automated fabrication and 3-D printing (p. 2316) 2016-08-11 (20 minutes)
• Clanking replicators (p. 171) 2016-11-30 (3 minutes)
• Approaches to limiting self-replication (p. 1004) 2016-11-30 (7 minutes)
• Self replication changes (p. 2842) 2017-01-16 (5 minutes)
• Clay fabrication objectives (p. 2111) 2017-01-16 (updated 2017-01-17) (3 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• A brief note on autonomous cyclic fabrication systems from inorganic raw materials (p. 2965) 2018-04-27 (1 minute)
• Elastic metamaterials (p. 719) 2019-03-19 (17 minutes)
• Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)
• Maximal-flexibility designs for printable building blocks (p. 1839) 2019-04-20 (18 minutes)
• Plastic cutters (p. 1074) 2019-04-20 (5 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)
• Computation with strain (p. 2812) 2019-06-13 (17 minutes)
• Foil origami robots (p. 2286) 2019-06-13 (updated 2019-06-14) (10 minutes)

Notes concerning “Self-sustaining systems”

• Simplified computing, down to the level of mining raw materials (p. 691) 2015-09-03 (22 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• MiniOS (p. 1091) 2016-12-28 (updated 2017-01-03) (6 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Real time windowing (p. 891) 2017-08-03 (9 minutes)
• Frustration (p. 3263) 2018-04-27 (2 minutes)
• Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952) 2018-04-27 (4 minutes)
• Bootstrapping instruction set (p. 459) 2018-11-06 (updated 2019-05-03) (19 minutes)

Notes concerning “Self”

• Bicicleta maps (p. 582) 2007 to 2009 (2 minutes)
• Using bytecode won’t make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)

Notes concerning “Sensors”

• Ghettobotics: making robots out of trash (p. 2747) 2013-05-17 (41 minutes)
• The Tinkerer’s Tricorder (p. 72) 2013-05-17 (updated 2014-04-24) (27 minutes)
• Starfield servo (p. 1709) 2016-08-30 (updated 2018-11-07) (13 minutes)
• Compressed sensing microscope (p. 306) 2016-10-06 (7 minutes)
• Passive ultrasound sonar (p. 295) 2016-12-28 (1 minute)
• FM chirp sonar (p. 351) 2017-07-04 (1 minute)
• Measuring submicron displacements by pitch bending a slide guitar (p. 905) 2019-05-05 (18 minutes)
• Things in Dercuano that would be big if true (p. 3136) 2019-05-24 (updated 2019-08-21) (24 minutes)
• Processing halftoning (p. 915) 2019-09-01 (15 minutes)
• Photodiode camera (p. 2265) 2019-09-04 (16 minutes)
• Audio tablet (p. 2178) 2019-09-28 (7 minutes)
• Camera flash extrapolation (p. 2792) 2019-11-12 (6 minutes)

Notes concerning “Serialization”

• HTML is terser and more robust than S-expressions (p. 562) 2007 to 2009 (4 minutes)
• Fast geographical maps on Android (p. 455) 2015-10-16 (9 minutes)
• Secure, self-describing, self-delimiting serialization for Python (p. 243) 2017-04-11 (8 minutes)
• ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)
• Immediate mode productive grammars (p. 898) 2018-09-13 (8 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)

Notes concerning “Sewage”

• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Home dehumidifier (p. 3131) 2018-05-20 (updated 2019-04-02) (12 minutes)
• Household thermal stores (p. 1533) 2018-12-02 (updated 2018-08-19) (27 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Structure from shading”

- Reconstructing a 3-D Lambertian surface from video with a moving light source (p. 3296) 2016-09-16 (1 minute)
- Cloth structure from shading (p. 84) 2019-09-01 (2 minutes)

Notes concerning “Sheet cutting”

• Planar lookup tables (p. 3105) 2014-04-24 (2 minutes)
• Making a mechanical state machine via sheet cutting (p. 1013) 2014-04-24 (updated 2015-09-03) (7 minutes)
• String cutting cardboard (p. 515) 2016-06-30 (5 minutes)
• Heckballs: a laser-cuttable MDF set of building blocks (p. 2782) 2016-08-17 (updated 2016-08-30) (24 minutes)
• Sun cutter (p. 56) 2016-09-06 (9 minutes)
• Simple state machines (p. 760) 2016-09-19 (updated 2016-09-24) (8 minutes)
• Laser cut next step (p. 824) 2018-04-27 (updated 2018-04-30) (7 minutes)
• Friction-cutting plastic (p. 2412) 2019-02-25 (8 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)
• Extending Heckballs (p. 3239) 2019-11-26 (6 minutes)

Notes concerning “SIMD instructions”

• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• Designing an archival virtual machine (p. 3203) 2016-05-12 (6 minutes)
• Further notes on algebras for dark silicon (p. 1753) 2016-09-17 (updated 2017-04-18) (23 minutes)
• Gradient rendering (p. 583) 2016-09-24 (11 minutes)
• Counting the number of spaces to the left in parallel (p. 1067) 2016-10-11 (5 minutes)
• Vector instructions (p. 2977) 2017-07-19 (2 minutes)
• Vectorized prefix sum (p. 529) 2017-07-19 (5 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• Bootstrapping instruction set (p. 459) 2018-11-06 (updated 2019-05-03) (19 minutes)
• Observable transaction possibilities (p. 2086) 2019-06-15 (10 minutes)

Notes concerning “Physical system simulation”

• We should use end-to-end optimization algorithms for 3-D printing design (p. 1550) 2015-09-03 (14 minutes)
• Topics to study in 2016 (p. 678) 2016-10-27 (updated 2016-11-15) (37 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Matrix exponentiation linear circuits (p. 355) 2018-12-18 (4 minutes)

Notes concerning “Sketchpad”

• Constant space lists (p. 3062) 2018-12-10 (10 minutes)
• Dercuano drawings (p. 64) 2019-04-30 (updated 2019-05-30) (18 minutes)
• Designing a drawing editor for well-factored drawings (p. 2115) 2019-05-07 (9 minutes)

Notes concerning “Small is beautiful”

• Notes on reading eForth (p. 1398) 2007 to 2009 (9 minutes)
• Notes on reading eForth 1.0 for the 8086 (p. 541) 2007 to 2009 (5 minutes)
• Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009 (13 minutes)
• Forth looping (p. 2025) 2007 to 2009 (16 minutes)
• IRC bots with object-oriented equational rewrite rules (p. 838) 2007 to 2009 (6 minutes)
• Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
• A survey of small TCP/IP implementations (p. 2616) 2007 to 2009 (4 minutes)
• Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
• mechanical computation: with Merkle gates, height fields, and thread (p. 2494) 2010-06-28 (36 minutes)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• An algebraic approach to 3D geometry (p. 669) 2014-06-03 (updated 2014-06-29) (22 minutes)
• Archival with a universal virtual computer (UVC) (p. 399) 2014-06-29 (17 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Making the CPU instruction set a usable interactive user interface (p. 59) 2015-09-17 (8 minutes)
• Simplifying computing systems by having fewer kinds of graphics (p. 1110) 2015-10-13 (10 minutes)
• Minimal GUI libraries (p. 663) 2015-11-14 (updated 2015-11-15) (5 minutes)
• Logarithmic maintainability and coupling (p. 2341) 2015-11-23 (7 minutes)
• Circle-portal GUI (p. 1151) 2016-06-03 (11 minutes)
• Compact namespace sharing (p. 237) 2016-07-25 (7 minutes)
• Executable scholarship, or algorithmic scholarly communication (p. 2137) 2016-08-11 (13 minutes)
• What’s the dumbest register allocator that might give you reasonable performance? (p. 2596) 2016-10-11 (15 minutes)
• Thredsnek: a tiny Python-flavored programming language (p. 1172) 2017-03-20 (7 minutes)

Notes concerning “Sonar”

- Passive ultrasound sonar (p. 295) 2016-12-28 (1 minute)
- FM chirp sonar (p. 351) 2017-07-04 (1 minute)
- Audio tablet (p. 2178) 2019-09-28 (7 minutes)

Notes concerning “Sorting”

• Cycle sort (p. 2344) 2013-05-17 (1 minute)
• You can’t sort a file whose size is cubic in your RAM size in two passes, only quadratic (p. 2311) 2015-05-28 (5 minutes)
• Ternary mergesort (p. 2161) 2015-09-03 (2 minutes)
• An almost-in-place mergesort (p. 740) 2016-09-07 (5 minutes)
• The paradoxical complexity of computing the top N (p. 1890) 2017-01-04 (7 minutes)
• String tuple encoding (p. 2419) 2017-04-28 (2 minutes)
• ASCIIbetically homomorphic encodings of general data structures (p. 3261) 2017-06-15 (2 minutes)
• Sorting in logic (p. 498) 2019-12-28 (2 minutes)

Notes concerning “Spaced practice”

• How to use “correct horse battery staple” as an encryption key, including a recommended 4096-word list (p. 2522) 2014-04-24 (44 minutes)
• The ultimate capacity of human memory if spaced-practice memorization works as advertised (p. 2442) 2017-01-04 (updated 2017-01-08) (14 minutes)

Notes concerning “Spark”

Notes concerning “Sparkling”

