Although this approach is not nearly as extreme as MapReduce in that way, it may also have some virtue in that direction, since it encourages you to break up your computation into small pieces that consume a few small inputs and produce a few small outputs; in cases like the Spark reimplementation of the Pregel programming model, this may involve "transposing" an algorithm, separating things that were previously together and bringing together things that were previously separate. If you were to run only one build step at a time, you might be able to improve your in-memory performance dramatically.

Additions 2016-06-22

Kragen Javier Sitaker, 2015-05-28 (updated 2016-06-22) (16 minutes)

Well, it's been a year and still nobody has done the above, so I guess I should do some work on it. What does a minimal executable version of it look like?

Maybe you have these pieces:

- a content-hash-addressable store which distinguishes between source data and cached data;
- a caching service which maps hashes of (deterministic) commands to hashes of their output;
- an execution service which returns the results of commands, either from cache or by computing them;
- a container to run commands in which grants them access only to read the data in their manifest and to produce an output tree;
- an ability for commands to delegate their output tree to further commands.

Do you really need all of those? What does the interface to creating output files look like?

Maybe a first step would be to think about what distributed MapReduce in this context looks like.

Eur-Scheme

Kragen Javier Sitaker, 2007 to 2009 (13 minutes)

So I was thinking about how to simplify Ur-Scheme further. Ur-Scheme is about 1600 lines of code so far. Something like half or a third of that is assembly code, represented in Scheme, mostly implementing the basic types (strings, conses, closures, heap variables, symbols, booleans, characters, nil, fixnums) and the basic control structures (procedure call and return, including tail-call elimination, closure creation, conditionals, sequences). The primitives thus defined total about 1100 lines of assembly-language output, so they're probably somewhere around 1000 instructions. (But it doesn't have a garbage collector yet!)

Having these things implemented in assembly definitely helps it reach the reasonable performance level that it does. But it would be nice to have a system that was a lot simpler and more portable, even if it was slower.

eForth's approach

The eForth Model 1.0 was a Forth system written to be maximally portable; the x86 version apparently contains 171 machine-code instructions in about 28 primitives, and everything else is built up on top of that in interpreted Forth words. The primitives were something like the following set:

- `lit` push a literal
- `exit` return from an interpreted subroutine
- `execute` call a subroutine whose value is on the stack
- `(if)` branch if top of stack is 0
- `(else)` branch unconditionally
- `next` update loop counter and possibly branch
- `!`, `@` store and fetch a cell in memory
- `c!`, `c@` store and fetch a byte in memory
- `rp@`, `rp!`, `sp@`, `sp!` get and set the return and operand stack pointers (for e.g. exception handling)
- `r>` pop the return stack onto the data stack
- `>r` push the return stack onto the data stack
- `drop` discard an item on the operand stack
- `dup`, `over` copy the top or second stack items onto the top of stack
- `swap` exchange the top two stack items
- `0<` test whether the top item is zero
- `and`, `or`, `xor` bitwise operators
- `!io` I forget what this does
- `?rx` return true if there's input waiting
- and there were primitives to send and receive a byte over a serial line.

I don't remember how eForth accomplished rightward bit shifts (e.g. for division), and I don't have it handy at the moment.

The Eur-Scheme Ideal

Could we build a Scheme with a similar structure — as little as possible in assembly code? Would it be simpler?

Ideally we'd be able to implement not only the normal Scheme

types, but also as much as possible of the run-time system, in Scheme, on top of a minimal set of machine-code primitives. That would mean heap allocation, garbage collection, some parts of closure handling, variadic function calls, and all the types mentioned above; the basic system would only have to support (non-closure) function call and return, some conditional (I'm using `%ifeq`), and `set!`; and primitives for accessing memory.

Two Approaches To `cons`

The implementation of `quote` in a compiler is kind of annoying; it's straightforward in an interpreter or a load-and-go compiler, but in a compiler that might run in a different interpreter, and that generates an output file rather than compiling things into memory, its representations of data have to be compatible with those produced by the definition used at run-time, regardless of whether that run-time definition is in Scheme, C, assembly, or something else.

Ur-Scheme's `pair` structure, created by `cons`, consists of three machine words in order: the magic number `0x2ce11ed` to identify it as a cons, the car, and the cdr.

Here are the two definitions of `cons` from Ur-Scheme, the run-time definition and the compile-time definition used by `quote`:

```
;; We define a label here before the procedure prologue so that other
;; asm routines can call cons
(add-to-header (lambda () (text) (label "cons")))
(define-global-procedure 'cons 2
  (lambda ()
    (emit-malloc-n 12)
    (mov (const cons-magic) (indirect tos))
    (mov tos ebx)
    (get-procedure-arg 0)
    (mov tos (offset ebx 4))
    (pop)
    (get-procedure-arg 1)
    (mov tos (offset ebx 8))
    (pop)))
;; Compile a quoted cons cell.
(define (compile-cons car-contents cdr-contents labelname)
  (rodatum labelname)
  (compile-word cons-magic)
  (compile-word car-contents)
  (compile-word cdr-contents)
  (text))
```

I've been considering a slight variation in which assembly-emitting routines return the location in which their result was placed. That would shorten the run-time code for `cons` above to the following slight variation; I'm not sure if this is clearer or not, but it's certainly briefer, at 6 lines of body instead of 9.

```
(define-global-procedure 'cons 2
  (lambda ()
    (mov (const cons-magic) (indirect (emit-malloc-n 12)))
    (mov tos ebx)
    (mov (get-procedure-arg 0) (offset ebx 4))
```

```
(pop)
(mov (get-procedure-arg 1) (offset ebx 8))
(pop)))
```

It would be ideal if the two could be generated from a single structure specification, but at present there are only three in-memory types that can be generated at compile-time: pairs, strings (which are variable-sized and mostly consist of bytes), and symbols (which point to strings). So it's not clear that such a struct facility would be a net win for simplicity.

Primitives for Accessing Memory: The Eur-Scheme Approach

So the garbage collector, the heap allocator, and the stuff out of which `pair`s and `string`s and so on are constructed need to be able to access raw memory. And it's important that the garbage collector and the heap allocator not accidentally call the heap allocator — you could easily get an infinite recursive loop; so their interface to raw memory shouldn't require heap-allocation.

Perhaps the best way to do this would be to support basically a subset of C: allow routines to declare local variables that are just machine words, which can be used as pointers, are allocated on the stack or in machine registers, and are somehow ignored by the garbage collector (because they aren't necessarily Scheme values or pointers to Scheme heap objects).

But I'm going to talk about another approach, which I think will probably be simpler. You have a `pointer` data type, like the `string` and `pair` data types of normal Scheme, and an explicit stack to save and restore `pointer`s on; and a set of `pointer`s that exist from the time the program starts, and are therefore not heap-allocated. In order to

For concreteness, there could be eight callee-saves pointers, called `%g0`, `%g1`, `%g2`, `%g3`, `%g4`, `%g5`, `%g6`, and `%g7`, and eight caller-saves pointers, called `%c0`, `%c1`, `%c2`, `%c3`, `%c4`, `%c5`, `%c6`, and `%c7`. There might be other `pointer`s around. For example, there might be some `pointer` constants created by the compiler, or `pointer` variables allocated on the heap by routines that aren't part of the garbage collector or memory allocator.

Then we need only a set of primitives for accessing them:

- `(*put! foo %p0)` store the value of a Scheme expression in `%p0` and returns `%p0`.
- `(*get %p0)` returns the value stored in `%p0` as a Scheme expression value. If the value is not, in fact, a valid Scheme object, this is likely to crash the program.
- `(*load! %p0 %p1)` fetch the value `%p0` points to in memory, stores it in `%p1`, and returns `%p1`.
- `(*store! %p0 %p1)` stores the value in `%p0` into the place in memory pointed to by `%p1`, and returns `()`.
- `(*load-byte! %p0 %p1)` and `(*store-byte! %p0 %p1)` are analogous, but only load or store the single low-order byte.
- `(*push! %p0)` and `(*pop! %p0)` save and restore `pointer` values from a special `pointer` stack, which surely has some maximum size, but in any case does not allocate memory from the heap.

• (*get-sp! %p0) and (*get-fp! %p0) get the machine-level stack pointer and frame pointer registers of the caller and store it into %p0, to support stack introspection (e.g. garbage collector tracing or backtrace printing.). They return %p0.
• Optionally, (*set-sp! %p0) and (*set-fp! %p0) set those machine registers, and (*get-psp! %p0) and (*set-psp! %p0) get and set the pointer stack pointer. These primitives could be useful for exception handling, but isn't necessary for the applications I've discussed so far.
• (*add! %p0 12 %p1) does pointer arithmetic, storing the contents of %p0, plus 12, into %p1, and returns %p1.
• (*add! %p0 %p2 %p1) does the same thing, but uses the contents of %p2.
• *and!, *or!, and *xor! are analogous to *add!.
• (*unsigned-<? %p0 %p1) returns a Scheme true or false value: true if the contents of %p0, interpreted as an unsigned number, are less than those of %p1, and false otherwise.

These 20 or so primitives are more or less sufficient for implementing things like the garbage collector and high-level data structures. None of them are particularly complicated; here's a possible implementation of the body of *load!:

```
mov (%ebp), %eax        # fetch argument zero, %p0 (src)
        call ensure_pointer     # error unless it's a pointer object
        mov 4(%eax), %ebx       # fetch its contents (the location to load from)
        mov (%ebx), %ebx        # fetch the pointed-to value from memory
        mov 4(%ebp), %eax       # fetch argument one, %p1 (dest)
        call ensure_pointer     # error unless it's a pointer object too
        mov %ebx, 4(%eax)       # store into its contents.
```

Those seven instructions are wrapped inside seven more instructions for procedure prologue and epilogue. This suggests that the total number of assembly instructions that you *need to write* to implement these primitives on a new CPU is somewhere around 7 * 20 = 140, plus the basic conditional, procedure call and return, and variable access. So you could probably port such a Scheme to a new CPU architecture with 300–400 lines of code or so, around twice the amount needed to port the eForth Model 1.0.

Of those 150–200 instructions that you need to write, some are in procedure prologues and epilogues that get duplicated 20 times for those 20 or so primitives. So you might end up with something like 400–500 lines of assembly output for the primitives.

Two More Approaches to cons

Again, the nested-assembly version of cons looks like this:

```
(define-global-procedure 'cons 2
  (lambda ()
    (mov (const cons-magic) (indirect (emit-malloc-n 12)))
    (mov tos ebx)
    (mov (get-procedure-arg 0) (offset ebx 4))
    (pop)
    (mov (get-procedure-arg 1) (offset ebx 8))
    (pop)))
```

The "subset of C" approach might look like this:

```
(define (cons car cdr)
(let-pointer ((rv (malloc-n 12)))
  (pointer-write (indirect rv) cons-magic)
  (pointer-write (offset rv 4) (pointer-val car))
  (pointer-write (offset rv 8) (pointer-val cdr))
  rv))
```

The Eur-Scheme approach might look like this:

```
(define (cons car cdr)
(*store! cons-magic (malloc-n 12 %c0)) ; cons-magic is a pointer constant
(*store! (*put! car %c1) (*add! %c0 4 %c2))
(*store! (*put! cdr %c1) (*add! %c0 8 %c2))
(*get c0))
```

`cons` doesn't have to save and restore the values of those `pointer`s because they're all caller-saves, and `cons` isn't calling anything else that might use them for its own purposes.

I think that's a substantial improvement in both readability and simplicity over the current assembly version, and it's not obviously worse than the subset-of-C version. This example leads me to suspect that defining routines in this fashion, rather than in assembly, would make for a considerably more concise and comprehensible Scheme system than Ur-Scheme.

References

Ur-Scheme is a subset-of-Scheme compiler I wrote to learn how to write compilers. It compiles itself; it's reasonably fast, despite being safe, and very small.

Automatic dependency management

Kragen Javier Sitaker, 2015-05-28 (updated 2015-09-03) (5 minutes)

A variety of software systems have used some kind of automatic dependency graph tracking to automatically recompute things, from Lotus 1-2-3 (and derived spreadsheets) up to current JavaScript frameworks like ReactJS and current big-data frameworks like Apache Spark. I'm thinking about some ideas related to this, especially inspired by Spark, and I thought I would look around and see what already exists.

It turns out a lot of fucking things related to this already exist, so I thought I'd write down a summary of some of them.

There are way too many for me to summarize, though.

Candidates not yet noted below: make; React; Meteor; redo; materialized views in databases; STMs; git-annex; database indexes; tabled predicates in Prologs; Merkle trees; immediate-mode GUIs.

Spreadsheet recalculation

Bob Frankston said in March 2015 that VisiCalc, the original spreadsheet, didn't include "natural order" (i.e. dependency-driven) recalculation, in order to fit into 16 kilobytes. He was responding to a tweet from Mitch Kapor explaining that Rick Ross had implemented that for the first time, in 1982, in Lotus 1-2-3. VisiCalc, instead, had an option to recalculate by rows or by columns. Since 1-2-3, though, spreadsheets default to dependency-order recalculation.

Dependency-order recalculation is comparatively easy for spreadsheets (although infamous thieves Rene Pardo and Remy Landau still got a US patent on it in 1983; Pardo claims to have done it in an "electronic spreadsheet" called LANPAR in 1969, but his lawyer denied it in court), because the total number of things that could possibly be recalculated is human-scale, all of them can be recalculated in only a single way, and so you can simply enumerate them and do a topological sort.

Nowadays, dependency-order recalculation is approximately unnecessary in spreadsheets; computers are so fast that human-scale spreadsheets could recalculate in milliseconds, so recalculating the whole spreadsheet after every keystroke would be reasonable. (They don't, but that's another story.)

ccache

ccache is a build accelerator specific to C, C++, and Objective-C. It hashes your source code, include files, compiler (well, typically just its size, mtime, and name), command-line options, etc., with MD4, and stores the compiler's output (including e.g. warning messages) in an on-disk cache in, normally, your home directory; future recompilation attempts whose inputs haven't changed will just reuse the previous compiler output.

In theory, this means that you could get most of the benefits of `make` for C and especially C++ programs by just wrapping your compiler in `ccache` inside your build script; rerunning the build script would rehash all your source files, copy the object files into your current directory, and then relink the executable. Depending on what you're compiling, this might be almost instantaneous, or it might be very slow.

Because Unix provides `ccache` with no reliable way to get a secure hash of the source files from the filesystem, it has to read them in their entirety to figure out whether they have reverted to an old version. I tried it just now on my netbook on a tiny three-kilobyte GLUT program, and it ended up reading about a megabyte of `.h` files in order to figure out that it could safely reuse the 2.7kB `.o` file from a previous compilation, taking 39 milliseconds in all, even though it made only about 365 system calls.

Truth maintenance systems

In Stallman & Sussman 1976, describing their pre-SPICE circuit simulator, we find, "If a user changes some part of the circuit specification (a device parameter or an imposed voltage or current), only those facts depending on the changed fact need be 'forgotten' and re-deduced, so small changes in the circuit may need only a small amount of new analysis." They are describing their invention of "dependency-directed backtracking", which later became known as a "truth maintenance system", and it's built with generalized constraint

propagation, which is substantially more general than the unidirectional dependencies mentioned in the other systems above, and one that supports finding a contradiction and backtracking from it to undo the set of incorrect guesses that led to it, and avoid that set in the future. You could use this kind of system, for example, to solve Sudoku puzzles rapidly.

A TMS, like the other systems above, remembers how every datum was deduced, but it does so not in order to promote computational efficiency by caching results, but rather to track the sources of problems — in this case, logical contradictions.

Dollar auctions and tournaments in human society

Kragen Javier Sitaker, 2013-05-17 (7 minutes)

Dollar auctions

A "dollar auction" is a simple kind of grift that involves no deception. You auction off a dollar bill, starting bids at five cents, under slightly unusual rules: the winning bidder pays their bid and gets the dollar, but the losing bidder pays too --- they just don't get the dollar. (In some variants, it's only the runner-up who pays; in others, everyone who bid.)

So, you can imagine, initially people are eager: they can get a dollar for five cents, if nobody else bids. But once other bidders start in (after all, they can get a dollar for ten, or fifteen, or twenty-five cents) the early bidders are faced with a difficult choice: lose their five or ten cents for nothing, or increase their bids to fifteen or twenty cents, netting some eighty cents --- less than they'd hoped, but gaining eighty cents is better than losing ten.

And the other bidder has the same incentive: they can bid the price up to thirty cents (gaining seventy cents) or stand pat at fifteen (losing fifteen). And so the bids keep going up.

Typically the bids will reach two or three dollars before the bidders give up. All the bidders lose money, even the winner. The auctioneer multiplies her dollar. None of the bidders want to play again.

Now, I don't know how to analyze this game with game theory. But, in terms of human psychology, it seems straightforward: however much you're losing now, you'll lose less if you increase your bid just that little bit more and win the dollar --- and sooner or later the other bidder will give up. But at some point it becomes clear that they probably won't give up until you've raised your bid by another entire dollar.

It's a great deal for the auctioneer.

But what does that have to do with the real world? We don't see dollar-auction epidemics, do we?

Graduate school

To get a Ph.D. in, say, neuroscience, you have to spend some five or ten years working as a Ph.D. student, typically as a research assistant in your advisor's lab. The RA position requires great intelligence and extremely specialized skills, the skills that will eventually justify granting you a doctorate, but it's paid just above minimum wage. Also, it typically involves a great deal of painstaking and boring work. So it represents a substantial opportunity cost to the student, at the end of which time you're awarded a Ph.D. in neuroscience.

But the Ph.D. is, in itself, worthless. (They usually don't even inscribe them on real vellum anymore.) It's a sort of license to apply for a neuroscience professorship [0], or a similar position in industry. These are really great jobs: you become world-famous (within the neuroscience community --- that is to say, there are thousands of

people around the world who will recognize your name and think you're cool), you get paid pretty well, the vacations are fantastic (without even taking into account travel for conferences), you have a staff of very intelligent and skilled research assistants to do the painstaking and boring part of your work for you, and in academia, the tradition of academic freedom means you can say almost whatever you want without fear of reprisal. (Unless it represents academic fraud.)

But there are many fewer such positions opening up each year than there are new Ph.D.s graduating. I don't have the numbers handy here, but it's something like one tenure-track position for every ten graduates. In order to get one of those positions, you have to appear better than somewhere around nine tenths of the other neuroscience grad students: based on the papers you published in grad school and whatever else you can persuade the school is relevant.

Which is to say, all of the Ph.D. students put in their years of hard work at low pay, but only the most productive ten percent actually win the "auction". The other nine tenths are left with an impressive degree and no job in the field.

Sounds a lot like the dollar auction, doesn't it? The only question is whether the graduate students are "bidding up" the "price" of a new tenure-track position to the point where it's "worth less" than what you "paid" for it, in terms of reduced earnings and scutwork. The psychology of the dollar auction suggests that they will, given the opportunity.

Who benefits in this case? Well, human knowledge, arguably the professors (certainly the well-established ones who had much less competition, thirty or forty years ago), and the university administrators.

[0]: I'm simplifying a bit here; the actual professorship is what you get after, typically, another ten or fifteen years of postdocs, adjunct faculty positions, and associate and assistant professorships.

iOS and Android Apps

You've probably heard the story of iFart, the 99-cent [1] iPhone app that plays recorded fart sounds and which sold millions of copies. Every programmer hears about it from their family, who want to know why they're not rich too. Couldn't you have written iFart?

But it turns out that nearly all the apps in the Apple iPhone App Store sell only a few hundred copies. There are hundreds of thousands XXX of iOS apps now, but only N million iPhone users (let's say 100M) who each only have around 100 apps installed. That means ten billion app installs, which means an average of 100k installs per app.

Who benefits? Apple, Google, and arguably the users of their devices

[1] I can't remember the details or look them up at the moment, so they may be wrong. It might have cost three dollars, say, or only sold hundreds of thousands of copies.

Garage bands

Most bands, famously, never earn any royalties; the record label pays them an advance against the royalties, but they never make enough royalties to pay back the advance. The advance itself is paltry

money. XXX

How to kick Kickstarter's ass

So the dollar-auction dynamic XXX

How about making the reward levels fixed-count instead of fixed-dollar? Say, the top ten donors each get a gold-plated widget, the next twenty each get a nickel-plated one, and the next forty each get a widget. Could this inspire the donors to donate more than they do today?

Capacitive droppers and transformerless power supplies

Kragen Javier Sitaker, 2019-09-18 (11 minutes)

Looking at STMicroelectronics's appnote AN392, "Doc ID 1863". It's a little bit shocking, though hopefully not literally; it contains a very cost-optimized, compact power supply circuit for microcontroller projects that can be kept safely away from the delicate bodies of the humans.

Quoting Horowitz and Hill:

> Never build an instrument to run off the powerline without an isolating transformer! To do so is to flirt with disaster. Transformerless power supplies, which have been popular in some consumer electronics (radios and televisions, particularly) because they're inexpensive, put the circuit at high voltage with respect to external ground (water pipes, etc.). This has no place in instruments intended to interconnect with any other equipment and should always be avoided. And use extreme caution when servicing any such equipment; just connecting your oscilloscope probe to the chassis can be a shocking experience.

Consequently they do not explain how to build such consumer electronics (though they promise that chapter *9x* will.) This appnote is about how to do it, a topic also occasionally discussed in the YouTube channel of bigclivedotcom. So how do they suggest doing it?

Outline of the capacitor-dropper circuit

They're running an ST6210 8-bit microcontroller directly off the hot side of mains current, connected to the touch sensor at the human's finger through two or three 4.7-MΩ resistors (thus at 340V peak you get 36 microamps or less, not enough to feel). The 5-volt rail is literally the hot side of the power line (though fused), but the "ground" is floating; a simple regulated capacitor dropper produces about 5 volts on the ground rail as follows. The neutral side of the power line is connected to an 820Ω half-watt resistor, which is connected to a 220-nF 400-V capacitor, which is connected to the low side of a 5.6-volt zener diode, whose positive end is connected to the 5-volt rail. A 1N4148 clamps the ground rail to be no more than 0.7 volts above the low end of the zener, and there's a 100-µF 10-volt energy storage capacitor connected between the ground and the 5-volt rail.

(This appnote is from 1998, so this is not capacitive touch sensing; instead, the human's finger forms part of a voltage divider between the hot and neutral powerline rails, protected by the megohms.)

How the regulated capacitor dropper works

This is not quite a standard capacitive voltage divider circuit.

The 220-nF capacitor produces a 12–15-kΩ reactance at 50–60 Hz, losslessly limiting the current to 20 mA by itself; I assume the 820-Ω resistor is to limit inrush current, because it has ≪1% effect at powerline frequencies. At steady state, with the storage capacitor charged, this current sloshes back and forth across the zener (remember that the high end of the zener is directly attached to the hot side of the power line), but when the zener is reverse-biased and

the capacitor is discharged, there's an easier return circuit path through the capacitor and 1N4148, which initially only has a 600-mV voltage drop before starting to conduct heavily rather than the zener's 5.6 volts. Once the capacitor is charged, though, the zener becomes the easier current return path, and the return current flows through it instead.

20 mA through 820 Ω gives you 330 mW, which is why you can't use a ¼-W resistor. The zener is also going to dissipate 55 mW. An ideal dropper capacitor wouldn't dissipate anything but real dropper capacitors will have some dielectric heating from the constant 20 milliamps, or 10 milliamps at 120Vrms; this will probably be on the order of 1 mW. The rest of the circuit should have much smaller power consumption.

They say their board uses 3 mA; the 100-µF storage capacitor will then discharge at 30 V/s, or 0.6 V in the 20 ms between 50-Hz peaks.

The results: regulated 5V from the powerline with five discrete passives

So with five simple passive components and no electromagnetics you get a regulated 5 volts directly out of the power line. It's just not safe to touch the circuit while it's turned on, or to connect it to any other circuits, and the dropping capacitor is a bit of a beast. In Capacitors: some notes on tradeoffs (p. 134) I have some pricing info on smaller, totally inappropriate capacitors; the 19.4¢ Nichicon UWT1H470MCL1GS is 47µF and 50V, so you would need strings of 8 of them to get the required 400 volts, but each such string would only have 6 µF, so you would need 38 such strings in parallel for a total of 304 capacitors costing a total of US$60. Capacitors designed for such applications would probably be smaller, cheaper, and cooler.

You probably don't need a bleeder resistor across the dropper cap (and the ST appnote doesn't show one); if you unplug it at the wrong part of the cycle, it could have 340 volts across it, but since it's only 220 nF, that's only 18 mJ, not enough to be dangerous to a human. It'll blow holes in your MOSFETs, though.

Unlike a standard capacitive voltage divider, the output voltage barely depends at all on the input voltage or the dropper capacitance. The dropper capacitor just serves to limit current and thus power dissipation. The output voltage is determined by the zener, or more precisely the zener minus the rectifier diode's forward voltage; the only relationship to the input voltage is that the output can't be more than the peak-to-peak input voltage (minus a couple of diode drops) and if it gets close you will have less current draw. Moreover, this power supply always draws very nearly the same current, whether anything is running from it or not, unless the current load is so high as to substantially drop the voltage in the power-storage capacitor.

This means, of course, that its efficiency is always terrible: as bad as 0% (when the load is turned off) and never much more than 30% or so.

The context: controlling mains power with triacs

The appnote isn't about regulated capacitor droppers; it just

mentions in passing that "the board supply comes from the mains through a simple RCD circuit". The appnote is actually about controlling triacs ("the least expensive power switch to operate directly on the 110/240 V mains"); it recommends using a microcontroller to inject a turn-on pulse at the appropriate point in the cycle. In the appnote ST recommended a BTA 16-600CW triac for motor control so as to need no snubber, but it needs 60 mA to trigger it. The more common (?) 95¢ T405Q-600B-TR I mentioned in My attempt to learn about jellybean electronic components (p. 1974) would work and only needs 5 mA, but would presumably require a snubber.

So in ST's appnote the inefficiency of this power supply is insignificant: if you're controlling a 700-watt vacuum cleaner with a 15-mW microcontroller, it hardly matters that you're burning 200 or 400 mW to get a regulated power supply, as long as you don't have dozens and dozens of vacuum cleaners plugged in for every one you're using.

Capacitive droppers for micropower IoT?

In Notes on the STM32 microcontroller family (p. 3176) I calculated datasheet power consumption for a number of STM32 processors; even without using power-down modes, a number of them would run at under 50 µA at 131 kHz, and with power-down modes you could reasonably reduce power consumption by another factor of 1000, although as mentioned in Can you bitbang wireless communication between AVRs? How about AM-radio energy harvesting? (p. 2509), it's easy to leak multiple microamps through your bypass capacitors. This suggests that 10 µA might be a reasonable current to design an embeddable powerline-powered IoT device for. (As long as it doesn't have to be controlling a triac or something, anyway.)

Adapting the above design for the lower current level, though, the dropper capacitor could be 220 pF instead of 220 nF, the storage capacitor could be 0.1 µF instead of 100 µF, and the input resistor would, I think, be unnecessary. Using the $C = \varepsilon A/d$ formula for capacitance, ε_r of 3 and an egregiously large plate separation of 1 mm, you could get the capacitance you need from 83 cm² of foil "shielding" wrapped around a plastic-insulated electrical line. (3 is a reasonable guess for many plastics.) That's a rather large chunk of foil, though, and a better option might be to run a high-efficiency buck regulator off a smaller piece of foil instead of just regulating with a zener.

If you're going to try to go with such a capacitive connection, you might want to do it on both the hot wire and the neutral wire, despite this requiring four times as much foil. That way, you have no dc connection to the powerline at all.

In theory at these current levels you could use reeally thin wires. In Balcony battery (p. 2377) I estimated that 142-µm copper wire would probably work for five-amp fuse wire. Suppose that's correct. Here the wire needs to carry ten thousand times less current, so it can have ten thousand times less surface area per resistance, which means it could be 21 times narrower and thus have 21 times less surface area and 441 times more resistance. But that would be 7-µm copper wire, which is going to be hard to find and maybe even a bit dangerous to

handle. If we take copper's resistivity to be 16.78 nΩ·m, as in Executable scholarship, or algorithmic scholarly communication (p. 2137), that wire is 436 Ω/m.

I'm pretty sure a 220-pF 400-V X7R ceramic capacitor would be a few millimeters in size and cost under a dollar, and that's a much better option than meters of foil snaking around your conduits and junction boxes. But it means that you need a direct non-galvanically-isolated electrical connection to the mains power and thus a fuse.

Real time windowing

Kragen Javier Sitaker, 2017-08-03 (9 minutes)

Your user interface is a hard real-time program and should be designed and implemented as such.

I've been thinking a lot about how to build a full computing environment "from scratch", in the sense that it wouldn't depend on any previously-designed hardware or software. This is for a few different reasons. One is Dan Ingalls's contention that if the system is too complicated for a person to understand, they are limited in how they can use it as a medium for creative expression. Another is that current systems are insecure by design, and for economic reasons, this is unlikely to change. A third is that current systems are irreversibly addicted to the astoundingly-high-performance computing hardware that we currently only know how to produce with correspondingly-astounding concentrations of investment, to the point that only three companies in the world — TSMC, Intel, and Samsung — are currently able to produce devices at the 10-nm process node.

But a fourth reason is that in some important ways, in particular user interface responsiveness, current systems are dramatically worse than they could be; fixing it will require a rewrite. There are other such ways, such as security, but I will focus on responsiveness here.

Hard real-time programming versus normal programming

There's an established discipline of "hard real-time programming", which I will distinguish from normal programming by first describing normal programming. In normal programming, the most important thing is that, if your program runs successfully, the output it produces is correct; the second most important thing is that it run successfully, or at least produce a helpful error message explaining what caused it to fail; and, if these criteria are met, it is always more desirable for the software to run faster, especially on average, so we would like the software to be as fast as possible, as long as that does not interfere with correctness or success.

Hard real-time programming is very different from normal programming; it's programming software for things like antilock brakes and jet engines. What distinguishes it from normal programming can be summarized in two slogans:

- Late answers are wrong answers.
- Failure is not an option.

That is, in hard real-time programming, each piece of output has a deadline; if it misses that deadline, it is worthless. Overdue answers are unusable. Consistency of execution time is more important than its shortness. Also, almost invariably, it is not acceptable for a program to fail some of the time, for example due to lack of resources. The antilock braking program must work every time you press the brake pedal, not 99% of the times.

Hard real-time programming isn't "hard" in the sense of

"difficult"; you can do it on an Arduino. It's "hard" in the sense that the deadlines that the program's execution must meet are hard.

Hard real-time programming and what I'm calling "normal programming" are two ends of a spectrum, representing two different reasons we might use computers. In normal programming, we run a program because we do not know what the output will be, but we want to find out, because we imbue it with some kind of meaning. In hard real-time programming, we know exactly what the output will be, and rather than goggling at it, we want to use it to control some aspect of our world.

In between there are many shades of gray, and most programs have some aspects of both. But it isn't unidimensional. For example, in "soft real-time programming", it's important to not miss deadlines, but results computed too late for their deadline are still of some use. In another category, somewhat incorrect answers are acceptable, as long as they are on time; there exists a whole field of algorithm design for this, known as "anytime algorithms", many of which are for mathematical optimization problems. More about this later!

Most of academic computer science focuses on normal programming, and most programming languages and tools are written with normal programming in mind. Enormously more code is written for normal programming than for hard real-time programming.

As a consequence of these profound differences, it is often impossible to repurpose code written for a normal program as a real-time program, or vice versa.

The user interface should be written as a hard real-time program

My core argument is that the part of the user interface closest to the user should be written as a hard real-time program, for the following three reasons:

• because human beings are very sensitive to user interface latency;
• because a crashing user interface is very similar to a whole crashing computer (or maybe a whole crashing cluster of computers);
• because they interact directly with video hardware, which generally pumps out frames of video at a constant rate, so pixels that are computed too late will be lost.

By "the part of the user interface closest to the user" I mean the hardware and code that interfaces with human-interface output devices, such as sound cards, video cards, or laser projectors, and human-interface input devices, such as touchscreens, accelerometers, microphones, cameras, mice, keyboards, and joysticks. If the same interface device is used as an interface to more than one different program, the user interface code in question has the task of safely multiplexing that device among those programs.

How are hard real-time programs written?

They are much smaller than other programs, because — partly because of being written with tools designed for normal programming, and despite what I said above about "hard" — they are actually harder to write than normal programs.

Typically they don't do any dynamic memory allocation, both because dynamic memory allocation generally takes a nondeterministic amount of time and because it can fail, which is not an option. As a result, they usually run in statically bounded memory space, making them formally executable by finite-state machines.

Typically when they do do dynamic memory allocation, they use simple arena allocators or per-type allocators, which are constant-time.

They virtually never use virtual memory. Virtual memory is instant death to hard real-time systems, except in the unusual case that the deadline is so long that it can tolerate disk seeks.

Typically they use very simple algorithms, because these are often easiest to prove time bounds for and because more complicated algorithms often require dynamic allocation.

More often than you would expect, they are written in assembly language, which simplifies the task of worst-case time analysis. Occasionally they are written in ladder logic or other such hardware-focused formalisms.

Often, they run on dedicated hardware, which is often a stripped-down microcontroller; timing becomes more predictable with less peripherals, no virtual memory, and less tasks per processor. Since in a sense the desired outputs are already known before the program starts, it is often possible to perform useful tasks even with very little processor power, so even today, many hard real-time systems run on 8-bit processors such as 8051s, PICs, and Z80s.

Formal methods of logical proof are somewhat more frequently used for hard real-time programs than for normal programs.

The above is, of course, somewhat idealized. But it provides the general outlines of the situation.

Anytime algorithms are not currently widely used for hard real-time programming, perhaps because they are viewed as exotic. An "anytime algorithm" is one that can provide an answer at any time after starting, but will produce better answers if allowed to run longer. Most often, these work by computing a series of progressively better answers, each an improvement on the previous answer. Many mathematical optimization algorithms, such as those often used to approximately solve constraint-satisfaction problems, work in this mode normally.

Instead of anytime algorithms, hard real-time programs typically use algorithms that execute in constant time or a time with a hard upper bound. Instead of amortized-constant-time or amortized-logarithmic- time algorithms, they must use algorithms with a worst-case constant or logarithmic time bound, and keep their dataset size small enough that the necessary linear-time-or-worse algorithms don't miss deadlines.

It's common to use bounded-size nonblocking FIFOs to communicate with real-time code.

How can a windowing server be a real-time program?

So suppose we undertake to make a user interface layer

Accelerating convolution and correlation with short periodic waveforms using OLAP marginal prefix sums

Kragen Javier Sitaker, 2018-06-05 (4 minutes)

All of what is below the line below is somewhat wrongthink. A cube is the wrong shape; what you want is some set of perhaps abundant, perhaps relatively prime *lags* with (possibly running) totals along each lag.

Running totals make incremental updates in the middle inefficient, but they permit efficient selection of arbitrary time-domain ranges. Running *second-order* totals permit efficient selection of arbitrary time-domain trapezoidal windows, which may actually be more valuable in many cases.

Here's an example:

```
 b   a             b   a             b   a             b   a             b
o

 2,  7,  6,  8,  8,  1,  9,  7,  2,  9,  8,  7,  1,  2,  3,  5,  4,  4,  6,  7,  4
o x

 2,  7,  6,  8,  8,  3, 16, 13, 10, 17, 11, 23, 14, 12, 20, 16, 27, 18, 18, 27, 20
o running sum by 5

 2,  7,  6,  8,  8,  5, 23, 19, 18, 25, 16, 46, 33, 30, 45, 32, 73, 51, 48, 72, 52
o running sum ii by 5

 2,  7,  6,  8,  8,  1, 11, 14,  8, 17, 16,  8, 12, 16, 11, 22, 20, 12, 18, 23, 15
o running sum by 6

 2,  7,  6,  8,  8,  1, 13, 21, 14, 25, 24,  9, 25, 37, 25, 47, 44, 21, 43, 60, 40
o running sum ii by 6
 c                   c                   c                   c
```

If we want the sums of the periodicity-5 component of x, we can just take the 5 last values of the second row. For example, 27 (column a) is 7 + 9 + 7 + 4, and 20 (column b) is 2 + 1 + 8 + 5 + 4. If we want the sums of the periodicity-5 component of some substring of x, we can subtract the 5 corresponding values from earlier; for example, the values 7, 6, 8, 8, 3 represent the totals after the first 6 elements, and we can subtract those from the final 5 elements to get the sums over this shorter interval.

The "running sum ii" lines are the running sums (with lags) of the corresponding running sum lines. This allows us to compute average values of the running sum over some arbitrary interval; with two such average values of the running sum, we can calculate the sum over an interval of the original signal, but with fuzzy boundaries on

the window.

Suppose that as you acquire samples from some signal, you assign them raster-wise to elements of a 6×5×7 "cube", maintaining a running total of the samples for each of the 6×5 one-dimensional slices along the Z dimension. This requires two memory updates (one add) per sample. When you finish with one such 210-sample cube, you move on to another.

Now, if you want to take the dot product of a 210-sample cube with an arbitrary waveform of period 6, you can start by generating the stride-6 totals from the pre-existing totals on the 6×5 face of the cube, which requires 24 additions. Then you perform your 6 multiply-adds and get your result.

You can take those 30 totals and add them up differently to get the periodicity-5 component of the waveform.

This structure accelerates several other variants of the same computation, too:

- If you only want to perform the dot product on a fortunately aligned 30-item or 60-item substring of the samples, you can take one or two rows of the 5×6 totals, rather than all of them.
- If you want to take dot products with several different period-6 waveforms, you can use the same totals.
- If the waveform is actually of period 2 or 3, rather than 6, you can do 4 or 3 additions instead of some of the multiply-adds.

Other dimensions may have different advantages. 12×14×13, for example, with 12×14 totals, gives you somewhat efficient dot products with waveforms of 2, 3, 4, 6, 7, 12, and *24* samples — because the 12×14 totals can be added up in groups of 7 to get the period-24 wave.

This data structure, then, allows you to do certain computations with short-period waveforms at very low cost, while also permitting efficient incremental updates.

Who is inventing the future in 2013?

Kragen Javier Sitaker, 2013-05-17 (1 minute)

Alan Kay, whose team invented object-oriented programming and the modern graphical user interface, famously said, "The best way to predict the future is to invent it." If that's true, then the people who *control* the future are the ones who are inventing it. So let's invent a future we want to live in!

Who are the people and projects inventing a future worth living in today?

• Yochai Benkler, inventing the economics of the post-scarcity world.

• Michel Bauwens, also, with his Peer-To-Peer Foundation.
• Marcin Jakubowski, and his Factor e Farm/Open Source Ecology/Global Village Construction Set project. See http://opensourceecology.org/wiki/Marcin_Log for what he's doing today.
• Nick Mathewson and the rest of the Tor project, trying to enable anonymous speech in the age of the internet.
• Kickstarter.
• Wikipedia, which has organized the world's knowledge and made it universally accessible and useful, completing the project of Diderot's Encyclopédie a few hundred years late. Jimmy Wales is its most visible spokesperson, but the vast majority of work is being done by thousands, if not tens of thousands, of volunteers.
• The Internet Archive.

Immediate mode productive grammars

Kragen Javier Sitaker, 2018-09-13 (8 minutes)

Immediate-mode GUI libraries, which are popular for some kinds of games nowadays, allow you to define your GUI structure by using the execution trace of a callback instead of an in-memory data structure. They can be used with immediate-mode graphics libraries to draw the GUI bit by bit as the function runs, requiring a really minimal amount of RAM. Aside from the advantage in memory consumption, this approach reduces or eliminates the cache-invalidation problem of redrawing the view when the underlying model changes; whenever you draw a frame, your drawing function fetches the most current state directly from the model.

An interesting feature of this approach is that there are at least two different reasons the library might call your callback: to *draw* the GUI or to *react to an event* in the GUI. For example, you might have a `button(x, y, w, h, label)` function with a boolean return value; when called in drawing mode, it draws the button and always returns false, but when called in reacting mode, it draws nothing, and returns true if the user just clicked on the button. So really your callback isn't so much a "draw interface" callback as a "describe interface" callback.

So I was thinking about using this approach for serialization of data structures.

Example application

I'm writing a VNC server, and the VNC protocol (though a beautiful dream compared to, for example, the Spice protocol or the X11 protocol) has some godawful things like `PIXEL_FORMAT` and `SetEncodings` in it. `PIXEL_FORMAT`:

No. of bytes	Type [Value]	Description
1	U8	bits-per-pixel
1	U8	depth
1	U8	big-endian-flag
1	U8	true-color-flag
2	U16	red-max
2	U16	green-max
2	U16	blue-max
1	U8	red-shift
1	U8	green-shift
1	U8	blue-shift
3		padding

`SetEncodings`:

No. of bytes	Type [Value]	Description

1	U8 [2]	message-type
1		padding
2	U16	number-of-encodings

This is followed by number-of-encodings repetitions of the following:

No. of bytes	Type [Value]	Description
4	S32	encoding-type

As it happens, the server is supposed to be able to either encode or decode `PIXEL_FORMAT`. It would be nice to be able to describe the `PIXEL_FORMAT` encoding with a function and derive both the decoder from it automatically; something like this, in Golang syntax:

```
func (p *PIXEL_FORMAT) format() {
        u8(p.bits_per_pixel)
        u8(p.depth)
        boolU8(p.big_endian_flag)
        boolU8(p.true_color_flag)
        u16(p.red_max); u16(p.green_max); u16(p.blue_max)
        u8(p.red_shift); u8(p.green_shift); u8(p.blue_shift)
        padBytes(3)
}
```

Now, as it happens, the way I'm doing this right now is with the Golang `encoding/binary` module, which uses reflection to slowly read the above description from the definition of a struct type:

```
type PIXEL_FORMAT struct {
        bits_per_pixel, depth, big_endian_flag, true_color_flag byte
        red_max, green_max, blue_max                            uint16
        red_shift, green_shift, blue_shift                      uint8
        _, _, _                                                 byte
}
```

That's all the code that's needed to describe the format above to `encoding/binary`, which can then both write and, in theory, read it (though I haven't actually tried this yet), and this is awesome. But `encoding/binary` doesn't support any variable-length data like the `encoding-type` list in `SetEncodings`, nor can it do things like "deserialize a client-to-server message", in which the first byte of the message contains the message-type.

This suggests an approach reminiscent of recursive-descent parsing with backtracking, which is a simple and fully general approach to parsing context-free languages, although it takes exponential time in the worst case (though see the Packrat parsing algorithm for a fix). When parsing, the input stream can manage an error status and a stack of backtracking points; when a parse fails, it sets the error status, which prevents further parsing from doing anything until the format

function backtracks to a non-erroneous backtracking point. This allows ordered choice among a set of possible parses.

A proposed solution

So let's think about what `SetEncodings` might look like in this form:

```
func (e *SetEncodings) Format(s *Stream) {
        LiteralByte(s, 2)
        PadBytes(s, 1)

        n := U16Split(s, len(e.encodingTypes))

        if s.Parsing() {
                e.encodingTypes = make([]encodingType, n)
        }

        for i := 0; i < n; i++ {
                &e.encodingTypes[i].Format(s)
        }
}
```

When marshalling, the `LiteralByte` call emits the byte 0x2; the `PadBytes` call emits the byte 0x0; the `U16Split` call emits two bytes with a big-endian encoding of `len(e.encodingTypes)` (say, 0x00 0x03, if it's 3), and returns the number it just encoded; `Parsing` returns false; and then each of the three `Format` calls to the items in `e.encodingTypes` invokes an `S32` function to emit four bytes serializing that encoding type.

When unmarshalling, the `LiteralByte` call consumes a byte, and if it's not 0x2, it marks the `Stream` as failed, so that all the future calls on it (until possible backtracking) will be no-ops. If it was successful, though, `PadBytes` consumes and discards 1 byte, and `U16Split` ignores its second argument, decodes two input bytes, and returns the decoded value. Then `Parsing` returns true, so the format function allocates the slice, and then the iteration parses each encoding type in turn, by invoking its `Format` method.

I'm not familiar enough with Golang's type system yet to know if there is a better way to express this function:

```
func formatSliceU16(s *Stream, items *[]Formattable, make_item func() Formattable
o) {
        n := U16split(s, len(*items))

        if s.Parsing() {
                *items = make([]Formattable, n)
        }

        for i := 0; i < n; i++ {
                items[i] := make_item()
                items[i].Format(s)
        }
}
```

The difficulty here is that the items in the slice of interfaces (assuming `Formattable` is an interface!) needs a separate factory function

to instantiate them, since this function doesn't have any other way to invoke the proper `Format` for the particular type of `Formattable` the caller was hoping for. This is pretty bad compared to just having a slice of `int32` values with some nominal type; if you have 60 of them, you have 61 heap allocations totaling 1680 bytes (assuming interface values are three 64-bit pointers, and not counting the size of the slice itself) instead of 1 allocation of 240 bytes.

Anyway, this `formatSliceU16` function would reduce the above `Format` method to this:

```
func (e *SetEncodings) Format(s *Stream) {
        LiteralByte(s, 2)
        PadBytes(s, 1)

        formatSliceU16(s, &e.encodingTypes, func() Formattable { return &encoding
Type{} })
}
```

Using the same API, and allowing the various scalar functions to be variadic, the earlier-mentioned `PIXEL_FORMAT` structure can then serialize and deserialize as follows:

```
func (p *PIXEL_FORMAT) Format(s *Stream) {
        U8(s, &p.bits_per_pixel, &p.depth)
        BoolU8(s, &p.big_endian_flag, &p.true_color_flag)
        U16(s, &p.red_max, &p.green_max, &p.blue_max)
        U8(s, &p.red_shift, &p.green_shift, &p.blue_shift)
        PadBytes(s, 3)
}
```

The KeyEvent client-to-server message can be formatted as follows:

```
func (e *KeyEvent) Format(s *Stream) {
        LiteralByte(s, 4)
        U8(s, &e.downFlag)
        PadBytes(s, 2)
        U32(s, &e.keySym)
}
```

Backtracking — not sure if this is the right approach

Suppose we are receiving a message from the client which might be either a `KeyEvent` or a `SetEncodings` (or other possibilities we might add). We could imagine writing an `Any` function something like the following:

```
func Any(s *Stream, result *Formattable, fs ...Formattable) {
        if !s.Parsing() {
                result.Format(s)
                return
        }

        s.SaveBacktrackingPoint()
        defer s.DiscardBacktrackingPoint()
```

```
        for _, f := range fs {
                f.Format(s)
                if !s.Failed() {
                        *result = f
                        return
                }
                s.Backtrack()  // Preserves backtracking point
        }
}
```

And then we could call it with something like the following:

```
var ke KeyEvent, se SetEncodings, msg Formattable
switch Any(s, &msg, &ke, &se); msg.(type) {
```

I'm not sure exactly how that would work for output; ideally you'd like to be able to use that same code to *generate* a client message, leaving the parsed message in the same place when parsing that it would have found it when emitting, so that any subsequent conditionals or logic on what the actual message was will be unified between the parsing and emitting paths.

In the particular case of client-to-server messages in VNC, this bidirectionality probably isn't that useful, because the client can just as easily call `&KeyEvent{downFlag: true, keySym: key}.Format(s)` in the appropriate place as it can call `formatClientToServerMsg(s, &KeyEvent{downFlag: true, keySym: key})`. But in cases where the variant type is embedded down inside some other data structure, the simplification could be considerable.

Kafka-like feeds for offline-first browser apps

Kragen Javier Sitaker, 2017-08-03 (5 minutes)

Suppose you want to build an offline-first browser app. A simple way to structure this is using a Kafka-like approach: all of the data in the app is stored in some set of append-only logs (or "feeds", as Secure Scuttlebutt calls them, or "topics", as Kafka calls them), each corresponding to a single writer (or "producer", as Kafka calls them, or "identity", as SSB calls them; for example, a particular profile in a particular browser on a particular user account on a particular computer). Synchronization of these logs is very simple, as long as there are never conflicting writes: for nodes A and B to synchronize log L, one tells the other the last entry they have in log L, and the other responds either by requesting the entries they don't have or by sending the other entries:

```
<A> my last entry in log L is 3258
<B> please send entries in L from 3201 to 3258
<A> entry 3201 in L is "joajgoiagjaesog"
<A> entry 3202 in L is "jogwj03280t02380"
...
<A> entry 3258 in L is "320820231di0w02"
```

or

```
<A> my last entry in log L is 3258
<B> entry 3259 in L is "302808gwahjg0saigj"
<B> entry 3260 in L is "]0ga0gjewagj0iew"
```

As long as there are never two machines creating conflicting entries in L, this protocol is simple, correct, and eventually consistent, regardless of the topology. SSB ensures this by requiring a public-key signature on each entry ("message") to prevent the propagation of unauthorized messages, and a previous-entry hash in each entry to prevent the log owner from propagating modifications to previously published messages, although they can still provoke desynchronization.

Nodes A and B might be a server and a browser, a browser and a server, or two browsers. As long as they are careful never to share information with anyone who isn't authorized to have it (SSB implements this by encrypting anything nonpublic, so that untrusted nodes can safely forward any message) it doesn't matter.

By itself, this provides, essentially, a group chat application. But an append-only data store can be used for any application.

For example, you could implement a centralized key-value store in a single log by appending (key, state, value) entries to it, where "state" is either "existing" or "deleted". The current state and value for a given key is just the most recent one in the log. This allows read-only slaves, and if you are sufficiently confident in your failover mechanisms, it could even allow for recovery after the loss of the master node.

If you want to allow multiple writers, though, you can achieve this with multiple logs, but you probably want to be able to at least detect lost-update conflicts; this requires expanding the entry tuple to ((key, parent), state, value), where "parent" is some ABA-problem-proof identifier of the previous state of the key, such as a secure hash of the entry that state was set in. If there are ever two entries with the same (key, parent), those entries are in conflict; the conflict must be resolved, through some application- specific mechanism. (In Git, this is done with a commit that has two parents; in Bitcoin, you instead use the block with the longest chain length from the root. The Git mechanism has the advantage that it records explicitly that the conflict has been resolved rather than forgotten.)

You could imagine a more sophisticated conflict-detection mechanism; for example, to commit a transaction, you could write some (key, transactionid, state, value) entries for the values modified, some (transactionid, entryid) entries for the entries that were read during the transaction, and finally a ("commit", transactionid) or ("rollback", transactionid) entry. Two or more committed transactions conflict if there does not exist an ordering in which none of them read versions of data that had been overwritten by a previous transaction.

A convenient way of structuring a key-value store program that uses this data store is to have it iterate over the entire history at startup time, constructing, say, an in-memory hash table of the latest value associated with each key — essentially replaying the history of the database. To reduce startup time, it could checkpoint a snapshot of the hash table along with the current entry numbers in each log; then, upon restart, it need only replay the entries since those offsets (as Kafka calls them). Indeed, it could store these snapshots in its own private log.

For some applications, it's reasonable to store the entire history of the application, either because the total volume of data is relatively small, or because the total amount of relevant data grows almost as fast as the entire history does. In other applications, it is necessary to forget old data because it takes up too much space. Kafka's approach is to, usually, store only the most recent data. This is probably the only approach compatible with the simple synchronization algorithm given above.

Measuring submicron displacements by pitch bending a slide guitar

Kragen Javier Sitaker, 2019-05-05 (18 minutes)

We should be able to get astoundingly precise positional and force measurements using the principles by which musical instruments are tuned, especially string instruments.

Genesis

A friend invited me to a work of musical theater tonight; despite the astoundingly adept dances, I was captivated by the designs of the improvised musical instruments — one being a Blue-Man-Group style PVC flapped pipe organ, where the players activate particular pipes by whacking their upper ends with heavy rubber flaps, and others being a sort of dulcimer or harp with six to ten strings each, in which one end of the string was anchored to the center of the bottom of a topless tin can, which can was screwed down to a wooden table, and the other end of the string was anchored to a hard object fastened to the table some distance away (I'd call it a "barrel", but in this context that word might be taken literally).

The thing that most captivated me was the extreme pitch bend the player would sometimes extract from the string by squeezing the can a little bit. Perhaps the rim of the can would lift by ten millimeters under this treatment, so the bottom where the string was anchored might be changing its natural position by two millimeters or so, but in all likelihood the can top was substantially more compliant than the string, so perhaps the string end was being displaced by half a millimeter or less out of the 500 millimeters or so of the string's length: a variation in length on the order of one part in a thousand. Nevertheless, the pitch bend was quite audible and even extreme, maybe more than a semitone.

Position sensing mechanisms

It occurred to me that this pitch-bending could be the foundation of very precise measurement techniques for measuring distance and thus size.

Audible pitch bending from string tension change

Electric guitar players commonly do pitch bends by shoving their guitar strings a centimeter or so to the side along the fret, thus lengthening the string. (Or they use the whammy bar, if they have one.) If the string is one meter in length, this would lengthen it to $\sqrt{(1\ \text{m}^2 + 1\ \text{cm}^2)} = 1.00005$ m, about 0.05 millimeters over a meter. Clearly the pitch bend is giving us a measurement of the string length that is sensitive to variations of some 50 parts per million, even better than I estimated in the paragraph above. (But maybe the strings connected to the cans weren't steel.)

How sensitive should we expect pitch bending to be to the position on the end of the string?

The Wikipedia article on the musical cent says that humans can directly hear pitch differences once they're larger than 5–25 cents, depending on musical training, on how high the pitch is, and on the harmonic content of the sound. A cent is a variation in frequency of about 578 parts per million, so the just-noticeable difference is on the order of 5000 to 20000 parts per million. The psychoacoustics article claims human frequency resolution is about 3.6 Hz in the 1–2 kHz octave, which is 1800 to 3600 ppm.

The Wikipedia article on classical guitar strings says and the Wikipedia vibrating-string article confirms and explains in more detail that the velocity of waves in strings is $\sqrt{(T/\mu)}$, where μ is the linear mass density and T is the tension. We can extrapolate that when the strings approach zero tension, the wave velocity (and thus the frequency) approaches zero, and when the tension varies by 1000 parts per million, the wave velocity varies by 500 parts per million. The frequency should vary by less than 0.5%, since the length of the string and its mass density are also changing, but the difference in those is much smaller, because the tension varies proportional to the difference from the string's natural length, while the length and mass density vary proportional to its difference from zero length, which is orders of magnitude larger.

So we should expect an audible pitch bend when the string *tension* changes by something like 5000 to 10000 parts per million, 0.5% to 1%. At most, for a steel string, the tension elongates the string by about 1% — after that, I think music wire will break, though most steels would deform plastically first — so you should always be able to hear an elongation of 2% of that, 0.02% of the total length, 200 parts per million. This is pretty close to the electric guitar number above.

But that's the *worst* case! We can do much better by putting the string under less tension. In theory, this should give us arbitrarily precise measurement of the string length, though only over correspondingly arbitrarily short distances. Indeed, I think this is one reason musical instruments are strung tightly, so that they won't go out of tune easily, and so that the string frequency doesn't rise for louder notes. In practice, I'm confident you can get one order of magnitude improvement: a length resolution of 20 parts per million.

Inaudible pitch bending and frequency counters

That, though, is assuming we're trying to detect the length by ear alone. Even a purely acoustic apparatus could improve on that: use two strings — a reference string of fixed length tuned to, say, 3000 Hz, while the measurement string is tuned to 3010 Hz at its default position. These will audibly beat at 10 Hz, more so if the second harmonic is attenuated (for example, by plucking or striking them in the center). It should be easy to hear differences in the beat frequency of 2 Hz or less, allowing an experimenter to hear variations in pitch of some 700 ppm, and thus variations in tension of 1400 ppm and in length of about 1.4 ppm.

But if we're thinking of an electronic measuring apparatus, rather than a purely acoustic one, we could straightforwardly just use a frequency counter to measure the frequency; these routinely have absolute accuracy of better than 1 ppm, and short-term precision even better than that. I think that would allow you to measure variations in length of about 0.001 ppm, 1 ppb.

At audio frequencies with guitar-sized 1-meter-long strings, 1 ppb is 1 nm, about 10 carbon atoms. If you use the same string under the same tension but only 100 mm of length, you get three octaves higher pitch (on the order of 10 kHz instead of 1 kHz) and resolution of 0.1 nm, about one carbon atom.

Electric guitar pickups

You can use an electric guitar pickup to detect very small movements of the string. Linearity isn't important, since the frequency is what we're interested in.

The slide guitar mechanism

The string-stretching mechanism described so far (call it the "whammy bar mechanism") has one big drawback: the apparatus is very large compared to the displacements being measured. So our hypothetical 100-mm-long, 0.1-nm-resolution sensor described above is only capable of making any measurement at all over the range of about a millimeter before breaking the string, and only about 300 μm with precision in the 0.1-nm range.

As an alternative, instead of altering the pitch of the string by stretching it, we could alter its pitch by sliding a "bottleneck" along it, as in slide-guitar playing. Only the length of the string up to the bottleneck vibrates, so its frequency gives us a proportional measurement of the bottleneck's position. This way, a meter-long sensor, for example, could read out a location anywhere within a 500-mm length while staying within a single octave.

The precision is correspondingly lower, but if you're using a 1-ppm-error frequency counter, you still get 1-micron resolution over a meter.

Trombone pipes

As an alternative to strings, you could use a column of air as your resonant medium, sliding one pipe inside another to continuously vary its length. The only advantage of this that occurs to me is that you can use any material at all. The precision and range should be comparable to the slide-guitar mechanism.

Delay line noise correlation and matched impedances

The above resonant mechanisms have certain problems with noise susceptibility and ringdown: it's quite reasonable to imagine that there might be vibrations in the environment within the range used by the instrument, and it would pick them up and could give erroneous readings as a result. Moreover, once they are resonating at some frequency, that vibration itself could bounce around inside solid bodies and be picked up even after the distance has changed — in effect, the instrument in the past produces its own interference in the future.

Instead of measuring a resonant frequency, though, you could generate random noise, or better still LFSR noise, and feed it into the measurement medium at one point and then read it back out — either at the same point after it's rebounded from the far end, or electronically at some other point, and measure the time lag with maximum correlation instead of a resonant frequency. In this case, the resonance of the medium is actually undesirable, and you can use the same matched-impedance technique used in electronic signal

transmission lines to prevent repeated reflection back and forth and the resulting resonance. That way, the signal you detect is a clean copy of a single lagged version of your input signal, not a sum of many past segments of the signal at different lags, progressively more attenuated.

A particularly interesting approach here is the slide-guitar approach, using non-contact sensing of vibrations in a wire as they travel past, for example using magnetic pickups, so that several sensors can share a single wire, which can end damped by a felt pad or something like that, beyond the sensors; or the trombone approach.

Free-air measurements

Once resonance is no longer needed, you might be able to dispense with the string or pipe and just transmit the ultrasonic noise signal through free air, permitting distance measurements at many points in space and thus triangulation. Stray reflections may give rise to multipath ghosting, but hopefully they can be kept manageable.

Sources of error

There are a variety of reasons that the temporal measurement from any of the three mechanisms discussed above might vary for reasons other than the displacements that we want to measure. We can try to eliminate these, or we can try to measure them and correct for them. For example, a free-air system should have at least one microphone a known, fixed distance away from the sound source, in order to correct for variations in the speed of sound in air.

Temperature

The natural length of the string will vary as it expands and contracts under the influence of temperature, potentially altering its tension, but in itself this need not introduce a large error — if the frame it's stretched on expands and contracts by the same proportion, its tension should remain constant. This may be difficult, since making the frame from music wire is probably not practical, and even if it is, the properties of music wire should vary by diameter.

The slide-guitar mechanism will, however, have a temperature-proportional error in position: if a movement causes the frequency to change by 0.1%, that represents a movement of 0.1% of its total length. But if it has expanded from 1000 mm to 1000.5 mm due to temperature, that 0.1% is now 0.10005% of its original length.

I think the whammy-bar mechanism will also have an analogous error: the Young's modulus of the string material will not remain constant with temperature, and indeed I think should have roughly the same thermal coefficient as the material's natural length.

Steel's coefficient of thermal expansion is about 10.8 ppm/° around room temperature, so we're easily looking at a 100 ppm error here if temperature is not controlled.

The trombone mechanism, however, suffers greatly from temperature drift, since the speed of sound in gases varies as the square root of the temperature. A variation of 2% in the temperature (5.5°) thus changes the tuning or time lag of the tube by 1%.

A potentially much bigger problem for the whammy-bar mechanism is that, when the surrounding temperature changes, the string will reach the new temperature much sooner than the frame

will; and if a human handles the device, they will warm it up where they touch it. If the string is steel 10° warmer than the steel frame, it will be ≈108 ppm longer, but if its strain was only 1000 ppm, that's an error of 11%, 110'000 ppm, in the strain.

The use of Invar or some similar material might be worthwhile if the apparatus cannot be protected from such variations in temperature.

Humidity and pressure

Solid materials should be pretty immune to pressure (at least until the mass of the air around the string becomes significant compared to that of the string — steel weighs about 8000 times as much as the same volume of air, and air's density varies only proportional to pressure, so this should be a source of uncontrolled variation of frequency in the 1 ppm range). Steel is pretty immune to humidity, too, but other possible string materials might be hygroscopic.

The trombone mechanism, including the free-air version, suffers the most here: although to first order the speed of sound in air doesn't vary with pressure, it does vary with humidity; since water replaces some air molecule with water molecules of roughly half the weight, it speeds up sound transmission by up to about half a percent, introducing a half-percent error (5000 ppm) in the distance measurement.

Creep

Creep can reduce tension over time if a string is under constant tension. Steel doesn't creep much at room temperature, which is how pianos can stay in tune for months or years at a time, but other possible string materials (and, even more so, frame materials) might creep rather badly. And it might be that these mechanisms are sensitive enough to detect creep phenomena in steel that usually go undetected.

Latency

It's desirable for position transducers to respond as rapidly as possible to help keep control loops stable.

The resonant approaches suffer from the need for vibrations to build up over potentially several round trips; the noise-correlation approach avoids this, but still requires at least one round trip if the microphone is colocated with the speaker. Sound in air travels at only 343 m/s, so measuring a distance of a meter is going to take about 3 ms. Music wire can transmit vibrations faster but you're still potentially looking at milliseconds of latency if you wait for the reflection.

However, with the noise-correlation approach, if you locate the sensor at the place whose position you're measuring, you don't suffer this latency (except in the whammy-bar mechanism, which inherently averages the propagation time over the time the signal is traveling through the string). You just need enough signal to correlate so that you don't get misled by noise. So you could have a feedback latency measured in microseconds (assuming the vibration frequencies are sub-MHz) instead of milliseconds.

Measuring force instead of displacement

The wire we're talking about here is elastic, which is how sound waves can travel over it in the first place. Up to now, the force needed to stretch it has been nothing more than a nuisance — hopefully we can use a thin enough wire that it doesn't exert too much force and disturb the thing we're trying to measure. But what if we use that very elasticity? Instead of stretching the string on a frame, hang an unknown mass from it and weigh it by way of measuring the sound propagation speed on the string. It's like the whammy-bar mechanism, but now our guitar has no neck.

Again, we should expect to be able to measure the lag with an error of about 1 ppm, translating to 2 ppm error in the tension, with (I'm guessing) 11 ppm/° of thermal error.

Topics

A minimal dependency processing system

Kragen Javier Sitaker, 2017-09-21 (3 minutes)

(See also Minimal transaction system (p. 2460).)

This is a miniature operating system in which computations are executed in response to changes in the filesystem, and which in turn can create more changes in the filesystem.

Transactions run. How they were started, I do not know; but they do run. A transaction looks at some part of the filesystem, then creates more files, then exits successfully, making its output files available to other transactions. The input files and dirents that went into creating them are automatically recorded; if any of them change, the transaction is re-executed, updating the files.

When a file is created, its creator specifies an invalidation policy. With the default invalidation policy, the invalid version of the file remains available while the transaction is being re-executed, and if the transaction doesn't change the file's contents, then transactions that depend on that file won't be re-executed either. There's also a "strict" invalidation policy which immediately invalidates any transactions that accessed the file, re-executing them afterwards. Attempts from outside of transactions to access a strict file that's being recomputed will block or give an error, I don't know.

(I'm not sure whether I need the same thing on read edges.)

A pure memoization variant

The fundamental operation is to apply a function to an argument, producing, eventually, a result. The argument and the result are namespaces — filesystem directories, basically; the function is a blob, a program. The system monitors which parts of the argument are accessed by the function and what system resources it needed and caches the production of the result on that basis.

On Linux, the minimal grain size for process execution is on the order of a millisecond; a fork/exit/wait loop takes about 130 µs per iteration at best on my laptop, up to a few milliseconds with large memory maps or on slower processors. If a function is going to take much longer than a millisecond, it should farm out the work to subfunctions as much as possible, enabling both caching and distribution. We might be able to do better and get down into the deep submillisecond range.

130 µs is about 200 base cases of `fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2)` in Python on the same machine.

How much data are we talking about caching? `yes` can feed data to `dd` at about 800 MB/s, or 800 kB/ms. `seq` can generate about 128 MB of numbers per second (128 kB/ms) and `gzip -9` compresses them by about 4× at about 1.8 MB/s (1.8 kB/ms) output, or 7.2 MB/s (7.2 kB/ms) input. So the individual output files we're caching could reasonably be from about a kilobyte up to about a megabyte, but of course larger results will contain many such files together.

Processing halftoning

Kragen Javier Sitaker, 2019-09-01 (15 minutes)

Lots of images in the modern world are overlaid with some kind of regular screen pattern. Halftoned images from newspapers, posters, and magazines; images printed on woven cloth or art paper with cloth imprinted on it; images photographed through window screens, security grilles, or microwave oven doors; signs printed on cloth-backed vinyl, illuminated from behind; GIFs using patterned dither; woodcut and metal engraving images; bus-window advertising, with its pattern of regular holes; shadow-mask and Trinitron patterns from CRTs; pixel-grid patterns from LCD matrices, especially low-resolution ones; silkscreened images with incomplete coverage; objects seen through mostly-opaque cloth; patterns of illumination on woven and nonwoven cloth and legs wearing fishnet stockings. Additionally, there are one-dimensional equivalents — PWM signals, audio distorted by clipping, and AM radio.

I suspect that these patterns are amenable to a number of interesting image-processing and other signal-processing algorithms.

Dehalftoning

Traditional newsprint monochrome halftone

A classic newspaper-article monochrome halftone image consists of a square lattice of black dots on a white background, rotated to some odd angle to minimize aliasing artifacts, whose varying diameters give varying "tones", which is to say brightnesses, to different areas of the image. In blacker areas, the dots lose their roundness and start to merge together, leaving isolated white dots, which start to become round.

In the frequency domain, we can analyze a small area of the image as containing some DC level, plus "dithering noise" added by the halftoning, which is entirely concentrated in the even harmonics of two spatial frequencies, one 90° rotated from the other but otherwise identical — the frequencies of the warp and weft of the halftone screen. If we look at different small areas of the image, the amplitudes (but not the phases) of these harmonics vary (in varying, non-monotonic ways) with the DC level; looking at a larger area of the image, this amplitude modulation manifests as sidebands on the "carrier signal".

The underlying process is not simply AM; the carrier signal is *added to* the underlying image gray level, and then the sum is thresholded (originally, through nonlinear chemical processing). The result has a maximum carrier amplitude at 50% gray, and zero carrier amplitude at either pure white or pure black; the second harmonic of the carrier is zero at pure white, pure black, and 50% gray, while reaching amplitude maxima at 25% and 75%, I think; and higher harmonics vary in ampitude more rapidly.

XXX even in one dimension, the Nth harmonic has N maxima and N+1 nulls; the odd harmonics are not missing (except at 50%!) so the below algorithm is wrong (and probably something simpler is

doable)

Linearly, shift-invariantly dehalftoning the newspaper

Given the carrier frequency and angle, it is fairly straightforward to construct a zero-phase linear filter kernel that sharply notches out the carrier frequency itself and precisely its even harmonics, leaving just the information-carrying sidebands, using filter inversion. The filter for the even harmonics is a ("feedback") comb filter; spatially it looks like a square grid of points (positive impulses) at the same angle as the halftone screen and twice its frequency; the filter for the fundamental looks like the heights of egg-carton foam, also making a square grid at the same angle, but without impulses or sharp edges; and inverting either of those turns it negative and adds a new, much stronger positive impulse in the center.

The convolution of these two notch filters provides a filter that eliminates the halftone screen entirely. However, without any spatial windowing, they only remove the part without any spatial variation whatsoever; you need to window them down to a spatially reasonable area, for example with a Gaussian window, in order to remove the harmonics that are prevalent in a given area.

This filter might still seem to have alarmingly large support for practical spatial-domain convolution, but due to its special structure, the multiplication-free sparse-kernel-cascade techniques described in Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) can compute convolutions with it very inexpensively.

There's one problem left over: DC is an even harmonic of the halftone-screen frequency — the zeroth harmonic — so the even-harmonic filter removes the DC signal we wanted to save, and we're left with only edges detected. To solve this problem it is necessary to high-pass-filter the even-harmonic-selecting kernel so that its DC response is zero, or at least less than ½ or so, ideally without affecting its relative response to the other harmonics. This is clearly doable by, for example, bidirectionally filtering the signal the even-harmonic filter detected with a high-pass Chebyshev filter before subtracting it from the original image pixel to invert it; but it's not immediately evident to me if there's a way to do it with the sparse multiplication-free approach.

The frequency-selectivity of this approach should give much better high-frequency response than the usual approach of just blurring the image — that is to say, it should preserve edges that are close to the frequency of the halftoning screen itself, and even those that are higher, assuming the halftoning approach is the traditional photographic analog approach, from which the dots can come out off-center and non-round.

Minor nonlinear enhancement

If the resolution is high enough, the intendedly-bilevel nature of the halftoned image can be used to nonlinearly correct some other errors: uneven illumination, uneven paper color, and uneven ink blackness can all be corrected by contrast-stretching the image with locally-varying black and white levels; a bit of morphological opening and closing might help due to the intendedly-contiguous nature of the halftone dots. Doing this for CMYK images is more complex, due to the 16 possible combinations of ink colors, but is

certainly possible with high enough resolution.

Some kind of nonlinear preprocessing is probably needed for CMYK images, because each color channel is normally printed with the halftoning screen at a different angle in order to reduce aliasing artifacts, and the inks interact nonlinearly (though I conjecture that in a negative image they might be closer to linearity). So you need to recover some kind of per-color-channel estimate before you go trying to dehalftone.

Linearly, shift-invariantly dehalftoning other images

The other kinds of images I mentioned above — backlit images printed on cloth-backed vinyl, images printed on Lambertian cloth, images with CRT shadow-mask patterns, and so on — mostly don't have the pattern of modulation of harmonics that characterizes the kind of screen halftoning used by newspapers and magazines. Instead, they have a grid pattern whose amplitude is multiplied by the image, pixel by pixel, without modulating the spatial spectrum of the grid pattern (unless there's sensor saturation, say). Nevertheless, the same linear filter should work.

This process is a much purer spatial equivalent of amplitude modulation as used in radio, although the carrier signal is not sinusoidal, and the baseband signal is still present; in general it consists of all the harmonics of two spatial frequencies, which is to say, the lattice generated by two vectors in frequency space.

Morphologically, shift-invariantly dehalftoning those images

In these cases, it ought to be possible to morphologically open or close the image in order to reduce the halftoning artifacts — depending on whether the artifacts are dark, as they usually are, or light, as in a photo taken through a window screen. This approach won't work (or will work very poorly) with newspaper halftoning, because the image data isn't encoded in the brightness or color of what is seen through the screen, but of the size of the "apertures". But for linearly-encoded data like this, it ought to work well.

This is closely analogous to how a crystal radio set demodulates AM radio, though without a tuner: the nonlinearity of the diode detector spreads the peak of the detected wave across the valleys in between.

Chroma subsampling

CRT and (low-resolution) LCD images are somewhat special among linearly-encoded halftoned images in that they have, effectively, color filters — the red, green, blue, and sometimes white subpixels are each limited in what colors they can carry. Nevertheless, in CRTs and in LCDs using subpixel rendering, they are used to carry both chroma and brightness information, relying on the lower resolution accorded to chroma information by the eyes of the humans.

Probably the best solution here is to do the dehalftoning process entirely in brightness-space, then add blurred chroma information to it afterwards.

Non-shift-invariant dehalftoning

A potentially more interesting approach is to try to identify which pixels depend on the "underlying image" and which are just part of the halftone screen and should be filled in based on some kind of filling operation from the underlying image (whether via mathematical morphology or some kind of more elaborate texture-synthesis algorithm). This is likely to work a lot better for, for example, photos taken through security grilles or microwave oven doors, than the algorithms above.

Low-resolution images are likely to have a lot of mixed pixels, so the model needs to handle partly-screen pixels.

The simplest kind of model here is one that estimates the phase, angle, and perhaps waveform of the screen; then multiplies the image by it pixel-by-pixel to selectively amplify the underlying image; then blurs that image or comb-filters out the screen frequency, as before, to estimate the underlying image. This is precisely analogous to an AM radio receiver mixing with a local oscillator.

Video or stereo data is probably very useful for these models, since correlations over time or over viewpoints will tend to separate the underlying image from the screen.

Optimization-based approaches

Given a computation that generates a halftoned image from an underlying image and other parameters such as halftone-screen angle and phase, an error metric accounting for the likelihood of things like sensor noise and ink squeeze, and a prior probability distribution over underlying images, you can use a generic high-dimensional optimization algorithm such as the popular variants of gradient descent to infer likely underlying images.

(See Image approximation (p. 2394) for more explorations along these lines.)

Image separation by demodulation

Consider a photo taken through a microwave-oven door. Most of the image consists of a reflection of the room behind the camera, but through the holes in the RF shielding grille we can see the scene inside the microwave.

As I said above, the inside scene is an amplitude-modulated signal, and we can recover it in the usual way, by mixing with a local oscillator or morphologically "rectifying" it, and then filtering out the carrier. However, another alternative is to filter out the carrier *and the sidebands*, leaving only the reflection of the room.

An improved estimate of either the baseband non-modulated image of the room or of the interior, amplitude-modulated image, allows us to do a better job of canceling its contribution to the combined image, getting a better estimate of the other image. In this way we can, to a significant extent, separate the original combined image into its constituent layers.

(The same approach can be used, of course, with temporally-modulated illumination; in a loose sense this is the basis of structured-light 3-D scanning.)

Canceling reflections of amplitude-modulated textures

As another example of the same phenomenon, on the bus home, there was an illuminated sign indicating which branch of the line the

bus was serving, made of fabric-backed vinyl and illuminated from within. This sign was just inside the windshield, near the bottom, so it created a strong reflection on the windshield, obscuring the image of the road.

With this approach, it should be possible to subtract the cloth-modulated reflection and see the road — if JPEG compression doesn't get to your image first and erase the subliminal road data.

Detecting amplitude-modulated textures in superimposed images

Consider instead looking out the window of a café where the sun is falling on a table. The newspaper on the table, lit by the sun, is reflected in the window; its reflection is superimposed on the image of the tree outside the window. Can you recover the newspaper front-page photo from a high-resolution combined image?

Newspaper halftoning has the solarization ambiguity I mentioned earlier — the spatial frequency spectra are symmetric around 50% gray. But, in theory, even the fundamental frequency and its second harmonic are sufficient to recover the gray level up to that ambiguity — but only if you know beforehand how strong they would be at their strongest. The third and fourth harmonics help further, because their own minima allow us to precisely calibrate the strength of the first and second harmonics.

(I say "minima" because the nulls are far sharper than the maxima, being as they are the crossing of a sinusoid with the X-axis, while the maxima are the peaks of those sinusoids.)

A similar problem is removing glare from a photograph of a glossy magazine. If the sensor didn't saturate and the photo didn't suffer lossy compression, the halftone-frequency information in the glare area contains most of the information, again up to the solarization ambiguity.

All of these presuppose that you can perspective-correct the image and obtain a reasonably correct estimate of the halftoning frequencies and angles, of course.

For mesh sizes below about 200 μm, diffraction starts to become a problem, and geometric-optics-based algorithms become increasingly inaccurate. The Airy radius $\sin\theta = 1.22\lambda/D$ of a 100-mm mirror at 555 nm is 6.7 μradians, which means that from more than about 30 meters away, a 100-mm mirror or lens can't image through a 200-μm hole; the mirror itself is visible, subtending about 0.2°, half the apparent size of the sun or moon. More-distant sensors would need to be proportionally larger. So you don't need to worry about drones too far away for you to see using these algorithms to see through your bedroom curtains.

Bottle washing

Kragen Javier Sitaker, 2014-04-24 (7 minutes)

Suppose you're washing out a bottle. You want to achieve the maximum dilution of the contaminants in the bottle for a given amount of water; a miser might phrase this as minimizing the amount of water needed to get the needed dilution of the contaminants.

If we abstract a little, we're repeating this process some number of times:

• dumping all the water out of the bottle except for the little bit that won't come loose, which contains all the remaining contaminants; call that remaining water volume V0;
• adding more water to dilute the water already in the bottle, up to some volume V1, diluting the contaminants by a factor V1/V0 by using an amount of water V1-V0, which we will then dump out when we repeat step 1.

After cycling some quantity V2 of water through this process, we've repeated it V2/(V1-V0) times, more or less, and achieved a dilution of (V1/V0)^(V2/(V1-V0)) times.

You might think that you don't want to go to extremes here. If V0 is one milliliter, and V1 is two milliliters, then on each cycle, you reduce the contamination by a factor of 3; so if you use twenty milliliters, you've reduced it by 3^{10}, almost sixty thousand. By contrast, if you dump all twenty milliliters in at once, you achieve only a dilution of 1/21, which is pathetic; and if you go toward the other extreme and use one microliter of water on each rinse cycle, you go through twenty thousand rinse cycles, each providing a 1001/1000 dilution, which you might think wouldn't make much difference. But it turns out that that adds up to a dilution factor of 480 340 920 times. (You need the first thousand rinse cycles just to get to a dilution of roughly e, 2.717, but every thousand rinse cycles then adds up to another factor of e, and e^{20} is almost five hundred million.)

That's about as good as you can do, though: rinsing with 20 times the amount of residual water that you can't get out will give you a dilution of up to e^{20}. And you can reach almost that optimum, three hundred million, say, with only 400 rinses, each of 50 microliters. At only 20 times the residual water, you don't get much additional benefit from reducing the amount of water on each rinse cycle below a twentieth or so of the residual water. However, because it's an exponential process, small differences in dilution will grow into larger ones as you repeat the process.

Which is to say that, perhaps unsurprisingly, a more or less continuous rinse is the ideal; you want to remove rinse water as fast as it's added. Allowing any amount of rinse water to accumulate that's significant compared to the residual, unremovable water will dramatically reduce the dilution you achieve. Once your effective number of rinses drops to 50, in the scenario above, you've lost more than an order of magnitude of dilution over 20 rinses.

Of course, if you have a way to reduce the residual water, that will be even more effective. Reducing the residual water is equivalent to

increasing the rinse water by the same factor, which increases the exponent on e; in the above example, reducing the residual water by 50 microliters pumps up the optimum from e^{20} to e^{21} (plus a bit), improving your final dilution by a factor of 2.7!

(This exponential sensitivity of the final result to the precise dilution ratio suggests use for sensitive measuring equipment. If you have a 1%-precision measure of the final concentration, say, you can derive an 0.05%-precision measure of the geometric-mean ratio of the ratio of the residual and rinse water in each step, or more if you repeat the dilution procedure more times.)

On the other hand, since it's an exponential process, the absolute magnitude of the problem is not so terrible.

The ideal is to achieve dilutions in the mole range (10^{24}), such that even if mole quantities of the contaminants were originally present, no molecules of them remain afterwards. (Succussion has not been shown to help.) The minimum to reach a dilution of 10^{24}, with the e^{20} limit above, is when $20 \approx 55.3$; that is, you need 55.3 times as much rinse water as the residual water. If for some reason you're stuck in a low-efficiency regime where you can't avoid rinse-water accumulation, such that each rinse cycle only dilutes contaminants by a factor of 2, you need 80 rinse cycles, which means you need 80 times as much rinse water as residual water. At 55 rinse cycles, you will have only reached a dilution of about 3×10^{16}, thirty million times more concentrated than with the optimal strategy.

That is, in more or less the worst case, your non-optimal rinsing strategy costs you only about 45% more water, even though when using the same amount of water, it's thirty million times worse.

(It's kind of amazing that it's feasible to achieve such extreme dilutions at all, let alone achieve them in your kitchen. Of course, there are always tricky details to get right, like that congealed grease spot full of PCBs that isn't getting diluted by your water. Don't get cocky.)

If your desire is not to remove every single molecule of whatever contaminants you have, but simply to reduce the pH of your laundry to the point where it won't deteriorate while drying or in storage due to the alkali, you have a much easier task. I'm going to guess that the pH of alkali laundry systems rarely goes above 10 and almost never goes above 11, and that reducing the pH to 8 before drying the laundry will provide adequate protection; that's a dilution of only 10^3, which you can achieve with 10 rinse cycles in what I described as "more or less the worst case" and 7 "rinse cycles" in the best case of continuous mixing.

Welp, guess it's time to rinse this laundry.

Solving the incentive problem for censorship-resistant DHTs

Kragen Javier Sitaker, 2016-09-07 (updated 2019-05-21) (3 minutes)

I was thinking about the incentive problem in DHTs.

DHTs sort of inherently mean you can't choose which node will host your data, right? You can choose which network, but if the nodes that your key hashes to are unfriendly, they can forget you ever tried to store data on them; and so there's no way to set up BitTorrent-like reciprocity, where other DHT nodes have an incentive to store my data so that I'll be more willing to store their data.

I'm wondering if there's a way to solve that problem without completely losing the desirable aspects of DHTs. In particular, node load in a DHT scales sublinearly with the system size, assuming churn is low (which is an incentive problem!), node count scales with data size, and update rate doesn't change. That would fit in, say, 64 bytes. But nodes might discard your data item because it's deemed to be an anti-Islamic data item, for example, if the DHT node happens to be hosted in Saudi Arabia, or a heretical data item if it happens to be hosted in a Christian country.

The data that is thus incentive-protected need not be large, because the data items can be very small and still be useful. For example, you could store a (key, favorableserver) pair that redirects querents to a server that you do have some kind of ongoing mutual relationship with, such as ownership, payment, or reciprocal storage.

One possibility is that there's some way to ensure that the DHT node can't erase *your* data with certainty without erasing *everyone's* data with some probability, which converts the incentive from a relationship with only you to a relationship with the entire network. (This is the motivation behind Verónica Estrada's helical entanglement work.) Like, if the node couldn't tell which data was yours.

Typically, DHTs already do store your data on multiple DHT nodes to provide some resilience in the face of node churn; even Karger's original "Consistent Hashing" paper from 1997 that Akamai was founded on explains that you can hash the URL to several different points on the circle, which will probably map to different servers; but this doesn't really solve the incentive problem.

As another way of thinking about the incentive problem, consider the case of expiry times. You have a DHT that typically maintains object validity fo ra day. But you want to store data in it that will be consulted perhaps once a week. If your publisher is reliable, it will re-store the data in the DHT nodes about every 12 hours, which is to say about 14 times as often as it's consulted. It would be a lot more efficient on an overall basis to persuade the DHT to store your data for a week or ten instead of a day, and also be more resistant to you being arrested for publishing un-Islamic material.

DHTs suffer badly from churn, and churn in practice is pretty high, which is arguably another aspect of the same incentive problem — how do you incentivize people to keep their nodes running?

Patterns for failure-free, bounded-space, and bounded-time programming

Kragen Javier Sitaker, 2018-04-27 (updated 2019-09-10) (42 minutes)

Often, the most convenient way to program a piece of software is to use garbage collection, recursion, and the Lisp object-graph memory model they were born in, often along with closures and dynamic typing. But these approaches have their drawbacks: almost any part of your program can fail or require unbounded time to execute. Sometimes it is useful to write programs that will not fail, even on a computer with finite memory, and will make progress in bounded time. For example, if your user interface stops making progress, your computer becomes unusable, even if the rest of its software is working fine (see Real time windowing (p. 891)); and, if the program on a microcontroller fails, there is often no sensible way for it to report failure, and physical processes it was controlling may run out of control, perhaps damaging equipment or killing some of the humans.

The basic incompatibilities are the following:

• In the object-graph memory model, heap allocation happens often, usually implicitly (although not in early versions of Java), can always fail, and can almost always take an unbounded amount of time.
• Closures in particular — at least, the way they are normally implemented — give rise to implicit heap allocation.
• Recursive function calls can potentially use both unbounded space (for the stack) and unbounded time. If you have no recursion and no closures, you don't strictly need a stack; it's purely an optimization.
• With dynamic typing, any primitive operation — and, in OO languages, any method call — can fail due to a type error.

Here I will discuss approaches that can be used to write programs that can execute in bounded time, bounded space, and without the possibility of error conditions arising.

These approaches are usually used in contexts where system resources are very limited, and so they are usually used in conjunction with a lot of optimization, which can reduce both the average-case resource use and the worst-case resource use of the program. However, they are conceptually distinct from optimization, even though they may be confused with it.

Static checking, including type checking

The most general technique is to check invariants before the program is run. An invariant that is (correctly) verified to hold by static reasoning cannot be violated give rise to a run-time error. For example, object-oriented programs in languages such as OCaml are guaranteed not to compile a method call on an object that might not support that method. This is almost true in C++, but C++ has enough undefined behavior that it is in practice impossible to make

any compile-time assertions about program behavior.

Such static checking can happen after compile time as well as before. For example, for TinyOS, a stack depth checker was developed that statically verifies the maximum stack depth of a machine-code program. (See also Techniques for, e.g., avoiding indexed-offset addressing on the 8080 (p. 3166) for more on how to do this.)

This generalizes to proving arbitrary properties of programs, as was done for CompCert and seL4.

Pointer-reversal tree traversal

Lisp systems traditionally used a mark-and-sweep garbage collector, which first *marks* all the nodes in memory that are accessible from "roots" (such as the stack or global variables), then *sweeps* through memory to find any unmarked objects, adding them to the free list. A simple implementation of the mark phase that handles only conses might look something like this:

```
(defun gc-mark (node)
  (when (and (consp node)
             (not (eq (mark-field node) *collection-number*)))
    (setf (mark-field node) *collection-number*)
    (gc-mark (car node))
    (gc-mark (cdr node))))
```

This is simple enough, but it sweeps a critical issue under the carpet: those recursive calls to `mark` eat up stack space. How much stack space do they need? Well, it can be as much as one level of stack for every live cons, if they're all in a single list! Normally traversing a tree through recursive calls like this is a reasonable thing to do, but this function is being invoked because the interpreter ran out of memory, except what it needs for the stack, and needs to free some up. So statically bounding the stack usage, as mentioned in the previous item, would be really super useful.

You might think we could rewrite it into a non-recursive loop:

```
(defun gc-mark (node)
  (loop while (and (consp node)
                   (not (eq (mark-field node) *collection-number*)))
    do (setf (mark-field node) *collection-number*)
    do (gc-mark (car node))
    do (setf node (cdr node))))
```

That way, if we have one huge long list `(a b c d ... zzz)`, we don't eat up our stack recursing down it; each cons of the list gets processed in the same stack frame as the previous one. But we still have a recursive loop which can still eat up space bounded only by the number of conses — it's just that now it has to look like `(((((...zzz...)))))` instead.

The fundamental problem is that every time we encounter a new cons, we encounter not one but two new pointers to follow, and so whichever path we choose to take, the number of paths not traveled by can always keep growing, one new path for each cons node we traverse.

If we could only leave some sort of breadcrumbs in those conses in order to avoid needing to allocate that data on the stack! Too bad they're already full of essential data.

Consider this implementation of NREVERSE for lists:

```
(defun nreverse (list)
  (loop with next with reversed = nil
     if (null list) return reversed
     do (progn
          (setf next (cdr list))
          (setf (cdr list) reversed)
          (setf reversed list)
          (setf list next))))
```

It isn't recursive and doesn't allocate any memory other than its three local variables. Nevertheless, `(nreverse (nreverse list))` will traverse the same list nodes twice, once forwards and once backwards, and it leaves them in the same state as before. By reversing the pointers, it maintains the state it needs to traverse the list again in reverse order.

This implementation of NREVERSE is a simple case of pointer-reversal tree traversal. Where regular tree traversal maintains a single pointer to the current node, we maintain two pointers: the current node and the previous node. (While executing a movement along the tree, we have an additional temporary pointer, called `next` above.) The previous node used to have a pointer to the current node, but no longer does; it now points to its own previous node instead. It happens that the backward traversal in this case is precisely the same as the forward traversal, but that is not the case in general.

To walk the whole tree, sometimes you'll be descending down the left branch (the car) and sometimes down the right branch (the cdr). That means that sometimes the previous node will have its car reversed and pointing to its parent, in which case when we return back up to it we want to descend down the cdr branch instead, and sometimes it will have its cdr reversed and pointing to its parent, in which case when we return back up to it we want to keep on returning back up to its parent. To distinguish these two cases, we need to store that one bit of per-node state somewhere, just like the mark bit, and typically we use a bit somewhere in the node itself, though there are other options. If you have three or four children on a node, you need two bits instead of one, and so on. When you finish walking the tree, you have undone all your mutations.

And that's Deutsch–Schorr–Waite tree traversal, which needs only a bit per node in the worst case instead of a word per node.

Deutsch–Schorr–Waite tree traversal is designed as a failure-free algorithm because, like most algorithms, garbage collection can only fail by running out of memory; but, in the GC case, that failure is an overwhelmingly likely outcome if you don't make it impossible.

You can use it for things other than garbage collection. You can implement a binary-tree search function using Deutsch–Schorr–Waite traversal, for example; you just choose which child to recurse down by comparing the key, and when you're traversing back up the tree, you always just go up to the parent, rather than sometimes traversing down to another child, as you do for

garbage collection. More interestingly, you can implement red-black tree insertion this way.

Using it for DAG traversal may be hairier; GC uses the mark bit to avoid endlessly revisiting the same nodes, but other traversal algorithms may not be able to.

An interesting thing about this traversal is that it's achieved by using mutation instead of the usual side-effect-free algorithms to traverse the tree, because the alternative to storing the breadcrumbs with mutation is to allocate memory for them, and that introduces failure. (See The Z-machine memory model (p. 2903) for some notes on a memory model that's all about tree mutation and was at one point used by a significant number of hackers.)

Of course, such a mutating tree traversal would be a disaster if it could be interrupted in the middle, for example, by an out-of-memory exception or a program interruption from the keyboard. But since what we're exploring here is precisely how to eliminate such exceptions from our system, we are justified in taking advantage of the benefits thus gained.

Note that, in the above loop, the number of pointers to a given node remains constant, except for the ephemeral copy in `next`. I think this is a necessary property of all such traversal algorithms on trees, which is to say, data structures with only a single pointer to each node; my reasoning is as follows.

If the reference count of such a linearly-referenced node drops, it drops to zero, and the node leaks. If you have a garbage collector, it may recover the node later, and you may be able to avoid turning a memory leak into an actual failure, but for reasons explained in the introduction, I don't think garbage collection is likely to be compatible with failure-free computing.

For the reference count of such a linearly-referenced node to increase, either it must be overwriting some other reference and decreasing its reference count, or it must be allocating new memory; neither of these is compatible with failure-free computing.

(The potential hole in this reasoning is that it's legitimate for the traversal algorithm to have some finite number of local variables like `next` above that potentially alias pointers found in nodes on the heap, but which may be the only access path to a node at some time. I'm not sure this is ever essential but I don't have a strong argument that it isn't.)

Swap is an adequate primitive for expressing such arbitrary permutations of pointers, and it guarantees that no pointers are duplicated or destroyed. The pointer permutation in the above NREVERSE loop could be thus expressed without temporary variables as follows, given a SWAPF analogous to SETF:

```
(swapf reversed (cdr list))
(swapf list reversed)
```

However, I do not have faith that such a microscopic approach to eliminating failure can scale to a whole computing system. In particular, a pointer cycle can be cut off from the rest of the object graph through such operations, and deciding whether or not that happens potentially requires whole-program analysis (or, worse, run-time whole-heap analysis).

Note that this approach to tree traversal does not bound the time needed for a tree traversal, only the space, and indeed it prevents you from killing the traversal process after a timeout to bound the traversal time cheaply.

(Linear trees (p. 1811) has more thoughts on this.)

Pagaltzis's wall-following tree traversal

You can do flexible immutable tree traversals in constant space if the tree nodes have parent pointers.

Aristotle Pagaltzis wrote the fascinating Tree traversal without recursion: the tree as a state machine in 2007, describing an algorithm for traversing a binary tree in constant space, if each node has a parent pointer as well as the usual child pointers; HN user kofejnik pointed out that the algorithm is equivalent to the standard wall-following maze algorithm, where you just keep your right hand on the right wall as you walk through the maze, so that whenever you re-enter a node with multiple exits, you exit through a new exit, your only state being your position and which way you're facing.

In summary, the next node and direction is either:

• the current node's left child, traversing down, if you're traversing down;
• the current node's right child, traversing down, if you're traversing up and the previous node is the current node's left child; or
• the current node's parent, traversing up, otherwise (when you're traversing up and the previous node is not the current node's left child; instead it will be the current node's right child).

This algorithm generalizes to general ordered tree traversal (you have to search through the child node pointers until you find the right one) and to cases where you don't want to traverse the entire tree for things such as database index traversal — you just pretend to have traversed the subtrees of no interest.

Pagaltzis pointed out in his article that, using node locks, the traversal can continue successfully even in the face of tree mutations as long as they don't detach a non-leaf node. But of course it won't traverse a consistent snapshot of the tree, and node locks eliminate its failure-free, bounded-time nature.

The Pagaltzis algorithm takes constant space and constant traversal time per tree node. However, to put bounds on the Pagaltzis algorithm's time to traverse the next leafnode — the metric of interest in many cases — you need to bound the depth of the tree, e.g., ensure that it doesn't degenerate into a linked list. If you can do that, though, you can also bound the space and time usage of a traditional recursive tree traversal.

Moving things in linked lists

Given an item `i` that is a member of a linked list and a place `p` in (the same or a different) linked list after which to insert it, you can move it to its new position in a failure-free, allocation-free, bounded-time fashion:

```
node *n = *i;
*i = n->next;
n->next = *p;
```

```
*p = n;
```

This is similar to the pointer-reversal tree-traversal approach described in the previous section; the end result is that you have permuted the pointers at `n->next`, `p`, and `i`. It is still failure-free even if `n->next` is a NULL pointer, but of course `p` and `i` must not be, and `i` must point to a node rather than null.

This operation is very commonly used in contexts like operating-system schedulers, where you might use it to move a job between different mutually exclusive queues. If one of the lists is a free list, this pattern becomes the next pattern, "fixed-size object pools".

Fixed-size object pools

If a program may be called upon to store some arbitrarily large amount of data at once, it cannot be both failure-free and bounded-time; however large its memory is, there is always the possibility that it will be called upon to store more data than there exists storage on the computer it is running on, and then either it must fail, or it must wait until more storage becomes available. So if a program is not bounded-space, it cannot execute failure-free in bounded time.

However, if there is an up-front limit to the amount of data the program needs to manage, and it's running on a computer with that much memory, it can be failure-free and bounded-time within that limit. Moreover, unless defeated by a too-clever-by-half operating system, it can verify that amount of memory is available at startup time — so it may fail to start up if running on a too-small machine, but then be failure-free thenceforth.

Preallocated object pools are a standard strategy for keeping time bounds on execution in this context: if your game needs to handle up to, say, 64 sprites at a time, you can preallocate and perhaps even preinitialize 64 sprite data structures and make a linked list of them. Then, whenever you need to allocate a new sprite, you grab the first node on that free list, a constant-time operation; to deallocate a sprite, you put it at the head of that list, also a constant-time operation.

Fixed-size queues to permit communication with non-failure-free systems

It's quite common for a computer system to contain some parts that have to be failure-free and use bounded space and bounded time, and other parts that don't; for example, a robot control system might contain one component that periodically toggles a pin to generate a waveform to control a servomotor, another component monitoring sensors and running a PID control algorithm that commands the first component what signal to emit, and a third motion-planning component that tells the PID control what set-point to use. If the waveform generator misses its deadlines (a few hundred µs of error at most is acceptable; RC model servos use a 50Hz pulse-position-modulation signal with a pulse width of 500µs to

2500µs encoding the commanded position, so 100µs of error is a 5% error), the waveform will have the wrong duty cycle, and the servomotor will receive the wrong command, possibly breaking the robot or a person near it. If the PID control algorithm misses its deadlines (typically a few milliseconds), the control system will at least oscillate and possibly go out of control. If the motion-planning algorithm runs slowly, though, the robot just takes longer to get things done.

This gives you a lot of freedom to have failures and missed deadlines in your motion-planning algorithm, but not if they can propagate to the waveform generator or even the PID controller. But clearly these components of the system need to communicate somehow.

The simplest approach is for them to share an atomically-updated variable; in an analog system, this might be the voltage on a wire connecting two of the components, or if we're running the PID controller on the same microcontroller that generates the waveform, a `volatile` variable written to by the PID controller process and read by an interrupt handler that generates the waveform, or an I/O register in a waveform-generation peripheral integrated into the microcontroller, like the AVR's timer/counter modules.

In the case of a `volatile` variable, though, we need to be careful of the danger of "torn reads": perhaps you're updating the value from 0x00ff to 0x0100, but on an AVR, that update involves sequentially setting two different bytes of RAM. If an interrupt handler runs between the two updates, it might see 0x0000 or 0x01ff and the robot might kill somebody.

(The "variable" might be arbitrarily large; you can think of framebuffers as being such "variables" shared between the main program and the display hardware, or in the case of the Arduino TVout library, the interrupt handler that generates the video signal. In this case "tearing" is manifested as on-screen "tearing" of images.)

This is similar to the CRT ADC case for which Gray invented Gray code, and so in this case you could try using Gray code to limit the magnitude of the torn-read error, but there are other more general solutions. One is to use a circular buffer to enqueue values to be communicated between components with different deadlines, a fixed-size queue that never blocks, in order to isolate failures within a given component.

XXX include implementation

This allows the PID component, for example, to isolate itself from failures in motion planning — if it goes to read messages from motion planning and none are there, it immediately gets a queue-empty message, a totally normal situation, and goes on about its business. Similarly, the waveform generator, if it has no new messages from the PID component, can go on about its business; and if there are interrupt handlers for the sensors feeding the PID controller, they too can add messages to a queue for it, not concerned about the PID controller's lack of adherence to their deadlines. If the queue gets full because the PID controller is failing, the sensor-reading messages will be lost, but the sensor-reading interrupt handler won't itself fail.

The same approach is essential in non-isochronous communication networks. If a gateway receives packets on one or more input streams whose maximum total input bandwidth is A, and forwards those

packets to one or more network interfaces whose total minimum guaranteed output bandwidth is B, then as long as A > B, it needs a bounded-size queue for outbound packets, and may drop packets at times. (Most commonly B = 0 because the common types of networks do not provide any guaranteed bandwidth.)

Anytime algorithms

"Anytime algorithms" or "interruptible algorithms" are a family of algorithms which can be interrupted at any time and get some kind of answer; if allowed to run longer, they can produce better answers. In particular, iterative approximation algorithms, which produce a series of progressively closer approximations to a mathematically correct answer, can be used as anytime algorithms.

For example, this Python implementation of the method of secants (from Separating implementation, optimization, and proofs (p. 780); see also Using the method of secants for general optimization (p. 1773)) is an anytime algorithm. It tries to find a zero of the scalar function `f` starting from guesses `x0` and `x1`, which are in general vectors:

```
def sec_seq(f, x0, x1):
    y = f(x0), f(x1)

    while True:
        yield x1
        x0, x1 = x1, x1 - y[1]*(x1 - x0)/(y[1] - y[0])
        y = y[1], f(x1)
```

After each iteration, `sec_seq` yields control back to the main program along with its current best solution; the main program can elect to resume it for another iteration or to accept that solution, either because it's adequately precise, because it's run out of time, or perhaps because a different approach to finding a zero is working better. (CPython doesn't allow us to prove tight bounds on the execution time of a single iteration, or to interrupt it either safely or in bounded time, but you could imagine a language that did; and, in some cases, even CPython's loosey-goosey behavior will be good enough.)

Anytime algorithms can exist in non-continuous domains, too — an optimizing compiler, for example, could reasonably work by constructing a correct but possibly slow compiled piece of code, then attempt various ways of optimizing it as long as there is time.

Mathematical optimization

A particular special case of anytime algorithms is the case of iterative mathematical optimization algorithms. Optimization, in this sense, is the mathematical problem of calculating the minimum of a function; for example, the minimum of $x^2 + x + 1$ is at $x = -½$, which can be calculated in closed form; minima of more complex functions are more difficult to find, and often we settle for local-search results rather than finding the global minimum.

In most cases, the objective is to reduce the function as low as possible, rather than rigorously guarantee that no other value is lower, and iterative optimization works by finding progressively lower and lower values.

So, for example, in SKETCHPAD, while it's *desirable* to satisfy the user's drawing constraints as quickly as possible, it's *necessary* to redraw the screen frequently in order to remain usable; so the relaxation procedure that seeks a satisfying value of the constraints runs a few steps before each screen redraw.

Optimization is a fairly general approach to solving "inverse problems", where we have a description of what properties a solution would have; optimization algorithms work especially well given a *fuzzy* description.

Constant-space representations

Traditional Lisps, Squeak, and newer versions of Python transparently overflow integer arithmetic into bignum arithmetic. This has the advantage that the results of integer arithmetic operations are always correct, while in many other programming languages, they may be only approximate, or they may overflow, either crashing the program or producing dramatically incorrect results.

However, this more common approach of producing approximate or dramatically incorrect results is often the price of failure-free, bounded-space, and bounded-time computation.

In signed 16-bit arithmetic, for example, 32767 + 1 = -32768, and 32767 + 3 = -32766; the first Ariane 5 rocket was destroyed by an arithmetic exception resulting from such an arithmetic overflow (though on a conversion from floating-point, rather than addition.)

Floating-point, as used for integer arithmetic in particular in JS, gives incorrect results for most operations, though not all. In 64-bit IEEE-754 floating-point, integer arithmetic (except for division) is exact up to 2^{53} = 9007199254740992.0; one result of this is that 9007199254740992.0 - 1 gives the correct result in most programming languages, while 9007199254740992.0 + 1 simply gives 9007199254740992.0 again. Under many circumstances, these errors are tolerable, although you can easily spend years on techniques to prove bounds on the errors in particular algorithms; and in many cases they produce results that are just wrong.

But both two's-complement integer arithmetic and floating-point arithmetic are usually constant-space and constant-time, and is often failure-free, although floating-point division by zero may produce a failure-free $\pm\infty$ value or, as in Python, an exception, depending on how things are configured; two's-complement integer division by zero almost invariably produces some kind of exception.

So what's the disadvantage of defaulting to bignums? Well, one of the first things I did with Squeak Morphic was to write an escape-time Mandelbrot-set renderer, but I had to set it to 16×16 pixels with a maximum number of iterations of about 10 or 12. (The Mandelbrot set is the set of complex numbers c for which the recurrence $z_i = z_{i-1}^2 + c$ remains bounded rather than zooming off to infinity as i increases, starting at $z_0 = 0$; escape-time rendering colors each pixel according to the number of iterations of the recurrence needed to exceed some limit, usually $|z| > 2$.)

When I set my iteration limit to a more reasonable number, like 256 or 100 or 30 or even 20, it took an unreasonably long time to render, or would hang completely. I was mystified; why was Squeak so slow?

A little investigation showed that the values of c, derived from

dividing pixel positions by the width and height of the array, producing exact rational numbers; so, for example, $z_4 = ((c^2 + c)^2 + c)^2 + c$ might involve calculating the eighth power of a number like 11/16, which is 214,358,881/4,294,967,296; but then z_5 would include its 16th power, which is 45,949,729,863,572,161/18,446,744,073,709,551,616; and so on. So my little Mandelbrot-set renderer was taking time — and memory! — *exponential* in the number of iterations.

Using an exponential amount of time is bad enough, but using an exponential amount of memory guarantees that you'll run out of memory before too many iterations.

Adding a decimal point somewhere was sufficient to get Squeak to switch from using exact arithmetic to using floating-point arithmetic, and suddenly I could use thousands of pixels and thousands of iterations.

So, constant-space arithmetic that doesn't crash on overflow is a useful way to make your arithmetic bounded-space, bounded-time, and failure-free, in the sense of not crashing (because of running out of memory or for any other reason).

More generally, if you are going to compute with some kind of entity, whether a number or not, in a failure-free fashion, you need to be able to represent it with a constant space bound, and usually in constant space. If your representation uses unbounded space, you cannot guarantee that your program will not run out of memory. (If it uses variable space with a constant bound, to get failure-free computing, you need to somehow ensure that space is always available when it needs to expand to its maximum size, which is feasible but usually more difficult than just always using the maximum size.)

But constant-space arithmetic gives you the wrong answer some of the time, which you could consider a software failure, even if the software doesn't consider it an "error condition arising". It is a widely shared observation that sometimes subtly wrong answers are worse than an outright failure, to the point that it's one of the core design principles of Python.

So, to use constant-space arithmetic without that danger, you need some extra care. There are three basic approaches: numerical analysis, overflow-safe arithmetic, and self-validating arithmetic.

Numerical analysis

Numerical analysis consists of statically analyzing your software to prove that it doesn't provoke the arithmetic errors inherent to constant-space arithmetic representations — in particular, the errors caused by the particular representation you're using — or that, if it does, the errors are acceptably small.

For standard C `signed` arithmetic, this involves statically ensuring that no overflow happens, because C `signed` arithmetic is undefined on overflow, which basically means that the compiler is free to break your program. The simplest approach is to statically associate constant upper and lower bounds with every arithmetic expression in the program, but this works only in the simplest cases; it fails for any code containing nontrivial loops. So, generally, you need to use bounds that are some kind of algebraic expression, rather than constants.

For wrapping binary arithmetic such as C `unsigned` arithmetic and the two's-complement arithmetic performed by CPUs when they are doing signed arithmetic, in many cases it isn't necessary to ensure that intermediate quantities don't overflow; it is only necessary to ensure that final results don't overflow. This is true for addition, subtraction, and I think multiplication, but not division; I think it is necessary that neither dividends nor divisors overflow.

For floating-point arithmetic, it's usually not a question of whether the result is correct — it's not — but of computing bounds on its error. The IEEE-754 standard guarantees that fundamental operations — +, -, ×, ÷, and perhaps surprisingly √ — are correct to within half an ulp, but offers less stringent guarantees for other operations, including exp, ln, exponentiation, and trigonometric functions.

Overflow-safe arithmetic

Self-validating arithmetic (e.g., interval arithmetic and affine arithmetic)

The object-embedding memory model

The object-embedding memory model eliminates certain failure modes from the object-graph memory model. In its pure form, all allocation is static, so there is no chance of any allocation failure. Embedded objects cannot be NULL, cannot be aliased (except via a pointer), and cannot be of the wrong type.

I suspect that this is one of the reasons for the empirically-observed reliability of C programs — although C has lots of undefined behavior and provides ample ways for programmers to shoot themselves in the foot, introduce failure, and introduce unbounded time and unbounded space, much of a typical C program is not touching those bits of the language. Although C has pointers, substantial parts of C programs use object embedding where programs in Java or Python would use pointers.

Records and sum types rather than arrays

Every time you index into an array (except with a constant index such as `a[0]`), you have a potential failure: the index may be outside the bounds of the array. Typical static program analysis techniques are too weak to prove that this cannot happen. In some cases this amounts to an allocation failure, as in the innumerable stack buffer-overflow bugs in 1990s C programs like NCSA httpd.

By contrast, if you have a (non-nullable) pointer to a known type of record, accessing the fields of the record is statically safe; it is constant-time and cannot produce failures. The pattern-matching approach used in ML allows this approach to extend to arbitrary Lisp-style object graphs; the compiler can statically verify that your pattern matching is exhaustive, statically ruling out run-time failures due to incomplete case analysis.

Arena allocators

If you allocate memory from an arena (or "region", in MLKit's term, or "pool", in the terminology of the Apache APR library) that is all freed at once, you get constant-time allocation and constant-time deallocation. To eliminate failure and bound time and

space usage, you then must merely prove a worst-case bound on the allocation of the program, and allocate a bigger arena than that.

Functional iteration/concurrency

Iteration protocols and per-array operations rather than array indexing

Hard priority scheduling

Wait-free and lock-free synchronization

Handling concurrency with locks or monitors introduces unwanted coupling between the time bounds of different processes: the worst-case execution time of code in a high-priority thread that needs to enter a monitor must include the time it needs to wait on whatever other thread might currently hold that monitor, which is to say, all code that can execute inside that monitor in any thread. Priority inversion, where a thread holding a lock that is blocking a high-priority thread has to sleep while an intermediate-priority thread runs, is perhaps the most severe manifestation of this problem, but it is more general.

Moreover, locks can produce deadlock, which results in a program failure; global analysis is required to rule deadlock out.

Interrupt handlers never use locks, because there is no mechanism to put the interrupt handler to sleep until the main program releases the lock, then wake it back up again. In some cases, the main program uses a lock (often with the big-hammer approach of disabling interrupts entirely) to lock out the interrupt handler entirely for a short time, but more generally, if the main program is doing something that an interrupt-handler execution might interfere with, it maintains the shared data in a consistent state the whole time, atomically committing its "transaction" at the end, typically with a compare-and-swap operation — a commitment which might fail if an interrupt handler ran in the meantime, requiring the main program to restart its transaction.

This same approach works for multiple threads of a program concurrently updating a memory area. It introduces a soft sort of failure — the need to retry a transaction — but, unlike locking protocols, it guarantees progress. In combination with hard priority scheduling, it entirely prevents a lower-priority process from slowing down a higher-priority process by forcing it to wait. However, the price is that if the lower-priority process can be forced to retry a transaction repeatedly, it can no longer guarantee time bounds on its execution.

Lock-free and wait-free synchronization algorithms are notoriously difficult to implement correctly.

Bounded-time, failure-free restricted virtual machines

Earlier I discussed how fixed-size queues can firewall failures and unbounded delays from propagating from one domain into another, enabling more-sensitive domains to be failure-free and bounded-time

while less-sensitive domains can be programmed in easier, more general ways. But fixed-size queues can only support a certain kind of arm's-length interaction; in many cases, more intimate levels of cooperation are desirable.

Bitcoin Script, BPF, and BPF's predecessor CSPF are loop-free virtual machines; a trusted virtual machine runs untrusted code in a timing-sensitive context (an interrupt handler in the case of BPF and CSPF!), which is safe only because the execution time is bounded by the script size. This allows fast-and-loose code like tcpdump, or your half-assed shell script invoking it, to safely execute code in a kernel interrupt context. And that's damn cool.

See Scriptable windowing for Wercam (p. 1256) for some thoughts on how to get a failure-free, bounded-time GUI with techniques like these.

Abstract interpretation with non-standard semantics

However, if you're writing most of your program in something comfortable like JS or whatever, it's going to feel pretty clumsy to have to write part of it in loop-free bytecode for a register machine.

Consider the case of pubsub. In the most general case, each subscriber has some Turing-complete filter function; you apply it to every message published to determine whether to deliver that message to that subscriber. It's often convenient to be able to run these filter functions in some kind of centralized message router, so that you don't have to send messages across a network to a subscriber that is just going to ignore them. But then, if the filter function uses unbounded space or time, the router might seize up. (Or it might fail.)

(There are some notes in Fast secure pubsub (p. 545) about how to do this by running the filter function in a transactional-memory-like sandbox.)