- Starfield servo (p. 1709) 2016-08-30 (updated 2018-11-07) (13 minutes)
- Sparkle wheel display (p. 1738) 2017-05-10 (6 minutes)
- Photodiode camera (p. 2265) 2019-09-04 (16 minutes)

Notes concerning “Sparks”

• Marking metal surfaces with arcs (p. 1993) 2016-10-06 (4 minutes)
• Compressed sensing microscope (p. 306) 2016-10-06 (7 minutes)
• Spark particulate sieve (p. 2047) 2016-10-06 (updated 2016-10-11) (7 minutes)
• Data archival on gold leaf or Mylar with DVD-writer lasers or sparks (p. 1455) 2018-04-27 (5 minutes)

Notes concerning “Sparse filters”

• Some speculative thoughts on DSP algorithms (p. 2590) 2014-04-24 (20 minutes)
• Can you make a vocoder simpler using CIC filters? (p. 2006) 2017-06-28 (updated 2018-06-17) (2 minutes)
• Recurrent comb cascade (p. 483) 2018-11-09 (updated 2018-11-10) (2 minutes)
• Sparse filters (p. 834) 2018-12-02 (4 minutes)
• Real-time bokeh algorithms, and other convolution tricks (p. 2661) 2018-12-18 (updated 2019-08-15) (23 minutes)
• The miraculous low-rank SVD approximate convolution algorithm (p. 747) 2019-08-14 (updated 2019-08-15) (31 minutes)
• Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) 2019-08-31 (updated 2019-09-08) (28 minutes)
• A bag of candidate techniques for sparse filter design (p. 3250) 2019-09-01 (18 minutes)
• Sparse sinc (p. 1880) 2019-09-15 (10 minutes)
• Sparse filter optimization (p. 2610) 2019-11-01 (5 minutes)
• Magic sinewave filter (p. 200) 2019-12-17 (6 minutes)

Notes concerning “Speech synthesis”

• Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
• Alphanumerenglish (p. 2882) 2015-04-06 (updated 2016-07-27) (6 minutes)
• English diphones (p. 2061) 2019-12-03 (5 minutes)

Notes concerning “Splines”

• Achieving smooth curves in scanline image generation (p. 1507) 2013-05-17 (1 minute)
• Polynomial-spline FIR kernels by integrating sparse kernels (p. 1819) 2014-04-24 (12 minutes)
• Very fast FIR filtering with time-domain zero stuffing and splines (p. 1146) 2015-09-03 (updated 2015-09-07) (13 minutes)
• Gaussian spline reconstruction (p. 656) 2016-06-05 (updated 2016-06-06) (5 minutes)
• Rasterizing polies (p. 2023) 2017-07-19 (3 minutes)
• A bag of candidate techniques for sparse filter design (p. 3250) 2019-09-01 (18 minutes)

Notes concerning “Spreadsheets”

- Automatic dependency management (p. 881) 2015-05-28 (updated 2015-09-03) (5 minutes)
- Usability of scientific calculators (p. 2379) 2016-09-29 (19 minutes)
- An IDE modeled on video games (p. 1959) 2019-04-08 (5 minutes)

Notes concerning “SQL”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Gittable sql (p. 85) 2015-09-25 (updated 2015-09-26) (6 minutes)
• The history of NoSQL and dbm (p. 45) 2017-04-10 (16 minutes)
• Database explorer (p. 225) 2017-06-20 (2 minutes)
• Toward a lightweight, high-performance software prototyping environment (p. 2938) 2018-12-10 (15 minutes)
• What it means that HTML is “not a programming language”, and why the ignorant sometimes think otherwise (p. 1555) 2019-09-09 (updated 2019-10-01) (24 minutes)

Notes concerning “Stacks”

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• A stack of coordinate contexts (p. 2987) 2007 to 2009 (9 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)
• Forth with named stacks (p. 2101) 2014-02-24 (7 minutes)
• Memoize the stack (p. 2021) 2015-09-03 (5 minutes)
• Would Synthgramelodia make a good base for livecoding music? (p. 2540) 2015-09-03 (8 minutes)
• Making the CPU instruction set a usable interactive user interface (p. 59) 2015-09-17 (8 minutes)
• A one-operand stack machine (p. 3242) 2016-07-24 (updated 2016-07-25) (12 minutes)
• Circuit notation (p. 1161) 2016-09-08 (updated 2017-04-18) (7 minutes)
• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• Generalizing my RPN calculator to support refactoring (p. 969) 2016-10-17 (12 minutes)
• A sketch of a minimalist bytecode for object-oriented languages (p. 1790) 2017-03-20 (updated 2017-06-20) (13 minutes)
• Reflections on rebraining calculators with this RPN calculator code I just wrote (p. 1717) 2017-04-11 (4 minutes)
• Secure, self-describing, self-delimiting serialization for Python (p. 243) 2017-04-11 (8 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• A stack of stacks for simple modular electronics (p. 1779) 2017-06-27 (5 minutes)
• An RPN CPU instruction set doubling as user interface (p. 177) 2017-07-19 (updated 2019-07-10) (21 minutes)
• Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code? (p. 952) 2018-04-27 (4 minutes)
• A simple virtual machine for vector math? (p. 986) 2018-11-06 (updated 2018-11-09) (15 minutes)
• A two-operand calculator supporting programming by demonstration (p. 2387) 2018-12-11 (22 minutes)
• Three-stack generic macro assembler (design sketch) (p. 1336) 2019-04-30 (8 minutes)