So suppose you have such a client–server pub-sub system, with a client library in Python, and you give it this filter function:

```
def wanted(message):
    if message.domain in whitelisted_domains:
        return True
    if message.length > 8192 or message.domain in blacklisted_domains:
        return False
    return spamminess(message) < spamminess_threshold
```

Python allows you to override attribute access and comparisons. This allows you to write an object like this:

```
class Comparator(object):
    def __init__(self, desc):
        self.desc = desc

    def __getattr__(self, attr):
        return Comparator(self.desc + '.' + attr)

    def __eq__(self, other):
        print(self.desc, '==', other)
```

```
        return False

    def __gt__(self, other):
        print(self.desc, '>', other)
        return False

if __name__ == '__main__':
    x = Comparator('x')
    x.domain in 'this is an example'.split() or x.length > 8192
```

When executed, this code prints:

```
x.domain == this
x.domain == is
x.domain == an
x.domain == example
x.length > 8192
```

That is, the `x` object has access to each of the things it's being compared with, and can choose the result of the comparison. If you invoke the above `wanted` function with such a `Comparator` object, it might produce output like the following before, presumably, it crashes the `spamminess` function:

```
message.domain == gmail.com
message.length > 8192
message.domain == godaddy.com
```

A slightly more sophisticated object could allow the caller to choose the results of the comparisons, in an effort to probe the tree of possible execution paths of the filter function. In this case, it could determine that if the first comparison returns `True`, then the filter function returns `True`; if not, but the second or third one returns `True`, then the filter function returns `False`; and then perhaps the function goes off into further calculations which raise an exception and terminate the probing process.

These observations permit the client library to compute a string of bytecode for the sort of restricted virtual machine described above, a bytecode function that calculates the same results as the filter function under some circumstances; this bytecode can then be sent to the server to prefilter the set of messages that get sent to the client.

I've used Python's operator overloading here because it's convenient, but operator overloading is just a particularly simple way of doing abstract interpretation with nonstandard semantics, not the only way. It's not even a particularly good way, in this case; it requires restarting the function from the beginning to explore each new execution path, and if `whitelisted_domains` is a `set` rather than a `list`, it fails silently.

The key relationship here, though, is that the failure-free, bounded-time code for the virtual machine produces a conservative approximation of the result of the more unrestricted code for the unreliable, loosey-goosey CPython virtual machine.

Stream processing

Forth assembling

Kragen Javier Sitaker, 2019-12-08 (updated 2019-12-11) (18 minutes)

Could you write an assembler with a smooth, backward-compatible path from raw binary (or, say, hexadecimal or octal) code up to a reasonable macro-assembler programming environment? Could it be smaller than existing assemblers? Maybe, but it's much easier to make a wrong turn and fall into the Turing tarpit.

The background

In an assembly-language program, traditionally, you have a sequence of operations that add bytes to the program being assembled and resolve labels, which may result in changing bytes that have already been assembled. The simplest operation is something like `db`:

```
db 0x1a                 ; clear screen
```

This appends the byte 0x1a at the current pointer (which I think is called `$` in traditional assembly-language syntax used by, for example, the CP/M assembler for the Intel 8080, as in this case; or `.` in AT&T or gas syntax) and advances that current pointer by one byte.

In an RPN calculation, by contrast, you have a sequence of operations that add numbers to a stack, advancing the stack pointer. If your RPN calculator is in hexadecimal mode and it processes the operation `1A` then it appends the number 0x1a at the current stack pointer and advances that current pointer by one stack item.

There is an obvious similarity between these two operations. But adding programmability to an RPN calculator is very easy. Can we exploit this? What happens if we try to incrementally add RPN calculation abilities to a minimal assembler? Can we put entire instruction sets into macro libraries, as Assembler bootstrapping (p. 2922) suggests (and points out was common in the past), if we simply conflate the operand stack with the memory space we're assembling intoo?

The simplest assembler

Jeremiah Orians took exception to my claim in Assembler bootstrapping (p. 2922) that a *minimal* assembler would have labels and macros, since his stage0, like Edmund GRIMLEY EVANS's bcompiler and various things we've discussed on kragen-tol and kragen-discuss over the years, starts from simply converting hexadecimal or octal into machine code. Now, it's merely a question of semantics whether such a program, which recognizes only hexadecimal or octal input, should be called an "assembler" or not --- normally an assembler recognizes instruction opcode mnemonics and handles labels --- but it's undeniably a very useful tool for bootstrapping.

So, for example, here's an MS-DOS 64-byte demo I wrote a few years ago, in an octal format such a program might accept, which can be obtained from `od -vbAn`:

```
260 023 315 020 304 057 211 350 367 056 001 001 211 305 061 306
061 322 211 301 061 333 210 367 211 337 301 373 002 001 337 211
303 301 373 010 001 337 001 367 133 046 210 075 103 123 211 303
301 373 004 001 332 211 323 301 373 004 051 330 342 326 353 306
```

As explained in An 8080 opcode map in octal (p. 1059), the Intel family of machine languages, including the 8080, the 8086, the i386, and amd64, and even the 8008 (as explained in Further notes on algebras for dark silicon (p. 1753)), are much easier to read in octal than in hexadecimal, and the code to convert from octal to binary is simpler than the code to convert from hexadecimal to binary (especially traditional 0123456789abcdef hexadecimal instead of 0123456789jklmno).

Here's such an octal converter in C:

```
#include <stdio.h>

int main() {
    int b = 0, c, d = 0;
    while ((c = getchar()) != EOF) {
        if ('0' <= c && c <= '7') d++, b = (b << 3) | (c - '0');
        else if (d) putchar(b), b = d = 0;
    }
    return 0;
}
```

`gcc -fomit-frame-pointer -Os -Wall -Werror -std=gnu99` on i386 compiles this function into 29 instructions in 63 bytes, although the executable file is 7340 bytes with 434 bytes of .text and hundreds of bytes of other cruft.

This is an assembly version of the machine code GCC generated:

```
        .globl main
main:   push   %ebp
        mov    %esp, %ebp
        push   %esi
        push   %ebx
        and    $~0xf, %esp
        sub    $0x10, %esp
reset:  xor    %esi, %esi
        xor    %ebx, %ebx
next:   call   getchar
        cmp    $-1, %eax
        je     end
        sub    $'0, %eax
        cmp    $7, %eax
        ja     emit
        shl    $3, %ebx
        inc    %esi
        or     %eax, %ebx
        jmp    next
emit:   test   %esi, %esi
        je     next
        mov    %ebx, (%esp)
        call   putchar
```

```
        jmp     reset
end:    lea     -8(%ebp), %esp
        xor     %eax, %eax
        pop     %ebx
        pop     %esi
        pop     %ebp
        ret
```

This is pretty reasonable code but it can obviously be cleaned up and whittled down a bit, especially if we suppose that crt0 doesn't care if we preserve its %esi and %ebx:

```
        .globl main
main:   xor     %esi, %esi
        xor     %ebx, %ebx
next:   call    getchar
        cmp     $-1, %eax
        je      end
        sub     $'0, %eax
        cmp     $7, %eax
        ja      emit
        shl     $3, %ebx
        inc     %esi
        or      %eax, %ebx
        jmp     next
emit:   test    %esi, %esi
        je      next
        push    %ebx
        call    putchar
        pop     %ebx
        jmp     main
end:    xor     %eax, %eax
        ret
```

That's 49 bytes of machine code, but of course it depends on C stdio and exiting via crt0, and also 8 of those 49 bytes are C stdio addresses. So a bare-kernel version might be more appealing:

```
        .globl _start
_start:
main:   xor %esi, %esi          # flag for whether we have data
        xor %ebp, %ebp          # the data we maybe have
next:   push %esi               # stack balance, also zero the buffer
        xor %eax, %eax
        mov $3, %al             # __NR_read
        xor %ebx, %ebx          # fd = stdin, 0
        mov %esp, %ecx          # buf on stack
        xor %edx, %edx          # count =
        inc %edx                #         1
        int $0x80               # system call, results in %eax
        dec %eax
        test %eax, %eax         # if not 1:
        jnz end                 # bail out
        pop %eax                # fetch character read
        sub $'0, %eax
```

```
        cmp $7, %eax
        ja emit                 # if non-digit, emit buffered byte if any
        shl $3, %ebp            # otherwise shift to make space for digit
        inc %esi                # and set flag
        or %eax, %ebp
        jmp next
emit:   test %esi, %esi         # Do we have buffered data to emit?
        je next
        xor %eax, %eax
        mov $4, %al             # __NR_write
        xor %ebx, %ebx          # fd =
        inc %ebx                #      stdout, 1
        push %ebp
        mov %esp, %ecx          # buf on stack again
        xor %edx, %edx
        inc %edx                # count = 1
        int $0x80
        pop %edx
        jmp main
end:    xor %eax, %eax          # __NR_exit =
        inc %eax                #            1
        int $0x80
```

This is considerably more instructions, 37, and back up to 67 bytes of code. But, linking with `-nostdlib`, the static stripped executable is 416 bytes with only 67 bytes of `.text`, without any trickery with minimizing ELF headers; Brian Raiter's whirlwind teensy tutorial succeeded in getting a 45-byte Linux ELF executable, so probably it's possible to get this executable to be about 112 bytes with such trickery.

Backwards-compatible assembly features

An interesting idea here is to add more traditional assembly-language capabilities in a backward-compatible way to this octal-dump language. A really straightforward thing to add would be an RPN operation like `|`, which replaces the last two bytes emitted with their bitwise OR. (More traditional operations include things like `+` and `-`, but `|` is more immediately useful.) So, for example, you could write the `211 305` in the above code, meaning `mov %ax, %bp`, as `210 1 | 0 5 300 | |`; in this case `210` is `mov` (or `lea` or `pop`), and `1` is the Ev <- Gv variant of it, while `300` is the "mod" for the register-register mod-r/m byte, `0` is `%ax`, and `5` is `%bp`.

This requires buffering up the program to be output, unlike the "assemblers" above. This expands it significantly to 88 bytes of code:

```
        .globl _start
_start: mov $output, %edi       # output pointer
reset:  xor %esi, %esi          # flag for whether we have data
        xor %ebp, %ebp          # the data we maybe have
next:   push %esi               # stack balance, also zero the buffer
        xor %eax, %eax
        mov $3, %al             # __NR_read
        xor %ebx, %ebx          # fd = stdin, 0
        mov %esp, %ecx          # buf on stack
```

```
        xor %edx, %edx          # count =
        inc %edx                #         1
        int $0x80               # system call, results in %eax
        dec %eax
        test %eax, %eax         # if not 1:
        jnz end                 # bail out
        pop %eax                # fetch character read
        sub $'0, %eax
        cmp $7, %eax
        ja emit                 # if non-digit, emit buffered byte if any
        shl $3, %ebp            # otherwise shift to make space for digit
        inc %esi                # and set flag
        or %eax, %ebp
        jmp next
emit:   test %esi, %esi         # Do we have buffered data to emit?
        je ops
        mov %ebp, (%edi)
        inc %edi
ops:    cmp $('| - '0), %eax     # was the character a |?
        jne reset                # if so, OR the last two bytes:
        dec %edi
        mov (%edi), %dl
        or %dl, -1(%edi)
        jmp reset
end:    xor %eax, %eax
        mov $4, %al             # __NR_write
        xor %ebx, %ebx          # fd =
        inc %ebx                #      stdout, 1
        mov $output, %ecx       # buf = output
        mov %edi, %edx          # count = output pointer
        sub %ecx, %edx          #                       - buf
        int $0x80
        xor %eax, %eax          # __NR_exit =
        inc %eax                #             1
        int $0x80
        .bss
output: .fill 65536, 1, 0
```

That 88-byte program, given the input `300 50 1 | | 300 50 1 | 300 50 1`, does output the bytes (represented in octal) 351 300 051 300 050 001.

Passing that assembly through `cc -nostdlib`, `objcopy -S -R .note.gnu.build-id`, and `od -vbAn` gives the following byte listing, from which the executable can reproduce itself:

```
177 105 114 106 001 001 001 000 000 000 000 000 000 000 000 000

000 000 000 000 000 000 000 000 000 000 000 000 000 000 000 000
013 000 000 000 001 000 000 000 006 000 000 000 270 200 004 010
270 000 000 000 130 000 000 000 000 000 000 000 000 000 000 000
001 000 000 000 000 000 000 000 021 000 000 000 010 000 000 000
003 000 000 000 000 220 004 010 000 020 000 000 000 000 001 000
000 000 000 000 000 000 000 000 001 000 000 000 000 000 000 000
001 000 000 000 003 000 000 000 000 000 000 000 000 000 000 000
020 001 000 000 026 000 000 000 000 000 000 000 000 000 000 000
001 000 000 000 000 000 000 000
```

More or less translating this back to C, we get this:

```c
#include <stdio.h>

char output[65536];

int main() {
    char *op = output;
    int b = 0, c, d = 0;

    while ((c = getchar()) != EOF) {
        if ('0' <= c && c <= '7') b = (b << 3) | (c - '0'), d++;
        else {
            if (d) *op++ = b, b = d = 0;
            if (c == '|') op--, op[-1] |= *op;
        }
    }

    fwrite(output, op - output, 1, stdout);
    return 0;
}
```

Or, in GForth:

```
: getchar tib 1 stdin read-file  swap 1- or if 0 else tib c@ 1 then ;
: read-to-end  begin  getchar while  over execute  repeat  drop  ;
create output 65536 allot   output value op  0 value b  0 value d
: digit 3 lshift or ;  : handle-digit  b digit to b  1 to d ;
: out d if  b op c!  op 1+ to op  then  0 to d  0 to b ;
: do-or op 1- dup to op  @  op 1- @ or  op 1- ! ;
: dispatch [char] | = if do-or then ;
: octal [char] 0 - >r  r@ 0 >=  r@ 7 <=  and if r> 1 else rdrop 0 then ;
: handle-byte dup octal if handle-digit drop else out dispatch then ;
: main ['] handle-byte read-to-end  output op output - type  bye ;
```

(That took me an hour to get working; I didn't know how file I/O

worked in ANS Forth, and it took me quite a while to work out that I'd left out the `drop` in `handle-byte`. I ran this as `gforth osmdf.fs -e main < foo.oct > foo.com`; it doesn't do the right thing when fed from a terminal.)

Or, in Python 2:

```
import sys

output = []
b = None

for c in iter(lambda: sys.stdin.read(1), ''):
    if '0' <= c <= '7':
        b = ((b or 0) << 3) | int(c)
    else:
        if b is not None:
            output.append(b)
            b = None
        if c == '|':
            output[-2:] = [output[-2] | output[-1]]

sys.stdout.write(''.join(map(chr, output)))
```

The next obvious step in the direction of a real assembler with mnemonics is enough of a macro system to enable you to write that as `mov1 %ax %bp rr | |`, which requires only being able to define words that expand to numbers, like EQU. And then after that you probably want something that allows you to write `%ax %bp mov-rr`, which requires `mov-rr` to be able to somehow insert an instruction byte *before* its arguments. We'd like to be able to define it at least as something like `: mov-rr swap 3 << | 300 | 211 swap ;` and maybe better as something like `: mov-rr { src dest } 211 300 src 3 << | dest | ;`.

So we end up in Forth

And the off-the-shelf design for that kind of thing is an indirect-threaded Forth. Minimally, it has an operand stack (in this case, this doubles as the code being generated, although with one word per item rather than one byte per item), a return stack so that subroutines can call other subroutines, and a dictionary it can look subroutines up in. Some subroutines in the dictionary, like the hardcoded `|` above, are implemented by machine code (the six bytes 117 212 027 010 127 377 above --- `dec %edi; mov (%edi), %dl; or %dl, -1(%edi)`). Normally it also has `@` and `!` operations to access a random-access memory. It has the possibility of adding new items to the dictionary, which can only be freed in a LIFO order.

And it's fairly straightforward to see how you could accumulate label relocations in the Forth dictionary as linked lists of pointers into the growing code, skip the operand-stack pointer around as desired to deposit code into different segments, and the other kinds of things you'd want to do in an assembler.

And, once we've settled on having a flexible interpreter in our assembler, we can implement core "assembler" functionality in the interpreted language. Above there's an example of how 10 lines of interpreted Forth can implement the functionality we needed 43 lines

of assembly language for. The Forth should have better compositionality, although in this case, the difference is mostly because the assembly is in a more vertical format --- the Forth is about the same amount of text.

But maybe we wouldn't want the interpreter to be Forth. If we're just looking for the absolute minimum interpreter that lets us shove the main assembler functionality out into macro libraries that get loaded when we run the "assembler", there may be a number of Turing tarpit possibilities, things like the lambda-calculus or SKI-combinators, although probably in Polish Notation or RPN syntax. So maybe the question of "the minimal assembler for bootstrapping" boils down to the well-trodden ground of designing a minimal interpreter instead. And maybe that's still true even if your interpreter also contains, in some form, the capability of the 49-byte octal bootstrapping program above, so that if you feed it a stream of octal bytes it will still faithfully convert them to binary.

Wikipedia people

Kragen Javier Sitaker, 2016-06-01 (6 minutes)

In Neal Stephenson's novel *Seveneves*, there is a group of people called Cycs who have undertaken to collectively memorize a carefully preserved five-thousand-year-old Encyclopedia Britannica. One of the characters is named Sonar Taxlaw, after the 17th volume, which she has full mastery of at her 16 years; she also has a loose acquaintance with the rest.

It beggars belief that a novel written so recently would have chosen the Britannica over a paper copy of Wikipedia, but what would the Wikipedia-based equivalent look like?

The English Wikipedia is about 5 million articles at this point and about 50 gigabytes of UTF-8 text, for a mean of some 10 kilobytes per article. The "Vital Articles" lists are carefully chosen subsets of 10, 100, 1000, and 10 000 (actually 9841) articles, which tend to be longer than the mean (which is dragged down substantially by stub articles, which are vanishingly unlikely to be Vital), at around 22 printed pages or 320 kilobytes each.

If we take Stephenson at his word that a 500-or-so-page Britannica volume can be adequately mastered by one bright person, then we have about 23 Wikipedia articles per person; so the Wikipedia Vital 100 could be summarized by four or five people, the Vital 1000 (close to Britannica in size) by about 44 people, and the Vital 10000 by about 440 people.

However, it is often the case that useful knowledge arises only from connections between topics. Suppose that instead we want to ensure that each *pair* of articles is present in the mind of at least one person, so that at least syntheses that need to draw on any two different articles have a chance to arise.

Here's one scheme for how to do that: divide the articles, perhaps randomly, into groups of 11, and make a matrix with a row and a column for each group of articles: 91 groups to cover the Vital 1000, say, gives us a 91×91 matrix. Then, assign a person to each above-diagonal cell in this matrix, (* (/ 90 2) 91) = 4095 people in this example. Have that person learn all 22 articles from their row and their column.

This seems somewhat wasteful: each person contains (* (/ 22 2) 21) = 231 pairs of articles, but (* (/ 10 2) 11) = 55 of them are shared with everybody else on their row, and another 55 with everybody else on their column. So only (- 231 55 55) = 121 of their pairs, just over half, are unique. So out of the total (* 4095 231) = 945945 pairings of articles in people's heads, you only have (* (/ 1000 2) 999) = 499500 unique pairs. Furthermore, a person who can master 23 articles could actually contain (* (/ 22 2) 23) = 253 pairs, which could potentially reduce the necessary number of people further to (/ 499500 253.0) = 1975. But it's not clear how to reach or approach that bound.

Regardless, the number of people needed to cover all the article *pairs* in this way is proportional to the square of the number of articles, or rather, the amount of information. So to cover all the pairs in the Vital 100 with the simple assignment scheme above, you would need only ten people.

Printing out all of English Wikipedia on paper at full size would use about 3.4 million pages; linearly reduced 4:1, at which point it's 3-point text that's barely still readable without a magnifying glass, would be about 212 thousand pages, or 212 reams of paper.

Wikipedia:Size notes, "In 2015, Michael Mandiberg published the English Wikipedia in 7473 volumes of 700 pages each via Lulu, an online e-books and print self-publishing platform, distributor, and retailer." Probably nobody has yet printed out all 7473 volumes, a total of 5.2 million pages of paper at a cost of US$500k, but he did print out 106 volumes for an art exhibit in New York. The Print Wikipedia blog post notes that the table of contents occupies 91 volumes.

Presumably the same 4:1 reduction trick would bring this down to 325 000 pages, a mere 465 volumes or 325 reams at a cost of US$31,250. At the standard 80 g/m², an A4 sheet weighs 5 g, so this printout would weigh 812 kg. Staples sells 75 g/m² US Letter paper in a case of 10 reams for US$56, so the paper alone would cost US$1820. However, their acid-free paper costs US$22 per ream and weighs 89 g/m², which would raise the price to US$7150. Presumably you could get the weight down by using thinner paper, as was normally used for encyclopedias and dictionaries, perhaps at a higher dollar cost. Wikipedia says "onionskin" typically weighs 25–39 g/m²; 30g would lower the weight to (* 325 500 (/ 30 16.0) .001) = 305 kg. Amazon lists a "9-pound" "FIDELITY" brand onionskin bond paper for US$25 per ream, weighing 3 pounds per ream, which works out to about 34 g/m². It's 100% wood pulp, but despite that, it's buffered, pH neutral, and 100-year rated. (1000 years is readily achievable.). If it's 50µm thick, then the shelf length in A4 size would be (* 325 500 50 .001 .001) = 8.125 m.

(Working out from the shitty basis weight standard, the basis ream for bond paper is 500 sheets of 17" × 22", which is how we know it's 34 g/m².)

Here in Argentina, the terminology seems to be "papel alcalino", and 75g "papel alcalino" costs only about US$10 per 500-sheet A4 ream. This would bring the paper cost of the whole Wikipedia project to US$3250.

Byte-stream pipe and antipipe façade objects for editor buffers

Kragen Javier Sitaker, 2017-04-10 (3 minutes)

I was pondering a design for gap buffers in C, trying to figure out the interface. At first I thought two access functions would be enough, one to read a range and one to write a range, in both cases to a raw char pointer. (Plus a function to get its length.)

Then I realized that meant that reading from or writing to a file would require an extra inefficient copy through an intermediate buffer. So I thought I'd want to add functions that take file descriptors, too, because that's a pretty important thing to do with strings, really the only thing other than copying them around in memory if you're on Unix.

But then I realized that I'd probably want to copy data from one gap buffer to another at some point, but for that I'd still need the extra inefficient copy. So I was thinking of adding another function, and then I realized what I was doing.

All that's needed here is a generic interface for piping byte streams around, which could be either push (a byte-sink interface) or pull (a byte-source interface). Then we just need pipe and antipipe façades for gap buffers, files, and raw char pointers.

C isn't that great for generic interfaces, but you could do it this way:

```
typedef struct {
    int (*write)(void *user_data, const char *s, size_t len);
    void *user_data;
} byte_sink;
```

Given a `byte_sink`, you can invoke it several times with different pieces of data. A gap buffer asked to write its contents to a `byte_sink` might invoke it twice, once for the part of the text before the gap and once for the part after it.

(In other contexts, a byte-sink interface might also include a close method, an error method, and so forth. In this case, the `write` function has a return value that I intend to use to indicate errors.)

Here `user_data` is used to distinguish different objects of the same type, since C function pointers aren't closures. I originally heard the term in the context of Tcl, but by now Lua, OpenGLUT, GLFW, GTK+ and GLib, Core Audio, systemd, and Box2D also use the term to mean more or less the same thing.

Then, to write to gap buffers, file descriptors, or raw byte buffers requires three different `byte_sink` write functions, and functions that return `byte_sink` wrappers for them; to read from gap buffers, file descriptors, or raw byte buffers, we need three different functions that take `byte_sink` arguments.

So instead of five functions, now we have nine functions. But now, in addition to being able to copy data into and out of gap buffers, we can also copy data from one file descriptor to another; and if we add a new string buffer type in the future (like an array of gap buffers) we

can copy data to and from it in the same way.

This is still kind of crappy for reading data from files, because it still involves an extra buffer copy — the file descriptor byte source function is obligated to allocate it.

Lisp 1.5 in a stack bytecode: can we get from machine code to Lisp in 45 lines of code?

Kragen Javier Sitaker, 2018-04-27 (4 minutes)

You can take the Lisp 1.5 metacircular interpreter (from e.g. http://www.righto.com/2008/07/maxwells-equations-of-software-oexamined.html, originally from p.13 of The Lisp 1.5 Programmer's Manual http://www.softwarepreservation.org/projects/LISP/book/LISP%20o1.5%20Programmers%20Manual.pdf, in M-expressions and directly write them as stack-machine code.

```
\ evalquote[fn;x] = apply[fn;x;NIL]
:EN$;
\ apply[fn;x;a] = [atom[fn] -> [eq[fn;CAR] -> caar[x];
\                               eq[fn;CDR] -> cdar[x];
:$r!x!f!f@a[f@1=[x@AA;]f@2=[x@AD;]
\                               eq[fn;CONS] -> cons[car[x];cadr[x]];
f@3=[x@Ax@DAk;]
```

This amounts to 54 characters for these four lines. Proceeding more or less in this way, the 21 lines of code from the Lisp manual should be about 280 characters, or about four lines. The non-Lisp primitives used here are taken from StoneKnifeForth, largely from Forth, and the meanings of the characters include:

- `:` defines a (one-byte) label as a function entry point;
- `;` returns from the current function;
- `!` stores NOS (next-to-top-of-stack) at the address in TOS (top-of-stack), popping both;
- `@` fetches the value at the address in TOS, replacing it as TOS;
- `[` pops TOS and conditionally jumps to the matching `]` if it was zero, thus enclosing a conditional;
- `=` pops TOS and NOS and pushes a value that is zero unless they were equal;
- literal numbers push themselves on the stack;

StoneKnifeForth defines 21 such primitives.

The other characters used are:

- `r`, `x`, and `f` are presumed to be elsewhere-defined addresses of memory cells that we can use for convenient storage of parameters `r`, `x`, and `fn` respectively — recursive calls, however, may need to explicitly save and restore such things on a Forth stack;
- `E` represents `evalquote`, and `$` represents `apply` (after its meaning in Haskell, I suppose);
- `A` is `car`, `D` is `cdr`, and `k` is `cons`.

You can implement the A (CAR) and D (CDR) operations with something like the following, presuming labels `c` and `d` pointing to appropriately-sized arrays in which to store the car and cdr pointers

themselves:

```
:Ac+@;
:Dd+@;
```

My recollection from doing this in C in 2007 https://www.mail-archive.com/kragen-hacks@canonical.org/msg00164.html is that there are a fair number of other things you need to implement that are sort of hidden under the covers here: input parsing, output printing, atom interning, memory management, call/return ("activation record management", as I said), and error handling. The C version was 154 lines of code that worked, plus another nonworking 23 lines of code for garbage collection, for a total of probably about 177 lines. Of that, 40 lines of C was devoted to the 21 lines of code from the Lisp 1.5 metacircular interpreter which could maybe be compressed down to 4 lines (284 characters) of line-noise stack code. If the same ratios held, the whole working Lisp would be 1254 characters of stack code, which is about 20 lines; 15–25 lines is probably a reasonable estimate, or maybe 45 lines if it's formatted to be as readable as possible.

It might be a somewhat better idea to do a simple Scheme, Lua, or Smalltalk instead, with proper lexical scoping, instead of the dynamic-scoping early-bound mistake that was 1960s Lisp. There's no reason to expect that they'll be much more code, but if they are, 1960s Lisp might be good enough.

Something like this is probably a reasonable way to bring up a more or less high-level language in a fairly minimal amount of code. This provides the following estimate for the part of the abstraction ladder to get to a high-level programming environment:

- 158 lines of Verilog: a CPU like the J1a;
- 132 lines of quasi-Forth: a quasi-Forth compiler to native code like StoneKnifeForth;
- 198 lines of Python or similar: a bootstrap interpreter to run it to get the initial native code, as in StoneKnifeForth;
- 45 lines of code like the above: a high-level programming language.

Total: 533 lines of code.

(Maybe 90 lines is a better estimate for the Lisp part.)

Of course, this doesn't include operating systems, filesystems, text editors, fonts, font rendering, networking, Verilog logic synthesis, and so on. But it's a start.

Toward a minimal PEG parsing engine

Kragen Javier Sitaker, 2018-06-06 (4 minutes)

So, tonight, prompted by last night's frustration with μSQL parsing of input, I hacked together a PEG parser with syntactic sugar in Python. It lets you write PEGs that look like this:

```
class Arithmetic(Grammar):
    sp = Lit(' ') | '\n' | '\t'
    _ = sp + _ | ''
    digit = Lit('0') | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'
    digits = digit + digits | digit

    number = (digits + '.' + digits | digits + '.' | Lit('.') + digits | digits) o
o+ _
    exponentiation = number + '**' + _ + number | number
    multiplicative = (exponentiation + '/' + _ + multiplicative
                      | exponentiation + '*' + _ + multiplicative
                      | exponentiation)
    additive = (multiplicative + '+' + _ + additive
                | multiplicative + '-' + _ + additive
                | multiplicative)
```

Then you can invoke e.g. `Arithmetic.additive.parse` on a string. Like μSQL, it has some major problems, but it more or less works — to a much greater extent than μSQL, in fact.

The implementation of this is about two pages of code, but I trimmed a version of it with slightly less magic down to under half a page:

```
from collections import namedtuple
class PE:
    __add__ = lambda s, o: Seq(s, o if isinstance(o, PE) else Lit(o))
    __or__  = lambda s, o: Alt(s, o if isinstance(o, PE) else Lit(o))
    __invert__ = lambda self: Neg(self)
class Lit(PE, namedtuple('Lit', ['text'])):
    def parse(self, text, position):
        if self.text == text[position:position + len(self.text)]:
            return self.text, position + len(self.text)
class Seq(PE, namedtuple('Seq', ['a', 'b'])):
    def parse(self, text, position):
        a = self.a.parse(text, position)
        if a:
            b = self.b.parse(text, a[1])
            return ([a[0], b[0]], b[1]) if b else None
class Alt(PE, namedtuple('Alt', ['a', 'b'])):
    def parse(self, text, position):
        return self.a.parse(text, position) or self.b.parse(text, position)
class Neg(PE, namedtuple('Neg', ['negated'])):
    def parse(self, text, position):
        return None if self.negated.parse(text, position) else (None, position)
```

```
class Nonterminal(PE):
    def __init__(self, name):
        self.name = name
    def parse(self, text, position=0):
        r = self.rule.parse(text, position)
        return ((self.name, r[0]), r[1]) if r else None
```

This half-page of code leads me to thinking about StoneKnifeForth and its kin, which was of course why I started playing with PEG parsers in the first place ten years ago. Such a parsing engine on top of a more primitive programming language would necessarily be more complicated — the code above implicitly depends on garbage collection, dynamic dispatch, recursive subroutines, Python's lax encapsulation, and even operator overriding for its brevity.

But I don't think the penalty would be that bad. It does need recursive subroutines, and Alt and Neg in particular need to save a previous text position on the stack. Seq doesn't need to save a previous text position, but it does save the result from its left-hand side to include in its own result. Nonterminal only needs to remember its own name.

If you're building up some kind of parse tree, which is probably a good idea if only to fix the associativity problem introduced by PEGs' lack of left recursion, you need to allocate it somewhere — but typically a very simple allocation strategy is adequate for that.

And the dynamic dispatch here could be taken care of rather simply with a switch over the different types of node in the tree representing the grammar. Something like

```
switch(node->type) {
case LIT:
   return memcmp(tp, node->v1, node->v2) ? fail : advance(node->v2);
case SEQ:
   if (fail == parse(node->v1)) return fail;
   char *v1 = result;
   return (fail == parse(node->v2)) ? fail : succeed(sequence(v1, result));
case ALT:
   char *saved = tp;
   if (fail != parse(node->v1)) return succeed(result);
   restore(saved);
   return parse(node->v2);
case NEG:
   char *saved = tp;
   if (fail != parse(node->v1)) return fail;
   restore(saved);
   return succeed(NULL);
}
```

although I'm probably glossing over any number of important things there.

Generic programming with proofs, specification, refinement, and specialization

Kragen Javier Sitaker, 2017-05-10 (6 minutes)

Here's a specification for sorting:

A. sorted(x) is some permutation p of x such that ∀i∈[0, #p-1): ¬ $p_i > p_{i+1}$.

Given a way of enumerating the permutations of a finite sequence and some relation >, this specification A is executable: you can enumerate all the permutations of x, and if you find one that satisfies ∀i∈[0, #p-1): ¬ $p_i > p_{i+1}$, you return it.

You can consider this algorithm, or an implementation of it for a given machine, a refinement of specification A, specialized for a given permutation-enumeration algorithm, data type, and ordering relation. You can write a proof that this plan correctly implements specification A, which is to say, it's a refinement of it. It isn't a very efficient plan, since it takes superexponential time in the worst case; you can also write a proof of that.

There isn't a clean separation between programs, algorithms, plans, and specifications; you can continue refining and specializing that specification toward something executable on a particular machine. Let's call the brute-force sorting algorithm that you would thus derive specification B.

(Some specifications may be uncomputable; for example, if you specify that a program should be fun to use, or compute Chaitin's number omega for a flavor of Turing machine, you will not be able to execute those specifications, even inefficiently. Even if the specification says to find a real number for which some potentially computable property holds, that may be uncomputable if the number itself is uncomputable. But if the specification says to find a computable real number for which the property holds, if one exists, then you can satisfy that specification by enumerating all possible programs. Henceforth I will disregard such uncomputable specifications in this essay.)

Given the premise that your relation > (or rather its negation ≤) is at least a weak partial order, you can write a proof that such a sorted permutation exists. Also, you can write a proof that the original specification implies that ¬∃i: $p_0 > p_i$, and that all the subsequences of p are sorted versions of themselves, including in particular p[1:], if it exists.

Given these (plus a couple more things), you can also write a proof that the following specification is equivalent to, and thus a refinement of, specification A:

C. sorted(x) is some permutation p of x such that ¬∃i: $p_0 > p_i$
and, if x is nonempty, p[1:] = sorted(p[1:]).

With a naïve backtracking search, this leads fairly quickly to

selection sort, given a proof of the usual linear-time minimum-finding algorithm; this is already a much more efficient sort. And you can write a proof of that. Let's call this algorithm specification D.

(I've been writing `sorted(x)` as if it were a function, but of course it is a relation; it is a bit of an abuse of notation to say that `p[1:] = sorted(p[1:])`.)

There are several characteristics of what we are doing here:

• Specifications are written in a form that is entirely independent of the other relations and data they are defined in terms of. Specification A does not say that `>` is a weak partial order, or that `x` is a finite sequence, or what algorithm to use to enumerate permutations. Instead, somewhere else, we write a proof that, IF `>` is a weak partial order, THEN specification A describes a nonempty set of permutations, and also specification B is equivalent to specification A.

• Some specifications are refinements of others, in the sense that they logically imply the specifications they are refinements of. Some of these refinement relations are only valid given certain premises, which amount to specializations of a specification. Some of these refinements are derived automatically; others are written by hand and then proved to be refinements.
• Some specifications are sufficiently specific that we can prove efficiency properties about them, such as specifications B and D; others are not, such as specifications A and C.

We can take as an analogy the process a SQL database uses to evaluate queries. First we write a specification in SQL of the query we want to run; then the database derives a plan that it proves is a refinement of our query — in this case, the plan will produce a specific sequence of tuples that is one of the sequences of tuples that would be a correct response to our query. We can understand much of compilation in this fashion, as well.

Moreover, we can do generic programming in this way.

What I'm describing here is very different from the usual programming process. Normally, we write a given subroutine only once, and we mix premises about what kind of data it's operating on and which other operations it's invoking in with the code. The compiler might derive a refinement of it for a given machine, but we don't derive them ourselves, and the compiler doesn't provide us with a proof that the machine code is a sound refinement of our source code, nor does it prove efficiency properties of the machine code.

Topics

Printed circuits on fired-clay ceramic

Kragen Javier Sitaker, 2019-08-13 (11 minutes)

Suppose you want to fabricate a grid of wires, like for a capacitive touchscreen. In theory there are lots of ways you can do this: etching or electroless plating of printed circuit boards (especially including flex), weaving insulated wires (ideally multistranded) into a flexible cloth, slicing aluminized mylar into ribbons and then gluing the ribbons onto paper, drawing graphite lines on both sides of a sheet of paper, etc., but I wanted to focus on the case of glazed ceramic.

The basic touchpad design

Let's say you start by making a bisque ceramic plate with a bunch of narrow gold-leaf ribbons running in parallel across it. Then you can add an engobe or other glaze on top of those ribbons (except, perhaps, along one edge where you are going to attach electrodes), then another set of ribbons running across that, perpendicular to the first. With the proper choice of glaze, this new set of ribbons will be insulated from the first set by the glaze. If you then want them to be insulated from the world, you can do a second glaze firing of the plate with another, lower-melting glaze on top of the ribbons, again with the possible exception of one edge.

This procedure should give you a grid of capacitively-coupled wires whose coupling is dependent on you touching the plate. This is also potentially useful as a macroscopic ROM: if you add some conductive paint to the surface at some junctions, it can act to increase the capacitive coupling at those junctions, thus representing information. Under suitable circumstances, this reader might even be able to capacitively read heavy graphite marks on paper.

Concrete calculations

Consider the case where each layer of glaze is 100 μm thick and has a relative permittivity of 5 (that of glass — see Measuring the moisture content of coffee and other things with dielectric spectroscopy (p. 1033)), the ribbons are 1 mm wide and 5 mm apart, and you place a conductive circle of 11 mm in diameter over one of these junctions. The capacitance $\varepsilon A / d$ between the wires without the circle is $5\ \varepsilon_0\ 1\ \text{mm}^2 / 100\ \mu\text{m} = 0.44$ pF, a capacitance small enough to be hard to measure. (ε_0, the vacuum permittivity, is about 8.85 picofarads / meter.) The capacitance between the upper wire and the circle is $5\ \varepsilon_0\ 11\ \text{mm}^2 / 100\ \mu\text{m} \approx 4.9$ pF, and the capacitance between the lower wire and the circle is $5\ \varepsilon_0\ 11\ \text{mm}^2 / 200\ \mu\text{m} \approx 2.4$ pF. So the series capacitance between the two wires is 1.62 pF, about four times larger than the capacitance without the conductive thing.

Detecting an extra 1.2 pF in a circuit usually requires a relatively carefully built measurement circuit to keep stray capacitances from drifting, but it's entirely feasible. A thinner glaze or one with higher permittivity, or wider ribbons, would provide larger capacitances which would be even easier to measure; but wider ribbons would also reduce the relative difference in capacitance between the

finger-present and finger-absent states. A thicker glaze would probably necessitate either high-permittivity ingredients or wider ribbons.

At 10 MHz, which is a convenient frequency, 1.62 pF gives a capacitive reactance of $(2\pi fC)^{-1} = 9.8\ k\Omega$, while 0.44 pF gives 36 kΩ. These numbers are large compared to the expected resistance of the wires in the plate: according to Paper/foil relays (p. 3273), gold's resistivity is $2.44\times10^{-8}\ \Omega m$, so a 1 mm × 100 nm × 100 mm wire is 24.4 Ω. (See Spark particulate sieve (p. 2047) for information on metal thicknesses.) But they are small compared to the input impedance of any random op-amp.

Other conductors

Gold leaf has the advantages of being cheap and of not oxidizing, even when ceramic is being fired. (Most of the ceramic I've done was fired at 1020° (see file `ceramics-notes`) but porcelain can be fired at up to 1400°; some earthenware made from ferrous clay can be fired as low as 600°.) I have the impression that the usual pottery gilding technique is somewhat more complicated than merely gluing gold leaf to the greenware or bisqueware before a firing, but I'm not sure why.

Some oxides are also conductive; indium tin oxide is the one commonly used for transparent conductors in LCDs, but zinc oxide and some heavy metal titanates are also semiconductors. Yttria-stabilized zirconia is conductive at high enough temperatures, and was formerly used as an incandescent element in Nernst lamps, and silicon carbide, though not an oxide, oxidizes slowly enough to survive ceramic firing. Some of these might be practical to deposit on the surface as part of a glaze, but I suspect that others would dissolve in the common glazes.

If you're firing in a sufficiently reducing atmosphere, you may be able to use powdered copper or copper oxide to get copper traces rather than gold leaf; for uses like printed circuits, this could offer immensely higher conductivity. (Gold is very nearly as conductive as copper, but gold's cost advantage in this context would come from being able to use a very thin layer of it, which gives it substantial resistance.) Carbon and many different metals might work in a reducing atmosphere.

Applications other than touchpads and ROMs

Of course you can solder other components to the traces thus produced and make a more or less conventional printed-circuit board, though perhaps at somewhat higher cost.

The HP 9100 used a ROM design somewhat similar to the above, but using inductive coupling rather than capacitive coupling, and using a now-traditional multilayer printed-circuit board rather than layers of ceramic glaze. Such an inductive ROM could totally work, and inductive sensing could also be used to detect the proximity of ferromagnetic materials rather than conductive ones.

The traditional reason for applying gold leaf to thin sheets of vitrified silicon dioxide was for a burglar alarm: the gold leaf running around the outside of a glass window was part of a Wheatstone

bridge, and either breaking it along with the glass, or shorting it out to avoid breaking it, would change its resistance enough to trigger the alarm. So you could use such embedded conductors for detecting not only touch but also breakage.

The resistance calculated above for the gold-leaf traces is in a range that would be usable for resistance heating, although common pottery is somewhat fragile to thermal shock, so the heating would need to be fairly slow. (I suspect this can be improved in the body of the pottery by foaming, but I don't know how to improve it in the glaze.) The gold itself will withstand fairly high temperatures. Silicon carbide and zirconia are other promising materials for printed heaters.

An induction coil, for example for a pancake motor, can be printed on a ceramic surface in this way. If it's to be used for high-power applications like motors, cooking, or other bulk heating, rather than sensing, you probably want the lower resistances achievable more cheaply with copper.

Gold leaf's extreme thinness could conceivably be used to fabricate extremely fine circuit details, if you can pattern it finely enough. For example, you could imagine traces of 100 nm thickness, as above, but only 100 nm width rather than 1 mm, spaced 100 nm apart. This would provide 5 parallel conductors per micron, so a 10-mm-diameter circle could contain a spiral pancake coil of 50'000 turns, which would be a fairly sensitive detector of varying magnetic fields.

The (presumably) high resistance and high dielectric strength of the glaze could enable electrostatic-like fields, perhaps capable of moving macroscopic objects such as bits of aluminum foil. According to How would you maximize the energy density of a capacitor? (p. 42), fused quartz doesn't break down until 30 MV/m; if the glaze is 10 MV/m, you could safely use voltages of up to about 1000 V with the 100-μm glaze thickness I guessed at above.

By exposing spark gaps on the surface of the plate, not placing glaze over them, you could fabricate a kind of multiplexed matrix display. Probably you could only illuminate one spark gap at a time, and you'd probably need a few hundred volts to reliably get a spark going in air. Unlike conventional printed-circuit boards, glazed ceramic will not become conductive when you arc across it (there's nothing to char) and the gases produced by the spark will not attack it; however, the plasma will gradually vaporize it, and perhaps more importantly, vaporize the spark-gap contacts, especially if they are thin gold leaf. Also, the device produces nitrogen oxides and ozone.

Since arcing produces substantial UV, you could possibly get pixels of different colors by depositing different fluorescent colored dyes under different spark gaps.

Selectively generating arcs as you sweep paper across the ceramic could be used to selectively char the paper, thus printing on it, though not in an archival-safe manner.

Glow/corona discharge in air might permit longer life than arcing. Such spatially selective application of glow discharge in air could be useful not only for making visible images with light but also for selectively activating chemically-inert surfaces such as glass or polyethylene, or selectively initiating polymerization or ozone bleaching.

Glow discharge in a low-pressure inert-gas atmosphere, of course,

gives you a neon bulb. I think that's also how gas-plasma displays work.

Such exposed pairs of contacts are also, of course, how rubber-dome keyboards work, at lower voltages than those needed for spark gaps; these can usually be operated by touching them with fingers as well.

Air-quartz flash bulbs are the gold standard for short non-laser light pulses for high-speed photography; such a spark gap over (largely-quartz) fired clay amounts to something similar to an air-quartz flash bulb. Aside from the uses in stroboscopy, an array of such spark gaps firing in a raster sequence produces short flashes of light emanating from different points; by focusing these through a lens onto an object, they scan a spot of light across it in a fashion similar to a flying-spot TV camera, but without moving parts. The resulting waveform of reflected light detected at some point P produces an image of the scene as seen through the lens, as if illuminated from point P. (See Flying spot reilluminatable stage (p. 2358) for more thoughts on this.)

Topics

Improving LZ77 compression with a RET bytecode

Kragen Javier Sitaker, 2016-04-05 (updated 2016-04-06) (3 minutes)

LZ77 compression uses backreferences of the form (distanceback, length). You could think of this as a call to a subroutine consisting of a sequence of previously produced characters: the distanceback is like a PC-relative jump destination address. But the length is curious: it tells how long the subroutine is! In ordinary machine code, several different subroutines can share a common tail by having different entry points, each of which falls through into the next; but in LZ77-land, several different "subroutines" can share a common *head* as well, by being "called" from "callsites" with different lengths.

This means, for example, that the word "compression" in the first paragraph here can serve as a source both for the prefix "com" in the word "common" later in the paragraph, and for the word "compression" in this paragraph.

However, is it worth it? It imposes the cost of indicating the length on the "caller", which seems like it might be dumb. Consider if instead we had

```
'LZ77 '
X { Y { 'com' } 'pression' }
' uses ... nes can'
Z { ' share a '; call Y; 'mon' }
'tail by having...nes" can'
call Z
'\n*head* as well'
```

In this approach, there's still a count, but it's in the "callee" rather than the "caller", so the expense of storing it is amortized across callers. Here I've written it as a "}" terminator rather than a count. And you can see that we don't lose the ability to use common prefixes, but we don't save anything unless a particular backreference is used more than once.

But what is the tradeoff? It depends on how exactly we do the storage. If we actually use a "RET" terminator, then we can share tails for free, just as in machine code. But nesting isn't free: either we need a matching start marker, or we need to replace nesting with an explicit call. X above can't be represented just as 'com' RET 'pression' RET; otherwise when you called it, it would return too soon!

• It could be represented as { { 'com' } 'pression' }, which gives you suffixes like "om" and "ession" for free, though not "ompression", at the cost of needing both begin and end markers.
• Or X could be represented as Y 'pression' RET, with Y defined earlier outside of the main flow, but the extra invocation of Y is probably larger than the begin marker.
• Or, instead of using a terminator, we could just put the count into the begin marker: "9:3:compression", counting the initial 3-letter string as a single element of a 9-element sequence. This loses the

ability to share tails for free.

With any of these three possibilities, you also now have the possibility of representing the distanceback with an index into a list of defined subroutines, rather than a number of bytes back. This should save a number of bits from the distanceback, effectively enabling much larger windows.

This is a relatively obvious tweak to LZ77, so it's probably been tried before.

Topics

The Bleep ultrasonic modem for local data communication

Kragen Javier Sitaker, 2018-12-10 (updated 2018-12-11) (8 minutes)

Suppose you want to transmit data a short distance between cellphones and Cortex-M0 devices like the STM32F0 family over ultrasound. What's the simplest thing that could possibly work?

You can probably generate and even analyze audio on the cellphone in a webpage, using the Web Audio API. This suggests that maybe you want to see if you can press biquad filters into service.

Probably FSK for the encoding, and probably the sweet spot for audibility by humans but not cellphones is around 18kHz. And the further apart you have your frequencies, the faster your tone-detection filters can work. If they're at 17.5kHz and 18.5kHz, for example, your Q could be only about 18 and still separate them by 3dB. A 17.5kHz square wave will be just a sine wave after it gets through a standard audio speaker — its second harmonic is amplitude 0, and its third harmonic is 52.5kHz, which is not going to get reproduced by the speaker.

A Q of 18 means you get about 1kbps, which is adequate for some applications. (?! where does this number come from)

You probably want some kind of hefty error-detection code so that you don't turn random noise into garbage data.

I was thinking that the Goertzel algorithm is the standard algorithm for tone detection, but if your microphone isn't picking up substantial harmonics, it's probably fairly harmless to just chop the signal with a square wave or modified square wave, and chopping with two square waves in quadrature should give you I and Q signals. However, 17.5kHz and 18.5kHz are 2.52 and 2.38 samples per cycle, respectively, at 44.1ksps, so quadrature chopping would be somewhat tricky! You'd have to resample to a higher sample rate first. You can definitely use Goertzel though.

You probably want to window the signals both on output and on input, both to avoid spectral leakage down to the audible spectrum and to improve discrimination between them. Empirically, a first-order moving average is not good enough here, unless it's sized specifically for the beat frequency.

I think a negative-weight feedforward comb filter on input, plus a bit more frequency margin, might help with frequency discrimination. Setting the 1/0 threshold requires some amount of adaptation, empirically, which suggests that a constant-weight code would be helpful; Manchester encoding is the simplest, though it discards half the bandwidth.

I'm thinking maybe 17500 Hz and 18970 Hz, which differ by 1470 Hz, which is a period of 30 samples. Halfway through that period, they're ½τ out of phase, and ¼ or ¾ of the way through (7.5 and 22.5 samples), they're 90° out of phase, so when one is at its maximum, the other is at its zero. So, for example, if $y(n) = x(n-7) - x(n)$, the 17500Hz signal is attenuated by a factor of 0.985 (-0.13 dB, hardly at all), while the 18970Hz signal is attenuated by -0.070 (-23 dB).

Perhaps better, if y(n) = x(n) - x(n-5), the 17500Hz signal is attenuated by -0.100 (-20dB) and the 18970Hz signal is attenuated by 0.812 (-1.8dB). Similarly, if y(n) = x(n-34) - x(n), the 17500Hz signal is attenuated by -0.050 (-26dB) and the 18970Hz signal is attenuated by 0.709 (-3dB).

So we could maybe filter each signal with a four-stage cascade. For 17500Hz:

```
y(n) = x(n-7) - x(n)
a(n) = y(n) * cis(17500 τ n/fs)
b(n) = a(n) + b(n-1)
c(n) = b(n) - b(n-30)
```

For 18970Hz:

```
y(n) = x(n-5) - x(n)
a(n) = y(n) * cis(18970 τ n/fs)
b(n) = a(n) + b(n-1)
c(n) = b(n) - b(n-30)
```

And in practice a(n) and b(n) could be combined into a single Goertzel stage, and the final c(n) stage can be decimated.

The initial comb-filtering stage, in addition to attenuating the opposing signal relatively by 23dB, also works as a single-pole high-pass filter. The 7-sample window has its lowest resonance at 3150 Hz and other resonance peaks at 9450 Hz, 15750 Hz (the one whose sidelobe we're using (?)), and 22050 Hz.

XXX Oh wait this is totally wrong. I was calculating those attenuations based on the value of $|\sin(\omega t)|$ at those points, but actually the attenuation we want is $|\cos(\omega t) - \cos(0)|$.

Thinking about how to *emit* the levels inexpensively, it occurred that Don Lancaster's Magic Sinewave approach might work well if the baud time is a common multiple of the carrier periods (i.e. a multiple of 30 samples at 44100 Hz), which is to say that the baud rate should be a factor of 1470 Hz. 490 baud and 735 baud (90 and 60 cycles respectively at 44100 Hz) suggest themselves. The idea is sort of like wavetable diphone synthesis: you divide time into 30-sample grains (≈0.68 ms) and during each grain time you play an appropriate precomputed grain according to the current bit, the following bit, and your position within the bit. So in the 735-baud case, for example, you have two frame positions and four situations (00, 01, 10, 11), so 8 precomputed grains. For machines with an audio DAC, in 16 bits at 44100 Hz, each of these are 30 samples and 60 bytes, so the total wavetable is 480 bytes. The 490-baud case would need 12 precomputed grains.

(This is assuming that we're using a window with support of less than two transition intervals.)

Machines without an audio DAC probably need to compensate by using a higher sample rate; this will be limited by their CPU load, CPU speed, and memory. Supposing they can afford 4 KiB of program memory to store the wavetables, that's 16384 samples, or 2048 samples per grain, which works out to 3.01 megahertz, which is a low enough speed that you don't need fancy signal integrity stuff, and maybe it's within reach of even things like AVRs (which would

probably need an external ADC to receive signals, anyway). This gives you about 68 bits per 44100sps sample; $\sqrt{68} \approx 8$, so I think you'll have a signal-to- quantization-noise amplitude of about 8, or 18.3 dB. That's not a wonderful noise budget but it's probably adequate. Possibly we can dither that noise up to very high frequencies where it won't even get digitized on the receiving end.

You might be able to win a bit more by just repeating the same grain during the transition for the 00 and 11 cases, taking advantage of the fact that those grains themselves are time-reversal invariant, and time-reversing the 10 and 01 cases.

XXX wait, 17500 isn't divisible by 1470.

I did try the comb filter thing. I'd forgotten that feedforward combs have sharp nulls and very broad peaks. It helps a lot.

Better: 17640 Hz and 19110 Hz. Those *are* divisible by 1470.

Thanks to Nick Johnson, Ezequiel Alfie, Alastair Porter, Florian Pignol, Arthur Sittler, Kia, Colby Kraybill, Eugene Jercinovic, Andrea Shepard, John Bognar, and Rick Bartells for all the things I've learned from them that enabled me to get this to work. I haven't even mentioned it to most of them, so don't blame them if it's bogus.

Generalizing my RPN calculator to support refactoring

Kragen Javier Sitaker, 2016-10-17 (12 minutes)

My regular netbook isn't working because I left the charger at work. I've managed to get this old Thinkpad to boot, though installing Ubuntu seems to be not working (this ten-year-old CD-R is probably corrupt, judging from the kernel log messages), and I can't remember the disk encryption password I set on this machine probably nine years ago, which leads me to think about how much hassle is involved in even the most basic computing tasks.

If only I had an easily bootable operating system I could fire up from this pendrive in a matter of seconds! If only I could add notes to it from anywhere anonymously, later accepting them!

I feel like my RPN calculator app may be a step in the right direction. In it, keys 0–9 add to the number at the current position in the RPN program (space works as a separator between adjacent numbers), and the program is executed after each edit to build up a stack of expressions that are then executed. Operator keys are used to combine expressions into larger expressions. The operator "," concatenates numbers into a vector, with the usual kind of APL broadcasting operations. The "l" and "e" operators are ln and exp, respectively, enabling relatively easy powers and roots. The "i" operator is the APL iota, but zero-based, allowing the instant construction of sequences covering some range.

Vectors are automatically plotted, as well as being displayed numerically. A somewhat generous estimated calculated precision is maintained for each number, and its display is limited to that precision, in order to improve the signal-to-noise ratio of the display.

Alt-left and alt-right (or, for phones, $ and &) perform structural editing of the RPN program, moving an entire subexpression left or right over other instructions. Left and right (or the parentheses) navigate the RPN program, showing you the intermediate value calculated at each node.

At present it lacks even the minimal abstraction ability to use the same value twice. For example, to compute the first six triangular numbers, you can use the sequence `6i6i1+*2/`, resulting in the expression `i 6 * (i 6 + 1) / 2`. But to change this to the first 10 numbers, for example, you must go back and edit both of the sixes.

It also lacks any kind of aggregate calculation, even summing or array indexing, any kind of mouse interaction, and decimal points.

Abstraction

I'm increasingly coming to the conclusion that stacks are good for expression evaluation, but too confusing when you try to use them for general-purpose data storage; the position of any given value relative to the top of the stack is constantly changing. So probably to reuse values, it's better to use registers, i.e. variables, rather than providing stack manipulation operators, at least in the context of interactive calculations.

However, a set of interactions has occurred to me that seem like

they should make abstraction by refactoring quite simple:

• # to fetch a value recently computed, repeated to refer to less recent such values; in effect this is the "introduce local variable" refactoring, but with a user interface based on the Mill CPU's belt, and no need to specify ahead of time which values will be reused. However, once you are done wrapping a computation in a definition in this way, later # operations will skip over its internal structure.
• : when within such a definition to turn the subexpression you're currently looking at into a parameter, pushing that subexpression out into every place where it's invoked, turning it into a function. If you do this with the entire contents of the definition, you have reversed the refactoring, and the subexpression evaporates.