Notes concerning “State machines”

• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• Simple state machines (p. 760) 2016-09-19 (updated 2016-09-24) (8 minutes)
• Finite function circuits (p. 2050) 2017-02-16 (updated 2019-05-17) (29 minutes)
• Parallel DFA execution (p. 2337) 2017-04-18 (9 minutes)

Notes concerning “VPRI STEPS”

- Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
- More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
- Frustration (p. 3263) 2018-04-27 (2 minutes)

Notes concerning “STM32 microcontrollers”

• Low-power microcontrollers for a low-power computer (p. 2602) 2016-09-06 (updated 2018-10-28) (18 minutes)
• A stack of stacks for simple modular electronics (p. 1779) 2017-06-27 (5 minutes)
• The TWI and I²C buses and better alternatives like CAN and RS-485 (p. 1638) 2018-06-28 (updated 2018-07-05) (24 minutes)
• Notes on the STM32 microcontroller family (p. 3176) 2018-06-30 (updated 2018-11-12) (42 minutes)
• Can you turbocharge the STM32 ADC to build an oscilloscope? (p. 137) 2018-07-14 (5 minutes)
• Inductor thermocouple sensing (p. 2037) 2019-06-01 (21 minutes)
• Really simple lab power supply (p. 240) 2019-12-10 (7 minutes)

Notes concerning “Strategy”

- Barcode receipts (p. 2359) 2007 to 2009 (6 minutes)
- High-risk behavior in context (p. 1485) 2007 to 2009 (5 minutes)
- Improving “science” in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
- Only a constant factor worse (p. 1648) 2013-05-17 (16 minutes)
- Dollar auctions and tournaments in human society (p. 884) 2013-05-17 (7 minutes)
- Complementary goods in home economics (p. 1878) 2017-07-19 (3 minutes)
- A tournament to decide which notes to devote attention to polishing (p. 1195) 2017-07-19 (2 minutes)
- Dutch auction raffle (p. 2474) 2018-06-05 (3 minutes)
- When should you give up waiting for the bus and just walk? (p. 2280) 2019-04-24 (5 minutes)
- Better be weird (p. 1831) 2019-06-17 (updated 2019-06-24) (9 minutes)

Notes concerning “Subterranean living”

Notes concerning “Surveys”

- Intro to algorithms (p. 2625) 2016-09-06 (4 minutes)
- Top algorithms (p. 913) 2018-07-29 (4 minutes)

Notes concerning “Sync”

• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• Kafka-like feeds for offline-first browser apps (p. 903) 2017-08-03 (5 minutes)
• Minimal distributed streams (p. 1844) 2018-04-27 (5 minutes)
• Rsync message base (p. 2463) 2019-11-08 (updated 2019-11-30) (29 minutes)

Notes concerning “Syntax”

• Enumerating binary trees and their elements (p. 1445) 2007 to 2009 (4 minutes)
• Forth looping (p. 2025) 2007 to 2009 (16 minutes)
• IRC bots with object-oriented equational rewrite rules (p. 838) 2007 to 2009 (6 minutes)
• HTML is terser and more robust than S-expressions (p. 562) 2007 to 2009 (4 minutes)
• Notes on Raph Levien's "Io" Programming Language (p. 1740) 2007 to 2009 (10 minutes)
• Iterative string formatting (p. 1392) 2013-05-17 (9 minutes)
• Forth with named stacks (p. 2101) 2014-02-24 (7 minutes)
• Range literals (p. 1719) 2014-04-24 (6 minutes)
• An algebraic approach to 3D geometry (p. 669) 2014-06-03 (updated 2014-06-29) (22 minutes)
• Entry-C: a Simula-like backwards-compatible object-oriented C (p. 564) 2015-04-05 (updated 2017-04-03) (24 minutes)
• Efficiently querying a log of everything that ever happened (p. 2506) 2015-09-03 (7 minutes)
• Toward a language for hacking around with natural-language processing algorithms (p. 1681) 2016-09-08 (7 minutes)
• Circuit notation (p. 1161) 2016-09-08 (updated 2017-04-18) (7 minutes)
• Graph construction (p. 3226) 2016-09-08 (updated 2017-07-19) (23 minutes)
• Pattern matching and finite functions (p. 1235) 2017-05-10 (14 minutes)
• Relational modeling (p. 1102) 2017-05-17 (updated 2017-06-01) (6 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• Ideal language syntax (p. 3260) 2017-07-19 (1 minute)
• General purpose layout syntax (p. 3117) 2017-11-10 (updated 2019-09-01) (34 minutes)
• Flexible text query (p. 2900) 2018-07-14 (4 minutes)
• Leconscrip: a family of JS subsets for BubbleOS (p. 2126) 2018-11-23 (2 minutes)
• How small can we make a comfortable subset of JS? (p. 1348) 2018-11-27 (updated 2018-12-02) (3 minutes)
• Binate and KANREN (p. 3189) 2018-12-02 (3 minutes)
• Minimal imperative language (p. 2175) 2018-12-10 (7 minutes)
• IMGUI programming compared to Tcl/Tk (p. 2333) 2018-12-24 (updated 2018-12-31) (8 minutes)
• IMGUI programming language (p. 103) 2019-01-01 (updated 2019-07-30) (21 minutes)
• A review of Wirth’s Project Oberon book (p. 431) 2019-02-04 (updated 2019-03-19) (63 minutes)
• Dercuano grinding (p. 2475) 2019-10-01 (12 minutes)

Notes concerning “Synthesis”

• Trees as code (p. 2488) 2016-05-10 (4 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)

Notes concerning “Tcl/Tk”

• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• IMGUI programming compared to Tcl/Tk (p. 2333) 2018-12-24 (updated 2018-12-31) (8 minutes)

Notes concerning “TCP/IP”

• A survey of small TCP/IP implementations (p. 2616) 2007 to 2009 (4 minutes)
• How inefficient is SNAT hole-punching via random port trials? (p. 1155) 2018-04-27 (2 minutes)

Notes concerning “Telescopes”

• Can you read the lunar lander’s plaque from Earth? Or write a new one? (p. 125) 2015-09-03 (9 minutes)
• Seeing the Apollo flags from Earth would require a telescope 27× the size of the Gran Telescopio Canarias (p. 309) 2019-04-10 (updated 2019-04-16) (2 minutes)

Notes concerning “Terminals”

• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• A proposal to support hypertext links in ANSI terminals (p. 486) 2013-05-17 (updated 2019-12-26) (13 minutes)
• What does a futuristic OS look like? (p. 2163) 2017-08-18 (updated 2019-05-05) (6 minutes)
• General purpose layout syntax (p. 3117) 2017-11-10 (updated 2019-09-01) (34 minutes)
• Speculative plans for BubbleOS (p. 2128) 2018-10-28 (updated 2019-02-24) (12 minutes)
• Dehydrating processes and other interaction models (p. 3208) 2018-12-28 (updated 2019-01-01) (36 minutes)

Notes concerning “Testing”

• Literate programs should include example output, like Jupyter, but Jupyter is imperfect (p. 1308) 2018-04-27 (3 minutes)
• The uses of introspection, reflection, and personal supercomputers in software testing (p. 2306) 2019-02-04 (updated 2019-03-11) (12 minutes)

Notes concerning “Textiles”

• UHMWPE clothes could be lightweight and sturdy (p. 3071) 2018-06-05 (3 minutes)
• Sandwich theory (p. 2450) 2019-08-05 (updated 2019-08-29) (31 minutes)
• Cloth structure from shading (p. 84) 2019-09-01 (2 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)

Notes concerning "The future"

- The economics of solar energy (p. 1175) 2008 (27 minutes)
- Predictions for future technological development (2008) (p. 341) 2008-04-19 (11 minutes)
- Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
- Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
- Who is inventing the future in 2013? (p. 897) 2013-05-17 (1 minute)