So, for example, in the case above about the triangular numbers, after having typed "6i", you could type "#", which would put the "i 6" into a subexpression, used twice. Maybe this would be displayed like this:

```
x = i 6 = 0, 1, 2, 3, 4, 5
x = 0, 1, 2, 3, 4, 5
x = 0, 1, 2, 3, 4, 5
```

Then, on typing "1+*2/", you would see something like this:

```
x = i 6 = 0, 1, 2, 3, 4, 5
x * (x + 1) / 2 = 0, 1, 3, 6, 10
```

If you move the pointer back to the 6 and type ":", you are pushing the 6 up to the level where x is invoked, making x a function; the result would be something like this:

```
x(y) = i y
x(6) * (x(6) + 1) / 2 = 0, 1, 3, 6, 10
```

At this point, the two 6es have become independent (although that may not have been the right default). To make them dependent again, you can put the cursor on the second one and type ## to fetch the first 6, then move right and delete the second one. The result would be something like this:

```
x(y) = i y
z = 6
x(z) * (x(z) + 1) / 2 = 0, 1, 3, 6, 10
```

If you go to the end and "#" it to turn the triangular-numbers calculation into a local subexpression, you get something like this:

```
x(y) = i y
z = 6
a = x(z) * (x(z) + 1) / 2 = 0, 1, 3, 6, 10
a = 0, 1, 3, 6, 10
a = 0, 1, 3, 6, 10
```

Now it may be desirable to make z a parameter of a. If you put the cursor on the first reference to z and use ":", you get this:

```
x(y) = i y
z = 6
a(b) = x(b) * (x(z) + 1) / 2
a(z) = 0, 1, 3, 6, 10
a(z) = 0, 1, 3, 6, 10
```

Then you can move over to the second z and use "##" to turn it into another reference to b, then delete the z:

```
x(y) = i y
z = 6
a(b) = x(b) * (x(b) + 1) / 2
a(z) = 0, 1, 3, 6, 10
a(z) = 0, 1, 3, 6, 10
```

If you now move the cursor onto the 6 in z and use ":", that will push it out into the invocations of z. That leaves z with nothing left to do, so it evaporates:

```
x(y) = i y
a(b) = x(b) * (x(b) + 1) / 2
a(6) = 0, 1, 3, 6, 10
a(6) = 0, 1, 3, 6, 10
```

(I'd also like to be able to manipulate programs the way rpn-calc manipulates algebraic expressions, building them up step by step with example values.)

During the course of these edits, there are times when a function will compute multiple values. For example, consider this definition:

```
a(b) = x(b) * (x(z) + 1) / 2
```

The RPN program is something like this:

```
local b  b x  z x  1 +  *  2 /
```

Upon introducing the second reference to b, but before deleting the z reference, it looks like this:

```
local b  b x  b z x  1 +  *  2 /
```

That works out to these expressions:

```
x(b)
b * (x(z) + 1) / 2
```

The question then is whether a, at that point, should be considered to be returning two values or merely computing x(b) and discarding the result.

Vectorization

To a great extent, not just loops but also nested functions can be eliminated entirely by sufficient vectorization, so to some extent this is an alternative to the previous item. Vectorization is less flexible but also more comprehensible.

The basic idea is that variables have values that depend on circumstances, and you can represent pretty much any variable as a scalar variable that depends on circumstances. For example, you could think of the altitude of land as a number, but one that depends on the latitude and longitude, and maybe time if you are modeling that. The textual content of an editor buffer is a character-valued variable that depends on the position within the buffer. The country of land is a categorical measurement which also depends on latitude and longitude. It is a sensible question what is the maximum altitude for each country, ranging across all the latitude/longitude pairs within that country.

You could reasonably display such vectors in tables, with one table for each set of circumstances that a vector's values depend on. Vectors depending on the same set of circumstances would be displayed in the same table. The traditional way to lay out such tables is with one attribute per column and one row per instance, but the reverse is probably better in this case, with one row per formula and one column per instance. As you calculated, rows would appear and disappear, with the formula displayed on their left followed by a sparkline.

It's not totally clear to me how to mix the display of the stack results with table-style display. Multiple hierarchical levels of circumstances are a reasonable thing to have; you could imagine using colspan cells within the same table to display values that depended on less than the whole set of circumstances, in particular including the empty set of circumstances: a scalar or constant.

The objective is to be able to add new circumstances later, as in the example above in which the altitude comes to depend on time as well as latitude and longitude; you could also imagine it depending on the reference spheroid (WGS 84?) and the data source being consulted. This suggests that aggregation operations (such as, for example, max) should specify a list of circumstances to range over all possible values of (and thus eliminate from the dependency list), rather than a list of circumstances to retain in the dependency list.

Constraints

Often the calculations I'm doing are in terms of the interrelated values of some mathematical model. The simplest interesting example is perhaps a sphere, which has a radius, a diameter, a cross-sectional area, a surface area, and a volume, any one of which determines all of the others. More complex models may involve conditionals, piecewise approximations from empirical data, and more parameters --- a cylinder, for example, has a volume, a radius, and a length, any two of which determine the third, as well as other properties, of course. It is desirable to express those relationships once for a given model and then derive an effective calculation procedure from that expression.

Units

It's very common for me to do calculations including measurement dimensions, and I wish my calculators were better at this. I often use units(1) to do the calculations, but it has some shortcomings:

- There's no way to define variables or functions or vectorize

calculations;
• Its output display defaults to expressing things in terms of fundamental units, which is often fairly confusing --- joules or volts, let alone farads, are difficult to recognize in that format;
• Often the input interpretation is surprising, and you may not notice an unexpected interpretation.

Electroluminescent matrix

Kragen Javier Sitaker, 2016-07-27 (2 minutes)

The first gas plasma screens for Plato used two grids of parallel wires which created plasma at their intersections; you could do the same with an electroluminescent material like ZnS:Cu or, maybe, $SrAl_2O_4$ (LumiNova).

For example, on a hard, flat insulating substrate such as glass, you could lay down a bunch of horizontal 100µm-diameter copper wires at a spacing of 250µm; on top of that, you deposit a 200µm-thick layer of small ZnS:Cu crystals, maybe dispersed in a binder ("electroluminescent paint"); and on top of that, you lay down another bunch of 100µm-diameter copper wires with a spacing of 250µm, this time vertical.

For example, *980 pixels horizontally (720 vertical wires) at this resolution would be 183 mm, and 6615* pixels vertically (990 horizontal wires) would be 251 mm. So you could get a very readable full-page monochrome display with 712800 pixels by controlling only 1710 wires, an average of 417 pixels per wire.

If you ground one of the horizontal wires, leave the others floating, and put an high-frequency AC voltage on some, but not all, of the vertical wires, you should get glowing spots where those vertical wires cross the wire you have grounded. The intensity of each spot should be jointly proportional to the voltage and the frequency. By switching from one horizontal wire to the next, you can draw an arbitrary pattern of pixels.

Potential advantages of this approach include very low cost, inexpensive fabrication technology, low power consumption, and very low duty cycle — ZnS:Cu, as used on analog oscilloscope screens, has a time constant of around nine minutes (???), while $SrAl_2O_4$ has a time constant of about 15 minutes. This would allow you to use a refresh time of several seconds or even minutes to hours rather than tens of milliseconds.

(I've been thinking for a while that if you have a laser you can rapidly deflect with mirrors, you could use that to paint an image on a glow-in-the-dark screen, thus avoiding the need for the vacuum and X-ray shielding of a CRT, and also the hundreds or thousands of wires used by this design.)

Memory safe virtual machines

Kragen Javier Sitaker, 2019-12-04 (14 minutes)

Pointer arithmetic gives your languages freedom to implement different kinds of storage, including stack-allocated, heap-allocated, structs, arrays, struct extension with new fields on the end, linked lists, and whatnot. But it poses difficulties for safety.

The Forth virtual machine is fairly simple; as described in Notes on reading eForth (p. 1398), Bill Muench's eForth model, about 176 machine-code instructions for the 8086, consists of EXIT, EXECUTE, _LIT, _ELSE, _IF, C!, C@, !, @, RP@, RP!, >R, R@, R>, SP@, SP!, DROP, SWAP, DUP, OVER, CHAR-, CHAR+, CHARS, CELL-, CELL+, CELLS, 0<, AND, OR, XOR, UM+, REDIRECT, !IO, ?RX, TX!, and BYE, plus the machine-code routines RESET, LIST1, and VCOLD. Of these, the ones that access linear memory are just C!, C@, !, and @, about 10% of the total. Everything that accesses memory does so by way of these four primitives.

However, when developing software and sometimes even when running it, it's very convenient to get crashes and exceptions rather than wrong answers, ideally as close to the bug as possible. Using such a simple memory model sacrifices that possibility, since there's no way to distinguish out-of-array-bounds accesses, or integers wrongly interpreted as pointers, from valid pointers. Moreover, this makes garbage collection impossible. Can we define a virtual machine that is *almost* as simple and flexible, but provides better safety properties?

The rest of the Forth model

We can categorize the eForth code into control flow --- EXIT (i.e., return), EXECUTE, _IF, _ELSE, and LIST1; stack manipulation --- >R, R@, R>, DROP, SWAP, DUP, OVER; meta-stack manipulation --- RP@, RP!, SP@, and SP!; I/O operations --- REDIRECT, !IO, ?RX, TX!; startup and shutdown --- RESET, VCOLD, and BYE; ALU operations --- _LIT, 0<, AND, OR, XOR, and UM+; and portability helpers --- CHAR-, CHAR+, CHARS, CELL-, CELL+, and CELLS. This is a good approximation of a minimal usable virtual machine, although probably subtraction, multiplication, and division would be welcome additions.

My StoneKnifeForth, inspired by eForth, has a different set of primitives, some of which are things eForth implements in interpreted Forth rather than in machine code, such as comments. SKF is about 1400 instructions. Its memory operations are @, !, and store, which last is C!.

The C pointer approach

Suppose we define an untyped virtual machine whose memory supports the four operations fetch word, store word, fetch byte, and store byte, with register arguments to indicate the memory location to access, and an allocate operation to allocate N bytes of new memory. How can we implement it efficiently with some degree of memory safety?

Maybe we can codify more or less the C pointer rules: make pointers be (segment, offset) pairs, say 32 bits for each; mere integers have a distinguished invalid segment value for the segment part, such as 0. Subtraction of two pointers produces an integer if the segments are the same or crashes your program if not. Addition or subtraction of a mere integer to a pointer produces another pointer within the same segment. Pointer comparisons for equality compare both the segment and the offset. Pointer comparisons for ordering crash if the segment differs. No other pointer arithmetic is valid. The virtual machine checks dereferences against an upper bound it stores for the segment.

The allocate operation creates a new segment and returns a pointer to its start.

None of this stops programs from storing pointers in memory with the store-word operation and then altering their segment bits; for example, the XOR one-pointer double-linked-list hack can be implemented in this way. That means that garbage collection is not safe.

This approach allows, for example, moving a struct that mixes pointers and non-pointers to a different part of memory, in the same or a different segment, merely using memcpy. Note, though, that the situation where this is most advantageous --- persistence to files or transmission across a network --- can't take advantage of this, because the segment bits will not be valid in the other process, whether separated by space or by time.

The KeyKOS approach

Suppose we want to be sure that a subroutine we invoke cannot forge pointers to random memory, but only access data it has been given segments for. To prevent pointer forgery, we must strictly segregate segment identifiers from character data and, for example, ordinary integers. It is okay for offsets into a segment to be freely intermixed with character data, though.

One way to do this is to have separate byte segments ("segments" in KeyKOS) and descriptor segments ("nodes" in KeyKOS). Descriptor segments contain only descriptors; byte segments contain only bytes. The virtual CPU contains both descriptor registers and integer registers. Memory access instructions take an address consisting of a descriptor and an integer offset; there are six of them --- load descriptor, store descriptor, load integer, store integer, load byte, and store byte. Descriptors can only be loaded from and stored to descriptor segments, while integers and bytes can only be loaded from and stored to byte segments. The only operation on descriptors, other than storing them or using them in a memory access, is comparison for equality.

There are a few variants of this approach. Rather than having separate segments, you could have a "data fork" (of bytes) and a "resource fork" (of descriptors) for each segment; this avoids the dynamic check, but means that instead of having separate `allocate_byte_segment` and `allocate_descriptor_segment` calls, you'd have one call that takes two arguments. This way, a data structure that contains both pointers (to, potentially, other segments) and byte data can be a single segment, rather than a descriptor segment that points to a byte segment.

Or the virtual machine could maintain a bit for each byte in the segment, indicating whether it currently contains descriptor bytes or non-descriptor bytes; loading it with the wrong operation would crash your program. Alternatively, only attempting to load a descriptor register from non-descriptor bytes would crash the program, while loading descriptor bytes into a data register would be fine.

This approach is not very compatible with the C or Forth view of the world, and like varying-sized inline objects, it leads to a certain amount of duplication in machine code --- you can't write generic virtual machine code that agnostically handles either pointers or byte data without caring which, even if you pass in a size, as you do with qsort(). But it does seem like it would be workable, and it permits garbage collection and prevents pointer forgery.

The Unix approach

Suppose that a "process" identifies descriptors with integers, like Unix programs identify files, when it makes "system calls"; we could call them "handles". It can never see the contents of the descriptors themselves, just the integers that refer to them in its own local namespace. (KeyKOS did this in practice too, but the integers were in a limited range, I think 0 to 15.) If a different process has access to the same descriptor, it is probably referred to using a different handle.

For accessing byte data, rather than using effectively pread(2) and pwrite(2) as in the proposals above, we can have an mmap(2) instruction which maps the descriptor's byte data into the process's linear memory space. But what about accessing descriptor data, as in `SCM_RIGHTS`, so that one descriptor can point to another? Well, I suppose you want an instruction something like openat(2), but taking an offset rather than a filename.

So this gives us something like the following interface:

• call(code1, handle1): starts a "new process" running code1 and waits for it to terminate. Code1 runs in a new linear memory space with access only to the resource identified by handle1; a handle to that resource is passed to code1 at startup.
• ret(): terminates the current "process".
• open(handle1, offset): returns a newly allocated handle to the offsetth descriptor in the directory identified by handle1.
• new(nbytes): returns a handle to a newly allocated segment of size nbytes.
• del(handle1): deallocates the resource identified by handle1, which may be a segment or a directory.
• mkdir(n): allocates a new directory with space for n descriptors in it.

• link(handle1, offset, handle2): sets the offsetth descriptor in the directory identified by handle1 to the descriptor identified by handle2.

• map(handle1): maps the segment identified by handle1 into the caller's linear memory space and returns the address where this happened.

Maybe not quite as clean as Unix's open, close, read, write, fork, exec, exit, wait, or Forth's C!, C@, !, and @, but it's manageable; and, unlike Unix, it provides full confinement. And it doesn't have a

way to prevent child processes from leaking memory; I thought about adding a "pool" parameter to "new" and "mkdir" and a "spawn" call that creates a child pool, and making "free" take a (handle to a) pool rather than a segment; this would allow limiting the resources used by child processes as well. But it does permit precise garbage collection, so in some sense pools are extraneous.

Of course, unlike in Unix, these operations are virtual machine instructions rather than system calls.

KeyKOS had an operation to weaken a regular key to a "sense key", a read-only capability, so that you could provide read-only access to a resource you had read-write access to.

This interface doesn't permit multithreading, since call() is synchronous, and so it can't be robust in this form against child processes that hang forever. KeyKOS handled this in part by requiring a "clock key" to run a process; if the referenced clock didn't have any time on it, the process couldn't run. The Unix approach is, rather alarmingly, to make subprocess invocation implicitly asynchronous, thus requiring the creation of a new task.

A transactional linear-logic approach

If you add any concurrency or crash recovery to the approach described above, there is a new class of serious potential bugs that the virtual machine cannot detect and signal. If a segment can be concurrently mapped by two different threads and is writable by at least one of them, they can have race conditions. If we were to take the Unix approach and make call() asynchronous, this would implicitly happen on every call(), since the parent process still has access to everything it's passed to the child.

If instead we *transfer ownership* of resources to the newly created child process, so that the parent cannot access them until and unless the child returns them, we can avoid this problem. But this means that, if recovery from failure is to be possible, the child must return them in case of failure and also in case of success.

Handling failures this way suggests that perhaps the child should be run in a separate transaction, with all of its writes held in abeyance until its successful completion. Handling successes this way suggests that perhaps freeing a resource should only be possible to someone who holds a descriptor to the pool the resource was allocated from. But, by itself, that will not prevent the child from linking its resources into a cycle that is inaccessible from outside. Something like the tree discipline of the Unix filesystem is needed to prevent that. See Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) section "Pointer-reversal tree traversal" about why I think approaches like this will tend to be insufficient.

A Rustier approach

If the same segment is mapped more than once by the same process, and one or more of the mappings is read-write, it may suffer aliasing bugs. The classic example of this is the trick for swapping two values without a temporary variable:

```
a ^= b;  // a == a0 ^ b0
b ^= a;  // b == a0 ^ b0 ^ b0 == a0
a ^= b;  // a == a0 ^ b0 ^ a0 == b0
```

which you would want to be a no-op if a and b were the same value, but which instead obliterates the value and replaces it with a 0.

Rust avoids this problem by "borrowing" references for a statically determined lifetime; although my Rust is pretty limited so far, if I understand correctly, the creation of mutable references and of read-only references is a prerequisite to accessing an object, no mutable reference to it can be created during the lifetime of any reference to it, and no reference to it can be created during the lifetime of any mutable reference to it.

You could imagine segments being treated in this way, dynamically rather than statically. To map a descriptor read/write into your memory space or to pass a mutable reference to it to another process or store it in a directory, there would need to exist no references or mappings to it anywhere; to map it read-only or to pass a read-only reference to it to another process or store it in a directory, there would need to exist no read/write mappings or mutable references to it anywhere.

I'm not sure if that approach is feasible, but it seems promising.

Why Thunderbird is inadequate for opening a 7-gigabyte mbox

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

I opened my mailbox in Thunderbird.

• importing the mailbox is a pain
• had to create a dummy account first
• takes a number of minutes to open the mailbox
• uses 800–950MB of VM and 400+MB of RPRVT memory to open the mailbox
• sorts by default by date message claims to be sent, although there seem to be anomalies; this clusters spam
• uses 7–9 minutes of CPU to render a threaded view, during which time the UI is unresponsive; when you sort by something else and re-enable the threaded view, it takes another 7–9 minutes
• is there a way to hide the junk messages?
• I marked a bunch of messages as spam and a bunch of other messages as read in order to train the junk filter. Then I (actually Beatrice) selected all messages with interesting-feature-A (which took less than a minute of CPU time, during which the UI was unresponsive) and selected "Run Junk Mail Controls on Folder" from the Tools menu. This marked a number of the messages I'd marked as read, but not as spam, as spam. There is no obvious way to distinguish the messages that I have marked as spam and the messages Thunderbird has marked as spam.
• on the plus side, Thunderbird doesn't seem to want to store its updates to message status flags as Status: headers in the messages.
• on the minus side, it seems to be storing that information in a 176MB Mork file, which could make it hard to get it into anything else.
• Despite the fact that Thunderbird isn't storing which-message-is-read information in Status: headers, it seems to believe Status: headers added by spammers.
• Thunderbird thinks I have about 500 000 messages in this mailbox. But I actually have about 800 000.
• Scrollbars are not useful on a 500 000-item list.

You can't construct optical systems with arbitrary light transfers, but you can do some awesome shit

Kragen Javier Sitaker, 2018-09-10 (11 minutes)

An optical system reversibly transforms a light input to a light output. In the geometrical-optics approximation, the light input (or output) is a function from $\mathbb{R}^4$ (four-tuples of real numbers) to spectra. If we reduce the spectra down to RGB, which is reasonable for some purposes, this is a function $\mathbb{R}^4 \to \mathbb{R}^3$; if we reduce it down to monochrome, which is reasonable for other purposes, it's a function $\mathbb{R}^4 \to \mathbb{R}$. We could think of this as a four-dimensional scalar field. One view of the four dimensions is that they are the X and Y coordinates where light enters (or exits) the system boundary and the θ and φ angles at which it enters. That is, the system can do different things with light that enters at the same angle at different points, or with different angles at the same point.

So, in monochrome, the overall system behavior is a function $(\mathbb{R}^4 \to \mathbb{R}) \to (\mathbb{R}^4 \to \mathbb{R})$. But this is still an extremely loose description, because there are many such functions that we cannot realize as an optical system, and there are others that we can realize only with great difficulty.

(In wave mechanics, the input and output are very much simpler; at a given wavelength, each point on the boundary of the system only has a single complex phase and amplitude. This fact allows holographic optics to achieve astonishing performance for single-wavelength systems. Unfortunately the situation with multiple wavelengths becomes complicated again, while geometric optics either depends not at all on wavelength or only depends on wavelength in a very simple way, with color filters and whatnot. So here I will focus on geometric optics.)

Conservation of energy

For reasons of convenience, I'm going to focus on optical systems that don't dissipate energy, so the amount of light coming out is the same as the amount of light going in. This seems like kind of a stupid focus, since all actual systems do absorb some light, often most of it. Then they convert that light into heat. But it turns out that, if we treat this as a sort of aberration, we can derive some very interesting properties of optical systems that don't have it, and then we can figure out how real systems behave by adding in light absorption as a sort of correction.

Reversibility

Another limitation, given conservation of energy, is that optical systems must be *reversible*. That is, if a certain beam of light going into the system produces a certain distribution of light coming back out of the system, if we send this second distribution of light back in,

it will come out as the first beam of light, just going the other way. This seems not to be true in our day-to-day experience, and this requires some examination. For example, a laser pointer shining on white paint produces a spot that can be seen from any direction, so we know it's throwing off light in every direction, in a way that's called Lambertian reflection, and yet light going into the spot from every direction doesn't go back into the laser pointer. We explain this by saying that the paint is full of many different microscopic facets, each of which throws off light in a particular direction when the laser hits it, and there are so many of them even in that little spot that the light seems to go in every direction at once! And if we could shoot a very, very thin beam of light at each facet, in just the reverse of the direction that the laser was making it shine before, all of those beams would be redirected perfectly back to where the laser pointer had been.

Now, in reality, these facets are often so tiny that the geometrical optics approximation breaks down, and we have to use wave mechanics to see what will happen. But it turns out that wave mechanics is reversible too; reversibility is not just a consequence of the geometrical-optics approximation, but a property of the wave-mechanical nature of light that survives in the geometrical-optics approximation.

But if our system consists entirely of macroscopic features — mirror-smooth surfaces that are perhaps curved or have edges, everything either polished metallic mirror-bright or transparent — then, indeed, any transformation that the system produces can in fact be time-reversed in this way. And you can do it in practice, not just in theory, because you don't need microscopically tiny slivers of light the way you do for the white paint.

This imposes some restrictions on the mathematical form of our system. It can't, for example, transform two different distributions of incoming light into the same distribution of outgoing light, because then if you time-reversed the outgoing light, it wouldn't know which of these two different distributions it should produce. The function must be bijective, invertible.

But is that the only restriction? Can we realize any arbitrary invertible $(\mathbb{R}^4 \to \mathbb{R}) \to (\mathbb{R}^4 \to \mathbb{R})$ function as an optical system? No, not even close.

One of the strongest restrictions is linearity.

Linearity

Most optical systems are linear, in the sense that different beams of light don't interact with each other. If you have some beam A and the system transforms it to f(A), and some other beam B and the system transforms it to f(B), then if you shoot both of those beams of light at the system at once, A + B, then the distribution of light that comes out will be exactly f(A) + f(B). You can have a lens, for example, bend one light beam a bit to the left, and the other a bit to the right, but you can't have it bend the first light beam to the right when the second one is present, or to the left otherwise.

Now, this is just an approximation, but under most circumstances, it's a very, very good approximation, and it takes very sensitive instruments to detect departures from linearity. It's actually a much better approximation than geometrical optics is, because you can see

the diffraction phenomena produced by wave mechanics very easily in everyday life, if you know where to look; they're quite strong whenever you have objects on the scale of a few microns involved, such as your eyelashes. They're rarely more than one or two orders of magnitude away from visibility. Departures from linearity, by contrast, are usually six or more orders of magnitude away from visibility. So nonlinear optical systems are substantially more difficult to build.

There are a few that are common, though. Fluorescence is usually pretty linear, but it often has a substantial time constant, which means that it departs from instantaneous linearity. Optically-pumped lasers, however, are a sort of nonlinear fluorescence phenomenon: you don't get a laser beam at all until the gain of the lasing medium rises past 1, as limited by the Q of your cavity. And the most common kind of green laser isn't a green laser at all; it's an infrared laser with a frequency-doubling crystal on the front of it, and that's a nonlinear phenomenon — it doesn't start happening until the light intensity is above a certain level.

Other nonlinear optical phenomena include phase-conjugating mirrors, Kerr cells, the self-focusing of intense laser beams, and soliton transmission, which is a sort of temporal analogue of spatial self-focusing. Any dielectric inevitably behaves nonlinearly to light passing through it, since its overunity refractive index is due to its response to the electric field of light being different from the response of the vacuum, and that's an effect that inevitably reaches a limit at some field strength. Normally, though, light's electric field is far too weak for us to notice this nonlinearity.

But, in the geometrical optics approximation, we invariably ignore these nonlinearities, because they are tiny in everyday life. So our transfer function is, in effect, transferring every separate light beam that could enter our apparatus into some distribution of light at the output. So our transformation function can be computed from a sort of point spread function of the form $\mathbb{R}^4 \to (\mathbb{R}^4 \to \mathbb{R})$.

However, the requirement that the function be *reversible* means that as the input light beam shrinks toward a perfectly collimated beam entering at a single point†, the output light beam must *also* shrink toward being such a thing, except perhaps at discontinuities. So it's actually even simpler, and this is a simple case of a more general principle called "conservation of étendue".

XXX is this really correct?

† For wave-mechanical reasons you can't actually make a perfectly collimated beam entering at a single point — there's a diffraction limit on the divergence — but here we're talking about properties of the geometric-optics approximation.

Conservation of étendue

Étendue is a quantity that

Translation-invariance

Electroforming and Electropolishing

Electric current passes through a battery electrolyte not as free electrons, as in a metal, but as positive metal ions, and this is true

whether you're charging or discharging the battery. The positive ions are formed from the metal at the surface of the positive electrode, which has electrons running away from it down a wire, through a circuit, and back around to the negative electrode, where they travel to the surface of the metal and neutralize arriving positive ions, thus transmuting them back into insoluble metal.

You can use this process to coat some random conductive thing with a layer of metal, which is called galvanizing or electroplating — or electroforming, if you do it long enough — or to remove a thin layer from the surface of a piece of metal, which is called electropolishing, or cathodic corrosion if you do it by accident, like on a metal ship hull.

Because electric fields are strongest around edges and sharp points, electropolishing tends to remove those, leaving a mirror-like finish on initially rough metal. Also, since it doesn't

At the currents typically used, this process typically deposits around a nanometer per second of metal on one electrode and removes around a nanometer per second from the other. Much lower or higher currents don't work as well.

Fresnel electropolishing

Holographic electropolishing

Cristina Fernández de Kirchner tweets about the attempt to kidnap Assange

Kragen Javier Sitaker, 2014-04-24 (3 minutes)

Volví de la Rosada. Olivos, 21:46 hs. Me avisan, Presidente Correa al teléfono. "Rafael?. Pasámelo".

"Hola Rafa, cómo estás?". Me contesta entre enojado y angustiado. "No sabés que está pasando?"

"No, que pasa?". Yo en babia. Raro, porque siempre estoy atenta… y vigilante. Pero recién había finalizado una reunión.

"Cristina. Lo han detenido a Evo con su avión, y no lo dejan salir de Europa".

"Qué? Evo? Evo Morales detenido?" Inmediatamente me viene a la mente su última fotografía, en Rusia…

Junto a Putín, Nicolás Maduro y otros Jefes de Estado. "Pero que pasó Rafael?"

"Varios países le revocaron el permiso de vuelo y está en Viena", me contesta.

Definitivamente están todos locos. Jefe de Estado y su avión tiene inmunidad total. No puede ser este grado de impunidad.

Rafael me dice que va a llamar urgente a Ollanta Humala para reunión urgente UNASUR.

Llamo a Evo. Del otro lado de la línea, su voz me responde tranquila: "Hola compañera, como está?". El me pregunta a mí como estoy!

Me lleva miles de años de civilización de ventaja. Me cuenta la situación. "Estoy aquí, en un saloncito en el aeropuerto…"

"Y no voy a permitir que revisen mi avión. No soy un ladrón". Simplemente perfecto. Fuerza Evo.

CFK: "Dejáme que llame a Cancillería. Quiero ver jurisdicción, Tratado y Tribunal al cual recurrir. Te vuelvo a llamar". "Gracias compañera"

"Hola, Susana". No querido, Susana Ruiz Cerruti. Nuestra experta en legales internacionales de Cancillería...

Me confirma inmunidad absoluta por derecho consuetudinario, receptado por Convención de 2004 y Tribunal de La Haya.

Si Austria no lo deja salir o quiere revisar su avión, puede presentarse ante la Corte Internacional de La Haya y pedir…

Siiii!, UNA MEDIDA CAUTELAR. No se si ponerme a reír o llorar. Te dás cuenta para que son las medidas cautelares.

Bueno, sino le podemos mandar algún juez de acá. Madre de Dios! Qué mundo!

Lo llamo a Evo nuevamente. Su Ministro de Defensa toma nota. En Austria son las 3AM. Van a intentar comunicarse con las autoridades.

Hablo con Pepe (Mujica). Está indignado. Tiene razón. Es todo muy humillante. Me vuelve a hablar Rafa.

Me avisa que Ollanta va a convocar a reunión de UNASUR. Son las 00:25 AM. Mañana va a ser un día largo y difícil. Calma. No van a poder.

A simple virtual machine for vector math?

Kragen Javier Sitaker, 2018-11-06 (updated 2018-11-09) (15 minutes)

Could you design a simple virtual machine for vector math that a wide range of existing and future vector hardware (SIMD instruction sets, GPUs, FPGAs) could execute efficiently? A sort of equivalent for C's virtual machine (viewing C as a virtual machine!) but aimed at things that can execute efficiently across a wide range of today's computers, not 1984's — a lowest common denominator that's low enough to get substantial parallelism on almost anything, but not so low that typical code is as slow as typical C code.

I think it's feasible.

Of course, nonportable code will always be faster, but the idea of the vector VM is to be fast enough to use portable code most of the time.

I was originally thinking of this approach as part of an archival virtual machine proposal, a successor to Chifir sufficiently improved to be workable, whose raison d'être was archaeological in nature — the objective is for an archaeologist finding the artifact to be able to implement the specified virtual machine as a fun afternoon hack, then load the ancient data into it and breathe life back into it. I thought maybe a pipelined vector design could work, but upon further consideration, I decided it wasn't well suited to compatible reimplementations without reference to an existing working implementation.

Still, though, I think it might be interesting for less demanding purposes, the sort of thing OpenCL and Vulkan are aimed at. It's sort of a microscopic SPIR-V with about 30 operations, or a VM for Wadge's Lucid.

Unfinished notes

Old Cray machines weren't parallel-SIMD, where you could add, subtract, multiply, take the square root, or whatever of each of 4 or 8 or 16 values in a single cycle; instead they had some 8 "vector registers" of, say, 64 single-precision floats, and vector operations on them which operated elementwise. But the machines didn't have 64 floating-point execution units; they might have 6. So a vector-to-vector operation necessarily took place one float at a time, but pipelined, with one result per cycle. Moreover, you could "chain" operations from one register to the next, and even to main memory. So, for example, you might compute mx + b, for vector values of the variables, as follows:

```
vectorload m_addr, V1
vectorload x_addr, V2
vectorload b_addr, V4
vectormul V1, V2, V3
vectoradd V3, V4, V5
vectorstore V5, y_addr
```

So with six instructions you would start the computation of the values, and then it might take 64 more clock cycles to finish. This is how the Cray-1 got 138 megaflops, bursting to 240 megaflops, in 1977, on an 80MHz clock.

It's also very similar to how Numpy gets reasonable performance for numerical code despite being an extension for dog-slow CPython. This, plus Python's "iterable" interface (now adopted by JS and Java), suggests the approach of computing abstract sequences of values (of some arbitrary length) rather than individual values or vector values of some fixed length, and including a stride argument in the vector memory fetch instruction.

Consider a matrix-matrix multiply C = AB. Here, in C-style row-major form (which is backwards from standard mathematical notation) C[i][j] = Σ_k A[i][k] B[k][j], or $C_{ij} = \Sigma_k A_{ik} B_{kj}$; writing that as nested loops:

```
C = {0}; // everywhere (this is not valid C syntax)
for (int i = 0; i < A_rows; i++) {
    for (int j = 0; j < B_rows; j++) {
        for (int k = 0; k < A_cols; k++) {
            C[i][j] += A[i][k] * B[k][j];
        }
    }
}
```

Thus written, the code is precisely equivalent if we swap inner and outer loops into any of the 6 permutations. As written, it totals each item of C separately, iterating over a column of A and a row of B for each one; but we could also, for example, multiply a cell of A by a row of B, sending the results to the corresponding row of C, merely by swapping the inner two loops:

```
C = {0};
for (int i = 0; i < A_rows; i++) {
    for (int k = 0; k < A_cols; k++) {
        for (int j = 0; j < B_rows; j++) {
            C[i][j] += A[i][k] * B[k][j];
        }
    }
}
```

That is, $C_i = \Sigma_k A_{ik} B_k$.

We could turn the inner loop here into a program that reads a vector from memory, multiplies it by a scalar (previously loaded from A), reads another vector from memory (the row of C), adds the product to it, and writes it back where it came from.

In the case where C has many more rows than columns, though, it would be more efficient to write a column at a time. This is the same kind of simple transformation:

```
C = {0};
for (int j = 0; j < B_rows; j++) {
    for (int k = 0; k < A_cols; k++) {
        for (int i = 0; i < A_rows; i++) {
            C[i][j] += A[i][k] * B[k][j];
```

```
      }
    }
}
```

That is, C[...][j] = Σ_k B[k][j]·A[...][k]. Here we are updating a whole column of C by adding to it the product of a scalar from B and a column of A.

This is of course not optimally cache-friendly (something the Crays didn't have to worry about) but it still might be a win if C has a sufficiently small number of columns.

Building a dataflow network on the stack

So suppose that we have a stack machine equipped with an additional stack where the items are not numbers but streams of some finite but possibly large length. By manipulating these streams, we can set into motion highly parallelizable computations which may involve orders of magnitude more computation than that required to interpret the instruction stream. The virtual machine does not know about multidimensional arrays, but it can efficiently execute some computations on them.

The crucial thing to note here is that the stream operations here treat different indices in the stream as completely separate; there is no way for anything that happens at index 0 in the stream to affect anything that happens at index 1 in the stream, or vice versa. So the execution of the entire stream is embarrassingly parallel. Whether that's useful or not depends on what you're trying to compute.

Sources

There are two operations which create a new sequence: `load(address, mode, stride, count)` and `iota(start, stride, count)`. (They can take their arguments from, for example, a different stack.) `load` produces a sequence of `count` items loaded from memory using `mode` (e.g. `uint32_t` or `float*8`) located `stride` bytes apart; if `stride` is 0, then all of them will be copies of the same value. `iota` similarly produces a series of `count` items; the first will be the number `start`, and succeeding items will increase by `stride`, which may be 0.

The span of addresses that will be accessed by `load` can be bounds-checked as soon as the `load` instruction executes, allowing the bounds check to be amortized over a potentially very large number of data accesses.

Sinks

There are correspondingly a few different final destinations we can send these streams to.

`store(address, mode, stride, count)` is the counterpart of `load`; it stores the values of a stream into memory. With `load` and `store` we can copy blocks of data around memory, translate it between different numeric formats, and transpose matrices by using different strides.

`argmax` and `argmin` each take two streams as arguments: an `index` stream and a `data` stream, which should be of the same length. When the streams are exhausted, they yield the `index` value corresponding to the largest or smallest datum from the `data` stream. If the `index` and `data` streams are the same, they thus produce the max or min of the stream.

`sum`, similarly, computes the sum of a stream.

Stream transformations

However, there are also a large collection of operations that operate elementwise on streams. For example, the `~` operation computes the bitwise NOT of the values in a stream, consuming the stream and producing a new stream of the altered values. The `+` operation consumes two streams (which should be of the same length) and produces a new stream of the sums of corresponding values from those streams.

The collection of stream transformations consists of the following 16 operations:

- `+`;
- unary `-`, which computes the numeric negation of each item in the stream;
- binary `-`, which subtracts streams elementwise;
- `*`, which multiplies streams elementwise;
- `divmod`, which consumes a stream of dividends and a stream of divisors, and produces a stream of floored quotients and a stream of nonnegative remainders;
- `<<`, which consumes a stream of quantities and a stream of bit shift distances, performing an arithmetic left shift on each quantity;
- `>>`, which is the equivalent right-shift — a logical right shift for unsigned quantities, an arithmetic right shift for signed;
- `|`, which computes the bitwise OR of two streams;
- `&`, which computes the bitwise AND;
- `^`, which computes the bitwise XOR;
- `~`;
- `\`, which computes the bitwise abjunction `(a & ~b)`;
- `<`, which consumes two streams and produces a stream of boolean values which is true when the value from the first stream is less than the corresponding value from the second;
- `=`, the same except that it tests for equality;
- `?:`, which consumes a stream of booleans and two streams of quantities, producing a single output stream; its values are quantities from the first stream when the booleans are true, and from the second stream when the booleans are false;
- `⌜`, which combines two streams to produce a stream of values that come from the first stream when those are greater, or from the second stream when those are.

Stream stack manipulation

You also have the usual collection of simple stack operations for the stream stack — `dup`, `drop`, `swap`, `over`, `rot`, `>R`, `R@`, and `R>`.

These are particularly important here because of their effect on the stream execution engine. While references to a dataflow network are live on the stack, the engine doesn't yet know what use will be made of them; it is only once the last reference has been removed from the stack that it can actually execute the requested computation. If they are `drop`ped, perhaps it need not do any computation at all.

XXX what happens if you request the sum or argmax of a stream while other references are still live on the stack? Maybe just eliminate `dup` and `over`, because the alternative seems to be unbounded buffering.

Why a stream stack

Why use a stack machine for building the streams instead of, say, a register-based virtual machine? Don't register-based bytecodes run faster?

The advantage of a stack machine is that the number of uses of each value is explicit, while in a register machine, it is implicit. If you have no `drop` operation or other way to discard a value, you know that all values are used; if you additionally have no `dup` or `over` or `R@` operation or other way to duplicate a value, you know that each value is used exactly once. The point at which no more references to a particular tree exist on the stack is precisely the point when it will not be used in the future.

Perhaps you could design a two-operand register machine with the same property, if each register has an "empty"/"full" bit like the memory words of the Tera MTA, such that using a register as a "source" operand optionally "empties" it, and reading from "empty" registers or moving to "full" registers is not permitted.

But a stack machine seems like a much simpler route to the same goal.

Okay actually fuck all this

So what you actually want is to construct a dataflow graph from a sequence of inputs to an equal-size sequence of outputs. And you want to do that while ensuring that your dataflow graph is acyclic, not only in the directed form but in the undirected form as well. (There's no good reason for that restriction, but I did talk about imposing it, at least possibly.) And then you want to launch it to go process stuff and then maybe get results.

In that case, wouldn't it be best to separate the graph construction and graph execution steps? And in that case, wouldn't it be best to be able to execute the same graph more than once? In my matrix multiplication example, for example, you want to run your inner loop m×n times (e.g. `A_rows` × `A_cols` times). There's no benefit to reconstructing the graph again every time through the inner loop!

Separating them also eliminates the problem of making sure all the lengths are equal — you supply the length, along with the input and output data addresses and strides, when you invoke the graph. And it eliminates the question of what to do when you invoke the `sum` instruction but there are still things left on the stack, because the sum won't be delivered at graph construction time in any case, but at graph invocation time.

(And in that case maybe when you instantiate the sum node, you give it a destination register, so that you can have several of them in the same graph.)

Getting back to the question of "a sort of equivalent for C" — is a stack-based virtual machine really the same level of programming as C? Wouldn't you want infix syntax for programming at C level? Why do you need some kind of bytecode representation of your vector dataflow graph? Wouldn't you be better off with a language extension for C, or maybe even a C library? And in that case, wouldn't you be better off with explicit node labels of some kind instead of this dopey stack-machine interface? I mean, it would be a lot easier to read your code, probably, even if infix is too hard to provide because C doesn't do operator overloading.

Vitruvius could have taken photographs

Kragen Javier Sitaker, 2016-07-30 (1 minute)

It turns out that in classical Rome (and possibly earlier in Lydia) the means for refining gold from electrum was to smelt the electrum with salt to oxidize the silver to silver chloride. (The modern nitric-acid process wasn't possible until nitric acid was produced; it was available by the 13th century, but wasn't available in classical Rome.)

Silver chloride is one of the silver halides used in photography; it can be used by itself. Silver chloride plus gelatin is by itself adequate to produce negative prints on paper (or papyrus) given enough light and time.

The Romans had gelatin, too; the widespread use of hide glue dates from Middle Kingdom Egypt. So they had the materials technology necessary for photography. We could be looking at Julius Caesar's hobby pinhole landscape photographs today if they had known about the properties of the materials they had at hand.

(Actually, I'm not 100% sure that the collagen in hide glue is sufficiently similar to gelatin; gelatin is collagen hydrolyzed either simply by boiling or more quickly with acids, bases, or proteolytic enzymes.)

Fencepost cognitive interface errors in text editing

Kragen Javier Sitaker, 2019-04-24 (24 minutes)

A substantial part of the work of editing natural-language text amounts to rearranging small pieces of it, and these pieces most frequently correspond to natural units, such as words, clauses, prepositional phrases, sentences, and paragraphs. Existing text editors fall far short of the optimum in this.

Emacs has commands for moving by and deleting characters, words, sentences, lines, S-expressions, paragraphs, and in some cases, pages. You would think that this would make it easy to do sequences like "go back five words, delete two words, and then insert them at the end (suitably defined) of the sentence." But if you attempt to apply that sentence to the end of itself, this is what you get:

"go back five words, delete two words, and then insert them at the end () of the sentence."suitably defined

Rather than, as you might hope:

"go back five words, delete two words, and then insert them at the end of the sentence (suitably defined)."

Similarly, you might hope that backward-word (M-b in Emacs parlance) would take you to the same position as backward-word backward-word forward-word (M-b M-b M-f), at least if there was a second word to move backwards over. But, as far as I know, it never does; the first sequence leaves you at the end of a word separator, while the second sequence leaves you at its beginning. Consequently, after the second sequence, you can use kill-word (M-d) to delete one or more words including any leading separators, which you can then insert again coherently at a position before another word separator. For example, starting from

can |then insert again coherently at

you can use M-f M-d M-d M-f C-y to get to this desirable state:

can then coherently insert again| at

You could make the same edit from this different starting position:

can then insert again coherently| at

by using C-f M-DEL M-b M-b C-y:

can then coherently |insert again at

M-DEL is backward-kill-word, which, unlike M-d, includes any *following* separators; thus the necessity for the initial C-f to avoid this mess:

can then coherently|insert again at

This requires slightly nontrivial cleanup, and the situation is worse in programming languages. Transient-mark mode, M-@, M-h, and C-M-SPC can help significantly, but they don't really solve the problem.

The underlying difficulty here is that in Emacs, a sentence is not a sequence of words; it is a sequence of alternating words and word separators, which contains nearly twice as many elements as words. Since it would take twice as long to get anywhere if the movement commands moved by such elements, they move past the large

elements, and you can use character-movement commands to fine-tune. Unfortunately, this leads to a lot of fine-tuning, user errors when you get the fine-tuning wrong, and unnecessary round trips to make sure the fine-tuning is right.

The same difficulty attends Emacs's commands for sentences and S-expressions, though typically not lines and paragraphs.

lowriter

LibreOffice Writer clones Microsoft Word's text editing command set, which in its turn is copied from early Macintosh, and thence from Bravo and Smalltalk. Its word movement commands (Ctrl-← and Ctrl-→) take you to the beginnings of words or the beginnings of non-space strings between words, and they are the same positions in both directions. Its word deletion command, Ctrl-Backspace, deletes back to these same positions, except that it also has stopping positions at the beginnings of paragraphs, even empty ones. (Also, lowriter considers embedded apostrophes, though not trailing apostrophes, to be parts of words; similarly, embedded commas are parts of words if they have digits on both sides of them, though periods are not.) It doesn't seem to have commands to move by sentences, although it does have movement by paragraphs (Ctrl-↑ and Ctrl-↓). This works better than Emacs's word-movement approach in most cases, but not all. The first example above, commanded as as Ctrl-← Ctrl-← Ctrl-← Ctrl-Shift-← Ctrl-Shift-← Ctrl-Shift-← Ctrl-Shift-← Ctrl-x Ctrl-→ Ctrl-→ Ctrl-→ Ctrl-v, yields this:

"go back five words, delete two words, and then insert them at the end of the sentence(suitably defined) ."

But the second example:

commanded as Ctrl-→ Ctrl-Shift-→ Ctrl-Shift-→ Ctrl-x Ctrl-→ Ctrl-v, comes out fine, though slightly different from Emacs:

can then coherently insert again |at

And the third example, which logically should have the same problem as Emacs, when commanded as Ctrl-Shift-← Ctrl-x Ctrl-← Ctrl-← Ctrl-v:

can then insert again coherently| at

instead also comes out fine; the space to the left of "coherently" was deleted immediately after the word itself, and upon being inserted at the beginning of "insert", a space is appended to preserve the pre-cut-and-paste word boundaries:

can then coherently |insert again at

If you paste into the middle of a word, spaces are inserted both before and after; if you paste into the middle of whitespace, spaces are inserted neither before or after. If you paste between a sentence-ending word and the sentence-ending punctuation, space is inserted before the pasted word, but not after; no corresponding cleanup seems to exist for pasting to the beginning of a sentence. However, if the string you deleted was "coherently ", with the trailing space, as it would be if you used the word movement commands to find both ends of the selection, or if it was "coherentl", not touching the final word boundary, none of this magic DWIM whitespace behavior happens.

I suspect that the reason for the DWIM behavior is that, in lowriter, if you select words by double-clicking with the mouse,

instead of using Ctrl-Shift-← and Ctrl-Shift-→, the space after the word is not included in your selection!

Also, in lowriter, triple-click selects by sentences, but doesn't include whitespace surrounding the sentence; this means that if you rearrange a sequence of sentences by triple-click and drag-and-drop, you have to clean up whitespace afterward, in a way exactly analogous to the Emacs word-separator problem described above. Quadruple-click (!!) selects paragraphs, but only single paragraphs; dragging outside the paragraph reverts to selecting by characters.

Vim

Vim's word movement commands (w and b, not e and ge) seem to be entirely consistent with lowriter, except that they treat apostrophes and commas like any other punctuation; and deleting, cutting, and pasting is consistent with movement, though of course without DWIM.

When programming in Emacs, I've often been frustrated by its word-movement commands skipping over long sequences of punctuation and whitespace as if they weren't even there. Vim's command structure is significantly better in this regard.

Eclipse

Eclipse's word movement commands have the same problem as Emacs's.

New editor design thoughts

What should the command set for a new editor look like?

Established movement-command convention

Assuming that MacOS and Microsoft Word are consistent with lowriter, violating their word movement and deletion command convention is costly; Vim's behavior is also consistent with it, and the behavior seems to be both more predictable and more frequently what is desired without DWIM magic. But the fact that lowriter does resort to DWIM magic behavior under fairly normal circumstances suggests that perhaps a better alternative is possible.

Selection-verb versus Emacs or Vim commands

The Smalltalk and Bravo selection-verb convention, imitated in Macintosh and in nearly all subsequent GUIs, of first selecting a region of text visibly and then applying subsequent commands to that region of text, is substantially more predictable than the Emacs and Vim approach of applying commands to regions computed after the command starts. Both the selection-verb convention and the Vim approach enjoy substantially better orthogonality than the Emacs command set, although by the same token the Emacs commands are often shorter:

```
|          | forward  | backward | mark              | delete/kill    | backw
ard delete/kill    |

| char     | C-f      | C-b      |                   | C-d            | DEL
                |
```

```
| word      | M-f      | M-b      | M-@                  | M-d           | M-DEL
, C-backspace      |

| sentence  | M-e      | M-a      | mark-end-of-sentence | M-k           | C-x D
EL                 |

| line      | C-p      | C-n      |                      | C-k (XXX),    |
                   |

|           |          |          |                      | C-S-backspace |
                   |

| paragraph | M-}, C-↓ | M-{, C-↑ | M-h                  | kill-paragraph | backw
ard-kill-paragraph |

| sexp      | C-M-f    | C-M-b    | C-M-SPC              | C-M-k         | ESC C
-backspace         |
```

Of these 27 different keystroke commands, I think only 16 are in my own subconscious repertoire, and that's after 30 years of this body using one or another Emacs. Some of those work in readline, or GTK (by default), while others don't, adding to the difficulty.

Ctrl-backspace

Ctrl-backspace is extremely valuable, more valuable even than backspace, because it eliminates not only keystrokes but also feedback round trips. (I mistyped that "trips" as "tirps", for example, and then used Ctrl-backspace to delete it and type the correct word.) Replacing Ctrl-backspace with a selection-verb sequence like Ctrl-Shift-← Ctrl-x (which does work in lowriter, for example) would be intolerable, unless both the selection and the verb were a single keystroke, could be released in an indeterminate order, and supported repeating without fiddly key alternation.

Multilevel cut and paste

Emacs's killing and C-y and M-y behavior is also extremely valuable: it means you don't have to decide ahead of time which deleted text you are going to want to paste later, and you don't have to worry about losing text on the clipboard by cutting something else. Every mainstream UI has supported multilevel undo for over 20 years, eliminating the danger of losing your undo information with a following command (the famous modal UI "edit" problem, in which "e" selected "everything", "d" deleted it, "i" went into insert mode, and "t" was inserted, losing the undo info.) It's long since time they supported multilevel cut and paste!

The Back button

Emacs's C-u C-SPC command, which pops the mark stack, is extremely useful for returning to editing what you were just editing before your last search; it's like a WWW browser "back" button, but inside a single editor buffer. It really needs a more convenient keybinding, one that can be repeated without key alternation. Browsers bind it to Alt-← and, historically, Backspace, although that's going away, but something you can type without taking your

fingers off the home row would be superb.

Text movement

Eclipse's Alt-↑ and Alt-↓ keybindings for moving a block of lines (either the current line, or the selected block, expanded to full lines) are one of the few code-editing features in Eclipse that I miss in Emacs and Vim. They don't work as well for text in paragraphs, since it tends to have logical boundaries that don't coincide with line boundaries, but you could imagine a similar command set that did work well; lowriter, for example, permits drag-and-drop rearrangement of text fragments with the mouse, although it doesn't provide ongoing feedback about the final result.

Emacs has a set of "transpose" commands which can in theory be used for this, but they are awkward to use: they only move single units (of whatever size: lines, sentences, sexps, words, chars — but not blocks of two lines or words or whatever), only forward, and only two of them have default keybindings that can be repeated without alternating keys (C-x C-t is transpose-lines, which doesn't take advantage of the transient map feature in recent versions of Emacs that, for example, allows C-x e e e to run the last keyboard macro three times.)

Movement via incremental search

Incremental-search, which originated in Emacs in the 1970s is extremely valuable, both for the usual search purposes and for cursor movement, as Jef Raskin showed in his work (on the Canon Cat, SwyftWare, The Humane Environment, and Archy). It's an even faster means of cursor movement than using the mouse. Unfortunately, Emacs's implementation of incremental-search is crippled for cursor movement in a few different ways:

• When searching *forward*, Emacs incremental-search leaves the cursor at the *end* of the search string, not its beginning. That means that if you want to move the cursor from "extremely" above to the start of "beginning" in this paragraph, you can't simply search for "beginning"; you'll end up somewhere in the middle of the word or at its end. Instead you must search for "its ", and the search is no longer effectively incremental — even though "it" is sufficient to uniquely identify the string you're searching for, you have to keep typing to get to the place you want. Alternatively, you can search for "beginning" and then issue an extra command to get from the middle to the beginning of "beginning"; this requires typing only up to "be".

• Emacs's incremental-search is modal, requiring an extra keystroke to terminate it. This can result in mode errors, where later keystrokes are erroneously used as part of the search key, but the larger problem is that it is a significant amount of overhead. The Canon Cat, for example, used its quasimodal "LEAP" to move by paragraphs by searching for paragraph breaks, or by "sentences" by searching for periods; releasing "LEAP" ended the search. Thus "search for the next newline" was "LEAP-Return", releasing "LEAP" after "Return", the same number of keystrokes as Emacs's M-a or C-e; it's a sequence of three events. Using C-s . RET in Emacs is, by contrast, a sequence of six events: Ctrl down, S down, release all, period

down, RET down, release all. A benefit of being modal in this way is that the same C-s and C-r keystrokes can repeat the search in different directions.

• As an additional problem, the particular keystroke Emacs chose to terminate incremental-search is RET or Enter. This makes it unintuitive and inconvenient to search for newlines (you can do it by typing Ctrl-J, although I don't know if I knew that until I tried it just now).

Vim's incremental search avoids problem #1, but still has problems #2 and #3, and actually problem #3 is even worse: /^V^J RET in Vim searches for NUL rather than LF. Searching for an actual linefeed in Vim requires /\n RET.

A separate tweak to text incremental search is to display further search hits in context in a separate pane once they're infrequent enough, allowing a smooth transition from in-context navigation to menu navigation.

Multiple cursors

The proprietary Sublime Text editor's multiple-cursor feature seems like a better alternative to keyboard macros under most circumstances, because it allows you to see the effects of all the "iterations" of your "macro" incrementally as you are composing it. But I'm getting off on a tangent.

Selection command design

Most of that is preamble to say that I think the selection-verb model is generally better, but you need sufficiently powerful selection commands to keep that model from being too clumsy. For rearranging text by word, sentence, or paragraph, perhaps you could use a command like Emacs's M-@, which extends the selection to the end of the next word, thus allowing you to select multiple words by repeating the command — but with semantics more like Emacs's M-h, which also extends the beginning of the selection to the previous paragraph boundary, if it isn't already there (except that it does the wrong thing if there's already a selection which wasn't created by M-h). So, in Emacs, M-h selects one paragraph, M-h M-h selects two paragraphs, and so on; a new editor could have keybindings that operate similarly.

Three such keybindings — select-word, select-sentence, and select-paragraph — would allow you to quickly select the span of text you want to operate on, if it's less than, say, four logical units long. Making longer selections would be faster with the mouse or using incremental search, requiring the user to strategize as to how to make the selection, and potentially causing long decision times around the break-even point due to the problem of Buridan's Ass; to the extent that we can avoid imposing the need to strategize on the user, we can shorten the path to the user's desire. (The kfitzat haderech is the ultimate user interface!)

S-expression selection is somewhat trickier because there are at least two potential directions the user might want to expand their selection: forward to the following expression, and up the S-expression tree. So a single keybinding for marking sexps will not suffice. Thus Emacs provides forward-sexp (C-M-f), backward-sexp (C-M-b), mark-sexp (C-M-SPC, which extends the region

forward), down-list (C-M-d), backward-up-list (C-M-u), up-list, kill-sexp (C-M-k), backward-kill-sexp (ESC C-backspace), and kill-backward-up-list. Maybe the right solution is to repurpose the select-word and select-sentence keybindings in programming-language modes.

Perhaps mouse selection can give an indication of the desired granularity of selection by its speed: if the mouse is moving too fast for the user to have intended to select at the granularity of a single character or even a single word, perhaps sentence or even paragraph granularity was intended. If the mouse selection starts out with the incorrect granularity, the user can correct it by moving the mouse faster or slower as they drag out the rest of the selection. This mechanism could smoothly incorporate probabilities from stochastic models of natural language to permit sub-sentence selections, including things like dependent clauses and prepositional phrases.

Delimiter behavior

But you still have the problem of the fenceposts or delimiters: when are they included in the selection and when are they excluded?

If there's an improved model of text that permits a better user interface for rearranging bits of it, I suspect it looks something like, "Paragraphs are sequences of sentences. Sentences are sequences of words." This avoids the fencepost problems described earlier, where you move by words, cut by words, and then paste, and yet you end up merging words or creating extra spaces. This is not too far from the model implicit in the Vim command set, where w and b take you to the beginnings of words or punctuation strings.