- Review notes for Chris Anderson's "Makers" (p. 1072) 2013-05-17 (5 minutes)
- The future of the human energy market (2014) (p. 1846) 2014-04-24 (19 minutes)
- 2025 manufacturing and economics scenario (p. 699) 2014-04-24 (24 minutes)
- What might Diamond-Age-like phyles look like in the real 21st century? (p. 1599) 2014-04-24 (9 minutes)
- In a world with ubiquitous surveillance, what does politics look like? (p. 1615) 2014-04-24 (11 minutes)
- Exponential technology and capital (p. 406) 2016-02-18 (updated 2017-07-19) (8 minutes)
- The internet is probably not going to collapse for economic reasons (p. 3194) 2016-09-06 (9 minutes)
- Hybrid RAM (p. 2877) 2016-09-24 (5 minutes)
- Current hardware trends tend toward raytracing (p. 1351) 2016-10-07 (4 minutes)
- Where did the Rubius comic book come from? (p. 1564) 2017-01-10 (4 minutes)
- Japan can achieve energy autarky via solar energy, but not much before 2027 (p. 2819) 2017-07-12 (4 minutes)
- The imbalance inherent in copyright systems (p. 2158) 2017-07-19 (2 minutes)
- Salt slush refrigeration (p. 1230) 2017-08-22 (updated 2019-10-08) (12 minutes)
- Commentaries on reading Engelbart's "Augmenting Human Intellect" (p. 2091) 2018-12-24 (updated 2018-12-25) (25 minutes)
- Gardening machines (p. 2365) 2019-04-02 (updated 2019-04-24) (32 minutes)

Notes concerning "Thermodynamics"

• Air conditioning (p. 1665) 2007 to 2009 (21 minutes)
• Pensamientos acerca de diseñar un calefón solar (p. 117) 2012-10-15 (2 minutes)
• Más pensamientos acerca de diseñar un calefón solar (p. 1713) 2012-10-15 (5 minutes)

Notes concerning “The Tinkerer’s Tricorder”

• The Tinkerer’s Tricorder (p. 72) 2013-05-17 (updated 2014-04-24) (27 minutes)
• Trellis-coded buttons to run a whole keyboard off two microcontroller pins (p. 2011) 2013-05-17 (updated 2019-06-13) (30 minutes)

Notes concerning “Toledo family”

Notes concerning “Toxicology”

• Coolants (p. 3235) 2017-07-04 (updated 2017-07-12) (11 minutes)
• Cold plasma oxidation (p. 2406) 2019-05-01 (updated 2019-08-21) (7 minutes)

Notes concerning “Trading”

• Incremental MapReduce for Abelian-group reduction functions (p. 331) 2015-09-03 (4 minutes)
• Assigning consistent order IDs (p. 1042) 2015-09-03 (3 minutes)
• Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333) 2019-07-03 (6 minutes)
• An affine-arithmetic database index for rapid historical securities formula queries (p. 2275) 2019-09-15 (15 minutes)

Notes concerning “Transactions”

• How can we usefully cache screen images for incrementalization? (p. 1077) 2013-05-17 (18 minutes)
• Simple dependencies in software (p. 2447) 2014-06-05 (9 minutes)
• Transactional screen updates (p. 2907) 2015-04-01 (10 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)
• Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257) 2016-07-23 (21 minutes)
• A REST interface to a software transactional memory (p. 3014) 2017-06-21 (2 minutes)
• A minimal dependency processing system (p. 911) 2017-09-21 (3 minutes)
• Minimal transaction system (p. 2460) 2017-09-21 (5 minutes)
• Composing code gobbets with implicit dependencies (p. 2437) 2018-04-27 (updated 2019-05-21) (3 minutes)
• Transactional event handlers (p. 139) 2019-01-24 (14 minutes)
• Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing (p. 1123) 2019-01-25 (7 minutes)
• Fast secure pubsub (p. 545) 2019-02-04 (updated 2019-12-03) (2 minutes)
• Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) 2019-02-08 (updated 2019-03-19) (23 minutes)
• Memory safe virtual machines (p. 975) 2019-12-04 (14 minutes)

Notes concerning “Transport”

• Subterranean glazing (p. 1126) 2016-09-06 (25 minutes)
• Ultralight tunnel personal rapid transit (p. 706) 2019-03-11 (15 minutes)

Notes concerning “Tree rewriting”

- IRC bots with object-oriented equational rewrite rules (p. 838) 2007 to 2009 (6 minutes)
- Term rewriting (p. 3221) 2017-07-19 (3 minutes)

Notes concerning “Types”

• APL with typed indices (p. 3264) 2013-05-17 (11 minutes)
• A principled rethinking of array languages like APL (p. 1995) 2015-05-16 (updated 2019-09-30) (31 minutes)
• What is the type of lerp? (p. 1985) 2017-01-08 (5 minutes)
• Generic programming with proofs, specification, refinement, and specialization (p. 958) 2017-05-10 (6 minutes)
• Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) 2018-04-27 (updated 2019-09-10) (42 minutes)

Notes concerning “Typing”

• The AL programming language, dimensional analysis, and typing: do different dimensions really exist? (p. 731) 2007 to 2009 (2 minutes)

• ML’s value restriction and the Modula-3 typing system (p. 1763) 2007 to 2009 (3 minutes)
• Fixed point (p. 807) 2014-04-24 (1 minute)

Notes concerning “Typography”