The sequence-of-words model does potentially have the problem lowriter's DWIM is trying to patch up: a sequence of words in a different context might need different word separators around them. For example, if I were to replace "around them" in the previous sentence by moving "in a different context" to the end of the sentence, including a space after that phrase would be inappropriate.

A possible solution to this problem might be something like the following data model:

- Words are nonempty sequences of alphanumeric characters, with possible exceptions for things like apostrophes and commas in numbers.
- Words are always terminated by word terminators, which are inserted automatically if not present, as Vim does with trailing newlines in a text file. All word terminators terminate nonempty words.
- Word terminators followed by words are displayed (and, in plain text, serialized) as spaces.
- Word terminators followed by punctuation or paragraph breaks are not displayed (or serialized in plain text).
- Spaces following other spaces or punctuation — anything that isn't a word — represent real spaces, not word terminators.
- Paragraph breaks are always preceded by a word terminator or real space, which is not displayed (or serialized in plain text).

This provides a bijective mapping between displayed character sequences and internal character sequences. In one direction, spaces following alphanumerics and preceding either spaces or

alphanumerics are converted to word terminators, and word terminators are inserted before punctuation that follows alphanumerics; in the other direction, word terminators are converted to spaces unless they precede punctuation.

In terms of commands:

- Word movement commands move to points which include the beginnings of words, beginnings of paragraphs, and beginnings of punctuation strings.
- Mouse selection of words selects between the same points word movement commands move to, and thus includes the fucking word terminators.
- Movement by sentences moves to the beginnings of sentences. The sentence terminator pattern
- Selection by sentences includes the sentence-ending punctuation, any following punctuation before space, and any following spaces, including the invisible space preceding a paragraph break, but not the space that often precedes the beginning of the sentence; that space belongs to the previous sentence. It also includes any punctuation at the beginning of the sentence following spaces that belonged to a previous sentence, such as an open parenthesis or open quote.

Like lowriter's approach, this provides the right behavior for cutting and pasting sequences of words from the ends of sentences to the middles and from the middles to the ends; however, it does so in a way that is predictable because it is consistent with its data model, rather than being a DWIM special case. Unlike lowriter's approach, it also provides the right behavior for cutting and pasting sentences from anywhere in a paragraph to any other sentence boundary in a paragraph. Like lowriter's approach, it still requires manual cleanup for cutting and pasting sequences of words to or from the beginnings of sentences. It differs from lowriter's approach when you select a word (or several words) with the mouse and either copy or move it to the interior or end of another word: in that case, it will paste with a space after it but not before, as lowriter does when you make the same selection using keyboard selection commands.

How well will these rules apply to programming languages, should you be editing a program in natural-language mode? Since the mapping between the internal representation and the serialized one is bijective, it shouldn't pose any particularly serious problems.

Scoring

I think the editor should use game mechanics to teach you to use its command set in the way we have Tayloristically determined to be the most effective.

Autosuggest

The editor should use a neural network pretrained on a corpus of existing open-source projects and natural-language text, then later trained on the things you actually write in it, to order and possibly even add autocompletion suggestions. It can also adjust the frequency of autosuggest suggestions to the circumstances: if the human frequently accepts a suggestion or peruses the options, it should offer suggestions more frequently.

High-precision control of low-stiffness sytems with bounded-Q resonances

Kragen Javier Sitaker, 2017-05-29 (updated 2017-06-01) (4 minutes)

By inverse-filtering the control signal applied to a plant by the estimated OTF of the control function, we can compensate for arbitrarily poor stiffness, up to limits imposed by the control-output bounds and the Q factor of series resonances in the system which impede our ability to impose rapid changes on it. The estimated OTF can be updated moment by moment from incoming sensor data, which permits compensation for mild nonlinearities in the plant; for example, the resonant frequencies of a robot arm may change as it is being extended. High-Q-factor series resonances impose notch filters on the spectrum of the OTF, making it poorly conditioned, thus requiring large components in the inverse filter. These large components can easily cause the inverse-filtered signal to have a very poor signal-to-noise ratio or to exceed the limits of the control actuators, requiring for example very large forces, velocities, or displacements. This problem can be ameliorated somewhat by using nonlinear optimization algorithms, rather than simply solving a linear system, in the control loop. However, in many cases, it may be better to change the design of the plant to damp the high-Q resonances. For example, in a mechanical system, these high-Q resonances can be damped and broadened by adding dashpots or other dissipative elements, thus trading off efficiency for precision control. Counterintuitively, the common approach of increasing rigidity can worsen the controllability of the system when using such an adaptive control algorithm, as it increases the Q factor of the system's vibrational modes, even as it moves them to higher frequencies. As more data is gathered about the system, it becomes possible to empirically estimate the variation of the control-feedback OTF over the plant's parameter space, thus enabling compensation for OTF nonlinearities in parts of the parameter space we expect to visit in the near future. If the control system can learn an OTF that is locally nonlinear or stateful, then nonlinear optimization algorithms in the control loop could potentially compensate even for such phenomena as gear backlash. Finally, using a self-validating analysis system such as reduced affine arithmetic, the control system can optimize not only to reduce the expected deviation between the plant's state and the commanded result, but even for the uncertainty in the plant's state.

All of the above is, to me at least, still somewhat speculative. I have a strong intuition that all of it is true, but a lot of work is needed to verify it in practice. It's about four times too long for a paper abstract!

How to investigate? Well, one thing to try is to simulate a simple physical system, like maybe a linear one-dimensional mass-spring-dashpot system connected to another mass-spring-dashpot system plus a little bit of measurement noise, and try to command it to make some movements with some different

kinds of control systems:

• Maybe a simple bang-bang control system;
• Simple proportional control;
• A tuned PID control system;
• The inverse-filtering-based system I describe above, in its simplest form;
• maybe more advanced forms of it if that seems like it would be better.

That should provide some kind of evidence that this is a good idea, before I get into more complicated plants.

The obvious way to do the simulation at this point is with SVG and JS in Chrome, using direct-mode solutions with maybe a second-degree approximation for the integrals, which will also make it easy to demonstrate to other people. Maybe I can make it game-like, which should make it easy to draw a desired motion with the mouse or a touchscreen in order to see how different control systems respond.

Maybe I can try some experiments first with Jupyter notebooks with Numpy to see what inverse-filtering a noisy signal looks like. Maybe I need to review how to compute the OTF of a linear mass-spring- dashpot system, because I'm pretty sure that's like a closed-form kind of thing.

Approaches to limiting self-replication

Kragen Javier Sitaker, 2016-11-30 (7 minutes)

Since self-replicating automata entered the fictional literature in Samuel Butler's Erehwon, humans have been concerned that their uncontrolled replication could be dangerous; notable examples include Karel Čapek's "R. U. R.", Lem's "Invincible", Dick's "Second Variety", Drexler's "gray goo", Star Control 2's "Slylandro Probe", and, in a way, Goethe's sorcerer's apprentice's broom. And, of course, our experience with biological self-replicating systems includes numerous troublesome examples of exponential self-replication, including locust plagues, cancer, all kinds of infectious diseases, toxic algal blooms, mold infestations, ant and other insect infestations, rats in cities, and cane toads in Australia. In computers, self-replicating code and related phenomena have caused many problems, from the TFTP "Sorcerer's Apprentice Syndrome" and the accidental fork bomb to the helminthiasis of the internet (the "Morris worm"); nowadays, self-replicating code is a mainstay both of computer security attacks (where it is often called a worm) and defense (where it is often called a security patch or security update).

Our experience with biological systems, however, is misleading when it comes to mechanical systems. If you want to design a self-replicating mechanical system to have a high degree of assurance that it won't continue running on its own, consuming more resources than anyone wanted to produce more replicas of the system than anyone wanted, there are a variety of strategies you can employ without unduly limiting the system's intentional uses.

• Large size.

One reason that cancer is such a problem in animals is that we are made from trillions of essentially autonomous units, each capable of self-replication, most of which (except for red blood cells) do in fact self-replicate in the regular course of events. This provides hundreds of trillions of opportunities for exponential self-replication to arise during the lifetime of a single organism.

By contrast, we can design the self-replication process of a robot to use convergent assembly, in which the minimal self-replicating unit is very large — rather than the tens of microns of a typical eukaryotic cell, it could be hundreds of millimeters, or even more than a meter, in diameter. This lowers whatever risk of exponential replication may exist by a factor of about a quadrillion.

By using convergent assembly, in which the robot contains many small manipulators producing parts to be assembled by asmaller number of larger manipulators, it is possible to obtain this desirable large size without paying an excessive cost in replication time, though this is not intuitive from examining biological models such as elephants, humans, or whales, with their perilously low fertility rates.

• Broadcast architecture.

Rather than keeping a copy of the full program to build a new

robot inside of each robot, as cells do, it has been suggested (originally by Laing, I think, as a way to reduce the size of the robot) to store the program in a centralized transmitter, broadcasting the subprogram for each stage in the process to all of the robots at once. In this way, no robot ever contains the full construction program at once; if the central transmitter ceases to transmit, perhaps because a human has hit the red EMERGENCY STOP button, the entire replication process will cease.

Concern about the space used for the program might seem quaint today when the system-on-a-chip the Raspberry Pi is built around has a gigabyte of RAM. However, this may be purely an artifact of our primitive macroscopic fabrication technology — semiconductor fabs are optimized for efficiently producing consumer products, so the wire-sawing process used to dice wafers has unacceptable waste below a scale of a millimeter or so. With self-replication, we may be able to usefully reduce robot size below the level where each autonomous unit contains space for hundreds of thousands of memory bits.

From a certain point of view, a convergent-assembly desktop factory is a broadcast-architecture machine — after all, what distinguishes the smallest manipulators from autonomous replicators is precisely that they are fixed in place in a larger assembly governed by a larger program they do not have access to.

• Manual process steps.

If the replication process turns a bucket of dirt and rocks into a bunch of robots, a simple way to prevent the process from running amok is to only fill the bucket through human intervention. For example, if the bucket is mounted on top of the replicator, a person could shovel dirt and rocks into it with a shovel. At a larger scale, the person could use a backhoe or a manually operated hydraulic excavator or power shovel capable of depositing hundreds of tons of material in a single operation.

The manual process step need not be the initial raw-material handling step; having a person manually pick up a bucket of finished parts from an autonomous digging part-fabricating robot and dump them into the parts hopper of an assembly robot would work too. If the human stopped carrying parts buckets, no further replicas would be produced. At the extreme, you could require a single human-executed final assembly step, such as installing a fuse or a magic word behind the robot's teeth, in order to bring the fully-assembled robot to life.

However, the raw-material extraction step of the process is the step most likely to cause damage to nearby objects such as buildings, other machinery, or humans, so it is the step most desirable to automate.

• Alternation of generations.

If robot type A is well-suited to producing robot type B, and vice versa, but neither is well-suited to produce others of its own type, then it is possible to employ either type of robots to produce an arbitrary quantity of the other type of robot, or other articles, without ever enabling exponential growth. Exponential growth is only possible if replication of both robots is possible at once — both construction programs and all the necessary raw materials must be present.

Alternation of generations may be desirable for material-processing reasons as well. RepRaps and similar FDM machines cannot replicate

themselves from raw materials because, among other things, they cannot manufacture their hotends (extrusion nozzles), because the hotends necessarily remain solid at temperatures that melt the thermoplastic extruded through them.

Moses, Yamaguchi, and Chirikjian refer to this kind of alternation of generations as a "cyclic fabrication system", saying, "It is cyclic in the way the game 'rock-paper-scissors' is cyclic: tools, materials, and fabrication processes are chosen such that one process creates tools used in the next process…" They suggest prototyping using a hard two-part polyurethane resin which can be cast in wax molds, which in turn can easily be machined by fully-hardened polyurethane; or using a low-melting metal alloy to make mandrels on which to electrodeposit softer but higher-melting metals such as copper and nickel.

The coolest bug in Ur-Scheme

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

One of the fun things about writing graphics code is that you get better bugs. In normal programming, bugs are mostly frustrating: they get in your way, make things harder, corrupt data you painstakingly created, or crash the program and interrupt what you're doing. But a lot of bugs in graphics code either look really cool or have no real visible effect.

At the moment I'm not writing graphics code. I'm writing an almost-Scheme compiler in itself. But I just created a really bizarre bug.

Here's a little bit of the assembly output from the compiler:

```
epacse__4:
        # compute desired %esp on return in %ebx and push it
        lea 4(%esp,%edx,4), %ebx
...
        movl (htgnel_gnirts__2), %eax
```

Where did `htgnel_gnirts__2` come from? Well, it's `_string_length` spelled backwards, followed by `_2`. And `epacse` is `escape` spelled backwards. I accidentally created a bug that *spells names backwards*. That's almost as funny as some of my graphics-code bugs.

How this happened requires a little bit of explanation. In Scheme, as in most Lisps, adding items to the beginning of a list is fast and safe, but adding onto the end of a list is either slow and bug-prone, safe but extremely slow, or very verbose and therefore bug-prone and hard to maintain. But reversing a list is relatively fast. So I wrote a function that looked like this:

```
(define (stringlist->string stringlist)
  (list->string (reverse (stringlist->string-2 stringlist 0))))
```

Because I thought stringlist->string-2 was going to have to build up a list of all the characters *backwards*, and then I was going to have to reverse it.

When stringlist->string-2 turned out to be able to build up the list of characters in the right order --- by adding them backwards --- I forgot to take out the `reverse`.

Incremental persistent binary array sets

Kragen Javier Sitaker, 2017-04-10 (4 minutes)

Nayuki wrote a very clear description of a data structure she calls a binary array set, or BAS. It's a linked list of sorted arrays in power-of-2 increasing sizes, merged upon overflow; insertion is θ(1) amortized (Θ(N) worst case), and membership testing is average-case and worst-case Θ((log N)²).

I asserted to a friend of mine that incrementalizing it to get Θ(1) worst-case insertion time was straightforward. The transformation also gives you an FP-persistent† version of the BAS data structure. Here I sketch the details.

Merging strategies

With power-of-2 array sizes, if you happen to be at a state with 1024 items, the immediately previous state will have had array sizes of 1, 2, 4, 8, 16, 32, 64, 128, 256, and 512. The item in the array of size 1 will have been merged zero times, the two items in the array of size 2 will have been merged one time, the size-4 array will have been merged from two size-2 arrays and thus each item in it has been merged twice, and so on; the 512-item array contains items that have all been merged 9 times. That is, the items in an array of size 2^n have been merged *n* times. So, in fact, under this merging policy, amortized insertion time per item is not constant; it is Θ(log N).

I thought we could do better using a multi-way merge. All the items in the 1024-item array have been through the same number of merges (10) because the behavior upon inserting the 1024th item is to merge it to produce an array of 2 items, which then must be merged and discarded to produce an array of 4 items, etc, doing a total of $10 \cdot 1 + 9 \cdot 2 + 8 \cdot 4 + \ldots\ 2 \cdot 256 + 1 \cdot 512 = 2036$ work, where each unit is a comparison and a couple of pointer copies. If we instead did a single 9-way merge using a 9-item binary heap, the average work per item is about 3.17, so we end up doing about 3200+1024 work instead. Memory locality is surely better; not counting the accesses to the tiny heap, we only have to do 1024 work this way.

This is not obviously better, and although I haven't done the analysis for real, I don't see a strong reason to expect it to get better asymptotically. So it's probably best just to use the simple strategy.

Incrementalizing

The basic idea is that every time you perform an insertion, you also do enough merge work to ensure that the merging stays ahead of insertion. This is somewhat tricky, in that we can't simply stop merging newly inserted data until the completion of a large merge further down the chain; that would kill our search-time guarantee. So at times a large merge must be paused while a small merge is performed.

As noted above, the

An incremental BAS state is either a merged BAS (one with no

† "Persistent" unfortunately has two conflicting meanings when it

comes to data structures; functional programmers use it to mean that modifying the data structure does not make its previous states inaccessible. By "FP-persistent" I mean this meaning, not the more common meaning of "retrievable after rebooting your computer".

Spring energy density

Kragen Javier Sitaker, 2016-09-05 (updated 2019-04-20) (3 minutes)

What's the maximum energy density of a spring? What material is best?

As you put more and more energy into a spring, eventually you will break it. The properties of the spring material put a limit on how much energy you can store in the material before you break it.

Typically the relevant numbers are yield stress (or elastic limit) and some kind of modulus of stiffness. Some springs are stressed in shear (like a torsion bar in torsion, or a coil spring in compression or tension), while others are stressed in tension or compression, like the surfaces of a leaf spring or a bow.

Common geometries, like the torsion bar, coil spring, or leaf spring, have a zero-stress region in the middle of the material, with stress increasing linearly up to the surface, where it is at a maximum. This geometry reduces the spring's energy density to half of the theoretical maximum for the material. Other geometries, such as tubular torsion bars or I-beam leaf springs, can reduce the wasted weight. Springs stressed in pure compression, like a squeezed block of rubber, or in pure tension, like a stretched wire, do not have this problem.

https://en.wikipedia.org/wiki/Shear_modulus say:

The shear modulus is one of several quantities for measuring the stiffness of materials. All of them arise in the generalized Hooke's law:

• Young's modulus describes the material's response to uniaxial stress (like pulling on the ends of a wire or putting a weight on top of a column),
• the bulk modulus describes the material's response to uniform pressure (like the pressure at the bottom of the ocean or a deep swimming pool)
• the shear modulus describes the material's response to shear stress (like cutting it with dull scissors).

It also gives a table:

Material	Typical values for shear modulus (GPa) (at room temperature)
Diamond[2]	478.0
Steel[3]	79.3
Copper[4]	44.7
Titanium[3]	41.4
Glass[3]	26.2
Aluminium[3]	25.5
Polyethylene[3]	0.117
Rubber[5]	0.0006

http://www.freebase.com/base/materials/solid_material/shear_modulus?instances= has 13 values for the shear modulus that are totally useless because they have no attribution and no units. (Also, they have no precision.)

http://www.engineeringtoolbox.com/modulus-rigidity-d_946.html gives these values:

Material	Shear Modulus - G - (10^6 psi)	(GPa)
Aluminum Alloys	3.9	27
Aluminum, 6061-T6	3.8	24
Aluminum, 2024-T4	4.0	28
Beryllium Copper	6.9	48
Brass	5.8	40
Bronze	6.5	44.8
Cadmium		19
Carbon Steel	11.2	77
Cast Iron	5.9	41
Chromium		115
Concrete	3.0	21
Copper	6.5	45
Glass		26.2
Glass, 96% silica	2.8	19
Inconel	11.5	79
Iron, Ductile	9.1 - 9.6	63 - 66
Iron, Malleable	9.3	64
Kevlar	2.8	19
Lead	1.9	13.1
Magnesium	2.4	16.5
Molybdenum	17.1	118
Monel metal	9.6	66
Nickel Silver	6.9	48
Nickel Steel	11.0	76
Nylon	0.59	4.1
Phosphor Bronze	5.9	41
Plywood	0.09	0.62
Polycarbonate	0.33	2.3
Polyethylene		0.12
Rubber		0.0003
Structural Steel	11.5	79.3
Stainless Steel	11.2	77.2
Steel, Cast	11.3	78
Steel, Cold-rolled	10.9	75
Tin		18
Titanium, Grade 2	5.9	41
Titanium, Grade 5	5.9	41
Titanium, 10% Vanadium	6.1	42
Tungsten		161
Wood, Douglas Fir	1.9	13
Zinc		43
Z-nickel	11	76

(See also You can stuff a UHMWPE hammock in your wallet (p. 799).)

The number I was looking for is called the “specific energy” or “elastic potential energy per unit volume”.

Making a mechanical state machine via sheet cutting

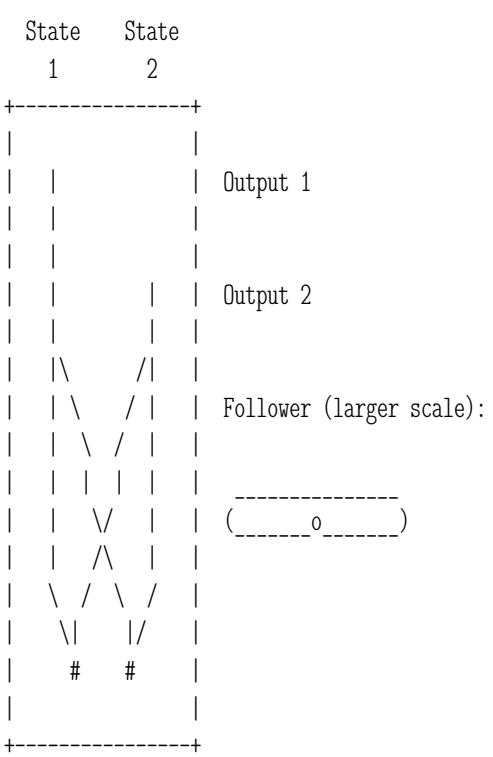
Kragen Javier Sitaker, 2014-04-24 (updated 2015-09-03) (7 minutes)

It occurred to me that there is a simple way to build lookup-table (LUT)-based mechanical finite state machines with planar fabrication. I think this is considerably less dense than than the heightfield- based LUTs I've written about previously. It represents the transition matrix as a maze of channels cut into a surface, with a single follower traversing the maze under the influence of springs and friction.

Press the button on the back of a pushbutton ballpoint pen, and the tip extends; press it again and it retracts. It's a mechanical state machine with two states that takes no inputs. It works by having a rotating cylindrical thingy that slots into guides in the outer barrel of the pen; they force it to rotate when it moves longitudinally.

We can extend this mechanism to more general state machines, that take N discrete inputs and transition arbitrarily between M discrete states, each of which has one of P discrete outputs. The input is encoded as a distance to which you push the thing corresponding to the ballpoint pen button against the spring; the state is encoded in the rotation of the barrel; and the output is encoded as a distance to which the spring is able to push back once the input is withdrawn. And the mechanism is changed somewhat to be able to handle general state machines.

For simplicity of diagramming I will unroll the cylindrical thingy to be planar. Here's a way to realize our ballpoint pen with my new scheme:



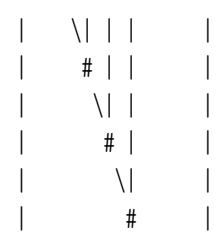
The paths here are smoothly curved channels in the plane. An oblong "follower" with rounded ends begins in either the State 1, Output 1 or State 2, Output 2 position at the top of the diagram, and

is then pushed down to the bottom. It's free to move horizontally, but has to overcome some friction to do so. Where the channels branch, the branch points are wide enough that it is kinematically capable of following either branch; but the horizontal friction ensures that it simply continues straight down; it follows the curves down to one of the transition points marked #.

When the input pressure is removed, it begins to return back upwards, but because it's at a branch point with an available vertical path it follows that branch rather than returning by the same path by which it came — and thus it ends up going to the other state. At the point that the two return paths cross, the intersection is not wide enough to allow the follower to turn to follow the wrong return path, like the shuttles in a trammel of Archimedes.

(If the plane were a cylinder, the two paths would not have to cross over each other, and that is in fact the approach taken by actual ballpoint pens. Also, they typically have a larger number of states, such as 8 or 12, but with only 2 outputs. And commonly they have a separate "nudge" in the thing propelling the follower vertically to push it into the return path, but that isn't strictly necessary.)

When there are multiple possible inputs, there will be multiple return branch points on each path down, branching off at different heights:



These different branch points are independently routable to arbitrary different next states. This lets you use any arbitrary transition function for your state machine. However, in the general case, all these separate M*N return paths need to be able to pass in parallel and cross over before getting back to the states, which puts a limit on how complex our state machine can be in a given space.

This mechanism provides fan-out, but not fan-in: unlike with the heightfield LUT, combining two separate inputs, such as two summands or multiplicands, must be done with some other mechanism. But such mechanisms can be fairly simple.

In addition to wrapping the transition maze around a cylinder, you can also wrap it around on a disc, as shown by the spiral cams in " Basic Mechanisms in a Fire Control Computer (1953)", using rotation rather than translation as one of your dimensions of motion; and indeed, if you distort the other dimension into a series of arcs, you can use rotation rather than translation for both of them, while retaining the compactness of planarity.

Heightfield LUTs are not novel

This video also shows that my heightfield LUT was already invented, in analog form for continuous functions in 1953; apparently it's called a "barrel cam". The Equation of Time Cam, from the first prototype of the Clock of the Long Now, is an example that I had seen. It compensates for the changing time of solar noon throughout

the year.

Investigating further, it turns out that, before 1953, the Jaquet-Droz automaton known as The Writer used a heightfield LUT, in the form of a stack of cams, to encode a vector font; this automaton is a pen plotter with a non-ASCII character set, in the shape of a small boy with curly hair. Three cam followers control the X, Y, and Z motions of the pen, and the axial displacement of the camshaft determines which character is produced. Wikipedia explains that the automaton was constructed between 1768 and 1774. It still works, more or less, and is demonstrated once a month at the Musée d'Art et d'Histoire de Neuchâtel.

In between the Writer and the Cold War barrel cams, the rotational dimension of the cam was generalized to be any continuous input variable, rather than just time; and the axial displacement dimension was generalized to be possibly continuous rather than discrete. I don't know when between 1774 and 1953 these two generalizations occurred, nor whether they might have been present in other machines even before 1774.

This is interesting to me because, as I wrote in 2010, LUTs have major advantages for mechanical digital computation: they're much easier to design than combinations of universal gates like NANDs or NORs, and they also involve many fewer moving parts. So it seems like you could have built a general-purpose digital computer in the 1700s, at least in Switzerland, if you had the idea that it was an interesting thing to want to build.

Bistable magnetic electromechanical display

Kragen Javier Sitaker, 2019-10-24 (16 minutes)

I recently watched a YouTube video by "GreatScott!" demonstrating a bistable magnetic electromechanical 7-segment display; each segment is a slot through which a moving part is visible, one part of which is white, while another part is black. There are 7 electromagnets on the back of the display; by passing a pulse of current through them in one direction or the other, a permanent magnet attached to this moving part is given a kick big enough to swivel the part and change the color of the segment. The permanent magnet has two stable positions in which it is attracted to a ferromagnetic core, so the display remains stable without applied power.

The display is multiplexed with a per-digit common ground, so that, for example, an 8-digit display with 56 segments requires only 15 wires — but 7 of them need to be bipolarity.

Digital electromechanical decoding

It occurred to me that in some sense this was excessive; 7 bipolarity signals (with distinct +, -, and 0 states) can encode $3^7 = 2187$ commands rather than the 14 needed to switch 7 segments or even the 112 needed to switch 56 segments. 7 *unipolarity* signals are enough to encode 128 commands, enough to switch 64 segments on or off. Moreover it should be feasible to route the magnetic flux in such a way that the decoding is done passively, by the magnets.

The crucial tricks are:

- You can route magnetic flux to an area by providing a low-reluctance path from a coil to that area; for example, a sheet of electrical steel, or more prosaically, a mild steel wire. (At kHz and higher frequencies, ferrites might be useful.)
- You can sum flux from different coils by terminating low-reluctance paths in the same area, but with enough of an air gap between them that there isn't a low-reluctance path between the different coils. It's sufficient that the flux they produce impinge on a magnet or magnets attached to the same movable part.
- You can route magnetic flux from either end of a coil, so you can get both subtraction and addition.
- By including fixed permanent magnets in the mix, you can include a constant term in these sums.

This allows you to set the flux in a given area to an arbitrary affine function of the currents in the different coils. Consider an area you want a movable permanent magnet to be attracted to only when the code 0001101 is present on the coil control wires. You route the positive ends of coils 0, 2, and 3 to that area, and the negative ends of coils 1, 4, 5, and 6, and include a fixed permanent magnet powerful enough to counteract the flux from just over 2 coils, but not more.

In this area, if coils 0 and 2 only are energized, they are not sufficient to overcome the fixed permanent magnet, and the movable

magnet continues to be repelled from the area. If coil 1 is additionally energized, it partially cancels the flux from coils 0 and 2, repelling the movable magnet even more strongly. Now if coil 3 is energized, we have 0, 2, and 3 fighting against 1 and the permanent magnet, not quite enough to overcome it; but if coil 1 is then de-energized, the balance flips, and the area becomes attractive rather than repulsive.

In practice this probably means that one such "balance point" is needed for each pixel — a position which can be made a stable equilibrium with the right combination of energized coils, but becomes an unstable equilibrium when power is removed — and once the movable part has been brought to this balance point, one of two additional coils is energized to tip the equilibrium in one direction or the other, while the other coils are de-energized.

(Slightly tweaking this, instead of using two additional coils, you could use one additional coil and a permanent magnet; this means that the balance point is not quite an unstable equilibrium when power is removed.)

So, simply by choosing the polarities with which each coil is coupled to each pixel, we can make a unique combination of coil activations the strongest for that pixel, then provide a permanent magnet strong enough to cancel any combination other than that one. In essence this is an electromechanical McCulloch–Pitts neuron.

Stable, high-coercivity rare-earth or even ferrite permanent magnets will work much better for this than unstable alnico magnets, because one of the magnets needs to have a strength that stably discriminates between the case where, say, 6 coils are activated in concert, and the case where 7 are.

A trick not needed: by using different thicknesses of ferromagnetic material, you can get different amounts of flux from the same amount of electrical current. This allows you to compute weighted sums and differences. However, though this trick is not needed, it is an alternative to using varying strengths of fixed permanent magnets in the different cells; it would allow them all to be the same strength.

PWM electromechanical decoding

A hard disk drive's head is positioned with a voice-coil actuator by running a precisely controlled current through a "voice coil", producing a precisely controlled magnetic field which moves the head to a precisely controlled position within a few milliseconds. Dynamic speakers work on the same principle, moving the speaker cone to what is in principle a precisely controlled position by producing a precisely controlled magnetic field with a precisely controlled ac voltage. Class-D audio amplifiers generate that voltage by, essentially, reactively low-pass filtering a PWM signal.

A very simple way of decoding PWM would put a floating magnetic compass globe, like those people used to have on their car dashboards in the 1980s, in an enclosure with a small transparent window through which a single digit could be seen, out of ten printed on the globe in different positions; a permanent magnet would align the globe to display "0" in its equilibrium position, and a coil producing a field at perhaps 120° from that of the permanent magnet could swivel the globe to any desired position 1–9 by applying an appropriate strength of field. A second coil producing a vertical magnetic field could provide a magnetic dip to counteract the globe's

tendency to return to a default horizontal position; this could be used, for example, to select from a larger repertoire of characters, or to engage mechanical interlocks that kept the globe from turning when power was removed.

(For some reason, the traditional way of doing this, the galvanometer, uses a mechanical hairspring rather than a permanent magnet to return the needle to its zero position when power is removed.)

If you have some array of magnetically-responsive pixels — for example, Dapper-Dan-style magnetic whiskers in tiny mostly-transparent plastic boxes, parts of which are opaque white — you can use a similar approach to scan a needle in a four-bar linkage involving two galvanometers back and forth over this array of pixels, activating a magnetic field at its tip to change the color of a pixel when appropriate. I think we can expect this to be slow and scale down poorly, but it would work.

Tiny permanent magnets behind white paper, or better still boundaries between magnetic poles behind white paper, could potentially make the pixels bistable in the absence of friction — the black filings would remain stably stuck to them in the absence of any applied magnetic field, even in the face of slight vibrations, but could be persuaded to leap to a different attractive spot by a temporary cancellation of the magnetic field with the needle tip.

An advantage of using magnetic-pole boundaries is that the field projected from the magnetic tip wouldn't have to be perfectly calibrated — any amplitude large enough to temporarily more than cancel one of the poles would cause all the pole boundaries around that pole to temporarily disappear, encouraging the filings to migrate to a different still-existing boundary between poles. By alternating the field a number of times, filings in the area could perhaps be vibrated loose from any frictional moorings that prevent them from vacating the area.

Even without any PWM signals, scanning one or more needle tips over a two-dimensional area could be effected by purely mechanical means, for example in a VCR-like helical pattern, or a Spirograph-like family of circles of the same radius rotated around a center, or a Lissajous pattern created by two elastic resonant modes of different frequencies. Then, a persistent image could be produced simply from a time-varying magnetic field at the needle tip.

Non-magnetic equivalents using electrets

Suppose that instead of magnetic fields we use electric fields, and instead of permanent magnets we use electrets, which have the potential advantage of being monopole-capable. (As far as we know, magnetism is not monopole-capable, but all the electrical particles we know of are electrical "monopoles", and so too are chunks of charged electret.) As described in Paper/foil relays (p. 3273), this should scale down rather well. This is more or less how e-ink displays work, but without the in-display decoding.

To be concrete about one possible realization, suppose we have some negatively-charged black electret particles suspended in oil in a tiny linear capsule; one end of the capsule is transparent, while the other end is opaque. We have some more negatively-charged electret embedded in the wall of the capsule near its center, slightly toward

the opaque end, so the particles tend to drift toward the ends of the capsule when no voltage is applied, and in particular if they start out precisely in the center, they will tend to drift toward the transparent end, making the capsule look black. Lines 0, 2, and 3 are connected through capacitors to electrodes wrapped around places near the center of the capsule, but not overlapping, so that their mutual capacitance is low. Lines 1, 4, and 5 are connected through somewhat larger capacitors to electrodes at each end of the capsule, and line 6 is connected through a capacitor to an electrode on the opaque end of the capsule.

If +5V is applied to all of lines 0, 2, and 3, this pushes a certain amount of charge through the capacitors onto the electrodes around the center of the capsule, calibrated to be sufficient to shift the equilibrium such that the suspended electret particles will tend to drift from the ends to the center of the capsule. If only two of these lines are energized, this will not push enough charge onto those electrodes to cancel the wall-embedded electret. If all three of them are energized, but also one or more of lines 1, 4, and 5, there will be a net positive charge in the center of the capsule, but a larger net positive charge at the ends, so electret particles will remain at whichever end they are. But if none of these inhibitory lines are energized, the particles will move to the center, or rather, into a cloud near the center but slightly toward the transparent end.

If lines 0, 2, and 3 are then grounded, the wall-embedded electret will repel the cloud back to the transparent end. But if first line 6 is brought high, it will move the cloud past the wall-embedded electret, and then when lines 0, 2, and 3 are grounded, the cloud will migrate to the opaque end instead.

Of course, the same seven lines can control 63 such capsule pixels in this way, with lines 0–5 varying between inhibitory and activatory roles on different pixels, and line 6 always controlling which way the equilibrium falls when the decoding lines are released. Different capsules may require different amounts of wall-embedded electret to cancel their varying numbers of activatory lines, or perhaps the series capacitances that set the charge could instead be varied.

This is substantially more complex than the current schemes of e-ink displays, and it requires fairly high precision of manufacture to precisely calibrate the varying amounts of electret in each capsule, as well as precision of design to distribute the electrical fields properly.

Non-magnetic equivalents using other kinds of actuators

We can easily go rather far afield with these ideas.

A scanning needle tip (whether raster, Spirograph, Lissajous, or otherwise controlled) of course can be activated in other ways. For example, mechanical actuation — in machining this is called a dot-peening machine and is used for alphanumeric part marking of malleable surfaces, and I've used a handheld "Vibro-Graver" version of the same process to mark my hand tools. In an electrolyte, voltage on a scanning needle tip can produce an image on a surface by selective electroplating or electrochemical machining (depending on polarity), and in air it can produce a corona discharge, which can selectively functionalize passivated surfaces (see Cold plasma

oxidation (p. 2406)) or produce light. If scanned over the same surface in an electrolyte for a long period of time, it can be used to 3-D print by electrodeposition or to cut an almost arbitrary cavity by electrochemical machining. On a few metals, like silver, such electrolytic processes can be used to induce a reversible, localized, dramatic color change; as mentioned in Electrolytic anodizing, with a small movable electrode (p. 3059), anodizing of titanium can produce quite brilliant colors through iridescence, and this can be done selectively to produce color images.

Some of the summing-and-differencing approaches discussed above might be usable to select individual "pixels" in such processes as an alternative to moving a needle around; for example, anodic dissolution of a metal workpiece will happen only in areas where there's a *net* current of positively-charged cations from the workpiece to the tool pixels, while it's possible to prevent anodic dissolution of tool pixels by making them out of carbon, and electroplating of the tool pixels with a suitable electrolyte. So if all but one of the tool pixels have a positive current flowing from them to the workpiece because of summing negative and positive currents, it should be possible to do selective electrochemical machining at the one pixel that is sucking up cations instead.

Relays

Most of the above methods can be adapted to activate electrical switches rather than optical pixels.

Worst-case-logarithmic-time reduction over arbitrary intervals over arbitrary semigroups

Kragen Javier Sitaker, 2012-12-04 (5 minutes)

(Probably a duplicate of a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees) (p. 1190).)

I don't have much time to write this, so I may end up sending out a version that's somewhat telegraphic.

There's an alternative to summed-area tables with a small, linear space cost and linear construction time providing worst-case logarithmic-time reduction over arbitrary intervals over arbitrary semigroups.

Explanation

Summed-area tables

Franklin Crow's 1984 paper, "Summed-area tables for texture mapping" calls them "summed-area tables", and Graphics Gems called them "sum tables". More recently, they're known as "integral images". In the one-dimensional case, they allow you to calculate the sum of values in an arbitrary interval in constant time by subtracting the values from the summed-area table at the ends of the interval: sum(f[m:n]) = -sat(f)[m] + sat(f)[n], where sat(f)[i] = sum(f[0:i]), for a suitably low value of 0.

Decimation

As an extension, you can use a decimated summed-area table, with values only present every (e.g.) 16th or 32nd index, without losing the constant-time property. You may have to consult the original array, but only up to 2*(16-1) or 2*(32-1) values of it, which is constant. This dramatically reduces the space cost of the technique.

Generalization over operations

You can generalize the sum-table idea beyond integer addition? Clearly they work fine for mod-N integer addition, vector addition, and the combination of the two (e.g. XOR). I think your operation only needs the properties of associativity and left inverse, and to preserve the constant-time property, you need the constraint that the operation must be computable in constant time.

(For the N-dimensional case, I think you may also need commutativity.)

A logarithmic-time alternative to sum tables for semigroups

But what do you do if you're interested in an operation that doesn't have a left inverse? For example, the "minimum" operation (or in general the meet operation of a meet-semilattice) can't have inverses of elements, because it's idempotent, so you can't compute it with a sum table.

But you *can* compute it in logarithmic time with a tree. Let

```
mint(f, m, n) = nil if m == n
              = (m, n, min(f[m:n]), mint(f, m, floor((m+n)/2)),
                                    mint(f, floor((m+n)/2), n)) otherwise
```

Now if you precompute mint(f, 0, f.length), which is a balanced binary tree with 2*f.length - 1 nodes, not counting the nils, and which can be computed in linear time, you can compute min(f[m:n]) for arbitrary m, n in logarithmic time given that tree. That algorithm is straightforward.

This algorithm applies to any semigroup over the elements; it can be used to calculate sums as easily as minima, although more slowly than using a sum table.

Space reduction: decimation

Analogously to sum tables, if your leaf nodes represent spans of some 16 or 32 elements instead of 1, you get a dramatic space reduction without losing the logarithmic-time asymptotic performance.

Space reduction: array storage

The contents of the tree produced by the mint() function depends only on m and n, except for the min(f[m:n]); and if f.length is a power of 2, it is a full binary tree. A full binary tree can be stored, as in the classic binary heap, in an array a such that the children of the element at a[i] are at a[2i+1] and a[2i+2] (zero-based). So you can store the minima for the tree in an array (without decimation, of 2*f.length - 1 elements) rather than allocating numerous nodes on the heap.

This requires a slight enhancement to the lookup algorithm to recompute the same (m, n) as the construction algorithm, rather than looking them up in the tree.

Constant-space bottom-up construction

If you construct the tree recursively, in addition to the O(N) space for the results, you need O(log N) stack space. But that is not necessary. If you're using the array storage suggested in the previous section, you can fill the array starting from the end, so that the only auxiliary storage you need for the construction process is a simple counter.

Enhancement: indices

In the case where the semigroup operation is exactly minimum or maximum over a totally ordered set, the value stored in each treenode will be the value of one of the items in the original array. In this case it is strictly more powerful to store the index of that item rather than its value. This may be useful if you have some other data that are indexed the same way.

N-dimensional case

This generalizes easily to k-d trees, although the efficiency guarantees are not as good.

Viral wiki

Kragen Javier Sitaker, 2015-10-15 (3 minutes)

Suppose that you wanted to preserve some textual library and ensure that it remained available. Perhaps you could ensure that by enticing people to comment and contribute, but requiring them to publicly self-host a replica in order to do so.

In particular, you could do this by requiring them to comment by adding the comment in their own local fork of the library and sending a pull request. They could self-host privately, or read without commenting, and remain private; but in order to comment, they would need to host a copy themselves and keep it online long enough for the author to pull from it.

This would ensure that many copies of this library would exist.

Ideally, downloading a replica of the library wouldn't take any more bandwidth than downloading a regular web page. But how much is that?

Right now, 2015-10-15, loading without cache:

Watching a high-resolution YouTube video can easily use 12 megabytes per minute.

So a median web page now is about 2MB of data in the initial load, and another several megs per minute. So it probably isn't useful any more to keep the initial load below, say, ¼MB, and you can probably use 16 to 64 megs of data transfer to do the whole replication if the user doesn't have to wait for all of that, but you probably don't want to cost them 128 or 256 megs. I say this even though finding all of the above sites frustratingly slow, except for Hacker News, because apparently people use them anyway.

(Chris Zacharias's famous "Page Weight Matters" tells about how he made YouTube much more useful in 2009 by reducing the Youtube watch page's weight from 1.2MB to 98kB, enabling its use in areas in Siberia and Southeast Asia where 98kB still took two minutes to load. I think that probably in 2015 the number has gotten substantially higher.)

Urban autarkic network

Kragen Javier Sitaker, 2018-04-27 (1 minute)

The ESP8266 uses 200 mA at 3.3V when operating, which is 660 mW. With a duty cycle of 4.5%, that's 30 mW; in sleep mode it takes a bit under 3 mW. People report success in getting it to average 18 mW. It costs about US$6. Brian Benchoff reports a range of 366 m with the antenna that's built into the printed circuit board. The IXYS SLMD121H04L solar cell costs US$6.20 in quantity 1 and yields 89 mW in, presumably, full sun; it's 43 mm x 14 mm (150 μW/mm²). So you could run an ESP8266 off it during the daytime with a fairly reasonable duty cycle, given reasonable power circuits. A 10000 μF 35V TDK aluminum electrolytic capacitor costs US$2.60 and is 22 mm diameter × 52 mm long; it can store, in theory, 6 joules, which is 9 seconds of full-duty-cycle operation.

You could set up a mesh network of solar-powered ESP8266s 250 m apart in order to provide a communication line. You could drop them in trees, on top of smokestacks, on the roofs of industrial buildings, painted black. Each board might cost US$25, so you would need to spend US$100 per kilometer.

Digital logic with lasers, induced X-ray emission, and neutron-induced fission, for femtosecond switching times?

Kragen Javier Sitaker, 2016-09-06 (3 minutes)

Create and destroy population inversions to make lasing gain positive or negative, thus providing high-gain amplification. Pipeline bits through optical fiber with length comparable to fiber diameter (≈8μm or 30fs, thus enabling switching speeds in the tens of THz). Doped fiber sections pumped from the side by another laser produce an AND gate in the obvious interpretation, but you can do better still with Manchester encoding: the stimulated emission from one pulse leaves behind a lack of population inversion which will attenuate following pulses for a while. Wideband-excitable materials like trivalent-erbium-doped fiber amplifiers may permit wavelength-division multiplexing in computation; the inhomogeneous-broadening-induced effect known as "spectral hole burning", usually considered a nuisance, thus provides a way for pulses at one wavelength to *suppress* pulses at nearby wavelengths. Dynamic memory can also be constructed by using a metastable population inversion to store each bit, as long as the spontaneous-emission half-life is long enough to permit a reasonably low-frequency refresh cycle.

Taking full advantage of these effects will require micron-precision optical-path-length matching.

Induced emission from metastable nuclei

Increasing characteristic operating frequencies with these approaches past the tens of THz requires stimulated emission or at least induced emission at shorter wavelengths. Induced or stimulated emission from nuclear isomers provides a plausible route to six to nine orders of magnitude faster operation; note that these timescales are so short that even deep-sub-nanosecond-half-life nuclear isomers could be useful, dramatically broadening the possible range of possibly useful substrate materials, which should reduce potential conflicts between this computational technology and proliferation concerns. Aside from the present difficulties of inducing metastable nuclear state decay, this approach has another serious difficulty: controlling the flow of high-energy gamma rays is more difficult than simply using optical fibers.

Neutron-induced-fission logic

Aside from the possibility of induced emission from majority-metastable nucleus populations, neutron-induced fission has been known since the 1930s and a practical energy source since the 1940s, and produces prompt neutrons within 10fs of the fission, and they can be channeled to some extent by neutron reflectors. However, it is not entirely clear to me how to use this effect for

computation, since I don't see how to combine two different neutron signals in anything other than a sort of logical OR. Moreover, aside from proliferation concerns, computational devices built using this approach would need the fissile nuclei physically replaced after firing, a process that will surely take at least microseconds if not entire seconds; so although a nuclear prompt-fission chain-reaction logic device could compute with propagation delays in the femtosecond range (if we figure out how to combine signals usefully), its clock rate would be very low.

Affine arithmetic has quadratic convergence when interval arithmetic has linear convergence

Kragen Javier Sitaker, 2016-08-24 (updated 2017-01-18) (10 minutes)

The standard interval-arithmetic approximation is wonderful for ensuring correctness, but it doesn't work very well in regions where the derivative is high. Functions can be perfectly regular in the analytic sense and still have an arbitrarily large derivative. As a result, if you are computing a function over an interval and you chop the interval in half repeatedly, you may end up merely chopping the function's result in half repeatedly. (Or not even that, if it has a singularity.)

Can we do better?

As an alternative, you might think we could conservatively approximate the function's value over that interval $x \in [a, b)$ with a triple (m, d, e) such that $x \in [a, b) \Rightarrow f(x) \in [mx + d, mx + e)$. Just as with simple intervals, there are many possible such triples that could be used; it may not be immediately clear which is the best choice, but I think it's the one with the smallest e - d value. (For a function given as an enumeration of points, there is a usually efficient algorithm beginning with its convex hull.)

The identity function on any interval is represented by (1, 0, 0); the constant k, similarly, is (0, k, k).

Addition and subtraction of such values is fairly easy and reminiscent of that with intervals. Multiplication may or may not have a local maximum which must be taken into account; division, as with interval arithmetic, may or may not have a singularity, as well as perhaps local maxima.

For a regular function, intuitively I expect that, when I divide a small enough interval in half, its derivative should vary by half as much over the interval, because on a small enough interval, its third and higher derivatives create too little change to matter, so it looks like a parabola.

I intuitively guess that the best approximation of a parabolic segment (in the e - d sense) is tangent to the parabola at the midpoint of the interval. Adding a linear function doesn't affect the e - d error, so for analysis we can add a linear function that brings both endpoints of the interval to the X-axis, with the midpoint horizontal. Now if we divide this into two sub-parabolas and do the same with them, their second derivative is the same as the original, but with only half as far to affect the parabola from the horizontal midpoint to the endpoint, it can reach only a fourth as high.

Therefore, I intuitively expect this approach to quadruple its accuracy when you chop an interval in half, so it will need half as many evaluations to reach the same accuracy of some arbitrary regular function as the simple interval-arithmetic method. As a bonus, it provides an approximation of the first derivative over that same interval, but it is not a conservative approximation.

I intuitively expect this accuracy improvement to be crucially

important for a composition of functions, since it means that the output of your approximation is in some sense more precise than its input — so you might not suffer progressive degradation as you get further from the input.

If you extended this approach to use a higher-order approximation than linear, you could perhaps tighten the bounds further; but this isn't necessary in order to get the precision-improvement property mentioned above.

When extended to multiple independent variables, this linear approximation approach requires linear extra work per independent variable; instead of a single variable m, you have a vector of coefficients $[m_0, m_1, ...m_n]$, and the dot product of this vector with the vector of independent variables $[x_0, x_1, ...x_n]$ gives you the approximation correction. Higher-order approximations would necessarily involve sets of coefficients at least quadratic in the number of independent variables.

Bisection methods potentially take time exponential in n in an n-dimensional space.

Arithmetic operations

As I said before, the identity function $i(x) = x$ is represented as $I = (1, 0, 0)$, and the constant function $k_n(x) = n$ is represented as $K_n = (0, n, n)$. But where do we go from there?

Given

- $x \in [a, b) \Rightarrow j(x) \in [m_j x + d_j, m_j x + e_j)$ $(J(a, b) = (m_j, d_j, e_j))$
- $x \in [a, b) \Rightarrow k(x) \in [m_k x + d_k, m_k x + e_k)$ $(K(a, b) = (m_k, d_k, e_k))$

Then what can we say about pointwise operations on these functions?

Addition is fairly simple. Clearly $j(x) + k(x) \in [(m_j + m_k)x + d_j + d_k, (m_j + m_k)x + e_j + e_k)$, so $(J + K)(a, b) = (m_j + m_k, d_j + d_k, e_j + e_k)$.

Subtraction is only slightly trickier; $j(x) - k(x) \in [(m_j - m_k)x + d_j - e_k, (m_j - m_k)x + e_j - d_k)$, so $(J - K)(a, b) = (m_j - m_k, d_j - e_k, e_j - d_k)$.

Multiplication starts to get hairy.

The product $j(x)k(x)$ is guaranteed to be in the interval

```
[min((mⱼx + dⱼ)(mₖx + dₖ),
     (mⱼx + dⱼ)(mₖx + eₖ),
     (mⱼx + eⱼ)(mₖx + dₖ),
     (mⱼx + eⱼ)(mₖx + eₖ)), min((mⱼx + dⱼ)(mₖx + dₖ),
                                (mⱼx + dⱼ)(mₖx + eₖ),
                                (mⱼx + eⱼ)(mₖx + dₖ),
                                (mⱼx + eⱼ)(mₖx + eₖ)))
```

However, which of the four alternatives is the minimum and which is the maximum might vary according to x. The first one expands out to $m_j m_k x^2 + (m_j d_k + m_k d_j)x + d_j d_k$, which can clearly change sign twice over some interval and possibly have a local maximum in the middle.

The quadratic term is the same across all four alternatives, but the linear term varies, and the combination of those two means that the location of the parabola's extremum can vary between the four; each of the four might be the minimum at some point in the interval!

In most cases, both j(x) and k(x) will have known sign on the interval — they are known to be either positive everywhere in [a, b) or negative everywhere in [a, b). If *either* of them meets this criterion, the solution is simple; if j(x) is known to be positive (i.e. $m_j a + e_j > 0$ and $m_j a + d_j > 0$), then XXX

Hmm, the answer to this isn't clear to me right now.

Coming back later to rethink this:

So the idea is that you represent a value y_i computed for some interval $\{x_0 \in [p_0, q0), x_1 \in [p_1, q_1), \ldots\ x_n \in [p_n, q_n)\}$ as some function $\Sigma_i x_i m_i + [d, e)$ associated with that interval, where "[b, c)" means "some unknown number e such that $b \le e < c$"; the representation of that value then is

$(d, e, [(m_0, p_0, q_0), (m_1, p_1, q_1), \ldots (m_n, p_n, q_n)])$

Then, when values are valid over the same interval, we can do relatively straightforward things for arithmetic operations, although I haven't worked out the details in cases of indeterminate signs for multiplication and division. When they are valid over different intervals, we can intersect their ranges and apply a subdivision operation.

In effect here what we are computing with are piecewise-linear approximations of functions with error bounds per piece, rather than individual intervals.

To take a concrete example, in raytracing, we have x_0 and x_1, the pixel coordinates, and we want to compute colors (r, g, and b) as functions of those two values. An approximate solution here is perfectly fine as long as the approximation isn't too wildly wrong. (And in fact common rendering algorithms are wildly wrong for some pixels, the ones that are close to object boundaries.) So we can start with a conservative approximation for, for example, $x_0 \in [0, 1024) \wedge x_1 \in [0, 768)$ — we can calculate the ray directions as intervals, calculate which objects could possibly be intersected by those rays, and calculate what range of colors and illumination those objects could potentially result in, eventually coming up with some kind of conservative approximation for the color gradient of the whole scene.

Once we have this conservative approximation for the scene as a whole, we can compare its error bounds to the error bounds we want to accept for our colors. If it's too large, we break up the interval into subintervals and redo the computation for each subinterval. In the past, doing things like this, I found that dividing into three subintervals was better than dividing into two. Unfortunately the representation gives us no clue as to which dimension is most promising to subdivide. In this case that is quadratically bad in some cases, but with many dimensions it is exponentially bad.

While you're doing the calculation, though, you have some idea how much of the error comes from each independent variable. If you could somehow include that information, with something like forward-mode automatic differentiation, you would have a much better chance of choosing good subdivision dimensions to reduce the error.

However, if you have both many independent variables and many dependent variables, this will be quadratically large. One possible solution to this problem is to redefine the indices of the dependent

variables as separate independent variables, as in the raytracing example in which ultimately there are only three dependent variables, r, g, and b. This, I think, makes the *reverse-mode* automatic differentiation problem computationally tractable, which should help some with the problem of picking which dimension to subdivide.

Measuring the moisture content of coffee and other things with dielectric spectroscopy

Kragen Javier Sitaker, 2019-07-16 (updated 2019-07-17) (28 minutes)

How can you measure the humidity of coffee, rice, beans, yerba mate, flour, oatmeal, polenta, wood, clay, concrete, soil, plastics, and so on?

The measurement techniques described in Trellis-coded buttons to run a whole keyboard off two microcontroller pins (p. 2011) can be applied to humidity measurement, but there are additional issues.

The importance of humidity

On Earth, humidity is a crucially important property for many purposes.

Food

Dried food stored with too much moisture can grow mold, and in particular mold on improperly stored legumes is one of the major causes of human liver cancer in the world, by way of aflatoxin contamination in the food eaten by the humans. Also, extra moisture in food represents extra weight that must be stored and sometimes moved, and food is often sold by weight, so standards of marketability impose maximum humidity contents on foods.

Deep freeze (p. 1465) talks a bit about moisture content of marketed dry food (11% or less for marketed soybeans, for example). Food storage (p. 2706) talks a bit about moisture as a factor in food decay.

Wood and wood products

Wood expands and contracts considerably according to humidity, and so must be dried to roughly the proper humidity before being made into things, so that it doesn't expand or contract too much after being assembled; also, ever since the development of lignolytic enzymes such as lignin peroxidase (probably at the end of the Carboniferous), already-installed wood is subject to attack by fungus if it's humid.

Additionally, humidity in installed wood can indicate the presence of termites, which will destroy the wood, or a water leak, which may destroy things in contact with the wood, as well as permitting fungal growth, as above.

Wood products like fiberboard and particle board are similar to wood in this way, but some of them additionally suffer direct degradation from being wetted. Most varieties of MDF expand about 60% in the cross-grain direction when they get wet, losing most of their already rather pitiful strength in the process, and the adhesives used in in particle board are also often degraded by getting wet, even if the moisture doesn't last long enough to permit mold attack.

Dry wood and wood products also provide substantial insulation

values, while their wet versions do not.

A design sketch of an air conditioner powered by solar thermal power (p. 2233) talks a bit about various organic hygroscopic substances, including wood, and how much water they can absorb: dry wood contains about 12% moisture, while wood in equilibrium with a humid atmosphere can contain up to 25% to 30% humidity.

Clay

The physical properties of a clay body† prepared for pottery-making depend sensitively on its moisture content. In a couple of percent near 20% water by weight, it transitions from brittle "dry" clay, which is still cool to the touch because of the heat-pipe effect as water evaporates from near the humans' fingers, to flexible "leather-hard" clay, which can still be broken, to fully plastic clay which can be deformed arbitrarily as long as it's kept in compression. (Like ductile iron, it still eventually reaches brittle fracture under sufficient tensile deformation.) A fully plastic clay body is a fucking amazing material for forming: it requires very little force to deform it, and because its elastic deformation is so small as to be very difficult to measure, which means that once you form it into a shape, it has very little springback as you remove the forming tool.

There's a further humidity reduction from "dry" to "bone-dry", at which point the object no longer feels cool to the touch, and is ready for firing. Bone-dry clay is still brittle, but considerably stronger than merely "dry" clay.

The precise moisture percentages at which the clay body transitions between these states vary fairly widely depending on the types of clay involved and the other ingredients.

As the clay body dries, it contracts, which sets up stresses in the object, which can deform it, and provokes some dimensional imprecision — the contraction is typically anisotropic due to not only anisotropic orientation of clay grains but also because of external forces present during the contraction process, so the shrinkage is somewhat unpredictable. Nearly all of this contraction is between the "fully plastic" state and the "leather-hard" state; there is dramatically less contraction from "leather-hard" to "dry", and none from "dry" to "bone-dry", and almost none from "bone-dry" to bisque-fired (sintered) ceramic. (Glaze-firing densifies the ceramic further, producing further contraction.)

In the plastic state, the clay is sticky and tends to adhere to whatever you use to form it, pulling it out of shape as the forming contact ends; once it is leather-hard, it is no longer sticky. Plastic clay in a dry atmosphere forms a thin leather-hard layer at the surface which can serve to ameliorate this stickiness.

So, if you form clay in the fully plastic state, you get substantial contraction and consequent imprecision upon drying to leather-dry. If you form the clay in the leather-hard state, you can get near-net shapes, but you are very limited in the deformations you can achieve. You can also *cut* leather-hard clay with a blade, getting glassy-smooth surfaces, although these do not survive bisque firing. Once the clay is dry, it can be further cut to shape with abrasive processes, at the risk of shattering the brittle piece.

So, precise measurements of clay moisture content, down to a fraction of a percent, are very useful for controlling manufacturing

processes, particularly automated manufacturing processes. The humidity at each of these transition regions depends on the precise contents of the clay body, but if you're using a well-controlled clay body, you can calibrate your humidity levels to that clay body and get reproducible manufacturing results.

† For making pottery, we mix clays with other materials, including of course water, but also sand, other "tempers" such as grog (powdered fired clay), flocculants, deflocculants, and organic gums, in order to balance the properties of plasticity, green strength, contraction, firing temperature, and strength after firing; this mixture is called a "clay body", although sometimes in the above I've sloppily called it "clay". Pure clay contracts on drying considerably more than commonly-used clay bodies do, and its green strength and even fired strength are much lower.

Concrete

Concrete needs water to harden, but I think that if it's too wet, atmospheric carbon dioxide can't penetrate, which slows the hardening process. If it dries out before hardening fully, it can become crumbly and impossible to harden. So, during hardening, it's potentially beneficial to monitor the moisture.

Also, continued exposure to water can degrade concrete, particularly if the water contains high concentrations of, for example, chloride or hydronium ions. And, as with wood, moisture in concrete can be a sign of water leakage, which can eventually result in damage to other objects if it continues. If the moisture is sufficient to saturate the surface of the concrete, it usually becomes very visible to the humans by darkening the concrete, but if the surface is kept somewhat dry by exposure to air, moisture in concrete can be entirely invisible.

So, monitoring moisture in concrete is useful both during hardening and long afterwards.

Soil

Soil moisture is crucially important for plant growth, because if there isn't enough moisture in the soil, plants can't suck it out of the soil, so they stop growing and eventually die. Also, if the moisture levels are too high, you get two kinds of fungal problems and a bacterial problem: too much water can suffocate symbiotic mycorrhizal fungi, which are extremely beneficial to land plants (although some land plants can survive without mycorrhiza); too much moisture can help non-symbiotic fungi to eat the plants; and, without access to nitrogen from air, rhizobial bacteria cannot fix nitrogen.

However, the particular level of soil moisture needed for plant growth depends on the salinity of the soil; roots have a harder time pulling moisture out of saline soils due to higher osmotic pressure.

Plastic

Many common plastics, notably including PET, nylon 6, and PLA, are hygroscopic; they absorb water from the air. In ordinary use, this is rarely a problem, or is even beneficial, but it has a couple of important effects on melting or hot-forming the plastics.

First, the absorbed water affects the plastics' specific heat, generally increasing it, so the plastic heats up more slowly. Second, although

these plastics are relatively stable in the presence of water at ordinary temperatures, they hydrolyze at the temperatures used for forming or melting them. (Also, PLA in particular, if kept wet, hydrolyzes to lactate over several months at body temperature, and several years at room temperature.) So they must be dried before molding, which is done by heating them to a lower temperature for several hours.

Static permittivity

Electric charge produces an electric field according to Gauss's law, $\nabla \cdot E = \rho/\varepsilon_0$, where ρ is the charge density and ε_0 is about $8.8541878 \times 10^{-12}$ A² s⁴ / kg m³. But, here on Earth, the electric field we observe is always lower than this prediction — usually about 0.06% lower in air, almost 5 times lower in glass, and almost 90 times lower in pure water. That is, to get a given field, we need about 0.06% more charge than this law would predict, or about 5 times as much charge if the region of interest is mostly filled with glass, or almost 90 times as much charge underwater. (Of course, unless our water is very pure, the charge will leak away over time through electrolytic currents, but we can do this measurement pretty quickly, in much less than a nanosecond, so the leakage is small.)

We explain this by a phenomenon called "electric susceptibility": we suppose that the molecules of the substance have their own electric fields, and they interact with the applied field. For example, in water, the two hydrogen atoms are kind of on the same side of the oxygen, and they have a small positive charge, while the oxygen has a small negative charge, less than an electron. So if we put a negative charge on the left of it, it attracts the hydrogens and repels the oxygen. Because water is a liquid, the water molecule is free to turn around, it tends to turn so that its hydrogens are on the left and the oxygen is on the right ("dipole relaxation"). So then the water molecule's own tiny electric field is subtracted from the electric field of the negative charge we put to its left, and in fact it cancels almost 99% of it under ordinary conditions. So we need 90 times as much charge to get the same electric field as we would predict from Gauss's law.

There are a few different ways that charges can move around inside the substance ("polarize") in response to the applied electric field. For example, in addition to molecules turning around, ions can move around ("ionic conduction"); crystal structures can deform ("ionic polarization"); electrical charge can flow to different parts of a molecule, especially a conjugated compound; and so on. As a general principle, though, because opposite charges attract each other, all of these effects *cancel* the field somewhat; they never make it stronger. The cancellation is never complete, either, because as it approaches completeness, the leftover field's influence on the charges approaches zero, so other influences on them are more important, like thermal motion. So we would expect that usually heat would make this susceptibility go down, and in fact we do see this with water: at 100°, we only need about 55 times as much charge as Gauss's law predicts, instead of the 88 times as much charge we need at 0°.

So usually when we apply Gauss's law, we apply it in the form $\nabla \cdot E = \rho/\varepsilon$, where the ε is a "permittivity" which is ε_0 multiplied by a "relative permittivity" or "dielectric constant" that includes the susceptibility of the medium, as well as the inherent "vacuum

permittivity" ε_0. So, for water at 0°, we say the relative permittivity is 88, and for water at 100°, we say it is 55.

(This effect is also the main reason light travels at different speeds through different substances, which is why transparent substances both refract and reflect light at their surfaces. Rutile — titanium dioxide — refracts light so strongly because its permittivity is even higher than water's, even though it's solid.)

Porous, dry organic materials like paper, wood, coffee, beans, and rice have relative permittivities around 4, which is much smaller than water's permittivity of 88. By coincidence, quartz sand's relative permittivity is also about 4 (it's 3.9) and so is concrete's (it's 4.5). So, if these materials absorb water, their permittivity goes up substantially.

Static relative permittivity is just an approximation

Consider the polarization of water again, though. It happens by turning the water molecules around so that their hydrogens are predominantly on the side toward the negative charge and their oxygens are on the side toward the positive charge. It happens that this effect is close to linear under normal circumstances: slowly applied fields that are quite small compared to the enormous electric fields inside the molecule. But, as you can imagine, this linearity breaks down under other circumstances.

One aspect of this is that it takes a certain amount of time for the molecules to come into this alignment, and some of the energy of the applied field is lost in the process — the molecules in liquid water are shaking around under the influences of one another's fields, and so if you apply a rapid enough jolt of electrical field, they won't respond fast enough. So as the time we're considering goes to zero, or frequency goes to infinity, the susceptibility also goes to zero.

(In optics, this variation of permittivity with frequency is called "chromatic aberration" or more generally "material dispersion".)

So you could imagine rapidly bringing some charge into proximity with some water, over a short time period, like an attosecond. At first you would observe the whole field predicted by Gauss's law in its pure form, the ε_0 form, but then if you left the charge there for a while, gradually the field would decay down to its usual level of about 1% of its original value. Most of the energy has gone out of the field. Where did it go?

And of course the answer is that it went into heating up the water molecules: as they rotated around to come into alignment with this sudden jolt of electrical field, they jostled against each other and gained some kinetic energy. And this is how we heat up water in a microwave oven, by applying an electrical field that goes the other direction every 210 picoseconds or so. This loss of electrical energy to heat is called a "dielectric loss". The dielectric loss is often combined with the dielectric constant into a single complex number called the "complex permittivity".

A thing to note there is that the different susceptibility mechanisms operate on different time scales. Ionic conduction is a great deal slower than dipole relaxation, for example, and water always contains some ions; water absorbed by organic matter or soil usually contains

an enormous quantity of ions. It happens that ions become more mobile when the temperature is higher, so the low-frequency permittivity of moist organic matter is dominated by ionic conduction, and so its permittivity goes *up* when it gets hot, instead of down like pure water's, at least until it's close to boiling. But, for the same reason, the permittivity of water with lots of ions drops sharply with frequency, much more sharply than pure water's, and above a few tens of megahertz, its permittivity becomes dominated by dipole relaxation and drops with temperature, for the reason explained above.

So, for example, carrots contain so many solvated ions that, at low frequencies, they have a relative permittivity of about 600 at 25°, which increases to about 850 at 45°, but around 100 MHz the permittivity of carrots is nearly invariant with temperature. Navel oranges, which contain many fewer ions, only have a relative permittivity of about 200 at 25°, which increases to 250 at 45°, and the point at which their permittivity becomes insensitive to temperature is about 40 MHz. (All of this is according to Nelson's 2006 paper, "Agricultural applications of dielectric measurements.")

(I am somewhat skeptical of the precision of these numbers; theoretical considerations suggest that they come from Maxwell–Wagner–Sillars polarization, which can give you arbitrarily large permittivities because the charges can be separated by arbitrarily large distances.)

Not only the permittivity but also the dielectric loss varies with frequency; the dielectric loss, too, falls with frequency in the limit, but may locally rise over some frequency range.

Another way this linear approximation can fail is with very strong fields. At the macroscopic field strengths we usually observe, the linear approximation is very good, but you can easily see that once, for example, all the water molecules are all pretty well lined up with the applied field, they can't align themselves any further to cancel an even stronger applied field; any further electrical susceptibility must be due to other effects such as the molecules bending, or charge moving around on them, or ions moving through the water, which are much weaker effects. So at high enough field strengths, the relative permittivity of any substance drops back to almost 1, just like its relative magnetic permeability. In optics these deviations from linearity are called the "Kerr effect", and they are one of a few ways to get nonlinear interactions between light beams or to electrically control light beams at subnanosecond timescales. (At even higher field strengths, though, the applied field is stronger than the fields that hold the molecules together and the substance will ionize. This alters its electrical and optical properties more radically.)

This nonlinearity is also very important in practice with ceramic capacitors; among the highest-dielectric-constant materials available are the piezoelectric ceramics barium titanate and lead zirconate titanate, which can have relative permittivities (dielectric constants) in the thousands, and they make possible high-capacitance chip capacitors. But when fully charged to their rated voltage, the capacitance of these capacitors can drop by almost half — the field is almost high enough to cause avalanche breakdown of the perovskite structure, and the permittivity of the dielectric drops dramatically at such high fields.

However, I don't think these strong-field effects are important to the moisture-measurement problem.

Another direction in which the linear approximation fails — for some substances — is in the limit of long time periods. The energy stored in a capacitor at a given field strength is proportional to the permittivity of the capacitor's dielectric; by using a higher-permittivity dielectric, you can store more energy in the same space. So why don't we use water-dielectric capacitors for everything except cases where miniaturization is paramount, since water is so much cheaper than lead zirconate titanate? It turns out that, in the limit of large times, water will always break down in a constant electric field, although the time it takes extends exponentially as the field is reduced. So water-dielectric capacitors do work, and they are used for some systems that need to release an enormous amount of energy very quickly, but they cannot hold their charge for a long time.

A third direction in which this approximation fails has to do with anisotropic materials, which can have greater permittivity in some directions than in others.

Applying permittivity variation to moisture measurement

So, suppose you have some ground coffee, and you want to know how much moisture it contains. The most straightforward thing to do is to place an insulated metal plate in contact with the coffee — for example, a copper pour on a printed circuit board, covered with solder mask — and charge the plate up to a given voltage, like 3.3 volts. The amount of charge needed for this will depend on the permittivity of the coffee. To measure the charge, you can allow the plate to discharge through a known, or at least constant, resistance, and measure the time constant of the decay curve. This gives you a measurement which depends on the moisture content of the coffee.

(For a sensor that isn't connected to earth ground, you might actually need two equal-size metal plates, one treated as "ground", to reduce variation due to the floating voltage of the instrument.)

The problem with this is that, as explained above, the measurement depends not only on the moisture, but also on the temperature. It also depends on how tightly packed the coffee is, because if there's more air mixed in with the coffee, that will lower the measured permittivity. And in situations where the measurement is being taken by placing some kind of handheld sensor against the coffee (or wood or whatever), rather than dumping the coffee into the sensor, you have the additional variables of the size of the air gap between the sensor and the coffee, and the percentage of the plate that is in contact with the coffee.

(I suspect, but am not certain, that all three of density, contact area, and air gap size will have essentially the same effect, in which case we can lump them together into a single unknown, "quantity of material".)

In an alternative arrangement, you run a sinusoidal AC voltage at a controlled frequency into the sensor plate (or plates) and measure the AC current that ensues, thus giving you a measure of capacitance, which varies linearly with permittivity; the phase shift between the

voltage and the current tells you how large the dielectric losses are. If you know enough about the substance whose humidity you're measuring, you can choose the frequency where its permittivity doesn't vary with temperature, only with density and humidity, and then you can use the dielectric losses to determine how much of the substance you're measuring.

More generally, at that point, it's just a matter of estimating two unknowns (moisture content and quantity of material) from two measurements (capacitance and loss factor).

By sweeping the frequency over a wide range, you can obtain a whole spectrum of complex permittivities at different frequencies, which in theory can provide you with an arbitrarily large number of possibly independent measurements. This could allow you to estimate a larger number of unknowns, such as temperature, moisture content, density, air gap size, and contact area, and perhaps even to distinguish between, for example, coffee, human flesh, and rice.

Another possibility is to use an array of smaller "pixel" contacts; for example, a 16×16 array of 4 mm × 4 mm contact areas separated by 1-mm gaps would enable an independent permittivity measurement on each pixel. This would reduce the problem of unknown contact area (where an unknown fraction of the sensor plate is in contact with the material being measured) and also permit the generation of images.

In the cases of soil and concrete, an important additional unknown is salinity. In soil in particular, higher salinity increases permittivity and conductivity, but makes water less available to plants, while higher moisture increases permittivity and conductivity, while making water more available to plants. So if we want to measure the soil's need for irrigation, but don't know the salinity, a simple permittivity measurement is insufficient — we need to estimate both the moisture content and the salinity, and probably the density and temperature as well. For irrigation measurements in particular, it may be feasible to supplement the permittivity measurements with resistivity measurements and thermometer measurements, if you're leaving the sensor embedded in the soil long enough to measure its temperature to some degree of precision.

An alternative approach to controlling for temperature effects is to intentionally heat the material being measured during the sensing process. The dielectric losses being measured will deposit a small and approximately known amount of heat into the substance being measured; since some of the temperature coefficients of permittivity we're talking about above are as high as 2% per degree (20000 ppm/K), even small temperature shiffts might be detectable, and might provide a much-needed additional dimension of variation. That is, you can map the complex permittivity of the sample not just at many frequencies but at many frequencies at many temperatures.

Harmonics and analog electronics

If you're generating the stimulus signal from something like an AVR Arduino, the signals you can generate are somewhat limited — the AVR can easily generate square waves of up to about 4 MHz, and I think that by hacking the SPI you can generate a somewhat noisy 8-MHz square wave. More modern cheap microcontrollers like the STM32L0 and STMF0 lines (see Notes on

the STM32 microcontroller family (p. 3176)) can easily generate square waves and pulse trains at a few tens of MHz. However, as mentioned earlier, the permittivity of moist organic material has important variations up to and above 100 MHz — in particular, you often have to go that high for the dipole-relaxation mechanism to be the dominant contributor to the dielectric constant.

However, an 8-MHz square wave has significant harmonics at 24 MHz, 40 MHz, 56 MHz, and 72 MHz. Perhaps a small amount of analog circuitry connected to the outside of the microcontroller could filter out a particular harmonic for later conversion.

However, if you're doing *that*, maybe you should just offload the whole oscillation and demodulation task onto analog electronics, reserving the microcontroller for just control.

Assigning consistent order IDs

Kragen Javier Sitaker, 2015-09-03 (3 minutes)

In a Java system I'm working on where we simulate trading, we end up with order IDs in the logfiles. Unfortunately, Java's default is to use randomized memory addresses or something for object hash codes, which vary randomly from run to run. This means we can't usefully diff our logfiles. Also, the IDs are 6 hexadecimal bytes.

I think a more useful way to assign order IDs would be with dates: represent the most useful aspects of the date in a short string. In particular, I'm thinking the last digit of the year (since our backtesting simulations cross years), some uniquish ID for the day inside the year (a bit over 8 bits of data, so we can expect a minimum of two characters for this), and then a serial number inside the day.

There's a standard notation for something close to this in the futures markets: ESZ4 is the ES contract with delivery in December 2014, with the letter Z identifying the month, in some sense identifying the fortnight within the year. If we use letters for fortnights in this way, we have 14 or 15 days to discriminate among with an additional letter or number to get to the day, which is entirely doable. Ideally this second letter will be lowercase, and avoid easily misread letters like l, i, and o. Then we can number the orders inside the day with digits.

This gives us IDs like Z4d3, for the third order on 2014-12-04. This is a huge improvement over the current situation: it's a third shorter, human-readable, and consistent from run to run.

From http://www.cmegroup.com/product-codes-listing/month-codes.html:

January	F
February	G
March	H
April	J
May	K
June	M
July	N
August	Q
September	U
October	V
November	X
December	Z

If we wanted to assign two letters per month, sequentially, consistent with the above, we could almost do it:

January	E F
February	G ???
March	H I
April	J ???
May	K L
June	M ???
July	N P

```
August      Q R
September   S T
October     U V
November    W X
December    Y Z
```

If we add B for the second half of February, A for the second have of April, and C for the second half of July, then we can do it, at some cost to consistency. If we're willing to accept that kind of inconsistency, then at the cost of a little more of it, we could eliminate another one: in the above chart, the CME letter is sometimes the first half of the month and sometimes the second. If we make it always the first half, and use out-of-sequence letters for the others, then we end up with this (the six out-of-sequence letters marked with *):

```
January     F B *
February    G C *
March       H I
April       J D *
May         K L
June        M E *
July        N O
August      Q R
September   U P *
October     V W
November    X Y
December    Z A *
```

Convolution with intervals

Kragen Javier Sitaker, 2015-09-07 (1 minute)

If we know that on $[x_0, x_0 + \Delta x)$ function f is always inside [a, b), and that on $[x_1, x_1 + \Delta x)$ function g is always inside [c, d), what can we say about that interval's contribution to their convolution (f * g) on $[x_0 - x_1 - \Delta x, x_0 - x_1)$? (I'm assuming here that this is the right interval, and I might have gotten it a bit wrong.)

I think that the contribution must necessarily be in $[ac\Delta x, bd\Delta x)$, if we assume that all of (a, b, c, d) are positive. (The other cases are important to cover in practice but conceptually don't matter much.) This gives us both an upper and a lower bound. We can extend this to the case of infinite Δx specifically and only in the case where either $a = b = 0$ or $c = d = 0$. Applying this approach to all possible intervals allows us to bound the convolution of two functions by working from an interval-wise decomposition of them.

It might be useful also to know the *integrals* of the functions over the relevant intervals, or at least bounds on them. The contribution to the convolution cannot be more than the product of the integrals (again, assuming all positive).

drag-and-drop calculator for touch devices

Kragen Javier Sitaker, 2015-09-03 (5 minutes)

I wrote an RPN calculator in DHTML, and it runs on my iPhone, but it isn't very usable. One problem is that it's misidentifying some keypresses (apparently shiftKey is false when you press the * on the on-screen keyboard on both Android and iPhone, but the keyCode is the same as 8, and so * comes out as 8, because I was too dumb to use a library) but it has bigger problems. The keyboard eats up a lot of the screen real estate; predictive text like Swype is totally incompatible with instant feedback; you have to switch keyboard modes to get to different operators; there are no arrow keys, much less a Ctrl key to use with the arrow keys; and pressing the wrong key is common, so undoing an error needs to be extra easy.

Fundamentally the issue is that command keys are a bad idea on these touchscreens. They have the usual problems with command keys (they're not discoverable, not selectively available and thus invisibly modal) but also the touchscreen offers very poor precision for keypressing. Instead, it's optimized for dragging, and pointing at things. You could use keys (ideally transparent ones!) for data input, but you probably shouldn't use them for editing.

I think you can usually get about 6 rows of about 4 buttons on a cellphone touchscreen, so a keypress can convey about 5 bits of information. But a drag stop can typically indicate a position to about 8 bits of horizontal precision and 8 bits of vertical precision, or 7 bits each easily — with the caveat that you can't see what the fuck is under your finger.

The ideal drag-and-drop behavior of mouse-driven systems is that, when you start dragging a thing that can be dropped in places, the places it can be dropped will light up, and in some cases emerge from invisibility, in order for the user to be able to discover them. Then you can carefully position the dragged item over the drop target and release it. If a given on-screen object wants to support several different actions from having the same thing dropped on it, those different things need to be different drop targets, perhaps positioned in active zones around it, which can become active only when a drag is in progress. Your drop action is the utterance of an RDF triple: the subject, perhaps, is the dragged item; the object is the object from which the drop target emerged; and your choice of drop target — a delta vector between the drop position and the object of your utterance — provides the verb.

(Naked Objects pioneered this approach to method invocation for business data processing UIs.)

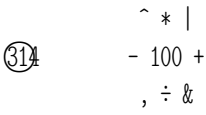
A problem with this on a small screen is that your drop targets need to be damned big for you to be able to see them around your finger, which means you can't have very many of them. Maybe you can dynamically zoom drawers or things as you drag around in order to effectively get more screen real estate, but man. So much loss.

One possible fix to this would be to have the "drop targets" emerge from the *object being dragged* rather than the stationary object; they can

protrude in all directions from under your finger, sort of like a pie menu.

In the calculator case, perhaps you have a number 314 and a number 100 that you would like to combine:

If you start dragging the 100 around, binary operators can begin to protrude from it, while the 314 lights up as a potential target:



and if you position one of those operators over the 314, it will light up; if you then release your touch, the two numbers can combine into a new formula. You can take advantage of the precision of dragging in order to unambiguously select the 314 as the target; if it is embedded in a compound formula, that formula might magnify as you approach it in order to reduce collisions.

Of course, if you could manage to drop the 100 directly on the 314, you could then pop up a pie menu of binary operators, but this seems both more cumbersome and less discoverable.

A different approach, taking advantage of the possibilities for multitouch interaction afforded by modern touchscreens, would be to use two separate fingers for different things, instead of a single drag-and-drop gesture.

Inflatable stool

Kragen Javier Sitaker, 2014-04-24 (6 minutes)

I was at a bus stop today and sat on a discarded inkjet printer. It occurred to me that it would be nice to have brought a stool to sit on while awaiting the bus, but stools are typically heavy and bulky; I'd want something that would fit into my purse (about a liter) without weighing much (the purse weighs about 1kg).

Generally stiff things that can resist compression are kind of heavy, but materials can resist a lot of tension even while being quite light. A simple rope of webbing, like a seatbelt, that could hook onto the roof of the bus stop in two places would make a practical, relatively comfortable, and quite strong hanging seat.

Another way of avoiding the need to carry around materials that can resist compression is to use air to support the compression, as in a balloon. The balloon skin only needs to resist tension, so you can make a pretty large balloon that doesn't weigh much. This couch, almost two meters long, weighs under 3kg: http://www.amazon.com/Blow-Inflatable-Furniture-Sized-Couch/odp/B00245MIAY. A comparably-sized couch made from foam might weigh 30kg.

But how little material could you get away with? I weigh about 100kg (980N) and sit on an area that's about 40cm×40cm, or 0.16m², so an air pressure of 6100 N/m² (6.1 kPa) is sufficient to hold me up. Ambient air pressure is about 101 kPa, so you only need to compress air very slightly to get it up to 101+6 = 107 kPa, say, by sitting on it.

How much material would you need in the skin of the inflatable stool to resist that air pressure? Very little. You can estimate hoop stress for a thin-walled cylinder as Pr/t, where t is the thickness. So the hoop stress of a 25-cm-radius cylinder containing 6 kPa(g) will be 6 kN/m² · 0.25 m / t, or 1.5 kN/m / t.

The biaxially-oriented polyethylene terephthalate film used for mylar balloons and potato-chip bags has a tensile strength of about 200 MPa, almost as strong as low-end aluminum alloys and a lot lighter and more flexible. It's commonly available in 10μm to 100μm thicknesses. To find the thickness needed to contain this pressure, we solve

```
200 MPa = 200 MN / m² = 1.5 kN/m / t
t · 200 MN / m = 1.5kN
t = 1.5 kN / (200 MN / m) = (1.5 / 200 000) m = 7.5 μm
```

If we figure on using a film of several times that thickness, say 20 μm, we should be pretty safe from bursting if we don't totally jump on the thing. How much would that weigh? $2\pi r^2 + 2\pi rh$, figuring 50cm height and 25cm radius, gives us a total area of 1.2m²; so 20 μm would be 24 cc. (7.5 μm would be 9 cc.) PET weighs about 1.38g/cc, so this would be about 33 g of plastic. This is acceptably small.

That's fine as far as it goes, but trying to sit on a paper-thin mylar balloon at bus stops will have some serious practical problems. In the summer, if you're wearing shorts, it will stick to your thighs in an

unpleasant way; but also, the part of it pressing against the rough cement with 6kPa and sliding around as you move will get cut up.

You can solve both of these problems by gluing woven cloth disks to the top and bottom of the plastic, probably the coarser the better. Coarser cloth will weigh more but allow better air circulation and protect more fully against abrasion; as the cloth gets sufficiently coarse, you might want an additional somewhat finer cloth layer between your skin and the burlap or whatever, or between the bottom of the balloon and the ground burlap. This introduces an undesirable tradeoff between weight and performance. Adopting a pattern imitating the reticulate venation of dicotyledon leaves, with a few thick veins separating areas of finer venation, could ease this tradeoff.

The cloth is likely to increase the weight to perhaps as much as 100 g, but we aren't done yet. Now we face the question of how to inflate the thing. It holds about 0.1 m^3 (100 liters) of air, which is around 30 lungfuls; inflating it by mouth would be a lot of work to have something to sit on for only, one hopes, a few minutes.

You could carry around a gas cylinder to inflate it with, but this is impractical; 100 liters of CO_2 is about 200 g. You'd need to empty three 88 g paintball-gun CO_2 cartridges to inflate it fully, and those cartridges weigh over 400 g each, so you'd be carrying around 1200 g of cartridges. Even the 200 g of CO_2 itself is unreasonably heavy.

The most promising solution I've seen so far for inflating things like this is the Windcatcher, which uses a sort of funnel with a low-pressure one-way valve to help you entrain air as you blow into the entrance. I don't know how much it weighs, but they were selling a bag using it for US$40 to their Kickstarter backers; a larger air mattress using it weighs 840g, but I hope that's mostly the bag.

Does SAAS make it harder to ship? I doubt it.

Kragen Javier Sitaker, 2007 to 2009 (7 minutes)

From a comment on the Smoothspan blog, by Damon Edwards of dev2ops.org:

A troubling trend I've noticed is how the benefits of "rock star" software development teams (small, highly skilled, highly motivated) are increasingly neutralized by poor operations.

In an ops heavy SaaS and on-demand world, the software development phase becomes an increasingly smaller part of an application's overall lifecycle. Time and time again we see great code sitting behind the bottleneck of QA, staging, performance testing, and then production deployment.

On the project plan, the "rock star" teams repeatedly deliver great code in record time... but at all but the smallest of enterprises, their "delivery" of code is a long way from where the business is actually realizing the benefit.

I don't know whether this is true or false, but if it's true, it represents the reversal of a trend touted by Philip Greenspun in 1998:

When I graduated from MIT in 1982, my classmates and I had but one choice if we wanted to get an idea to market: Join a big organization. When products, even software, needed to be distributed physically, you needed people to design packaging, write and mail brochures, set up an assembly line, fill shelves in a warehouse, fulfill customer orders, etc. We went to work for big companies like IBM and Hewlett-Packard. Our first rude surprise was learning that even the best engineers earned a pittance compared with senior management. Moreover, because of the vast resources that were needed to turn a working design into an on-sale product, most finished designs never made it to market. "My project was killed" was the familiar refrain among Route 128 and Silicon Valley engineers in 1982.

How does the Web/db world circa 1998 look to a programmer? If Joe Programmer can grab an IP address on a computer already running a well-maintained relational database, he can build an interesting service in a matter of weeks. By himself. If built for fun, this service can be delivered free to the entire Internet at minimal cost. If built for a customer, this service can be launched without further effort. Either way, there is only a brief period of several weeks during which a project can be killed. That won't stop the site from being killed months or years down the road, but very seldom will a Web programmer build something that never sees the light of day (during my entire career of Web/db application development, 1994-1998, I have never wasted time on an application that failed to reach the public).

And by Paul Graham in 2001:

One of the most important changes in this new world is the way you do releases. In the desktop software business, doing a release is a huge trauma, in which the whole company sweats and strains to push out a single, giant piece of code. Obvious comparisons suggest themselves, both to the process and the resulting product.

With server-based software, you can make changes almost as you would in a program you were writing for yourself. You release software as a series of incremental changes instead of an occasional big explosion. A typical desktop software company might do one or two releases a year. At Viaweb we often did three to five releases a day.

I see four possible interpretations:

• Damon Edwards is wrong, and in fact the software development phase is not "becoming an increasingly smaller part of an application's overall lifecycle" as a result of "SaaS", which is what Graham called "server-based software" and what Philip Greenspun called "a service", and in fact the per-user cost to deploy software is continuing to

shrink.

This is a plausible answer; Moore's Law continues to grind away giving us more MIPS per watt and MIPS per CPU, the cost of bandwidth was still falling last I checked, and perhaps more importantly, EC2 and S3 and Hadoop and Puppet and MogileFS and `aptitude` and Xen and `monit` and Cacti and `backuppc` and `nginx` and `perlbal` and `memcached` and Nagios and Erlang and Varnish and Capistrano are reducing the amount of human effort it takes to administer a given number of CPUs and increasing the number of users each MIPS can support. Maybe Damon sees operations becoming more difficult because the internet is still growing, and so the biggest services have to deal with more users now than in 2001 or 1998.

• The effort required to deploy software on centralized servers really is growing out of proportion to the effort required to write it in the first place, and that's because of the dependence on centralized servers. If the software could run on the machines of its users, the way Firefox or BitTorrent or Skype or Emacs does, the users would be the ones deploying it. Of course, they might still find that difficult, but that wouldn't be visible to the software authors; they would just see that nobody was using their software, not the hours of frustration expended trying to install it. But a lot of that deployment effort can still be moved into software (that's the point of InstallShield, `aptitude`, `easy_install`, RubyGems, CPAN.pm, Fink, Darwin Ports, Xen, AppEngine, and so on, although the diversity of items in that list suggests that the job is far from over), and with the effort that can't be, people can avoid duplication of effort by sharing solutions online.

Just because the software runs on its users' machines doesn't mean it can't be providing a networked service; consider BitTorrent or Skype or, for that matter, Sendmail, ircd, or INN.

• The effort required is growing, but not because of centralized servers. But I do not know of any other plausible candidates.

• A post by Jesse Robbins on O'Reilly Radar 3 suggests that some startups get their operations highly automated early on, so they can easily deploy their changes, while others screw up and end up with a mess, and spend lots of time on operations. If this is correct, then Damon Edwards is wrong in thinking that operations *inevitably* consumes a greater and greater proportion of the resources available; he's just working with dumb groups who dig themselves into big holes.

When and why exactly should your code “tell, not ask”? That is, use CPS?

Kragen Javier Sitaker, 2014-01-08 (4 minutes)

Here I explain "tell, don't ask" in terms that explain when and why it's valuable, without the resorts to metaphor and simplistic heuristics often used in the teaching of object-oriented design.

One of the widely respected principles of object-oriented programming is "Tell, don't ask." In the unhelpful metaphorical language often used to describe OO design principles, it is said that, rather than asking objects about their state, you should tell them what to do: send them a message, don't ask them a query. Especially don't ask them a query and then use the results of the query to decide how to modify their state; if you're doing that, you should instead move the logic into that object.

The problem with all of this is that, so stated, it doesn't have enough context. What are we trying to achieve with tell-don't-ask? When might the drawbacks of telling exceed the drawbacks of asking, if ever? How can you tell when you've missed an opportunity to tell instead of asking? What do you do when you think you want the benefits of tell-don't-ask but you can't figure out how to get telling to do what you want? That's what this post is about.

CPS

In the land of compiler implementation, especially the Scheme school, tell-don't-ask is known as programming in " continuation-passing style", or "CPS". It turns out that, if you have polymorphic method calls or closures, and you don't have a stack-depth limit (or you have tail-call elimination) there is actually no limit to the expressiveness of a program that never uses any return values. You can take a program written with return values and transform it, completely mechanically, into a program where no function has a return value.

In a sense, this is obvious: machine code doesn't, generally speaking, have functions or return values, just subroutine call and return instructions. So to execute a program, a compiler must transform it, mechanically, into a form that doesn't need return values. Typically, return addresses and function arguments are pushed onto a stack in RAM, or stuffed into registers and then later placed on the stack. There are various ways to think of the resulting process. CPS takes the position that the return-address and local-variable data on the stack for the calling function is essentially a closure, which is invoked as the last thing that the callee does.

This shows how to transform a function call into a CPS function call: you take the rest of the caller, after the function call is to return, and package it up into a closure that you pass to the function. For example, given this JavaScript function:

```
function add_numbering(parent, domnode) {
```

```
  parent.numbering[parent.numbering.length-1]++;
  var number = parent.numbering.join(".") + ") ";
  insert_before(text(number), domnode.firstChild);
}
```

Suppose we want to transform the concatenation of the trailing ") " into CPS style. It's an invocation of the built-in string-concatenation operation +, which yields the return value we are going to turn into a text node and insert into the document. A generic CPS version of + would take an additional argument that is a closure to which to pass the concatenation result:

```
function concat(a, b, k) { k(a+b) }
```

And we can make the transformation by packaging up the tail end of the function like so:

```
function add_numbering(parent, domnode) {
  parent.numbering[parent.numbering.length-1]++;
  concat(parent.numbering.join("."), ") ", function(number) {
    insert_before(text(number), domnode.firstChild);
  });
}
```

If you've used Node.js this should look really familiar; Node uses explicit continuation-passing style for I/O functions. It does this because one of the freedoms CPS gives you (to be listed later!) is the freedom to suspend a computation and resume it later.

Generalizing this, if you have some function call

Nobody has yet constructed a mechanical universal digital computer

Kragen Javier Sitaker, 2014-04-24 (6 minutes)

The FIBIAC demonstrates an electromechanical machine that calculates the Fibonacci sequence under control by punched cards; later, Chris Fenton, the author, built a purely mechanical version, called The Turbo Entabulator. It's a three-counter machine. He asserts that the machine is not capable of calculating anything more complex than the Fibonacci sequence, but I think it may be able to go a bit beyond this.

Fenton recommends The Mechanism of Weaving, which describes how mechanical weaving machines worked in the late 19th century, and how mechanical computers should have worked.

An artificial muscle computer is a four-page paper from November that claims to describe a general-purpose computer built from 13 artificial muscle relays and a sliding-block mechanical tape memory, implementing the (2, 3) Turing machine proven to be universal by A. Smith, previously conjectured by Wolfram. Artificial muscle relays are electromechanical devices in which an electric artificial muscle compresses a "piezoresistive dielectric elastomer switch". However, this Turing machine is only universal if you first initialize its memory to a certain repeating pattern, requiring machinery that the authors have not implemented. The authors admit they were not able to program it to perform even an addition. In my view, this machine falls short of implementing universal computation.

None of the above have a significant amount of memory. The FIBIAC has almost 30 bits; the Turbo Entabulator has almost 10 bits; and the artificial muscle computer has 8. Konrad Zuse's mechanical Z1 had considerably more, 1452 bits, organized into 64 general-purpose and two special-purpose registers of 22 bits each. However, the Z1 fell short of universal computation because of its lack of control flow, even aside from the finite memory size that has been an unavoidable limitation of all computers constructed so far.

As I wrote before (in the post about heightfields and string) I think the threshold where a stored-program computer becomes interesting, e.g. capable of interpretation or compilation, is around 2K or 4K of RAM, that is, 16 to 32 kibibits. The Z1 was interesting with fewer bits because it, like Fenton's machines, ran its program from a separate read-only memory; the same could be said of microcontrollers, which commonly have less than 256 bytes of RAM --- some as little as 32 --- but invariably have at least 2K of program, and of the Atari 2600, whose RAM was 128 bytes but whose ROM could be up to 64K.

So an interesting question here is how to make a mechanical computer with 16 kibibits of memory. The Z1 had a mechanical latch for each bit, but it might be more practical to use some largish quantity of homogeneous material, like a disc or drum memory, that can be reversibly transformed.

It's not the only option, though. Consider a horizontal 64×64 matrix with a thread hanging from a spring at each point. Below, the threads are clamped in 128 clamps: one clamp that clamps all the threads on each row, and one that clamps all the threads on each column. The clamps maintain thread tension against the springs, so that if a spring happens to be stretched to some position, the clamp prevents it from contracting. If you open a single row clamp and a single column clamp, then a single thread is released, and its spring is free to contract --- unless something is pulling the other end of the thread to a new position before allowing the clamps to reclose. If the machinery can distinguish 16 positions for a given thread, that thread can be said to store 4 bits, and so we have our 16 kibibits.

You don't actually need 128 clamps; if you route the threads through something that keeps them from catching or moving laterally, such as a smooth pipe, you can address an individual thread out of 4096 with only 24 clamps, each of which clamps half the strings. Each string thus must pass through 12 clamps. For a sufficiently large number of threads, ternary addressing would slightly reduce the number of clamps, but 4096 threads is not large enough; you would also need 24 clamps for base 3 or base 4 addressing of 4096 strings. Base-4 addressing would halve the number of clamps any individual string passed through (to 6), and by the same token halving the number of strings in any individual clamp (from 2048 to 1024).

Given the additional complexity of the pipes and the probable difficulties in clamping 1024 strings, the optimal number of clamps for this number of strings is probably somewhere in between 24 and 128. Base 16, which would mesh particularly well with the base-16 contents I suggested above, would run each string through three clamps instead of two, and thus need 48 clamps, each clamping one-sixteenth of the strings (256 of them).

It might turn out that 256 strings is too many, and we need some kind of "chip select" as well as row/column/plane selection.

Rarely are function-local variables in Forth justified

Kragen Javier Sitaker, 2018-04-27 (10 minutes)

This was a big epiphany for me in Forth: you usually shouldn't use function-local variables. Instead, use "global" variables. This is true to some extent in PostScript, too, though less strongly.

First, a disclaimer: don't take what I say about Forth too seriously, because I've never written a significant program in Forth, only exercises like a self-compiling compiler. I've never done anything more than a few hundred lines of code in PostScript, either.

Traditional Forth lacks function-local variables. Function-local variables are crucial to Smalltalk, Lisp, and Algol-family programming for three reasons: lexical locality, recursion, and closures. Forth solves these in different ways, so **it's okay to use non-function-local variables instead**, and this has a benefit for factorability of the code. I would say "it's okay to use global variables instead", but one of the reasons it's okay is that they aren't really global in Forth.

Lexical locality

In Algol-family languages like Pascal or C, if a variable isn't local to a function, it's global to the entire program, which means it be modified by any code at all, including not only other files in your project, but even library modules you don't have the source code to.

By contrast, in Forth, a variable's scope extends only from the point of its declaration over the code that lexically follows it, up to the point where you switch to a different wordlist (or, in traditional Forths, vocabulary) or define another variable with the same name. This is not as small a scope as a C or Pascal function, but it's a much smaller scope than a C or Pascal program, so the variable name collision problem is manageable.

The point about another variable with the same name bears repeating: if you declare another variable with the same name in Forth, the old declaration stops being visible, and each part of the code uses the version of the variable that was visible when it was being compiled.

Languages like Python or Common Lisp are somewhere in between: a global variable (defined with `defparameter` or `defvar` in CL) is not global to the entire program, but just a single module. This reduces the seriousness of the problem.

PostScript, with its odd hybrid of Forth and Lisp semantics, is closer to the Algol family in this sense — its symbols ("name objects") are not module-scoped like Common Lisp symbols, nor are their scopes lexical as in Forth. You can dynamically add and remove dictionaries from the dictionary stack, but this is clumsy (it must be done in every function) and error-prone.

Recursion

In languages like Pascal or C, any function is potentially recursive, which means that if its local variables are not stored in stack-allocated

memory, they could get overwritten by recursive calls. Moreover, local variables are the only language-native mechanism provided for stack-allocation of memory; without them, simple things like recursive-descent parsers become major feats of software engineering.

In languages like Smalltalk and Python, the problem is even worse, because nearly any infix operator in your method could result in a recursive call chain that includes the same method. So even methods that are not intended by their authors to be recursive are likely to need to be re-entrant. (The gradual introduction of pervasive multithreading in the modern C ecosystem has had a similar effect.)

Also, Smalltalk, Lisp, Python, and functional languages like ML strongly encourage you to use recursively-defined data types.

The net effect of all of this is that, in these environments, function-local variables are vastly preferable to statically allocated variables.

By contrast, in Forth, recursion is very much the exception; recursively-defined data types are unusual, and functions can only call functions that are defined textually earlier in the program, except using `RECURSE`, `DEFER`red words, or similar mechanisms, which are unlikely to pop up without the author noticing them. And, if you want to save and restore the value of a variable for a recursive or potentially recursive call, you can do so fairly easily using the operand stack; `A @ B @ RECURSE B ! A !` saves the values of `A` and `B` during a recursive self-call, doing explicitly what Perl 4 or a dynamically-scoped Lisp would save local variables implicitly.

In PostScript, again, the situation is intermediate; recursive function calls are just as easy as in Lisp, and it's easy to define recursive data structures, although at least the native list-like data structure is an array, not a linked list. But PostScript shares with Forth relative ease at explicit saving and restoring variables on the operand stack. PostScript also doesn't have the tricky ad-hoc polymorphism that can give rise to unexpected recursion in Smalltalk and Python; it does use first-class function values pretty often, but rarely in ways that lead to unexpected recursion.

So function-local variables are not necessary to permit recursion in stack languages, and recursion is typically less of a danger.

(It's worth pointing out that function-local variables are not sufficient to make recursion safe. Recursive code can easily get stack overflows or suffer re-entrancy bugs related to nonlocal data structures, and so is prohibited in things like MISRA C.)

Closures

Pascal has very limited closures, which are also present in GNU C, although little-used. In vanilla C, the only way to get the equivalent of a closure — for example, for `qsort` — is to store the data it needs in statically allocated variables, which breaks re-entrancy and thus causes multithreading problems. (glibc provides a `qsort_r` function that takes a userdata parameter to solve this problem.)

Languages like (modern) Smalltalk, Python, Common Lisp, Scheme, Ruby, and JavaScript have closures and use them extensively. So function-local variables become a crucial mechanism for encapsulating state in objects of indefinite extent.

In the Forths that have added local variables, local variables do not provide closures; neither does PostScript support closures with local

variables, since PostScript's dictionary stack amounts to purely dynamic scoping, like Lisps before Scheme. Forth, instead, provides closures with the `CREATE DOES>` mechanism, which is explicit rather than implicit about what state is being stored. I don't know what the PostScript equivalent would be, although I bet you could hack something together with runtime code generation.

So function-local variables do not provide closures to augment the expressive power of PostScript or Forth, the way they do in many modern programming languages.

It's okay to use non-function-local variables in PostScript and especially Forth

In summary, function-local variables in Forth aren't needed for lexical locality, recursion, or closures, and when they're available, they also don't provide closures. And function-local variables in PostScript aren't needed for recursion, and they don't provide closures. So the advantages that make them a no-brainer in other families of languages are weaker or absent. What about the disadvantages?

Function-local variables are more costly in Forth or, especially, PostScript, than in other languages. Consider this particularly egregious case of stack abuse in PostScript (from Heckballs):

```
% Calculate distance from x1 y1 to x2 y2
/dist { 3 2 roll sub  3 1 roll sub  dup mul exch  dup mul add  sqrt } bdef
```

Probably a better way to write this is as follows:

```
/dist { 4 dict begin  /y2 exch def  /x2 exch def  /y1 exch def  /x1 exch def
        x1 x2 sub dup mul  y1 y2 sub dup mul  add sqrt  end } def
```

There are two interesting things to note here:

• The new definition is almost twice as long, 32 rather than 19 tokens, and includes a new error-prone `end` at the end. Also, it isn't clear that it's more readable, as the parameters are necessarily listed in reverse order.
• The new definition isn't as safe to use with `bind def`, because that introduces the danger that the variables `x1` and so on might accidentally be bound to some definition in the enclosing environment, rather than being local variables as intended. (As it happens, in this case there are no such variables, and `bind def` would have worked fine.)

Suppose that instead we use non-function-local variables:

```
/dist { /y2 exch def  /x2 exch def  /y1 exch def  /x1 exch def
        x1 x2 sub dup mul  y1 y2 sub dup mul  add sqrt  } def
```

The size penalty is somewhat less, although we run an even worse variable-collision risk, since this will clobber any values of x1, y1, x2, and y2 that any other function is using at the time — a problem much less likely in Forth.

We could conceivably refactor this into smaller pieces:

```
/is-p1 { /y1 exch def  /x1 exch def } bdef
/is-p2 { /y2 exch def  /x2 exch def } bdef
/dx { x1 x2 sub } def  /dy { y1 y2 sub } def  /sq { dup mul } bdef
/dist { is-p2 is-p1  dx sq  dy sq  add sqrt } bdef
```

In PostScript, you can still do this with function-local variables:

```
/is-p1 { /y1 exch def  /x1 exch def } bdef
/is-p2 { /y2 exch def  /x2 exch def } bdef
/dx { x1 x2 sub } def  /dy { y1 y2 sub } def  /sq { dup mul } bdef
/dist { 4 dict begin  is-p2 is-p1  dx sq  dy sq  add sqrt  end } bdef
```

You can't do that in Forth, any more than you can in C, which makes using function-local variables in Forth very costly to both the flexibility and the predictability of your code. To my mind, predictability is key to its readability.

So using function-local variables, although it's a viable strategy in PostScript, isn't nearly the slam-dunk obvious win that it would be in more conventional languages. In Forth, often, it's actively counterproductive.

An 8080 opcode map in octal

Kragen Javier Sitaker, 2019-08-28 (updated 2019-11-24) (11 minutes)

The 8008, 8080, 8086, i386, and amd64 instruction sets are, unfortunately, usually given in hexadecimal; but they are dramatically more readable in octal. The 8080 opcode map in particular can be drawn rather neatly using octal.

i386 and amd64 examples

Consider this segment of amd64 machine code:

```
400575:     ba 02 00 00 00          mov    $0x2,%edx
40057a:     be 64 06 40 00          mov    $0x400664,%esi
40057f:     bf 01 00 00 00          mov    $0x1,%edi
400584:     e8 a7 fe ff ff          callq  400430 <write@plt>
400589:     ba 01 00 00 00          mov    $0x1,%edx
40058e:     be 41 10 60 00          mov    $0x601041,%esi
400593:     bf 00 00 00 00          mov    $0x0,%edi
400598:     e8 a3 fe ff ff          callq  400440 <read@plt>
```

Here it is in octal:

```
400575:     272 002 000 000 000             mov    $0x2,%edx
40057a:     276 144 006 100 000             mov    $0x400664,%esi
40057f:     277 001 000 000 000             mov    $0x1,%edi
400584:     350 247 376 377 377             callq  400430 <write@plt>
400589:     272 001 000 000 000             mov    $0x1,%edx
40058e:     276 101 020 140 000             mov    $0x601041,%esi
400593:     277 000 000 000 000             mov    $0x0,%edi
400598:     350 243 376 377 377             callq  400440 <read@plt>
```

Here you can see that, for example, all the “load immediate” instructions are "27x", with "x" representing the register: 2 for %edx, 6 for %esi, 7 for %edi, and so on. As it turns out, there are precisely 8 registers that can be addressed in this way, corresponding to the 8 octal digits. And these register numbers are consistent across instructions; here we can see (in some i386 code, from httpdito), 0 representing %eax, 1 representing %ecx, 2 representing %edx again, and 3 representing %ebx (yes, the numbers are not in the same order as the letters):

```
804811c:    120                             push   %eax
804811d:    122                             push   %edx
804811e:    350 354 377 377 377             call   0x804810f
8048123:    132                             pop    %edx
8048124:    130                             pop    %eax
...
8048130:    102                             inc    %edx
8048131:    271 353 226 004 010             mov    $0x80496eb,%ecx
8048136:    061 333                         xor    %ebx,%ebx
8048138:    103                             inc    %ebx
```

```
8048139:        103                     inc     %ebx
```

By contrast, in hexadecimal, the immediate-load instruction ba 02 00 00 00 and the "pop %edx" instruction 5a represent %edx as "a", while "push %edx" and "inc %edx" are 52 and 42 respectively, representing %edx as "2". Moreover, note that in hexadecimal, both "push" and "pop" of registers are "5x", while in octal they are "12x" and "13x" respectively.

So this is the sense in which I say 8086, i386, and amd64 machine code are dramatically more readable in octal. The octal digits correspond neatly to the bitfields in the instruction encoding, in most cases. But even the 8086 opcode map is rather large.

The 8080 opcode map

By contrast, every 8080 opcode is a single byte, though some are followed by one or two bytes of immediate data, so a full opcode table is only 256 cells. It, too, is more comprehensible in octal than in hexadecimal, organizing the instruction set into four 64-byte "pages", although it has some cases where an inconveniently-located two-bit field identifies one of the 8080's 16-bit register *pairs* rather than a single 8-bit *register*. A simple permutation of the rows and columns ameliorates this.

(Beware! None of this has been tested, and it would be surprising if I had found all the errrors in it.)

The 0xy page is largely register-pair operations, occupying three or four columns, with three single-register operations, occupying eight columns:

```
 oxy   x
 B  D  H  M  C  E  L  A
 BC  DE  HL  SP  BC  DE  HL  SP
 0  2  4  6  1  3  5  7
 y  0  NOP  -
 2  STAX  STA  LDAX  LHLD  LDA
 4  INR (increment register)
 6  MVI (mov immediate)
 1  LXI  DAD (double add)
 3  INX  DCX
 5  DCR
 7  RLC  RAC  DAA  STC  RRC  RAR  CMA  CMC
```

The 1xy page is entirely devoted to the MOV instruction, except for 166, which would logically be MOV M, M but is instead HLT.

```
 1xy   x (dest)
 B  D  H  M  C  E  L  A
 0  2  4  6  1  3  5  7
 y
 (src)  B  0  MOV
 D  2
 H  4
 M  6  HLT
 C  1
 E  3
 L  5
 A  7
```

The 2xy page consists of single-operand instructions that implicitly act on the accumulator A, but unlike the oxy page, the operand is in the final octal digit, not the middle one. If laid out consistently with the other pages, this makes the instructions columns:

```
2xy  x
0  2  4  6  1  3  5  7
y
(src)  B  0  ADD  SUB  ANA  ORA  ADC  SBB  XRA  CMP

D  2
H  4
M  6
C  1
E  3
L  5
A  7
```

Finally, the 3xy page contains all the control-flow and stack operations, plus some miscellaneous operations; some operate on register pairs, some on registers, some on neither. Three of these operations (Rcc, Jcc, Ccc) contain a 3-bit condition-code operand instead of a register operand, and the RST instruction contains an interrupt vector number.

```
3xy  x
B  D  H  M  C  E  L  A
BC  DE  HL  SP  BC  DE  HL  SP
NZ  NC  PO  P  Z  C  PE  M
0  2  4  6  1  3  5  7
y  0  Rcc
2  Jcc
4  Ccc
6  ADI  SUI  ANI  ORI  ACI  SBI  XRI  CPI
1  POP  POP
PSW  RET  -  PCHL  SPHL
3  JMP  OUT  XTHL  DI  -  IN  XCHG  EI
5  PUSH  PUSH
PSW  CALL  -
7  RST
```

Why?

The 8080 is interesting to me not just for nostalgic reasons (many of my first computers in the 1980s were Z80-based) but because it's nearly the smallest existing computer demonstrably capable of self-hosted software development with an assembler and running a usable user interface, at least if you have a character generator or printer connected to it. The PDP-8 and LGP-30 are simpler, but John Cowan tells me most PDP-8 development was actually done on a PDP-10 and cross-compiled, as with modern embedded microcontrollers, and the LGP-30 was normally programmed in machine code, with the programmer doing the "assembly" beforehand with pencil and paper. By contrast, although much significant software for the 8080 was written on a PDP-10 (notably Microsoft BASIC), much of it was written under CP/M on the 8080 itself.

Wirth's RISC for Oberon and James Bowman's J1A Forth CPU

are other reasonable candidates, and both are fairly inspired designs with much simpler instruction sets than the 8080, but I think both require more transistors than the 8080, and the available software for them is somewhat lacking.

The GreenArrays F18A CPU design requires, I think, fewer transistors than the 8080 (certainly the MuP21 did) and has a simpler and much more powerful instruction set, but almost no software exists for it, and in particular there is no published self-hosted development environment, as far as I know. (The 18-bit address space is nine times the size of the 8080's, but the chips made so far have only 64 words of RAM per CPU.)

By contrast, the 8080 has existing self-hosted assemblers as well as compilers for Turbo Pascal, Fortran, small-c, Tiny-C, and BASIC; computer algebra systems; display text editors; CP/M, which includes the assembler, a rudimentary filesystem, file management utilities, a REPL, and a debugger; and at least two free-software operating systems — Drew DeVault's KnightOS and David Given's CP/Mish. Yet you can fit the whole 8080 instruction set on a sheet of paper, and its full documentation is a 15-page chapter in the Intel manual.

This is an inspiring example of what is possible, even if the 8080 instruction set itself is kind of clumsy and lame, with the benefit of 40 years of hindsight. Its very imperfection is encouraging — it shows that even deeply flawed hacks can have enduring value and even achieve greatness.

BDS C

I *just learned* that there's a public-domain full C compiler for CP/M written in assembly; BD Software C (aka "BDS C") was dedicated to the public domain in 2002. According to p. 264 of Byte August 1983, this was one of the fastest C compilers available for CP/M, and supported a fairly complete version of the C language (well, for the platform.)

> I, Leor Zolman, hereby release all rights to BDS C (all binary and source code modules, including compiler, linker, library sources, utilities, and all documentation) into the Public Domain. Anyone is free to download, use, copy, modify, sell, fold, spindle or mutilate any part of this package forever more. If, however, anyone ever translates it to BASIC, FORTRAN or C#, please don't tell me.
>
> Leor Zolman
> 9/20/2002

From my point of view, at least, the availability of this software catapults the 8080 architecture from being a vaguely plausible but implausibly inconvenient architecture to program for, to being a simple architecture with a viable self-hosting development toolchain.