- The continuous-web press and the continuous press of the World-Wide Web (p. 1134) 2017-03-20 (6 minutes)
- Ideal language syntax (p. 3260) 2017-07-19 (1 minute)
- Dercuano stylesheet notes (p. 374) 2019-04-28 (updated 2019-05-09) (72 minutes)
- How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)
- Dercuano grinding (p. 2475) 2019-10-01 (12 minutes)

Notes concerning “Ubicomp”

Notes concerning “UHMWPE”

• Spring energy density (p. 3106) 2016-05-28 (updated 2016-06-06) (13 minutes)
• String cutting cardboard (p. 515) 2016-06-30 (5 minutes)
• Differential spiral cam (p. 512) 2017-07-19 (9 minutes)
• Dyneema (p. 123) 2017-07-19 (2 minutes)
• Absurd household materials (p. 532) 2018-04-26 (updated 2018-05-18) (8 minutes)
• You can stuff a UHMWPE hammock in your wallet (p. 799) 2018-05-15 (updated 2018-10-28) (11 minutes)
• UHMWPE clothes could be lightweight and sturdy (p. 3071) 2018-06-05 (3 minutes)
• Three phase oscillating belt (p. 214) 2018-10-28 (4 minutes)
• Spiral chinese windlass (p. 2915) 2019-07-23 (updated 2019-07-24) (7 minutes)
• Fabric optimization (p. 1526) 2019-10-28 (updated 2019-10-29) (17 minutes)
• Bootstrapping rope bridges and other tensile structures with UHMWPE-bearing drones (p. 2950) 2019-11-25 (5 minutes)

Notes concerning “Ultrasound”

• A unicast phased-array ultrasonic “radio” (p. 3077) 2013-05-17 (4 minutes)
• Passive ultrasound sonar (p. 295) 2016-12-28 (1 minute)
• Bubble display (p. 1542) 2017-01-24 (updated 2017-08-03) (1 minute)
• The Bleep ultrasonic modem for local data communication (p. 966) 2018-12-10 (updated 2018-12-11) (8 minutes)

Notes concerning “Uncorp”

Notes concerning “Unix”

• Git data (p. 2823) 2007 to 2009 (5 minutes)
• User-per-group (UPG), umask, and “Permission denied” on shared Git repos via ssh (p. 2481) 2007 to 2009 (4 minutes)
• Writing math in Unicode with the Compose key (p. 1863) 2007 to 2009 (2 minutes)
• Handling Landsat 8 images in limited RAM with netpbm (p. 1884) 2014-04-24 (4 minutes)
• What would a better Unix shell look like? (p. 2831) 2018-11-27 (1 minute)
• Raid zim (p. 253) 2019-01-17 (updated 2019-02-08) (1 minute)
• Text relational query (p. 1223) 2019-08-28 (10 minutes)

Notes concerning “Ur-Scheme”

- The coolest bug in Ur-Scheme (p. 1007) 2007 to 2009 (2 minutes)
- Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009 (13 minutes)
- Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)

Notes concerning "Utopias: proposals unlikely to be realized for improving things"

• What's wrong with ../../? (p. 2304) 2007 to 2009 (2 minutes)
• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
• A proposal to support hypertext links in ANSI terminals (p. 486) 2013-05-17 (updated 2019-12-26) (13 minutes)
• Logarithmic maintainability and coupling (p. 2341) 2015-11-23 (7 minutes)
• US$10M for a new, much better McMurdo Base, or less (p. 2879) 2016-05-18 (updated 2016-05-19) (7 minutes)

• Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333) 2019-07-03 (6 minutes)
• The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271) 2019-11-24 (updated 2019-12-03) (32 minutes)

Notes concerning “Video”

• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• Reconstructing a 3-D Lambertian surface from video with a moving light source (p. 3296) 2016-09-16 (1 minute)
• VCR oscilloscope (p. 213) 2017-05-10 (updated 2017-06-20) (2 minutes)
• Flying spot reilluminatable stage (p. 2358) 2017-05-15 (1 minute)
• Broadcast ECC with graceful degradation, or avoiding the cliff effect (p. 2045) 2018-12-18 (5 minutes)
• Audio video boustrophedon sync (p. 858) 2019-04-03 (2 minutes)
• Photodiode camera (p. 2265) 2019-09-04 (16 minutes)

Notes concerning “Vim”

• Quasimode keyboard (p. 2693) 2018-07-14 (24 minutes)
• Text editor design for e-ink displays (p. 3079) 2018-10-28 (23 minutes)

Notes concerning “Virtualization”

• Notes on running QEMU on Debian Etch (p. 1646) 2007 to 2009 (3 minutes)
• Running your regular desktop in QEMU? (p. 292) 2007 to 2009 (3 minutes)

Notes concerning “Vocoder”