Notes on SIP VoIP in 2019

Kragen Javier Sitaker, 2019-06-07 (updated 2019-06-28) (8 minutes)

Looking at getting a SIP provider for international calls. I am somewhat impeded by not knowing anything about SIP and RTP, although I have a SIP client on this phone.

An overview, as I understand it: SIP is the standard call setup protocol for VoIP; RTP is the protocol used for the actual data. The company that hooks up VoIP calls to the PSTN (public switched telephone network) is called a "SIP provider" or "ITSP" ("internet telephony service provider"). Much of the SIP business currently comes from companies who want to hook up their PBXes to the PSTN. A "DID" ("Direct Inward Dial [number]") is a non-toll-free incoming phone number. An "ATA" is a SIP-speaking device you can plug an analog phone into.

SIP phones can speak directly to each other over the internet as well.

Notes on particular providers

voip.ms

Voip.ms seems to be one of the default choices, and I think it would cost US$1.50 per month for E911 service (though maybe that's optional?), US$0.85 to US$1.25 per month for an incoming phone number (plus US$0.40 to set it up), and about US$0.01 per minute both inbound and outbound, including to "toll-free" numbers. You need a minimum of US$15 prepaid to do incoming or outgoing calls, but you can sign up for an account and use their voice call test thing without paying. They offer a broad spectrum of features.

SIPStation

SIPStation offers service at US$24.99 a month for a monthly plan, plus (?) US$1 per month plus US$0.024 per minute.

Vitelity

Vitelity apparently no longer allows new customers to sign up for VoIP since merging with Voyant in February 2018; they're 100% focused on the VoIP VAR market now.

The FreeSWITCH Wiki page has a lot of stuff about working around problems, which I take to mean that they were very popular, not that they had a lot of problems.

Google Voice

Google Voice apparently does support SIP but will cut you off if they detect you're calling 1-800 numbers from a non-US IP address. Added to that is the constant menace that they may link your phone number to your Google account, so a problem on one means losing the other. Not an option I'd ever consider.

Flowroute

Flowroute charges US$1 for setup and US$1.25 per month, plus the Federal Universal Service Fund charge (of some unknown amount?) plus US$0.012 per minute inbound and US$0.0098 per minute

outbound. They default to business accounts but also offer personal accounts. They have technical details.

The FreeSWITCH Wiki page just offers some XML from 2013.

Vonage

Vonage mostly doesn't offer SIP, though the FreeSWITCH Wiki page explains that secretly they do through resellers. Not an option.

Bandwidth.com

Bandwidth.com focuses on "the biggest brands" and has a free trial.

The FreeSWITCH Wiki page explains how to make it work as of 2011.

Notes on particular pages

The above is partly collated from the below.

Freeswitch.org has a list that is far too long to consider. But the page for voip.ms, aka Swiftvox (last updated 2014) shares chunks of XML to use to configure, I guess, FreeSWITCH, to work properly with voip.ms. Also implies voip.ms defaults to being configured for "ata device, ip phone or soft phone", which is what I have, of course.

A year ago, jhalstead was looking at "FlowRoute, Vonage, voip.ms, nextiva, Sipstation". Someone else in the thread suggested Telnyx; another person seconded the FlowRoute recommendation, and cyberchaplain said, "I've personally used Bandwidth, Level3, Flowroute, callwithus and voip.ms and can't complain about any of them really." Others mentioned Vitelity, Touchtone Communications, and Spectrum/TWC, and a Nextiva employee tried to persuade them to switch to hosted. This suggests that, at the time, FlowRoute and voip.ms were the popular options. But this thread is mostly oriented toward companies with PBXes.

An ad for Vitelity used SIPStation as their comparison competitor. The ad seems to be directed at small businesses like a "hardware store or restaurant" who want to get phone service for on the order of US$3.99 a month (vs. US$100 with SIPStation), but also those who want to "scale up to hundreds of trunks". It also mentions SIPStation's ability to spoof caller ID as a benefit, allowing you to use SIPStation for outgoing calls while receiving your incoming calls on a different number. The main point of the post seems to be that it's good to pay by the minute rather than by the phone line, and an addendum notes that eventually SIPStation switched to charging by the minute too. Another addendum notes that Vitelity is now Voyant Communications and "has halted new registrations for the time being".

An ad for SIPStation from 2017 touts the benefits of their pricing; its example company is paying US$499 a month for two locations with 10 lines, but by using SIPStation's "trunk groups" they can switch to just 15 lines an pay only US$374.25 a month. Pretty cheap if you're a company with multiple offices and dozens of employees, I guess.

voip.ms publishes their pricing information as follows:

Outgoing Calls, USA Rates

- Premium Route: $0.0100 (1¢) per minute
- Toll-Free Numbers Value Route: Free

• Toll-Free Numbers Premium Route: $0.0106 (1.06¢) per minute
• e411: $0.99 per call. Must be activated by customer in settings
Incoming calls, USA / Canada DID Per Minute Pricing

• Monthly Fee:
USA: $0.85 to $1.25
Canada: $0.85 to $1.70
• Per minute inbound:
$0.009 to $0.0125
• One time setup Fee: $0.40
• Billing Increment: 6 seconds
• Channels: 25
• Intended Use: Any
Extras Features

• E911/911 $1.50 per month

Seven months ago Blade_Fox moved from Vonage to voip.ms, though they didn't explain why, and wanted help getting SMS working. Mizzlezz, in the comments, is using Bandwidth.com.

Last year johndrwhosmith was looking for recommendations for a "hosted/cloud PBX", saying they were thinking of Nextiva, and slayter commented:

do not use voip.ms unless you are experienced in VOIP or intending for residential usage. They have failed to register as a telecom in Canada and could even be shut down tomorrow with nothing to say about it.

Maybe I'm being too blasé but I don't see that as a big problem.

Four years ago `pseud_o_nym` was going to "port" their phone number from Comcast to ring.to, and RocketTech99 recommended looking at voip.ms (though it was "not [their] favorite provider", they "have a very low entrance cost".)

Two years ago, jrdbm, a reseller of Bandwidth.com's VoIP service, asked for help with some porting problems, and got recommended FlowRoute.

This thread from last year explains when Google Voice cuts you off. People are also recommending voip.ms and Callcentric in there, but I think the Callcentric recommendation is from someone who works at Callcentric.

Counting the number of spaces to the left in parallel

Kragen Javier Sitaker, 2016-10-11 (5 minutes)

Suppose we want to transform a sequence like this:

```
.#....#.#..#....#.....##.#..#....#
```

into another sequence as follows:

```
.#....#.#..#....#.....##.#..#....#
10123401012012340123450010120123 40
```

which is to say, for each position, we want to compute the number of places to the left that you have to go to find a #. (This problem comes from a problem I'm thinking about with regard to coregistration of potentially translated sparse bitmaps with their pointwise products.)

This is super easy in an imperative language:

```
for item in seq:
    if item == '#':
        count = 0
    yield count
    count += 1
```

However, that approach is inherently serial. What does it look like to reformulate this in a way that we can compute with a prefix sum, so that we can automatically parallelize it?

Parallel prefix sum algorithms require the addition operation over which they're computing the sum to be associative, and no associativity is evident in the above at first glance.

The fully general procedure for this transformation on such loops over input is to formulate each iterations of the loop as a function from previous state to next state, the function in question being determined by the input on that iteration of the loop, and then to apply the prefix-sum algorithm to these functions with the "addition" operator being functional composition.

In this case, the loop state is merely `count`, and there are two possible functions:

- on #, `count` is set to 1
- on ., `count` is incremented

Thinking of these as functions from a previous to a next state, they are λc.1 and λc.c+1. These do not form a set that is closed under composition; under composition you have the set {n∈ℤ | λc.n, λc.c+n}, more or less. (λc.0 and λc.c+0 actually don't occur.) The composition rules are then the following:

- (λc.n) ∘ (λc.m) = λc.n
- (λc.n) ∘ (λc.c+m) = λc.n
- (λc.c+n) ∘ (λc.m) = λc.m+n

• (λc.c+n) ∘ (λc.c+m) = λc.c+(m+n)

(These are just the two functions + and K, of SKI-combinator fame.)

You can write this in OCaml with an appropriate data type as follows:

```
let compose = function K a -> (fun _ -> K a)
                     | Plus a -> function K b -> K (a + b)
                                        | Plus b -> Plus (a + b)
```

I feel like this algebra is some kind of semigroup that I should recognize. It isn't commutative, it has no inverses, and although λc.c+0 would be an identity element, that doesn't actually occur in my problem. But it is associative, which is all prefix-sum needs.

From the sequence of `count` values, you can reconstruct the desired original inputs: they're one less than the `count` values.

Given a representation of this set of functions, say =n for λc.n and +n for λc.c+n, you can compute the function in parallel in logarithmic time as follows:

```
 . # . . . . # . # . . # . . . . # . . . . . # # . # . . # . . . . #
+1=1+1+1+1+1=1+1=1+1+1=1+1+1+1+1=1+1+1+1+1+1=1=1+1=1+1+1=1+1+1+1+1=1
  =1  +2  +2  =2  =2  =1  +2  +2  =2  +2  +2  =1  =1  +2  =2  +2  =1
      =3      =2      =1      +4      =4      =1      =3      =4  =1
              =2              =5              =1              =4  =1
                              =5                              =4  =1
                                                              =4  =1
                                                                  =1
                                                              =4  =1
                              =5                              =4  =1
              =2              =5              =1              =4  =1
      =3      =2      =1      =5      =4      =1      =3      =4  =1
  =1  =3  =5  =2  =2  =1  =3  =5  =2  =4  =6  =1  =1  =3  =2  =4  =1
=2=1=2=3=4=5=1=2=1=2=3=1=2=3=4=5=1=2=3=4=5=6=1=1=2=1=2=3=1=2=3=4=5=1
 1 0 1 2 3 4 0 1 0 1 2 0 1 2 3 4 0 1 2 3 4 5 0 0 1 0 1 2 0 1 2 3 4 0
```

In theory, this only takes 14 computational steps on each of 34 processors, rather than the 34 needed to calculate the same thing serially. In practice, it is going to be difficult to find hardware that can realize a 2x speedup on that problem. But for 4096 positions instead of 34, it should only take 26 steps rather than 4096, so you do eventually get a speedup if you have enough hardware, even if your chunk size is larger.

This was only possible for this algorithm because the state kept from one loop iteration to the next was relatively compact. If the state grows proportional to the number of iterations (or worse), you will never get a speedup.

What kind of Sufficiently Smart Compiler would it take to analyze the serial program and parallelize it in this way? Because here's the code you get to write in OCaml for the parallel version:

```
type counter = K of int | Plus of int
let compose = function K a -> (fun _ -> K a)
                     | Plus a -> function K b -> K (a + b)
                                        | Plus b -> Plus (a + b)
```

```
and init = function '#' -> K 1 | _ -> Plus 1
and final = (-) 1
in prefixsum init compose final
```

which I feel is not just longer but dramatically less clear than the serial version

```
for item in seq:
    if item == '#':
        count = 0
    yield count
    count += 1
```

even though the latter is in some sense written at a lower level of abstraction.

Piezoelectric engraving

Kragen Javier Sitaker, 2017-07-19 (4 minutes)

You should be able to engrave permanent images on metal or glass using a ceramic or metal stylus on a flexing piezoelectric arm with no joints, somewhat similar to the needle of an STM or AFM. Aluminum oxide (sapphire) is probably the easiest ceramic to use, although it provides no electrically-conductive feedback about contact; metal (hardened tool steel, say), or conductive ceramics like tungsten carbide, would remedy that shortcoming, allowing sensitive calibration of engraving depth.

The total movement range of such a setup is likely very small, in the neighborhood of a millimeter, but it can potentially micro-forge the surface of the metal with sub-nanometer resolution, enabling the direct engraving of holograms. I'm not sure what it will do on glass, but I think it's possible to get it to make scratches rather than just break the glass.

To take a random example, the American Piezo catalog lists a "PSt 150/5x5/7" osi-type piezoelectric stack actuator of 5 mm × 5 mm, 9 mm long, with a maximum stroke of "13/9" µm (not sure what's up with the two numbers), 800 nF capacitance, resonant frequency of 100 kHz, 120 N/µm of stiffness, 1600 N of blocking force, with a maximum load of 2000 N, operating from -30 V to +150 V. If you hook up three of these things in parallel to a chunk of metal with a grain of aluminum oxide on its tip, they could jam that grain 9 µm into a bit of aluminum, titanium, glass, or even steel, pull it back out, move it into a different position, jam it back in, and repeat, at 25 kHz (two octaves below resonant) without any difficulty.

If the chunk of metal has a 10:1 aspect ratio, for example if the piezo actuators are attached to it 20 mm apart and it's 200 mm long, then you can wave that little grain of sapphire back and forth by 90 µm, almost the width of a hair. Some kind of flexure-lever arrangement to amplify this by another factor of 10 might be a good idea.

You could presumably engrave data on a little spot at about 50 kbps in this way. (They also offer flat chip actuators with a shorter stroke but much higher resonant frequency, like 500 kHz.) But then you would probably need some kind of repeatable positioning apparatus to engrave over a wider area.

The pressure generated is enormous. Supposing that the tip is up to 25 µm in diameter, 1600 N spread over 490 square microns is 3.3 terapascals. Different metals have yield stresses in the range of 90 MPa (copper) to 2.5 GPa (piano wire), with around 500 MPa being normal; this is 6600 times lower. (Actually annealed aluminum is down around 15–20 MPa.) Sapphire's ultimate tensile strength is only around 1.9 GPa, and diamond only 2.8.

(Oops, actually the force and pressure from the actuator is potentially 3× that if you have three parallel actuators.)

So you really could find a way to gear these actuators up by a factor of 1000 or so, it would give you a stroke of 9 mm with potentially nanometer precision, and still plenty of force to engrave the surface. (I suppose this is why normal STMs use bending actuators.) If you

could still manage 50 kbps, although this seems more dubious, you could engrave a 9 mm square area at 500-nm resolution at 0.0125 mm² per second, filling the whole area in about two hours. This is a good timescale.

Unfortunately, at least the Physikinstrumente devices that gear up piezoelectric actuators in such a fashion have much lower resonant frequencies, like 150 Hz.

As an alternative, maybe you could use electromagnetics, which can also reach up into the MHz range.

Review notes for Chris Anderson's "Makers"

Kragen Javier Sitaker, 2013-05-17 (5 minutes)

I didn't know he was a programmer.

His central thesis seems to be that digital designs, because they're files and therefore copyable, can be shared online --- and therefore, I suppose, will be; and that this will result in empowering individual inventors: "Would-be entrepreneurs and inventors are no longer at the mercy of large companies to manufacture their ideas." (p.29)

I'm probably not the best critical audience for this thesis, since it's a thesis I've been promoting myself since at least 1999. So I'm already prepared to believe it.

How could this decentralization and empowerment fail? One way would be in the way that Facebook and Apple have tournamentized software development, creating an incentive structure in which the aggregate value created by "app" vendors is dramatically less than the amount spent creating the apps, and only the very best apps are profitable. Anderson says, (p.61) "Today we are seeing a return to a new sort of cottage industry," while acknowledging that the original cottage industries "were always at the mercy of the industrialists." (p.60) He's optimistic that since the invention and not merely the manufacturing are distributed (indeed, in the model he promotes, it's the reverse: the manufacturing is centralized in service bureaus) that the new cottage industrialists will have the power to set their own prices and generate high profits.

Anderson's usual carelessness about the truth is in evidence; on p.44, for example, he talks of "spinning multiple threads of cotton from flax", a feat worthy of Rumpelstiltskin; on p.47, he repeats the gross distortion that the privatization of common grazing grounds was an "Improved farming method" that "avoided the 'tragedy of the commons' problem", which has been amply rebutted elsewhere; he claims, "The original Moore's Law, named after Intel researcher Gordon Moore, described the twenty-four-month doubling of processing power per dollar that has characterized the computer industry since the 1970s," (p.84) which contains at least four factual errors and possibly five; "a mathematical equation of how to make it... [i]s actually the way CAD programs work" (p.85); he consistently misapplies the term "scale-free network" (p.136) in a way that suggests he has no idea what it means: a network where there are a lot of nodes with many more connections than average, such that the fraction of nodes with more than k connections is proportional to k to some power around -2 or -3;

He refers back to his first book, *The Long Tail*, to explain his thesis: in the absence of shelf-space restrictions, many more books became profitable to sell, and too with music, software, and anything else that you can download. He cites a "shift in culture toward niche goods." But the strong version of the thesis in *The Long Tail* was that the majority of Amazon's sales came from books you couldn't find in your local bookstore; that is, that niche goods were not only more popular, but more popular than the "mainstream" goods that

shelf-space restrictions used to confine us to. That turned out to be wrong, because of bad estimates of Amazon's sales numbers. You can, of course, make it true by choosing your arbitrary dividing line between "mainstream" and "niche" to be above the median, but it turns out that if you do that, then there's an awful lot of "niche" books in bricks-and-mortar bookstores too. ("Even Wal-Mart now sells more than a hundred kinds of mustard," p.78.)

His enthusiasm for his new model of production ("the perfect combination", p.80; "anyone can get access to manufacturing and distribution", p.89; "this is revolutionary", p.97; "MakerBot is...a revolutionary act...a political statement", p.104;) turns me off and makes me doubt his objectivity.

One thing that I thought was interesting and new is the distinction he draws between Toffler's "mass customization" (Dell computers, Nike ID shoes, monogrammed iPads, etc.) and his new prediction of "a mass market for niche products" (p.88).

There are numerous useful tidbits of information; a square foot of laser-cut plywood or plastic might cost US$15 (p.107); the names of popular service bureaus like Ponoko and Pololu (p.107); the names of popular 3-D design web sites like Thingiverse (XXX); "entrepreneurs...price their product at at least 2.3 times its cost" (p.117); the reward hierarchy 3D Robotics uses to entice contributions from DIYDrones members (p.121); unfortunately, I worry that Anderson's lack of reliability on things I already know means that he's not a reliable source for information in things I don't.

Plastic cutters

Kragen Javier Sitaker, 2019-04-20 (5 minutes)

My flesh has a Young's modulus much less than that of steel, but by holding a file or saw in my hand I can cut steel. The force on my flesh is the same as the force on the steel — except for a nearly irrelevant term of tool weight — but it is distributed over a larger contact area.

Similarly, I think we can produce plastic machinery that can cut harder materials, such as steel, by holding small "tools" or "teeth" of ceramic or hardened steel. The small tools might not themselves be of particularly ideal geometry — perhaps they are the results of crushing a zirconia knife or a silicon wafer with a hammer, for example — if the plastic machinery and control system is adapted to the particular geometry they have, if it uses sufficiently low cutting forces, and if the geometry has sufficiently sharp points (though points that are too sharp will slow down cutting).

The first part of the idea is simply that the rigidity of the connection between the tool and its holder should be at least comparable to, and ideally exceed, the rigidity of the contact between the tool and its work — each of which is a Young's modulus multiplied by a contact area. So if, for example, the tool holder is nylon or polystyrene, with their Young's modulus around 3 GPa, while the workpiece is a titanium alloy with a Young's modulus around 110 GPa (steel is around 200 GPa), the contact area on the workpiece needs to be more than 40 times smaller than the contact area on the tool holder — ideally more like 400.

That's actually the less important criterion, though; it's actually possible to cut with a tool held by a tool holder that deflects more than the material does, although it's going to need complicated control algorithms to get decent precision that way. The more important criterion is that the tool holder's yield strength needs to be greater than the ultimate strength of the cut surface — the first being the yield stress multiplied by the contact area, the second being the ultimate stress multiplied by the tearing area. Titanium's ultimate strength is 900 MPa with 6% aluminum and 4% vanadium; A36 steel's is only 400 MPa. Meanwhile 6–6 nylon's yield stress is around 45 MPa and polypropylene's is around 12–43 MPa.

So, even though the strength criterion is more important than the rigidity criterion, you can meet the strength criterion easily if you can meet the rigidity criterion, because common materials vary much more in elasticity than they do in strength.

For cutting softer materials like wood, bone, or fingernails, broken glass teeth would work fine.

Suppose that the tooth is silicon carbide, with its Young's modulus of around 450 GPa. (I don't know what its ultimate strength is, but I don't think it will often come into play here, since I assume everything else around it will break first under the desired low-shock conditions.) Suppose you're pushing it into A36 steel, with its 200 GPa modulus and 400 MPa ultimate strength, and that the splitting part of the metal is comparable in size to the contact area, which is, say, about a 1 mm circle, 0.79 mm². To get the steel to cut,

you need a force of 314.159 newtons, which will also have compressed the steel immediately around the cut by 0.2% and the tooth by 0.1%. If your holder is 6–6 nylon, then in order to not yield at 45 MPa, it needs a surface area of 7 mm² pressing on the root of the tooth, and that plastic will squish by 1.5%; to squish by less than 0.2% it would need to be 52 mm², an 8-millimeter-diameter circle — a rather large chunk of carborundum! The parts of the workpiece and the tooth holder ("gum"?) further away from the tooth will be resisting the same force over a larger cross-sectional area, unless the workpiece is very small, so the deformation will be less.

These rather demanding dimensions for the tooth and tooth holder can be improved by using an intermediate material between the plastic and the ceramic, such as brass, aluminum, or steel, into which the tooth will be set in order to be grasped by the plastic. In the above example, the 8-mm-diameter circle of plastic could be grasping a chunk of aluminum, brass, or steel, which in its turn grasps the tooth itself, and is perhaps brazed or soldered to it.

The fable of the specialized fox

Kragen Javier Sitaker, 2019-08-17 (1 minute)

A fox was hunting and had just caught a rabbit, and just after he began eating his dinner, a wolf appeared behind him.

"Hello," said the wolf, "I wanted to talk to you about economics. Have you heard how specialization improves productivity and brings prosperity to everyone?"

"No," said the fox.

"If we each specialize in the area where we have the most comparative advantage, we can get better at it and be more productive. Shall we try it?" said the wolf.

"Okay," said the fox.

"I see you're very good at hunting, so I think it would be great if you specialized in hunting, and I'll just specialize in allocating the resources that result from your work," said the wolf. And so he ate the rest of the rabbit the fox had caught.

"Well," said the fox, "I'm not sure I like this kind of prosperity. But I guess I can have a couple of specializations, right, as long as they don't conflict with yours?"

The wolf assented.

"I think I'll specialize in urination."

The next week, the wolf died of an exploded bladder.

How can we usefully cache screen images for incrementalization?

Kragen Javier Sitaker, 2013-05-17 (18 minutes)

Earlier: http://lists.canonical.org/pipermail/kragen-tol/2012-July/000963.html

Okay, so, if you write your program purely in terms of pure functions, you can memoize those functions, perhaps applying a global caching policy to their results to optimize throughput or limit expected latency. I've written about this a bit before.

You can do a bit better than pure functions: you can run arbitrary code with read-only access to the entire program state, as long as its access to that state is mediated by a sort of software-transactional-memory layer that records everything it reads. Then you can automatically invalidate the cached result whenever any of the state variables that fed into it are changed or invalidated.

I was thinking about trying to apply this paradigm to a smallish program this weekend, one which redraws the screen frequently. I'd like it to just redraw the relevant part of the screen. At the moment, I'm sending text and escape sequences to a tty, but more or less the same principles apply if you're updating a framebugger.

The program displays a spreadsheet-like table with editable text in the cells. Sometimes it updates the layout.

But most keystroke events result in a single letter being added to the screen, overwriting a blank space, or a single letter being replaced with a blank space; many others result in highlighting one cell of the table and unhighlighting another.

There are perhaps 100 characters per line and perhaps 20 lines on the screen, for about 2000 characters in total. The simplest way to make the program work is to redraw the whole screen after every keystroke, which does run acceptably fast on modern hardware. But this does something like 2000 times as much work as necessary: 22 Moore's Law years, taking us back to about 1980. It would be nice to find an approach to only redraw the changed part of the screen, not even the entire line.

Now, if you're only looking at the bytes coming out of the program, you can achieve this by redrawing an in-memory screen image, comparing it to the previous screen image, encoding the delta in bytes, and sending that to the tty. But that doesn't really touch the orders-of-magnitude issue.

Variable per character

You could have a couple of transactional-memory variables for each character position on the screen, and *monitor* a function for each of those characters. To update the screen, you'd see which characters had changed, and iterate over them sending them to the screen. This has presumably order-of-magnitude overheads, but it ought to be scalable.

What does the function for a character look like? Something like

```
char_to_show(x, y) = (highlight if is_current(cell_obj) else normal)(char)
where:
    cell_obj, label_index = table_cell_covering(x, y)
    label = label_of(cell_obj)
    char = label[label_index] if label_index < length(label) else ' '
```

Each of these functions could reasonably be cached, but `table_cell_covering` is kind of a bear, because it depends on the current layout, which depends ultimately on the contents of every cell that isn't to the right:

```
table_cell_covering(x, y) = cells[col][y], dx
where:
    col = find_col(x, 0)
    dx = x - col_start(col)

find_col(x, col) = col if found_col else find_col(x, col+1)
where:
    found_col = (col == n_cols - 1 or col_start(col+1) > x)

col_start(col) = 0 if col == 0 else col_start(col-1) + col_width(col-1)
col_width(col) = col_width(col, n_rows)
col_width(col, row) = 0 if row == 0 else max(col_width(col, row-1), w)
where:
    w = length(label_of(cells[col][row-1]))
```

Now, `col_start` can clearly be cached usefully: it has a small number of distinct argument values, and it depends ultimately only on the lengths of the labels of the columns of `cells` to the left of the requested position. You could alternatively cache `col_width`.

But that means that if you change the label of, say, the bottom left cell, the `col_start` values of every cell in the matrix needs to be revalidated --- just in case you changed the width of the first column. Usually you won't have, but if you did, the whole screen might need to be updated. You'd have to redo the `col_start` computation to see that it hadn't changed, and then, if you'd propagated an "invalidated" notification downstream to the `find_col`, `table_cell_covering`, and `char_to_show` computations, follow it up with a "revalidated" notification.

But that means you're delivering thousands of "revalidated" notifications, which is basically what you were trying to avoid in the first place.

How could you avoid this?

• Eagerness: instead of merely invalidating `col_width(col, row)` when you change `cells[col][row-1]`, necessarily propagating the invalidation to `col_width(col)`, `col_start(col+1)`, and so on, you could simply re-evaluate `col_width(col, row)` immediately, probably coming up with the same value again and avoiding pushing the change further downstream.

• An idea that doesn't work: Deep validation checking: instead of propagating the invalidation flag to thousands of character positions, so that the operation of cache validation for `char_to_show(x, y)` is O(1), you could make the is-valid check on the character position dig into

the dependencies and dependencies of dependencies of the character position, so that whenever you run the is-valid check on any of the changed character positions, it notices whether a relevant cached `col_start` value has changed. This doesn't work because it presupposes that you're iterating over all the thousands of character positions in order to figure out that you need to update only one character position on the screen, which is what I was trying to avoid in the first place.

• Aggregation: Instead of making each of the 2000 or so character positions a tracked variable, divide the screen into about sqrt(2000) regions: say, half a line each, which should give you about 40 variables. Then your initial invalidation notification ends up affecting, say, half the screen, but that's only about 20 invalidation notifications; and then you can iterate over those 20 chunks of visible text and figure out that 19 of them are still up-to-date, and the other one has changed, and redisplay its 50 characters. This means that you're doing about 100 things (including redisplaying 50 characters) instead of 2000, but that's still a long way from 1.

Side-effecting transactions: I don't think they'll work

In transactional memories used for concurrency control, your transaction code can choose any arbitrary variable in the STM to write to. Your writes are buffered, and if your transaction successfully commits, they become visible to later transactions, and if there are currently running concurrent transactions that have read the modified state variables, those other transactions are aborted.

By contrast, I've been proposing a purely-functional computational model here. The problem is that it's fairly absurd to think of going through a computation like this:

```
char_to_show(x, y) = (highlight if is_current(cell_obj) else normal)(char)
where:
    cell_obj, label_index = table_cell_covering(x, y)
    label = label_of(cell_obj)
    char = label[label_index] if label_index < length(label) else ' '

table_cell_covering(x, y) = cells[col][y], dx
where:
    col = find_col(x, 0)
    dx = x - col_start(col)

find_col(x, col) = col if found_col else find_col(x, col+1)
where:
    found_col = (col == n_cols - 1 or col_start(col+1) > x)
```

in order to figure out what to draw in a *single character position in a terminal*, even if `is_current`, `label_of`, and `col_start` are all fully cached. (If you extrapolate this example to pixels, the problem is even worse.)

Consider, by contrast, this imperative push-based code:

```
show_cell(row, col) =
    cell = cells[col][row]
```

```
label = label_of(cell)
x = col_start[col]
width = col_width[col]
start = row * screen_width + x
len = length(label)
memcpy(&screenbuf[start], charptr(label), len)
memset(&screenbuf[start + len], ' ', width - len)
color = (highlight if is_current(cell) else normal)
memset(&attrbuf[start], color, width)
```

This is doing about the same amount of work as the pull-based code above, but it's displaying the entire cell, not just a single character!

The basic problem here is that each cell of the table only affects a small number of character positions on the display. It's reminiscent of the problem with the functional stream-based "unfaithful Sieve of Eratosthenes" that Melissa O'Neill identified in her paper, *The Genuine Sieve of Eratosthenes*; where she says:

> In Eratosthenes's algorithm, we start crossing off multiples of 17 at 289 (i.e., 17× 17) and cross off the multiples 289, 306, 323, . . . , 510, 527, making fifteen crossings off in total. . . .
>
> After finding that 17 is prime, the unfaithful sieve will check all the numbers not divisible by 2, 3, 5, 7, 11 or 13 for divisibility by 17. It will perform this test on a total of ninety-nine numbers (19, 23, 29, 31, . . . , 523, 527).

Analogously, to figure out what to draw at the character position (60, 4), my side-effect-free table-drawing code must ask whether column 60 is in table column 0, then whether it's in table column 1, and so on, until it finds the correct column; and then it must do the same computation again for column 61, and column 62, and so on. By contrast, the imperative algorithm can do the analogous computation with a simple array lookup, and then it can handle the entire string contents of the label with a simple `memcpy`, which processes several bytes per cycle.

So it would be nice to make this work. But I don't think it will, because of the invalidation problem inherent in imperative overwrites.

STM dependency tracking works because you don't need to know what other variables a transaction could conceivably have read or written, had it found different values in the variables it did read; if need be, you can abort and restart the transaction with the new variable values, and record its new behavior.

In this case, though, we're interested not only in the variables that the transaction *did* write to, but the variables it *could have* written to. In this case, for example, we'd like to know what screen positions our cell could have written to if the layout had been different: either the cell itself was wider, overwriting positions to its right, or the cells to its left were narrower, so it overwrote positions to its left.

This is an insoluble problem as long as the code running inside the transaction is written in a Turing-complete language. You could maybe do it if it's expressed in something more restrictive and

"declarative", but this is enough to make me give up on this line of inquiry.

Composing the screen image from cacheable pieces

The problem with the above approaches is that you have lots of branching out in the dataflow graph: ultimately, the contents of every cell at least potentially affects the contents of every character position on the screen that isn't to its left.

What if we go the other way instead? Instead of branching out, we branch in: many table cells get turned into cacheable chunks of screen, which are composed into a screen image.

At first glance, this seems to be a non-solution: what do you do with the screen image? It's 2000 characters. Do you want to iterate over all of them?

Consider how you'd implement the `label_of()` function described above in a language like C, without thinking about caching, in particular for a cell whose label is really an integer, not simply a string; or maybe it's in a format like "t >> 6", where the 6 is an integer that can vary over time. You'd like to be able to cache the results.

You could dynamically allocate a string buffer, serialize the number into it (expanding it if necessary), and return the new string, attempting to communicate to the caller that they were responsible for deallocating it when they were done with it. (Maybe if your program was too efficient, you'd use reference counting.) But that's sort of wasteful; in the end, the string contents are going to get copied into some kind of screen image or something.

A disadvantage of the above method is that the cell can produce an arbitrarily long label, which means you need dynamic allocation, at least in principle. This is sort of silly if you're generating a label to fill a fixed-size space on the screen. You could use the interface provided by the `read` system call: when you call `read`, beyond telling it which file you want to read, you pass it a buffer pointer and a maximum length, and it writes your result into that buffer. Then you could pass the render-cell functions pointers to the relevant parts of your screen buffer.

For more flexibility, you could provide an "output" callback, which can be called, maybe more than once, to add characters to the label. This approach subsumes the previous two, since your output callback could simply add to a string buffer, but it could instead update a screen image. For caching purposes, we can consider the image produced by calls to the output callback to be the "return value" of your cell rendering function.

So suppose this is the interface we use for the things that generate parts of the screen contents: we pass in a "window" object to draw into, and we consider its dimensions part of the arguments for the sake of caching; it has a "subwindow" method that can be used to generate a smaller window to pass to subfunctions. Then we can do things this way:

```
image_of_table(win) = image_of_columns(win, n_cols)
image_of_columns(win, col) =
    if col > 0:
```

```
        start = col_start(col)
        image_of_columns(win.subwindow(width=start, col-1), col-1)
        image_of_column(win.subwindow(left=start, width=col_width(col)), col-1)
image_of_column(win, col) =
    if win.height > 0:
        image_of_column(win.subwindow(height=win.height-1), col)
        image_of_cell(win.subwindow(top=win.height-1), col, win.height-1)
image_of_cell(win, col, row) =
    color = highlight if is_current(cell) else normal
    win.show(label_of(cells[col][row]), color)
col_start(col) = 0 if col == 0 else col_start(col-1) + col_width(col-1)
col_width(col) = col_width(col, n_rows)
col_width(col, row) = 0 if row == 0 else max(col_width(col, row-1), w)
where:
    w = length(label_of(cells[col][row-1]))
```

(The imperative syntax here is fairly grating. It would probably be clearer to write these as expressions of some kind.)

Here, if you update the label of the upper-left-hand cell, it will initially invalidate `col_width` of the first column, the image of that cell, the image of its column, and the images of every set of columns; but it will not immediately invalidate the images of each other column, nor the other cells in the same column. If the newly-recomputed `col_width` is the same, the images of the other cells in the column will also not need to be recomputed; and so the only call to `win.show` will be for that single cell. The other cells and columns will be composited into the screen image in the same place they were before, which amounts to no change.

If you update a cell further down and to the right, the block of columns to its left remains cacheable, as do the block of cells above it — again, assuming they aren't invalidated by a changed `col_width`. In cases like this, you can reduce the number of invalidations by dividing screen regions up in a binary fashion rather than linearly:

```
image_of_column(win, first_row, col) =
    if win.height > 1:
        mid = win.height div 2
        image_of_column(win.subwindow(height=mid), first_row, col)
        image_of_column(win.subwindow(top=mid), first_row + mid, col)
    elif win.height == 1:
        image_of_cell(win, col, first_row)
```

(This strategy should be abstractable into higher-order functions for vertical and horizontal stacks.)

If the implementation of `show` actually stores its arguments into such a screen image, the updates to the screen image can be done without any heap allocation. However, if you're running a unified caching layer, you need to maintain the metadata that says which screen regions were produced by calling which functions with which arguments; in this case, there are about two or three such cache metadata nodes per cell that was displayed. I estimate that each such node is around 12 words, 48 bytes on a 32-bit machine, and the number of cells involved might be 100 — so 4800 bytes, less than three times the size of the screen in question. (And that's if you don't

discard any of the nodes.) I'm not sure if there's a reasonable way to manage that metadata without dynamic allocation.

Now, suppose that our screen image isn't just a flat array of bytes (or two of them), but instead, a replicated object that produces a data stream of the updates made to it to an interested observer. When a call to `win.show` is made, or if the cache copies data from one place in the screen image to another, the observer is informed.

Such an observer is just what you need to produce a stream of updates to send to a terminal emulator.

Generalizing and simplifying the screen-image example

So what do we have here? We seem to have constructed a sort of special-purpose cache manager for a certain kind of object, rectangular regions of a terminal screen. Was this necessary? How big is the benefit? And how many special-purpose cache managers will we want to make over time?

Topics

Ideas to pursue

Kragen Javier Sitaker, 2018-05-05 (updated 2018-08-16) (6 minutes)

As usual, I'm full of a lot of different ideas I'd like to investigate more deeply and develop into useful things. Among these are:

• Manufacturing robot: I want some kind of precise positioning system that I can use to deposit or remove material. The shortest path to this is likely inkjet printer carriages, but I need to figure out how to physically hook electronics up to their linear encoders, and then I probably need to rig up some kind of PID control to drive them with.

• The bed platform: I need to build a thing in my bedroom to turn it into more of a bedroom and be able to move in. This involves buying or salvaging more steel studs, hooking them together, and putting some shit on top, and then at least some kind of cloth around the edges.
• Extending the calculator: I have a somewhat awesome interactive calculator, but it still needs a lot of work. It would benefit a lot from localStorage, decimal points, and fixing editing so that I can add new numbers next to existing ones, and also from a multitouch UI.
• Multitouch UI: I have a promising prototype that isn't yet good enough to do anything useful.
• Ice vest: something to enable me to comfortably weather the summer in Buenos Aires.
• Dependency-driven recalculation: crossing `make` with Apache Spark.
• Graph notation: a general way to represent digraphs as relatively short sequences of symbols.
• Magic Kazoo: a synthesizer you can hold in your mouth and play like a kazoo
• Constraint-based quantitative modeling: a system for building quantitative models that can include things like three-dimensional shapes.
• Ghettobotics: bootstrapping a bitchin electronics lab from garbage.
• Quasicard: a generative form of hypertext that supports exploratory data analysis
• Stuff with optimization: a whole list of things that I should be able to attack with mathematical optimization, including:

• Dithering.
• Image approximation under other constraints, such as mosaic tiles or gradient swatches, using a psychovisual model.
• Or, for example, with an XY robot, an ink model, and a psychovisual model.
• Melody transcription.
• Magic Sinewave synthesis (with a given reactive filter and switching losses, say).
• Sparse approximation of convolution kernels (generalizations of the Hogenauer filter).
• Kinematic control.
• Topological optimization for panel cutting.
• FEM in general.

• Text layout, as TeX's badness-minimization approach. But e.g. for JSON.
• Toolpath optimization?
• Analog filter design.
• Relatedly, IIR filter design.
• Structure from motion, photogrammetry, and structure from shading.
• Tool choice from mesh model and tolerances — using more precise tools where tighter tolerances are needed.
• Circuit design from available components (measured e.g. with an M328)
• Execution planning in e.g. a query planner, where there are multiple possible ways to compute the same result.
• Index design for a database, which is the same thing taken up a level of abstraction — which indices would minimize query cost?
• Weld placement on weldments to optimize their strength
• Automated bricolage from gluing together found objects
• Mesh complexity reduction with bounded error
• Curve approximation with minimal numbers of control points
• List decoding of noisy signals
• Signal approximation (of e.g. audio signals) from given primitive signals and combining operators and a closeness metric (e.g. a psychoacoustic model). One aspect of this is audiomontage, where you combine prerecorded sounds to produce a desired sound, as in notjustmoreidlechatter.
• Speech recognition, given a speech synthesis program and a psychoacoustic model.
• Generating knitting patterns from triangle-mesh 3-D models
• Generating laser-cutting patterns from mesh models
• Cost optimization of laser cutting under various constraints, e.g. bounded error to a mesh model, or visual similarity using a psychovisual model.
• Cache allocation optimization
• Planning a travel path through a city to minimize cost, discomfort, worst-case or average-case travel time, or some combination
• Image coregistration
• Tensegrity design given constraints (e.g. maximum rigidity for comfort, minimum rigidity, minimum strength, impact energy, strength under given loads, support points)
• Graded-index optical systems with no surface scattering
• Materials property estimation from experimental results
• Circuit or electronic component estimation from experimental results
• Design of linkages or composite materials to produce a given force-displacement curve or force-displacement-time curve
• Inverse filtering to compensate precisely for known output transducer imperfections, including nonlinearities
• Also, of course, for input transducer imperfections
• Optimizing a predictor of the next sample used for compression (including lossless compression) for a given image or sound.
• Estimating a convolution kernel from two simultaneous signals, such as a stereo recording of someone talking in a church. Basically this is just inverse convolution.
• Beamforming

• Toolpath planning not just from a 3-D model but also, for example, to approximate a given grayscale image by, for example, carving plaster.
• Attributing motivations to human choices, e.g. social network analysis from Facebook "like" data
• IQlight design from mesh
• Robot path planning
• Robot attitude and position information from sensor data — actually SLAM as a whole
• Most-probable-fault diagnosis from a fault tree and observations
• Inferring a fault tree from observations
• Experiment design for fault diagnosis given a fault tree and partial information
• Learning a model of a controllable system (e.g. a robot arm) in order to control it and know where the controllable zones are
• Designing a procedure for a controllable system to optimize the important tolerances instead of the less important ones; this broadly includes things like planning to cast surfaces that don't need precision followed by grinding surfaces that do, but also planning to position workpieces such that the things that need precision are in the zones where your actuator and feedback are most precise
• Constraint satisfaction for 3-D modeling
• qyap
• a small, safe IRC client
• a daisy-chaining bus for simple programmable electronics

Fast sea salt evaporator

Kragen Javier Sitaker, 2017-06-01 (3 minutes)

The standard approach to making sea salt is to evaporate the seawater in salt ponds over a period of months to years. This time period is determined by the depth of the salt layer you want to end up with, the concentration of salt in the water (35 g/ℓ), the enthalpy of vaporization of water (2.26 MJ/kg), and the terrestrial solar constant — the irradiance from the sun at the surface of the Earth. (Or, really, its average over time, filtered through the atmosphere and clouds — "mean insolation". Peak terrestrial solar irradiance is typically about 1000W/m² but mean insolation at temperate latitudes is only about 180–280 W/m².)

(A small additional amount of heat is also added by air as it blows over the water, bringing in some solar heat from the surrounding area.)

However, the typical practice is actually to move the brine to smaller pools once it becomes more concentrated, thus evaporating most of the water over a large-area solar collector, then piling up the salt.

The vapor pressure of the water is dependent on the salinity; pure water will only condense at a relative humidity of 100% (by definition), but in the final stages, where the salt solution is saturated (359 g/ℓ) and salt begins to crystallize, the equilibrium favors condensation above 75.5% relative humidity (at 0°, slightly increasing with temperature). So heating the air somewhat may be necessary for the final stages of evaporation, to keep them from running backwards.

In theory, you should be able to adapt this progressive concentration to a continuous-flow process with a very large number of "ponds" and a very small amount of water, thus producing a continuous flow of salt very rapidly from seawater.

While the sun is shining at 1000W/m², water evaporates at 442μℓ/m²/second, producing salt (if the process gets that far) at 15.5 mg/m²/s. Given 4m² of solar collectors, this could give you 62 mg/s of salt, or a kilogram or two of salt per day, depending on how much the sun shines. If your collectors are merely water ponds 10mm deep, the collector contains 40 liters of water at any given time, which means that any given parcel of water on its way through the system will take about 6 hours to evaporate completely.

Possibly a more interesting approach is to use reflective solar concentrators to collect sunlight over a much larger area than the area actually covered in water. For example, if you could achieve three suns of concentration, water could pass through the system in only 2 hours, and as a bonus, you could heat it to a high enough temperature (up to 209°) to sterilize it as it entered, minimizing biofouling problems.

A Sunday in 2014

Kragen Javier Sitaker, 2014-02-24 (3 minutes)

I'd planned to do laundry at a friend's house today (since she has a washing machine and I don't), and to write some code for the $work project. First, I went out to find the hours for Teatro Ciego, petting a small spotted dog locked up in a neighborhood store on the way home, and then at home I began to write about a friend's idea.

Much to my surprise, the doorbell rang; a French sculptor I hadn't seen in maybe a year had dropped by unannounced, and so we went to sit nearby to meet a tall lesbian musician from Darmstadt. Neighborhood kids were playing dodgeball noisily against the metal shutters closing a storefront, so we sat elsewhere and caught up on our respective lives.

The musician arrived, irritated at having taken the wrong bus, and we walked around the neighborhood, buying empanadas on the way to the park. I introduced her to capresse empanadas, and she told me about her pessimism about Bitcoin and Wikipedia, based in part on the history of radio, in a mix of Portuguese and Spanish. Later, in my apartment, sweating from the summer heat, the three of us sipped green tea from atop a styrofoam cooler chest wrapped in cellophane tape.

Perhaps too late in the day, I texted my friend about the laundry. I never got a reply.

The three of us went to a bar where the musician would perform later. I ate a cold raw pickled eggplant burrito, which wasn't quite nauseating, as plump and tattooed young Argentines played rock to thunderous applause, despite their inability to sing in tune. Crammed between walls hung with psychedelic surrealist paintings, the crowd demanded an out-of-tune encore. A disheveled woman in a plaid shirt fanned herself and, inadvertently, me, with a folding fan, as I drank a Speed Unlimited energy drink — like a Red Bull with less vitamins.

The musician got up to play. She sounded like Janis Joplin, and is by far the most skilled musician I've ever heard perform in this bar. Instability in the power supplies for their green LEDs gave rise to a distracting yellow flicker in the spotlight.

A bespectacled young man with a mustache at the table in front of me, wearing the only button-down shirt in the bar, took his Android phone out of his satchel to check the time.

A tattooed young couple gazed into each other's eyes across a table nearby, stroking one another's hands before leaning slowly across the table for a quick, perfunctory kiss before parting.

Walking home, I pass a small boy in a baseball cap picking through the garbage, and then a middle-aged grandmother with her daughter and baby granddaughter doing the same. On a busier street, a young woman showed necklaces laid out on a blanket to a mother with covered hair and her two yarmulke-clad boys.

MiniOS

Kragen Javier Sitaker, 2016-12-28 (updated 2017-01-03) (6 minutes)

I want to write a minimal self-sustaining programming environment to work from.

What's the absolute minimum you need for a self-sustaining programming environment?

You need a user interface including some kind of text editor, stable storage, a compiler, and a bootloader. The stable storage thing needs to support at least some minimum of version control, so you can store previous versions of the code, if nothing else. And a textual user interface needs a font, which means you need some kind of drawing program.

It's probably also almost unavoidable at this point to support network access, hotplugging, power management, foreign filesystems, cryptography, and HTML; it would be very useful to also have type checking, JS, and a debugger.

If it's going to be self-sustaining down to the hardware design level, it also needs a CPU design, a RAM design, and some kind of circuit layout and simulation tools. If the CPU design is written at some higher level than netlists, it needs to be able to synthesize RTL from whatever the CPU design is expressed in and to synthesize netlists from RTL.

If it's additionally going to be self-sustaining down to the hardware fabrication level, it needs servo control algorithms, a cyclic fabrication system, motion planning, finite element simulation and optimization, and some 3-D geometry handling (even if only voxels).

User interface

For a visual UI, minimally you need at least one font, some kind of text layout system (to put text into lines, if nothing else), and enough rendering to get it onto the screen. It's also very desirable to have mouse support and windowing, especially for the drawing program.

A text editor needs to efficiently support movement, insertion, deletion, text search, and cut-and-paste, at least on the sizes of files you're likely to encounter. You may also need some interface to load and save files in it, if you have files.

There also needs to be some kind of way to invoke other programs that you've written; Emacs does this with ^J and M-x, as well as the shell.

You also need drivers for keyboard (or touchscreen) and mouse, if present.

Stable storage

You need some kind of filesystem. It doesn't need to necessarily be a traditional hierarchical filesystem, although that would ease compatibility with existing systems, but there needs to be some way to not have to retype everything from memory every time you power-cycle the machine. Smalltalk and other image-based environments do okay here, but they imply you need some kind of hot code upgrade facility, and then you have to build in some other way of doing version control.

Forth's filesystem is probably the most minimal here: the "files" are sequentially numbered disk blocks.

Compiler

For a self-sustaining system, interpreters are optional, but compilers are mandatory. The compiler can be very simple, down to simply concatenating prewritten snippets of code and fixing up pointers, but it needs to exist, or you can't ever run your code. Furthermore, you need two duplicates of it: an executable bootstrap compiler or interpreter that can run on some existing system, and a source-code compiler that can run under the bootstrap as well as compiling itself.

My experience with Ur-Scheme makes me think that dynamic typing, a relatively simple grammar, ruthlessly polysemic data types, and making everything explicit will minimize the difficulty of writing the self-compiling compiler. My experience with peg-bootstrap and Prolog makes me think that backtracking and similar logic-programming or constraint-solving tricks can simplify tokenization and parsing down to a very simple task. My minimal experience with Forth makes me think that you probably do want syntax and typechecking.

Bootloader

The bootloader is almost entirely dependent on the environment you're running in. UEFI lets you load whatever you like from a certain version of the FAT filesystem, already in 32-bit mode. BIOS is hairier, but you still only need a few dozen instructions.

Network access

An OS without TCP/IP is not useful for most purposes nowadays. Wi-Fi, maybe via a USB dongle, is perfectly adequate at the physical level, but you still need the whole stack on top of that. Contiki's lwip is the standard in tiny TCP/IPs, but it's sixty thousand lines of C. The VPRI tiny TCP/IP stack is much smaller, but I don't know where to find it or how to get it running.

Hotplugging

Lack of hotplugging is what doomed sysvinit in Linux, leading to its replacement with a poorly-designed monstrosity called systemd. I'm not totally 100% sure about why plugging devices into a "hot" USB network requires rewriting the entire software stack while plugging devices into a "hot" Ethernet doesn't, but there you have it.

You need some kind of event bus to coordinate responses to either kind of event, so you can't get by with the traditional Unix IPC mechanisms of pipes and a shared global mutable filesystem, unless you want to have to poll all the time. But this broadcast/multicast IPC mechanism could totally run as a user process. Then again, in Minix even memory management is a user process.

Power management

Foreign filesystems

Cryptography

HTML

Type checking

A 2007 overview of matrix barcodes

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

There are a bunch of 2-D barcode systems, with varying capacities.

PDF-417 is one of the older and better-known systems. It can handle up to 1108 bytes of binary data, and there are GPL PDF417 encoders and decoders --- http://www.totalshareware.com/ASP/detail_view.asp?application=40°1548 is "Grandzebu"'s Windows XP version, and then there's http://sourceforge.net/projects/pdf417encode/ "pdf417_encode" by "jtlien". There's a "pdf417decode" as well at http://dataconv.org/apps_barcode.html the "ooosawaddee3pdf417" homepage --- this is a very slightly modified version of Ian Goldberg's 1997 decoder from http://www.isaac.cs.berkeley.edu/tools/pdf417-1.0.tar.gz --- unfortunately that software does not have a free license, or any explicit license, actually. There's a SourceForge project at sf.net/projects/pdf417decode which claims to be GPL but seems to be the same unlicensed code, plus a bunch of new code to support error correction. There's a reasonably nice description of how PDF-417 works at http://grandzebu.net/index.php?page=/informatique/codbar-en/pdf°°417.htm.

DataMatrix/Semacode is a higher-capacity 2-D barcode, with up to 1556 bytes; I don't know if it's patent-safe. There's a GPL decoder in C# at http://datamatrixdec.berlios.de/index.php/Main_Page with a couple of releases from late 2006.

QR Code is the highest-capacity 2-D barcode in common use, with up to 2953 bytes (when it's 177x177 pixels); with gzip -9, that's enough space to encode the Project Gutenberg version of Genesis up to Genesis 3:5, 1624 words. Denso-Wave has promised not to enforce its patents against it. There seems to be a lot of activity around it lately, especially in Japan. There's a GPL decoder in Java at http://qrcode.sourceforge.jp/ or http://sourceforge.jp/projects/qrcode/ --- ThoughtWorks's .NET library doesn't seem to be free software. QR code is JIS-X-0510 and ISO/IEC18004. There's a comprehensive introduction at http://www.denso-wave.com/qrcode/qrfeature-e.html and an occasionally-updated blog in Japanese at http://www.qrcodeblog.com/.

Approaches to 3-D printing in sandstone

Kragen Javier Sitaker, 2017-08-03 (5 minutes)

There are five common adhesives or cements which work to turn sand into sandstone at low temperatures: plaster of paris, portland cement, slaked lime, clay, and sodium silicate.

Plaster of paris (dehydrated gypsum, i.e. calcium sulfate hemihydrate) is soft and weak. It is inert until exposed to water; then it sets in about 45', producing a fair bit of heat. It will set underwater, is nontoxic, and is a bright white. If used outdoors, rain will gradually erode it. It introduces under 100µm of surface roughness. On MercadoLibre 30 kg goes for AR$162 (at AR$18.20/US$, that's US$8.90 or US$0.30/kg).

Portland cement (calcium silicates with some aluminum and iron silicates) is strong and hard. It takes about 6 hours to set, which can happen underwater, but part of the setting process involves absorbing CO_2 from the atmosphere. It is highly alkaline and can cause chemical burns. It has a substantial thermal coefficient of expansion, which can cause cracks. The results are not suitable for high-temperature use (e.g. metal casting) because the trapped water will cause steam explosions. It is typically gray. On MercadoLibre 50 kg goes for AR$142 (US$7.80 or US$0.26/kg); the white grade costs about three times as much.

Slaked lime (calcium hydroxide) can be mixed with portland cement or applied alone. It sets entirely, over the course of hours to days, by absorbing carbon dioxide from air, and consequently will not set underwater. It's nearly as strong and hard as portland cement, but has a much smaller thermal coefficient of expansion. It's even more alkaline. The finished material is porous, although it can be waterproofed with soap, forming materials known as qadad and tadelakt. It forms a brilliant white. On MercadoLibre 25 kg goes for AR$67 (US$3.70 or US$0.15/kg).

Clay is a class of phyllosilicate hydrate minerals that plasticize significantly with the addition of more water, absorbing the water and expanding, then contracting again and hardening as the water evaporates. This process can happen very rapidly, but the strength of the resulting material is very low. However, the product can then be fired in a kiln, first dehydrating the clay and then sintering the clay particles into a ceramic. Bentonite clays are the traditional adhesive in the greensand used in metal casting; they are among the most plastic and expansive. Ball clays and kaolin fire to a bright white color. 25kg of bentonite costs AR$180 on MercadoLibre (US$9.90 or US$0.40/kg).

Sodium silicate is a class of mixtures of silica and sodium oxide; it sets over the course of days by absorbing carbon dioxide, and can be hardened instantly by the application of concentrated carbon dioxide gas or liquid acids. Some grades are very alkaline, but those are more difficult to find. It dissolves in water, forming a dense solution; generally this requires high temperatures and pressures, so it is usually sold predissolved. I haven't compared its strength to the other

cements mentioned above. It's sold on MercadoLibre as "bloqueador silicato" for AR$1670/20ℓ (US$91 or US$4.60/kg), although I think I've found somewhat lower prices.

There are other cements, including magnesium oxychloride, magnesium phosphate, magnesium oxysulfate, calcium aluminate, and bacterially-decomposed urea with calcium salts, and wollastonite with phosphoric acid. Unfortunately, I don't know where to get the ingredients here, or they have other disadvantages such as the smell.

Construction sand itself goes for AR$575/m³, and a m³ is about 2.4 tonnes. This is US$32 (US$0.013/kg). So to the extent that you can replace binder with sand filler, you can drop the materials cost of your printed object almost proportionally, while increasing its strength; with binders mostly in the US$0.15–0.40/kg range, except for sodium silicate's US$4.60, the sand doesn't comprise half the cost of the object until the binder is down to 3%–10% of the mix, and generally none of these binders are so awesome as to allow you to use so little binder.

For 3-D printing, whether powder-bed or nozzle-deposition, the optimal material would be free; remain liquid or powder forever while in storage, but harden instantly as soon as it was activated; would be very strong; and would be colorless, so that you could pigment it however you liked.

Barrel safety

Kragen Javier Sitaker, 2018-07-14 (3 minutes)

Water in 200ℓ drums is a reasonable thing to want to store in your house, both for drinking and for thermal storage, but water spills can cause serious property damage and even electrical hazards. How can we store it in an inherently leak-safe way?