• Dumb vocoder (p. 1391) 2017-05-10 (2 minutes)
• Can you make a vocoder simpler using CIC filters? (p. 2006) 2017-06-28 (updated 2018-06-17) (2 minutes)
• Is a phase vocoder or a bunch of PLLs a more efficient way to listen to all FM radio stations at once? (p. 1405) 2018-06-17 (updated 2019-07-29) (7 minutes)
• Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) 2019-06-16 (updated 2019-07-05) (39 minutes)

Notes concerning “Wang tiles”

Notes concerning “Water”

• Passively safe solar hot water (p. 1333) 2012-10-15 (updated 2012-10-16) (6 minutes)
• Waterproofing (p. 429) 2015-09-03 (4 minutes)
• ¿Se puede armar un colector solar de agua caliente que anda en invierno acá en Buenos Aires? (p. 2911) 2017-04-17 (2 minutes)
• Energy storage in a personal water tower: pretty impractical (p. 2044) 2017-07-19 (2 minutes)
• Salt slush refrigeration (p. 1230) 2017-08-22 (updated 2019-10-08) (12 minutes)
• Heating my apartment with a plastic tub of hot water (p. 1310) 2018-06-17 (3 minutes)
• Barrel safety (p. 1097) 2018-07-14 (3 minutes)
• Hot water bottles (p. 3066) 2018-07-14 (4 minutes)
• Sous vide (p. 2921) 2019-04-02 (2 minutes)
• Waterfryer (p. 1462) 2019-04-20 (1 minute)
• Intermittent fluid flow for heat transport (p. 521) 2019-07-10 (4 minutes)
• Methods of pumping ice-vest coolant silently (p. 2415) 2019-09-28 (12 minutes)
• Why you can't run a diesel engine on water and diesel fuel with electrolysis (p. 345) 2019-11-24 (2 minutes)

Notes concerning “The Wercam windowing system”

• A nonscriptable design for the Wercam windowing system (p. 3092) 2018-10-26 (updated 2018-11-13) (6 minutes)
• Scriptable windowing for Wercam (p. 1256) 2018-10-26 (updated 2019-07-24) (26 minutes)

Notes concerning “Wikileaks”

• Cristina Fernández de Kirchner tweets about the attempt to kidnap Assange (p. 985) 2014-04-24 (3 minutes)
• What are Bitcoin’s uses other than sidestepping the law? (p. 2159) 2019-03-11 (updated 2019-07-05) (6 minutes)

Notes concerning “Wikipedia”

- Wikipedia people (p. 948) 2016-06-01 (6 minutes)
- Everything is money? (p. 1859) 2019-08-31 (4 minutes)

Notes concerning “Win32”

- Developing Win32 programs on Debian (p. 609) 2007 to 2009 (12 minutes)
- Win32 startup (p. 2439) 2007 to 2009 (2 minutes)

Notes concerning “Window systems”

• Running your regular desktop in QEMU? (p. 292) 2007 to 2009 (3 minutes)
• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• How can we usefully cache screen images for incrementalization? (p. 1077) 2013-05-17 (18 minutes)
• Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB (p. 1520) 2013-05-17 (9 minutes)
• More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) 2015-08-18 (updated 2015-11-02) (165 minutes)

Notes concerning “Write-once read-many (WORM) memory”

- Cycle sort (p. 2344) 2013-05-17 (1 minute)
- ISAM designs for Tahoe-LAFS (p. 3199) 2016-09-07 (2 minutes)
- A language whose memory model is a bunch of temporally-indexed logs (p. 1359) 2019-05-12 (updated 2018-05-21) (20 minutes)

Notes concerning “Wrong”

• Steampunk spintronics: magnetoresistive relay logic? (p. 1315) 2013-05-17 (15 minutes)
• Saturation detector (p. 1588) 2013-05-17 (3 minutes)
• Improving LZ77 compression with a RET bytecode (p. 964) 2016-04-05 (updated 2016-04-06) (3 minutes)

Notes concerning “Z machine”

- The Z-machine memory model (p. 2903) 2017-07-19 (4 minutes)
- Constant space flexible data (p. 352) 2018-04-27 (5 minutes)
- Constant space lists (p. 3062) 2018-12-10 (10 minutes)

Notes concerning “Zooming user interfaces (ZUIs)”

• Circle-portal GUI (p. 1151) 2016-06-03 (11 minutes)
• Do visually expanding images evoke an orienting response, or the startle response, and what does that mean for ZUIs? (p. 1805) 2016-06-03 (14 minutes)
• Ideas to explore (p. 2794) 2017-05-29 (updated 2019-09-15) (3 minutes)
• How to make Dercuano work on hand computers? (p. 1371) 2019-05-18 (updated 2019-12-30) (56 minutes)