This is a problem with waterbeds, too, which commonly contain 1000ℓ or so of water. The usual solution with waterbeds is to surround the vinyl bladder with a stiff plywood frame with an impermeable polyethylene liner; this way, when the vinyl eventually ruptures (as warm, plasticized vinyl under continuous stress eventually does) the water will be safely contained within the frame, as long as no holes in the liner have previously escaped detection.

You might think that this solution works so well for waterbeds precisely because the inner water container is flexible — if it starts to leak, the water outside of it will tend to collapse it, and the overall level of water will not rise above the edge of the frame. But a little thought will show that this is a fairly general property of such systems, even if the inner container is rigid. If you have a 200ℓ plastic drum of water standing on end inside, say, a 230ℓ bucket that is as tall as the drum, if water begins to escape, once the water level outside the drum equals the water level inside, it will stop rising, even if the drum is floating at that point (which will happen with polypropylene drums). Hopefully some kind of alarm will have gone off before this point, intake shutoff valves will have been closed, drains will have been opened, etc.

However, an additional layer of protection could be provided by a large tray holding several drums. Consider a rectangular array of N round 200ℓ drums next to each other. Each occupies π/4 of its square cell, 79% of it, leaving the other 21% empty. If you have four such drums in a 2×2 array, the empty space in the tray amounts to 86% of a square, which is 109% of the volume of one of the drums. So, if any one of the four drums breaks open and spills its contents, walls around the four-drum unit up to their height would keep any of it from escaping, even if the bottle were filled with air until all the water escaped. In a 4×4 array holding 3.2 tonnes of water, walls up to ¼ of the height of the drums would be adequate to provide such a containment service against the total failure of any single barrel.

This is not the only safety measure that is needed — as I said, automatic shutoff valves, drainage routes, and alarms are highly desirable, and of course there are the usual issues of cleanliness.

(Relatedly, I've previously written about inherently-safe fuel storage by floating small bottles of ethanol in water tanks.)

Immersion plating of copper on iron with blue vitriol

Kragen Javier Sitaker, 2016-09-24 (8 minutes)

I'd previously thought about copper-plating everything in the house like US pennies for antibacterial reasons, but it seemed like it would be a huge hassle, what with cyanides and electric current and so on. But it turns out that iron in particular has an extremely easy electroless way to plate it, discovered by alchemists many generations ago: immersion in solution of blue vitriol oxidizes some iron on the surface into green vitriol, replacing it with copper.

This might be interesting for decorative purposes as well, including selectively marking part of an iron or steel surface.

Nowadays this is called "immersion plating" in the "metal finishing" trade, whose bible is the Metal Finishing Guidebook, or sometimes "displacement plating". There's a standard test for cleanliness using 2 oz./gal. of copper sulfate with 0.1 oz./gal. of H_2SO_4 RT, I suppose to immersion-plate copper wherever the steel is clean. A bronze-displacement-plating solution uses 7.5 g/ℓ stannous sulfate, 7.5 g/ℓ copper sulfate, and 10–30 g/ℓ sulfuric acid at 20° for 5 minutes.

Stannous sulfate is deliquescent but relatively nontoxic; you can make it by a displacement reaction with tin and copper sulfate, so it isn't necessary to buy it. I suspect you can make it with tin-lead solder and copper sulfate; if lead sulfate forms, it should be nearly insoluble.

At times this copper deposits in a powdery fashion, and apparently this also works on zinc, or more generally can displace any less noble metal with any more noble metal; reading on the "galvanic series" or "seawater series" or "electrolytic series" is suggested. Instructables has photos of the powdery copper deposit and reports better results with some electroplating. Caustic cleaning and an acid dip ahead of time are reported to give better results; electroplating success with salt and ethylene glycol was also reported to work, with the electrolyte recipe 100 cc white vinegar, 1 heaping teaspoon kosher salt, 3–6 cc of ethylene glycol.

Professional metal finishers don't recommend trying to do this, although they're concerned about questions like durability and pore-freeness as well as appearance, antisepsis, and adherence. They explain that the reason copper cyanide or copper pyrophosphate works better for electroplating is that the copper is "tightly complexed", so it won't plate out onto the steel without a current applied. "Finishing.com has been on the air 20 years now and no hobbyist has ever reported back that they achieved robust copper plating on steel from kitchen or hardware store chemistry. Maybe you'll be first; I hope so," immediately followed by someone reporting success in electroplating with copper sulfate from an electrolytic-copper anode, sulfuric acid, phosphoric acid, and dish detergent as a brightener.

The electrode potentials are confusing. More noble metals seem to be more positive, while more reactive metals are more negative. Zinc

makes its first appearance at -1.2, and iron at -1.2 also (but with cyanide), with tin at -1.1, alkaline iron at -0.9, silver (with sulfide) at -0.7, gold (with cyanide) at -0.6. Silver's last appearance is at +2.0. Copper can be displacement-plated with tin, although it's not trivial, and tin can also be displacement-coated with copper (with just copper sulfate).

In particular, though, it seems like immersion plating of silver and gold onto copper or onto nickel are popular; I'm not finding much information about immersion-gold-onto-copper (ECIG and related processes) though. One paper on immersion-gold-onto-nickel gives the recipe of "immersion gold bath…at 80 °C, where 2 g ℓ^{-1} $Na_3Au(SO_3)_2$, 40 g ℓ^{-1} Na_2SO_3, 15 g ℓ^{-1} NaS_2SO_3, and 10 g ℓ^{-1} $Na_2B_4O_7{\cdot}10H_2O$ were contained".

The important thing about the potentials, I think, is that iron is more noble than zinc, tin and copper are more noble than iron, silver is more noble than tin and copper, and gold is more noble than silver.

Popular Mechanics May 1906 gives the recipe of 1 oz. blue vitriol dissolved in 6 oz. water with ½ oz. sulfuric acid, but I think it was suggesting using that as the electrolyte for a copper-zinc battery for electroplating.

The ASTM test A-239 describes how to use the Preece Test to find the thinnest spot in a galvanized coating. The current version is A-239-14. The 1995 version A-239-95 prescribes 36 g of copper sulfate pentahydrate per 100 g of distilled water, plus an excess of $Cu(OH)_2$, about 1 g/ℓ, enough to not dissolve completely, or CuO of 0.8 g/ℓ; the solution should be 1.186 g/cc at 18°. The result is that this removes the zinc coating and, when it gets down to the steel underneath, deposits "bright, adherent copper deposits" that cannot be removed "with an ink eraser".

Instructables has a CC BY-NC-SA copper acetate electroplating recipe, using acetate from vinegar and 3% H_2O_2. It comes with an excellent introduction to electroplating. (Copper acetate is somewhat toxic. It bioaccumulates with a biological concentration factor of over 100, but it was used as a green food coloring in the 19th century and had a large death toll.)

Copper sulfate is sold as fertilizer and fungicide for AR$145 per kg (US$9.50/kg) by Cristina at e-Moyos on MercadoLibre. This is the pentahydrate, which is 25.5% copper by mass (because it's $CuSO_4$, 159.6 g/mol, water is 18.02 g/mol for a total molar mass of 249.7 g/mol, and copper is 63.55 g/mol), so this works out to US$37/kg for the copper. This is not a good price for copper; the USGS average 2015 published price for copper is 277¢/lb., which works out to US$6.11/kg. But it's high by less than an order of magnitude. The Amazon price is US$33.40/5 lb., which is more expensive at US$14.70/kg.

(It loses four of its water molecules, amounting to 28.9% of its mass, upon heating to 109°, and reabsorbs them at 63°, so it might be useful as a powerful and compact desiccant; however, upon heating to 650° it emits SO_3, so it may not be very safe, depending on how well-controlled the regeneration temperature is. But this is beside the point.)

Machinery's Shop Receipts and Formulas gives several recipes for such things; one of them suggests "brassing" with "a quart of water and ½ ounce each of sulphate of copper and pro-tochloride of tin",

which would have the great advantage that brass is both more yellow (less red) and a lot easier to keep polished. Nowadays tin protochloride, which is what's used for tin-plating cans, is called stannous chloride or tin(II) chloride, and it's a relatively safe chemical (in fact it's E512), but apparently a little bit tricky to deal with in solution. It's a lot harder to find than blue vitriol.

Other recipes from the collection suggest using e.g. "hydrochloric acid diluted with three times its volume of water, in which a few drops of a solution of sulphate of copper is poured". Others suggest using e.g. zinc chloride: "saturated solution of zinc chloride with a very little copper sulphate added, say a half-dozen drops of copper sulphate to a spoonful of zinc chloride solution". Zinc chloride is a deadly corrosive deliquescent salt of zinc that is considerably more easily available than stannous chloride because of its wide use as an acid welding flux.

Another recipe from the collection suggested caustic cleaning followed by charcoal cleaning, presumably to remove the caustic.

US patent 3,715,289 from the early 1970s gives a formula for a rather complicated brightener for copper electroplating; it says previous brighteners have included "casein, animal glue, sugar, urea and thiourea and their derivatives and polyvinyl alcohol."

Topics

Relational modeling

Kragen Javier Sitaker, 2017-05-17 (updated 2017-06-01) (6 minutes)

Suppose I want a cylinder with a given mass and aspect ratio made out of a material with a given density. For example, an aspect ratio of 10:1, made of quartz with a density of 2.65 g/cc, and weighing 1kg.

It's easy to write down and verify the equations that govern this system:

```
diameter = 2 · radius
area = π · radius²
volume = area · length
mass = volume · density
aspect_ratio = length / diameter

mass = 1 kg
aspect_ratio = 10/1
density = 2.65 g/cc
```

And it's not that hard to solve algebraically:

```
length / diameter = 10
length = 10 · diameter = 20 · radius
volume = π · radius² · 20 · radius = 20 · π · radius³
volume = mass / density = 1 kg / (2.65 g/cc) ≈ 377 cm³
377 cm³ ≈ 20 · π · radius³
6.00 cm³ ≈ radius³
1.82 cm ≈ radius [excluding the two complex solutions]
diameter ≈ 3.64 cm
area ≈ 10.4 cm²
length ≈ 36.4 cm
```

Except I got it wrong the first time I did it, coming up with a mass of 552 grams instead of 1000, because I calculated π 1.82 cm² instead of π (1.82 cm)², spending about 10 minutes on the problem. Then when I tried to apply it to some other cases in a spreadsheet, I accidentally used 20 instead of 2 · aspect_ratio, getting nonsensical answers.

The standard approach to reducing the hassle of problems like this is to solve the equations algebraically to get a procedure to compute radius, diameter, cross-sectional area, and length given mass, aspect ratio, and density, or perhaps just volume and aspect ratio:

```
radius = ∛(volume / 2 π aspect_ratio)
diameter = 2 · radius
length = 20 · radius
```

Then you can package this procedure up as a subroutine and use it many times, instead of doing the algebraic manipulation each time.

But it would be nicer to be able to simply specify the relations — or even refer to them from somewhere — and have the computer find a solution.

Spreadsheets offer a simple form of this as "Goal seek". In

Gnumeric and other similar spreadsheets, you can enter the problem this way, for example:

	A	B
1	Radius	5
2	Area	=pi()*B1^2
3	Diameter	=2*B1
4	Aspect ratio	10
5	Length	=B4*B3
6	Volume	=B5*B2
7	Density	2.65
8	Mass	=B7*B6

And then you can tell "Goal seek" to set B8 to 1000 by changing B1. However, this isn't composable (you can't use a "goal seek" as a formula in a cell), must be manually recomputed (or recomputed by a macro) when the inputs change, and can't be applied across a range (for example, if you have several different aspect ratios to solve for). So it's a step in the right direction, but it's awkward to use. Mac Excel has a somewhat more powerful constrained minimization solver called "Solver".

"Goal seek" and "Solver" and similar metaheuristic solvers can often find solutions to problems that have no closed-form algebraic solution.

There is a tradition of numerical constraint programming going back to the 1970s for creating graphics in systems like METAFONT, IDEAL, and Linogram, typically limited to cases that could be efficiently solved without recourse to possibly nonterminating algorithms. For interactive use, though, such restrictions seem like overkill — and, in many cases, modern solvers can make short work of problems that have no closed-form solution.

That is to say, maybe constraint logic programming over infinite domains would be a handy tool to have for calculations like this.

You could also imagine composing my example model above from existing submodels. For example:

```
circle:
    diameter = 2 · radius
    area = π · radius²

prism:
    volume = area · length

oblong:
    aspect_ratio = length / diameter

cylinder:
    circle
    prism
    oblong

uniform_solid:
    mass = volume · density

cylinder
```

```
uniform_solid
mass = 1 kg
aspect_ratio = 10/1
density = 2.65 g/cc
```

In this case everything is just all glommed into a single namespace, like with inheritance, but you could imagine composing it slightly differently with some hierarchy. For example, maybe this is a better model of a cylinder:

```
cylinder:
    circle c
    diameter = c.diameter
    prism p
    cross_sectional_area = p.area = c.area
    length = p.length
    oblong
```

Here we are namespacing the circle and prism attributes to subnamespaces, then explicitly exporting `p.length` and `c.diameter` to where `oblong` can find them implicitly.

We could imagine a froodier set of models with further properties like this:

```
circle:
    diameter = 2 · radius
    area = π · radius²
    perimeter = π · diameter

prism:
    volume = end.area · length
    surface_area = 2 · end.area + length · end.perimeter

cylinder:
    circle c
    prism p
    p.end = c
    oblong
```

Here, `prism` takes an `end` argument, which has to be something with an `area` and a `perimeter`, such as `circle`.

This shows how to include properties with values more complex than simply a number, thus enabling hierarchical decomposition of the problem (although, lacking conditional recursion, you can compile the hierarchical structure thus generated into a set of atomic variables with constraints between them). You could imagine including properties whose values are displayed as, for example, images, sparklines, or 3-D meshes.

I've written the above values with units, because that helps me a lot with interpreting things during debugging and in being assured that the result is in fact correct.

In terms of type systems, as I said, you could say that `prism` needs an `end` argument with both `area` and `perimeter`; but actually if you were to give `prism` a `length` and an `end` argument with just `area`, it could still compute the `volume`. And you could imagine that if you gave it a

`surface_area`, `volume`, `length`, and `end.area`, it could compute `end.perimeter`. I'm not sure exactly how to formalize this, but it seems like it could be useful to carry such deductions out as far as possible.

Drone cutting

Kragen Javier Sitaker, 2019-06-11 (12 minutes)

Squirrel-cage induction motors are obsolete except in environments where weight and size is of no concern; BLDC motors are now superior in every way, often by two orders of magnitude.

The old motor

I have a ¼-horsepower 1430-rpm electric motor here, adequate for running a grinding wheel or something through the V-pulley it's got stuck on it. I think it's originally out of a washing machine; I bought it used. It's got a big capacitor wart on the side, because it's a single-phase motor, and that's a much less inefficient way to get a single-phase motors to start up than the hack in a shaded-pole motor. I haven't opened it up, but I'm pretty sure it's a squirrel-cage induction type, because it says "1430 rpm", and does seem to run at a pretty fixed speed. It's got cooling slots in the ends so you can blow dust into it.

It's rated for 2.4 amps at 220 volts, which works out to 530 W. ¼ hp is only 186 W, so presumably 2.4 A is the current it draws if the spindle stalls; these motors aren't that inefficient. I haven't measured either its power input or its power output.

I don't have a scale handy, but I feel like it weighs about 10 kg, and it's 150 mm in diameter and about 200 mm long.

The thing I want to point out here is that this is not a very good power density, on the order of 20 W/kg and 50 W/ℓ.

Milling machines

I was just watching a YouTube video by Stuart de Haro entitled "Milling machine anatomy", which is largely about the Bridgeport Model J head for Bridgeport milling machines, the most popular milling head for hobbyist metal milling in the US. We're talking about a floor-mounted mill with an X–Y table a couple of meters long, capable of precision on the order of 25 or 50 microns. (In this case it's equipped with a DRO that reads in microns, or 2.5-micron units in medieval-unit mode.) It's got this big honking motor on the back, hooked up to a variable-frequency drive, bigger than the motor I've got here, and my man Stuart explains that the Model R ½-horsepower milling head is "relatively light duty" (and for that reason he's never actually seen one, though he teaches machining at a college).

So we can deduce that, for Stuart and other Bridgeport machinists, one horsepower (746 watts in modern units) is adequate for the meter-scale workpieces they like to chew on, but half a horsepower (373 W) is "light duty" and would slow them down. And that, I suppose, is why they're willing to deal with these heavy honking motors on their milling machines.

Quadcopter motors

Modern electric quadcopter drones result from truly astounding progress in battery and motor technology. On MercadoLibre here in Argentina, I find a Turnigy BC2836-8 motor designed for

quadcopters for AR$2090 today (at AR$44.50/US$, that's US$47.) This motor weighs 70 g, measures 28×28×36 mm, wants to be driven with a 30-amp or 40-amp "ESC" (the kind of VFD you use for a BLDC motor), is rated at 1100 "K_V" (rpm per volt), and is rated at 336 W, intended to be driven from 2–4 LiPo batteries. (A Singaporean vendor lists the same motor at US$13.)

That is, this motor is almost *twice the power* of the big honking 10-kg beast I have here in my living room. But it weighs a bit under 1% of what the big motor does. I'm guessing it costs about 10%, too.

Four 3.7-volt LiPo batteries in series would be 14.8 volts, and 336 watts at that voltage would be 22.7 amps, so the volts and amps pretty much check out. At 1100 "K_V", its maximum speed should be a bit over 16000 rpm, which is pretty plausible.

So this works out to 4800 W/kg and 15000 W/kg, about 200–300 times better than this big motor.

In part this is made possible just by running the thing eleven times faster, which is made possible by having much better bearings and designing the thing to depend on an ESC. At a given torque, running the motor eleven times faster is going to give you eleven times the power. Permanent-magnet brushless "DC" motors like this one ("BLDC motors") also use rare-earth magnets, typically NdFeB, which gives them higher field strength and thus higher torque — although in theory it's possible to achieve similarly-high flux densities in induction motors. (The "electrical steel" used in squirrel-cage cores saturates at 1.6–2.2 T, while NdFeB's remanence is "only" 1–1.3 T.) Another significant factor may be cooling: the drone motor is of course designed to operate in the propeller downwash, which is a wonderful level of air-cooling. Finally, the drone motors are presumably designed for an MTBF of tens of hours, while the ¼-hp motor is designed for an MTBF of tens of thousands of hours.

BLDC motors can also maintain the optimal phase relationship between the rotating magnetic field applied to the stator and the magnetic field of the rotating rotor, enabling them to maintain the same torque at any speed; induction motors, by contrast, have a fixed torque–speed relationship which reaches zero torque at their natural or unloaded speed.

Permanent magnets are much smaller than field windings, which exist in the induction motor in the form of the copper "squirrel cage" within the rotor. This may account for a substantial fraction of the mass and volume of the motor, though far from 99%.

Neodymium magnets also have about an order of magnitude greater resistivity than iron does (1.1–1.7 μΩm, compared to iron's 0.1, though electrical steel's resistivity is higher than that), which might diminish eddy-current losses, and of course there are no hysteresis losses; although these are more properly efficiency concerns rather than power-density concerns, they do have some effect in that more power losses result in more necessary cooling.

Sometimes the low Curie temperature is cited as a disadvantage of neodymium magnet motors — it's only 310–400°, so the magnets will be destroyed if the motor ever overheats that much. However, I think the solder joints and winding insulation will fail at a lower temperature than that.

Milling with drone motors

So how could you build a milling machine or engine lathe with these little motors? Well, you probably need several of them, such as ten of them. (You don't want to be running the motors at their maximum power if you want them to last; as I said above, they aren't designed to last.) You'd need to gear them down. Our homeboy de Haro tells us that the spindle speeds in his classroom range from 50 rpm to 5000 rpm; trying to run that off this wimpy ¼-horsepower squirrel-cage motor I have here could require gearing it *up* by a factor of up to 3.5, or down by a factor of almost 30, although in actual fact you would probably use a VFD.

By contrast, you'd probably want to run the drone motors faster and gear them down. Maybe you could run them at 2000–6000 rpm, for example, although that difference in speed is less than I expected: you'd be gearing them down by factors of only 1.17 to 40, probably. You could imagine, though, that you'd want to take advantage of the drone motors' higher speeds to support higher milling speeds for small cutters.

Dremel-style cutting

Dremel-style small-cutter milling is potentially really interesting, especially coupled with the larger number of axes of control that smaller, cheaper, higher-power motors and control systems make possible. The conventional CNC way to mill weird shapes — shapes that are far from the shape of the stock they're milled from — is to convert most of the stock into chips, a slow and expensive process that becomes somewhat faster if you apply a large roughing milling cutter and a high-powered motor to the task. Smart machinists, and all but the most stubborn manual metalworkers, often use slitting saws and bandsaws to quickly, but imprecisely, remove much of the material ahead of time, thus avoiding much or all of the milling. With a six-axis machine, though, you could do this step under CNC control, using not only slitting saws but also narrow endmills or even drill bits or wire saws. Narrow endmills demand potentially much higher spindle speeds to reach the same surface speed, which is necessary for optimal tooth life.

Narrow endmills suffer from extremely low rigidity, resulting in chatter, imprecision, and potential breakage inside the part. Tapered endmills improve this situation dramatically; they already exist and are occasionally used in CNC milling even on three-axis machines. ConicalEndMills.com suggests using them for "draft angle & chamfer machining in all materials," for example. But maybe they could be much more widely applicable with high-speed motors and five- or six-axis control.

Fluid-cooling of stators

Wikipedia tellls me that the obstacle to even higher power densities in small BLDC motors is commonly heat dissipation: the motor must be small to spin fast, but this limits its available cooling surface area. Permanent-magnet BLDC motors put the windings, which are the primary heat-generating part of the motor, on the stator, which has a solid connection to the outside world — this facilitates getting the heat generated within them out, as well as getting the prodigious amount of current they use in. However, most of them still rely on air cooling

at this point, especially in the realm of quadcopters, where unobstructed high-speed airflow is not only guaranteed by construction but kind of the whole point.

Heat pipes are one possible way to improve the situation: you can run heat pipes through the stator to get heat out quicker. Heat pipes, unlike thermal conduction, can transfer heat at a rate that does not diminish with distance.

Another alternative, though, is forced-fluid cooling, in which a coolant fluid is pumped through channels in the stator to transfer heat out. Air is one common coolant (and, as I said above, in common use for these motors) with many advantages but also some drawbacks — its heat capacity is orders of magnitude lower than other viable fluids. (See Coolants (p. 3235) for a survey.)

One of air's key advantages as a coolant is its low viscosity, which enables it to cool even long, thin channels effectively. But, by adopting a fractal geometry for the cooling channels similar to that of vertebrate circulatory systems, we can enable the rapid, efficient circulation of even fairly viscous coolants. See Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) for more details and further applications.

Simplifying computing systems by having fewer kinds of graphics

Kragen Javier Sitaker, 2015-10-13 (10 minutes)

One way you could simplify computing systems is by having fewer redundant kinds of graphics. Typical computing systems have many different systems for windowing, drawing text, specifying fonts, making translucent windows, representing vector graphics, drawing and representing 3D graphics, zoomable graphics like maps, and doing text layout, among other things. For example, you might have VT-100 emulation, Xlib, PDF, Quartz, SVG, <canvas>, HTML with the CSS box model, PostScript, OpenGL, POVRay, H.264, MPEG-4, PNG, GIF, and JPEG, all on the same machine. Each typically has different tradeoffs related to performance, flexibility, and visual quality, but most of them just suck on all axes.

What if we had a graphics system that was both sufficiently expressive to cover nearly all of these applications, but also sufficiently performant to run in real time, while having a sufficiently simple implementation as to be understandable by a single person? Dan Amelang's Gezira and Nile are an influential effort in this direction (for the aspect of graphics that involves rendering to pixels, anyway), but they're resolutely two-dimensional.

Immediate-mode versus structured-mode

In my view, immediate-mode graphics APIs like <canvas> and PostScript have more predictable performance and substantially simpler code than structured-mode graphics systems like SVG.

File formats

File formats and graphics APIs are intimately related. At the simplest level, you can treat a file format as a "graphics API" in the sense that you can draw stuff by piping a stream of bytes to a decoder for that format; but the relationship goes the other direction too.

Of course, structured-mode graphics systems have this nailed down: all they have to do is serialize the in-memory object graph using a generic serialization system, and they're done. Direct-mode APIs are more complicated.

A "recording" of a sequence of direct-mode drawing operations can be "played back" by reinvoking the same operations in a new context, so a drawing API is in some sense capable of being serialized as a file format. This is the idea behind, for example, the WMF "Windows Metafile" vector format, which is just a serialized sequence of Windows GDI drawing operations. However, file formats and drawing APIs have some divergent needs.

First, graphics file formats typically benefit from having some kind of non-sequential access, for example for drawing particular areas, particular layers, or particular pages. Typical ways of selecting the graphics of interest doing this include bounding boxes, quadtrees, k-d trees, BSP-trees, and bitmaps of grids.

Second, programs using drawing APIs often want to make decisions about what to draw based on conditions that hold in a

particular case. For example, level-of-detail rendering is the name for a family of techniques that render images in more detail when you are zoomed in to see them, consuming more time, including things as simple as approximating Bézier curves with a larger number of straight lines; and of course programs often use bounding boxes to avoid spending time drawing objects that are offscreen or invisible because of some other clipping or occlusion.

You could imagine running such a program under some kind of backtracking replay system that inspects it to see what environmental conditions it's testing, snapshotting it at each test and later re-executing the conditionally-skipped parts, in order to derive the first of these things from the second. But that's not going to be universally applicable and anyway it's kind of rocket science.

A less-transparent, lower-tech approach would involve executing level-of-detail-conditional or bounding-box-conditional code in a fashion like how IMGUI libraries handle the logic for menus and windows that aren't currently being displayed:

```
if (bbox_visible(x0, y0, x1, y1)) {
    render_foo();
    render_bar();
    for (int i = 0; i < baz_count; i++) {
        render-baz(bazzes[i]);
    }
    end_bbox();
}
```

With this approach, interactive drawing can avoid rendering things inside the given bounding box if it is outside the display bounds, simply by returning false from `bbox_visible`, and metafile rendering can always return true from `bbox_visible`, but nest the objects thus constructed inside a bbox. Optionally, metafile rendering code could return false when you're inside a sufficiently small bbox, in order to support programs that want to do infinite level-of-detail rendering.

(My entire premise here is that we should forget about 2D graphics and just do 3D graphics, leaving 2D graphics as a special case where you're using an orthographic projection or something. So really these would be bounding volumes, not 2-D bounding boxes.)

Third, both direct-mode and structured-mode drawing systems are capable of returning general information to the program that's doing the drawing, not just pointwise questions like "is this layer visible" or "is this bounding volume visible". This is hazardous to file

Tiny POVRay code

POVRay is among the most flexible of these graphics systems. For example, https://mscharrer.net/povray/rays/ is an animation of manta rays swimming in a hazy ocean, made from these 464 fairly obfuscated bytes of POV-Ray code, written by Jeff Reifel in 2008:

```
#local
C=clock*pi;#macro
B(N,F)sphere{0F/7
1scale
1-pow(I.5)translate-I*F*x
```

```
rotate
y*N*90rotate-N*x*pow(5I)*10*sin(I*2-C*8+i)scale.2+x*.8translate-x}#end#local
i=C;#while(i<2*pi+C)#local
I=0;blob{#while(I<1)B(1,7)B(-1,7)B(0,3)#local
I=I+.01;#end

rotate<-90cos(i*3)*-45i*pi*36>translate<sin(i)+2*sin(2*i)5+cos(i)-2*cos(2*i)3*sin
(3*i)+7>*2rotate
x*37pigment{slope
y}}#local
i=i+pi/8;#end
light_source{<0,60,99>1spotlight}media{intervals
6scattering{2rgb<.1.2,1>/99}}
```

However, rendering the 300-frame looped animation on that page involved casting 685 million rays and took fifty thousand CPU seconds, two or three minutes per frame. That's only about 2 million rays per frame or 14000 rays per CPU-second.

What if your drawing primitives were sufficiently powerful to allow you to get graphical effects in such a tiny amount of code? It'd be a little bigger without the minification, but not that much. My POVRay is pretty rusty, but I think it is supposed to read as follows:

```
#local C=clock*pi;

#macro B(N,F)
    sphere {
        0F/7
        1
        scale 1 - pow(I, .5)
            translate -I*F*x
                rotate y*N*90
                    rotate -N * x * pow(5I) * 10 * sin(I*2 - C*8 + i)
                        scale .2+x*.8
                            translate -x
    }
#end

#local i=C;

#while (i < 2*pi+C)
    #local I=0;
    blob {
        #while (I < 1)
            B(1, 7)
            B(-1, 7)
            B(0, 3)
            #local I=I+.01;
        #end

        rotate <-90, cos(i*3)*-45, i*pi*36>
            translate <
                      sin(i) + 2*sin(2*i),
                      5 + cos(i) -2*cos(2*i),
                      3*sin(3*i) + 7
```

```
                    > * 2
                rotate x*37
                    pigment { slope y }
    }
    #local i=i+pi/8;
#end
light_source { <0, 60, 99> 1 spotlight }
media { intervals 6 scattering { 2 rgb<.1, .2, 1>/99 } }
```

That's still only about 35 lines of code. I mean, who knows how long he took tweaking it.

One promising approach to things like this is to use some kind of interval arithmetic or Monte Carlo rendering for level-of-detail rendering: render as much as you can before the frame deadline and display the result, and add more detail as long as the scene remains static. This is what Blender does, for example, with rotations of large meshes.

Computing performance

One of the biggest levers we have available now to simplify things is computing power to do things we couldn't do in the past, just because it was too expensive. What's the smallest amount of computing horsepower we can expect?

A Raspberry Pi 2 costs US$40 right now and can do about 250 megaflops on the CPU and 24 gigaflops on the GPUs, supposedly; a 64-Pi Version 1 Model B cluster hit 1.1 GFLOPS on LINPACK, or about 17 megaflops per Pi, and version 2 is supposedly 4 to 6 times as fast in aggregate, thus 70 to 100 megaflops. Hackaday got 93 double-precision megaflops per core, and 1186 VAX MIPS, on the Pi 2. Also, it was able to shade 900 texture-mapped triangles at 40 fps, although previous tests erroneously reported twice that at about a megapixel of resolution. That's only 36000 triangles per second.

Supposing that we can get 3 gigaflops out of a Pi 2 (geometric average of the 400 megaflops from the Hackaday results and the 24 supposed gigaflops from the GPUs) and we want 60 frames per second at 1 megapixel, we can spend up to about 50 floating-point operations per displayed pixel. Maybe I'm naïve, but that seems like it ought to be enough to do pretty decent antialiased rendering of some textures.

Derivative and interval approximations of imagery

Suppose you calculate a sparse approximation of the gradient of the screen image (the Jacobian, I guess) relative to the quantities in a scene model. Then, when you update the scene model slightly, you can multiply the update through your sparse gradient matrix to get a linear approximation of the change in the rendered image.

Calculating a gradient of the screen image relative to the scene model sounds like rocket science, but apparently automatic differentiation is now a well-established technique that can be applied to FORTRAN scientific codes of substantial size. In forward mode, it implies a constant-factor slowdown.

Alternatively, instead of doing the rendering with points and

derivatives, you could do it with interval arithmetic, which allows you to determine conservatively how big of a change in the input is needed to create any change at all in the rendered scene.

Electrodeposition 3d printing

Kragen Javier Sitaker, 2016-02-19 (4 minutes)

Suppose you have a matrix of 2×2 copper electrodes per millimeter. So if you have a 100×100 millimeter area, you might have 200×200 electrodes, a total of 40,000. To each you have attached a transistor. On top of this matrix, you have a bath of electrolyte containing, for example, copper salts. If you lay a sheet of metal atop this bath of electrolyte at a depth of less than half a millimeter or so, you can selectively copper-plate certain parts of the sheet, printing a copper pattern on the sheet, by passing current through some of the electrodes and not others.

You can renew the electrodes to some extent by taking the workpiece out, replacing it with a sacrificial copper sheet, and reversing the current.

With this approach, you could conceivably electrodeposit one layer after another of copper until you have generated whatever shape you desire, gradually lifting the workpiece out of the bath. However, copper plating is a slow process, with deposition speeds of tens of microns per hour. The very short distance traveled by the current in this approach might allow the process to run a little faster.

This suggests that this approach might be more practical at a smaller scale: if your deposition rate is 10 microns per hour, that's about 2.8 nm per second. So you could reasonably space your electrodes 500 microns apart and electrodeposit your copper in 500-nm layers, one every three minutes. If you are doing this over a 10mm×10mm square chip, each layer contains 400 million voxels, or about 2 million per second, which is an eminently feasible data rate. Filling a cube in this way would require 1000 hours (plus the time to refresh the electrodes), so you probably want to make thin things instead.

The ability to deposit multiple different materials, such as copper and zinc, or copper and nickel, or gold and nickel, or nickel and tin, or copper and chromium, or lead and chromium, seems like it would dramatically extend the reach of this technique, allowing the construction of metamaterials with vanishing thermal coefficients of expansion, high-current-density batteries, or bimetallic structures that deform in predetermined ways according to temperature, for example.

Material cost is likely to not be an issue, except for extremely exotic materials and maybe gold. A milliliter of gold weighs about 0.6 troy ounces, or about US$1000; above I estimated that the device would need 1000 hours to deposit it, using about US$1 of gold per hour, but probably costing significantly more than US$1 per hour in labor to operate. Other normal metals cost orders of magnitudes less. Extremely exotic materials might include things like pure lanthanides (as opposed to Mischmetall) and isotopically pure metals.

Using a molten-salt electrolyte like the Hall-Héroult cell, rather than an ionic-solution electrolyte, might allow electrodeposition that is more favorable in one or another way: for example, you could electrodeposit aluminum and other metals that react too easily with water.

Of course, the ability to selectively electrodeposit controllably doped semiconductors in this way would be immensely valuable, but I don't know of any semiconductors that would be viable candidates by themselves. It might be possible, though, to selectively electrodeposit a doped metal, then oxidize the metal into a semiconductor by exposing it to an oxidizer, maybe at high temperature. For example, you could oxidize zinc to zinc oxide or zinc sulfide, lead to lead sulfide (galena), copper to copper oxide, or titanium to titanium dioxide.

Compressing REST transactions with per-connection state

Kragen Javier Sitaker, 2018-04-27 (11 minutes)

Generally speaking, the REST constraints that requests and responses be fully self-describing and that servers be stateless makes REST protocols fairly bandwidth-intensive, not suitable for low-bandwidth links (in the range of 0.001–10000 bits per second). This is actually cited as one of the drawbacks of REST in Fielding's dissertation. But there is an approach fully within the spirit of REST that can fix this.

Inspirational examples from HTTP

A web server wants a web browser to display a page with some inline images. So it sends the browser some HTML containing the URLs of the images. The HTML is interpreted in the context of that connection, allowing the server to use short "relative URLs" to refer to the images. If the browser already has the images, it can avoid fetching them again (according to a caching policy which may have many factors, including commitments made by the server about image changes and demands made by the user about freshness) and thus use very little bandwidth. Or, if the connection is using HTTP/2 or SPDY, the server has the option to "push" the images to the browser before they are requested, if it thinks the bandwidth cost is worth the potential improvement in latency.

A web browser wants eBay's web server to add a product image to an image a user is listing on eBay. Rather than sending the image data, it sends an URL to an imgur image, thus using very little bandwidth.

The generalization of the inspirational examples: including by reference, context-sensitive abbreviation, caching

These are two examples of a more general mechanism for enabling the REST architecture to work well even for applications with very stringent bandwidth constraints. Specifically, any large chunk of data is made into a separate resource and *included by reference* rather than inlined; the references are *abbreviated in a context-sensitive way* according to the context of the connection; and the chunks of data are then *cached* so that they need not be fetched every time.

You could argue that allowing the client to use context-sensitive abbreviations in its request amounts to requiring the server to maintain session state, a violation of REST. But as long as this abbreviation layer is a layer below the requests and responses, it affects the protocol semantics no more than the RFC3749 data compression that used to be a feature of TLS before the CRIME and BREACH attacks were discovered.

The crucial properties are that any request message that would be valid on one connection at some time is also valid on a newly opened connection at that time, even if its on-the-wire representation might

need to use more bytes, that the amount of abbreviation state is small, and that the client knows the entire session state to be able to tell the server in a new conneciton if necessary. This largely preserves the advantages of the client-stateless-server style REST derives from: visibility is preserved because a monitoring system can easily maintain the abbreviation state, partial failures (of a server) are no more difficult to recover from, and the server is free to close connections to free up resources whenever desired.

A database query example, starting with HTTP

For example, suppose you want to run a query against a large database and fetch some of the results. You could send a request like this (newlines added for clarity):

```
GET http://elephant-server/walrusdb/v18032
    ?q=select+*+from+walruses+where[2000 bytes omitted]order+by+size
    &p=1&n=10
```

to fetch 10-item page 1 of the results of a 2000-character query, evaluated on immutable snapshot 18032 of some walrus database. This is a workable interface, but inefficient, because every page of results is going to involve a 2100-byte request. Suppose instead that you could say this:

```
GET http://elephant-server/walrusdb/v18032
    ?q=https://pastebin.com/raw/FhnZFrGN
    &p=1&n=10
```

This gets us down to 90 bytes, a 23-fold improvement. If the server doesn't have a valid cached version of the query, it can go fetch it from Pastebin and cache it. (Pastebin marks it as cacheable for 1801 seconds.) What's more, the server can cache the query plan and even query results as long as that cache item is valid — and the cache key is only 34 bytes.

If at some point the server decides to evict the query from its cache, this is transparent to the client.

Departing a bit from HTTP

But we can do better. First, note that in real, non-proxied HTTP/1.0, we didn't actually say

```
GET http://elephant-server/wa...
```

because we allowed the connection context to determine the scheme and host/port parts of the URL. Instead, we said

```
GET /wa...
```

substantially abbreviating the URL. Later on, because of the IPv4 address shortage, we decided that it was better to put it back in, and so we ended up with this as a backwards-compatible hack:

```
GET /wa...
```

```
Host: elephant-server
```

And, later still, TLS gained SNI, which would in theory allow us to take the "Host:" header back out. In fact, maybe HTTP/2 did. I don't know.

Anyway, suppose that we use some kind of escape sequence to represent base URLs, and that each request includes the base URL it's for, and that there's a separate kind of request line that defines such an escape sequence. If we use "$" for clarity, rather than the perhaps more realistic choice of some kind of unprintable character, we end up with this:

```
$s=http://elephant-server/walrusdb/v18032
$p=https://pastebin.com/raw/
get $s?q=$p/FhnZFrGN&p=1&n=10
```

So now, at the cost of 71 extra bytes at connection establishment time, each of our requests is down to 30 bytes.

Involving Pastebin is kind of shitty, though. Your queries are public, Pastebin can alter them as they wish, they are identified by 8-letter strings, and it may take you a long time to upload them there even if the server doesn't use them. It would be much better if the client of the query processor could simply be the server for when the query processor wants to fetch the query; then it could allocate resource identifiers as it sees fit, reducing them down to perhaps two letters or digits until it gets over about 3700 of them.

You could do that with connection-specific resource identifiers, but that's kind of suboptimal because then a connection loss and reconnection invalidates the server's cache. A better approach is for the client to generate a session signing key and sign the responses with it. Then it only needs an abbreviation for its public key or a hash thereof. For example:

```
$s=http://elephant-server/walrusdb/v18032
$p=dat://12c09257a5f9320fb00b769bf6b68b17fee5c33a1b6c89b723941a06e7c7b19e/
ihave $p
get $s?q=$p/2q&p=1&n=10
```

Now we have 126 bytes of setup, but we're down to 24 bytes per request, 20% less, with no external servers or non-end-to-end encryption involved, without losing connection-to-connection cacheability.

24 bytes per request is little enough that it would be usable over a 300-baud modem — although the response might be unpleasantly large, depending on how the response is structured.

Attempts at tighter encoding: CoAP (fail)

You could try to do better than 24 bytes. For example, CoAP tries to provide a tighter encoding of HTTP-like semantics, but without requiring a reliable connection-oriented protocol underneath. It isn't successful in this case:

```
>>> import aiocoap
>>> req = aiocoap.Message(code=aiocoap.GET, mtype=aiocoap.CON, mid=1)
```

```
>>> req.opt.uri_path = ('$s',)
>>> req.opt.uri_query = ('q=$p/2q', 'p=1', 'n=10')
>>> req.encode()
b'@\x01\x00\x01\xb2$sGq=$p/2q\x03p=1\x04n=10'
>>> len(_)
24
```

What it buys us is that the message-id and the request for confirmation are bundled into the first four bytes along with the GET. (GET itself is represented by the second byte being 0x01; 0x02 is POST, 0x03 PUT, and 0x04 DELETE; 0x45 'E' is the most common equivalent of HTTP 200 OK, while for example 0x84 is 4.04 Not Found.)

Attempts at tighter encoding: ncompress and gzip (these help)

ncompress implements LZW and has very little overhead and almost no codec latency. The following file contains 10 requests and, without compression, is 367 bytes, including 126 bytes of initial setup.

```
$s=http://elephant-server/walrusdb/v18032
$p=dat://12c09257a5f9320fb00b769bf6b68b17fee5c33a1b6c89b723941a06e7c7b19e/
ihave $p
get $s?q=$p/2q&p=1&n=10
get $s?q=$p/2q&p=2&n=10
get $s?q=$p/2q&p=3&n=10
get $s?q=$p/2q&p=4&n=10
get $s?q=$p/2q&p=5&n=10
get $s?q=$p/2q&p=6&n=10
get $s?q=$p/2q&p=7&n=10
get $s?q=$p/2q&p=8&n=10
get $s?q=$p/2q&p=9&n=10
get $s?q=$p/2q&p=10&n=10
```

This works out to 36.7 bytes per request. ncompress reduces it to 241 bytes, or 24 bytes per request; the initial setup was inflated to 135 bytes, but the marginal cost per request was then just 10.6 bytes.

By comparison, if we rely only on ncompress with no other abbreviations, we could try this:

```
ihave dat://12c09257a5f9320fb00b769bf6b68b17fee5c33a1b6c89b723941a06e7c7b19e/

get http://elephant-server/walrusdb/v18032?q=dat://12c09257a5f9320fb00b769bf6b68b
17fee5c33a1b6c89b723941a06e7c7b19e/2q&p=1&n=10

get http://elephant-server/walrusdb/v18032?q=dat://12c09257a5f9320fb00b769bf6b68b
17fee5c33a1b6c89b723941a06e7c7b19e/2q&p=2&n=10

get http://elephant-server/walrusdb/v18032?q=dat://12c09257a5f9320fb00b769bf6b68b
17fee5c33a1b6c89b723941a06e7c7b19e/2q&p=3&n=10

get http://elephant-server/walrusdb/v18032?q=dat://12c09257a5f9320fb00b769bf6b68b
17fee5c33a1b6c89b723941a06e7c7b19e/2q&p=4&n=10
```

```
get http://elephant-server/walrusdb/v18032?q=dat://12c09257a5f9320fb00b769bf6b68b
17fee5c33a1b6c89b723941a06e7c7b19e/2q&p=5&n=10

get http://elephant-server/walrusdb/v18032?q=dat://12c09257a5f9320fb00b769bf6b68b

```

Uncompressed, this is 1359 bytes. Compressed with ncompress, it is 626 bytes. We can conclude that ncompress is not an adequate replacement for the abbreviation system.

What about LZ77? With gzip -9, this same file compresses to 168 bytes, 16.8 bytes per request, the best showing so far. However, that's relying somewhat on a certain amount of cross-request compression. Flushing the compressor after every line brings the compressed size up to 266 bytes — 26.6 bytes per request. We can conclude that gzip is a nearly identically performing replacement for the abbreviation system.

Why not both? gzip -9 reduces the abbreviated 367-byte version we started with to 171 bytes, or 17.1 bytes per request; 127 bytes of this is the initial setup, leaving only 4.4 incremental bytes per request thereafter. However, if we flush every line, it's even worse than before — up to 283 bytes.

Clients composing things from pieces on the server or out in the world

Suppose the server you're talking to supports constructing some kind of filesystem environment to run programs in. You tell it what the filesystem looks like (with a list of Docker-like layers or a Git-style tree hash or whatever) and it downloads whatever files it's missing.

Suppose the files are mapped to resources on the network. Now you can build your filesystem environment from references to files that are located on the server itself, if it happens to also be a fileserver, but also on other servers near it, as well as files you yourself have. And you can do all of this without making the server responsible for maintaining that state in any kind of long term. You just need some kind of naming system for the resources.

Unifying abbreviations with resources

Transactional memory, immediate-mode structured graphics, serialization, backtracking, and parsing

Kragen Javier Sitaker, 2019-01-25 (7 minutes)
(Originally posted at https://write.as/s7f1ywj0jh735.md)

The standard API designs for graphics APIs are "immediate mode" and "retained mode". In immediate mode, you emit a series of drawing operations, which typically change pixels, and that's how you make your graphic. This means you can emit more drawing operations than there are pixels in the canvas, and in some cases you can do animations by sending a series of operations. Memory usage and performance are predictable, but not necessarily very good. `<canvas>`, PostScript, GDI, and Xlib are immediate-mode APIs.

Retained-mode APIs, by contrast, maintain a set of graphical objects in memory, and the API lets you create and modify those objects. Often they're arranged into a tree structure by containment. Typically they are a lot more of a pain to use and use a lot more memory. The SVG DOM is a retained-mode API.

Immediate-mode APIs, although they're often easier to use, have a few drawbacks:

• It's a little bit tricky to make antialiasing work.
• You can't zoom. Or, rather, zooming involves redrawing. And that's slow.
• The drawn objects can't be clickable because they don't have persistent identities.

This bit about redrawing, though, that's interesting. Presumably the entire structure of your immediate-mode graphic somehow inheres in your code combined with the memory state it is interpreting. As long as you can re-execute the code deterministically, you can redraw or inspect whatever other behavior of the code you would like to inspect.

Memory transactions and caching

Optimistically-synchronized transactional-memory systems also rely on the ability of bits of code to re-execute deterministically, as does Umut Acar's Self-Adjusting Computation. Optimistic TMs will roll back a transaction when another transaction has written to a shared variable that it has read, retrying it from the beginning with the new value, potentially as late as when it attempts to commit. (Some TMs also allow writes to leak out during transaction execution; in these cases, if another transaction reads those writes, it must be rolled back and retried if the writes are rolled back. This can lead to livelock.)

The basic idea is that, if you can track all the bits of memory that the code reads from outside of its ephemeral internal state, you can be sure that the code would produce the same results if it were executed

again; and if you control its outputs, you can undo those results if necessary. This allows you to confidently cache the results of running it, among other things.

What if we did this with immediate-mode drawing? If we divide our drawing into a series of possibly nested transactions, the transaction system can provide the advantages of a retained-mode API potentially without all the expense —– the transaction system can intelligently trade off memory space against the possible inefficiency of having to re-execute. It can, for example, compute a bounding box for each transaction, and then, when zooming, only re-execute transactions that impinge on the visible screen area. (You could also offer an a-priori bounding-box function which tells you whether any of a given bounding box is visible, so as to avoid executing things inside of it, but this conflicts with the transaction system's necessity for the viewport not to affect the drawing; a reasonable compromise is to offer a "clip" function which limits the visibility of further drawing to a given bounding box.)

Also, of course, being able to confidently re-execute an immediate-mode drawing enables us to detect clicks, if that's a thing we want to do.

Data serialization

We can apply an analogous approach to serializing and deserializing data structures, with the highly desirable benefits of being able to orthogonally cache serializations and writing the serialization and deserialization code as one routine. An IMGUI library like Dear ImGui might establish a mapping between a character buffer and a widget on every drawn frame:

```
ImGui::InputText("string", buf, IM_ARRAYSIZE(buf));
```

We might analogously establish a mapping between a character buffer and a chunk of the input/output stream:

```
int len = strlen(buf);
little_endian_32(&len);
bytes(buf, len);
```

When serializing, `little_endian_32` will serialize `len` to the stream (as a little-endian 32-bit binary number, I suppose); when deserializing, it will overwrite its current value with the value deserialized from the stream. Then `bytes` correspondingly reads or writes the given number of bytes.

We could imagine running the above in a transactional context that tracks its reads and the output bytes and is thus able to cache the output bytes and not re-execute the code when the inputs haven't changed.

Backtracking

A transaction system is perfectly entitled to checkpoint partially-executed transactions so that it can restart them from a checkpoint, rather than from the beginning, if it needs to retry them. This may be more expensive (it needs to save the entire ephemeral state of the transaction, not just the program counter and inputs) but

at some point it may be less expensive. This corresponds to chronological backtracking in AI search — if you checkpoint the transaction before returning the results of each nondeterministic choice, perhaps implemented as a read of a transactional variable, you can run a chronological-backtracking search over its execution space, searching for a set of nondeterministic choices that yields a successful execution.

We can do better, though; with nested transactions, we can do non-chronological backtracking as well. Normally the failure of a nested transaction will result in the failure of the outer transaction as well, but the nested transaction may depend on far less input data than the outer transaction. The inputs to the nested transaction (its arguments and the set of nondeterministic choices made within it) comprise, for the purposes of backtracking, a nogood set. This should allow some degree of non-chronological backtracking, although it doesn't allow the transaction system to direct the search procedure to nondeterministic choices with fewer remaining alternatives.

In the context of serialization and deserialization, chronological backtracking amounts to recursive-descent parsing, and the transaction system is capable of the kind of memoization that allows Packrat parsers to guarantee linear-time parsing. I'm not sure if it's possible to derive Earley parsing from recursive-descent parsing in this way.

Reducing working sets

Although all of the above is written from a big-computer perspective, the thing that originally attracted me to immediate-mode GUIs was Arduino menu systems. I hacked together an Arduino menu system that uses only a few bytes of RAM by using ImGui principles — from one call to the next, it only tracked the user's position in the menu tree, but the menu tree itself was generated on demand by callback code, which of course was not stored in RAM.

Subterranean glazing

Kragen Javier Sitaker, 2016-09-06 (25 minutes)

For some time I've dreamed of towns where all the building is underground, and the surface is devoted to soil — gardens and parks — but with some exposed windows to the sky. Subterranean construction faces a number of objections, one of which is a concern that it will be dim and dark, due to a lack of natural light.

We can achieve natural lighting conditions in almost entirely underground construction, with populations at low-urban densities, despite agriculture sustainability.

What it looks like

You're standing on a grassy, gently rolling hill, in the shade of a tree-sized sculpture, sort of shaped like a rotifer or sea lily, with a cap some five meters across and eight meters tall atop a three-meter-tall stalk that must be metal to support that much weight, although it looks like sandstone. The stalk is some 1.5m across, and the sandstone is warm to the touch if you put your arms around it. The cap is not vertical, and the stalk is not straight; it bends noticeably towards the southwest.

A flagstone path winds its way down the hill; a bit further down, it runs between some bamboo boxes containing raised-bed gardens, some filled with a mix of leafy deep green plants, leafy purple plants, and flowers, and tall stalks of corn, while others contain clearly recognizable onions mixed with staked-up tomatoes and eggplants. No other buildings are in sight, just gardens, hills, forests, and waterways, and a few other organically shaped sculptures.

You walk down the sunny flagstone path between the gardens to a narrow brook, only about a meter wide but flowing slowly along its meander. A stepping stone beckons you across, but you follow the flagstones along its bank. A mix of trees lines its other bank, none more than about three meters tall, because this is a new forest; it's dominated by fast-growing pines that are culled once slower-growing fruit trees have been nurtured in their shade. A clump of four-meter-tall bamboo, some culms three centimeters across, is visible a bit upstream.

A few meters downstream, the brook splashes down a little cataract into a pond, some seven meters across. Through the water of the pond, you can see the pond bottom clearly. Among its algae, you can see a number of rocks on the bottom; although many are opaque, as one normally expects, some of them are round and shining, like ovoids of dark glass. By the side of the pond is a weeping willow. Trails of bubbles are coming up on part of the pond's surface.

Another grassy hill is next to the pond; over its crest is visible a sort of wooden arch, standing alone, with what appears to be a large wooden snailshell atop it. The flagstone path curves around the hill. Rather than accepting the pond's invitation to swim, you follow it past a pink granite boulder protruding from the side of the hill. There is a three-meter-wide circular door in the boulder. You touch it and enter, ducking slightly and closing the ponderous door behind you with little effort, due to its high-precision bearings. It seals tightly.

You are in a three-meter-wide corridor with an arched ceiling, sloping down into the hill and beyond. Although it's not as blinding as the sunny meadow outside, it's brightly illuminated from all sides; the walls have the appearance of stained-glass windows, a brilliant glow from within illuminating the deep blues and reds that form the images on their surface.

The air in the corridor smells fresh, despite the apparent hermetic seal on the door and lack of noticeable draft inside.

You walk down the mild slope of the corridor, past a door labeled STAIRS near the entrance, past some 24 meters of the luminous murals, around a bit of a curve, past some benches, to a grouping of three large doors at the end of the corridor, two made from laminated bamboo and one apparently a dark-stained hardwood. The top of your head is now a bit lower than the threshold of the door through which you entered. You knock on the door of your host.

They open the door to welcome you. You enter, noticing that the door is quite a bit heavier than you would expect a laminated bamboo door to be.

The apartment is nearly circular, some 11 meters across, and as brightly illuminated and fresh-smelling as the corridor. It is nearly silent; the machine noises we often hear in conventional housing, from refrigerators, computers, air conditioners, etc., are completely absent. Also, there are no cars outside, and even if there were, the noise would not reach you underground. You hear only the sounds of your friend and yourself.

The walls here are white plaster, smoothly curving into the ceiling, rather than the luminous stained-glass look of the entry corridor. The upper parts of the walls and ceilings are illuminated by what seems to be sunlight, shining up at it from tiny alcoves in the walls. The ceilings are only three meters high, no higher than those of the corridor, because you are barely below ground at this point.

A 2-meter-wide round hole in the floor of the four-meter-across round room in the center of the apartment has a bamboo railing around it, providing a view to the four-meter-tall lower story. An archway on the outer edge of the apartment, near the door to the corridor, leads to a gently sloping two-meter-wide helical ramp curving around the perimeter of the apartment; after almost one and a half turns, this reaches the floor below, rendering the entire apartment wheelchair- accessible without elevators.

The total floor area of the apartment, not counting this outer helical ramp, is some 190m² (2045 sq ft); it is divided into ten rooms of different sizes, with different ceiling heights. The central downstairs room has a two-meter-wide hole in its four-meter-high ceiling leading to the three-meter-tall upstairs, for a total of over seven meters; while other parts of the downstairs have lofts for storage built over them, lowering the normally four-meter ceilings down to 2½ meters, and there are even a few alcoves where an adult cannot stand comfortably.

Different parts of the apartment are illuminated by different ways and to different degrees. Some parts have quartzite and agate protruding from the walls, brilliantly glowing from within; other parts have the ceilings flooded with sunlight; others have the stained-glass effect from the entry corridor.

There is another emergency-exit door labeled STAIRS in the

lower story of the apartment, and also another mysterious door, which turns out to link to an on-demand electric very-light-rail system allowing you to travel to other nearby houses even when it's snowing at speeds of 40 kph (11 m/s).

What "natural lighting" normally means in architecture

Brian Knight explains (confirmed by the Passive Solar Primer) that for passive winter solar heating of homes, you want 9–12% of the floor area of the house in south-facing windows, in the context of the 35° north latitude of Asheville, NC. "More than 12 percent puts the house at risk of overheating unless the design includes extra thermal mass," he explains. This tells us that we can get enough natural light to make people happy with our architecture with only about 10%.

But that's not 10% of the sunlight; that's 10% of the floor area in the form of vertical south-facing windows. At 35° latitude, you're only getting about sin(35°) ≈ 57% of that amount of sunlight, a bit more in summer, a lot less in winter. If you're getting the light from windows facing the heavens instead of standard horizontal windows, you only need about 5.7% of the roof space to gather the necessary light. And that illumination will be stabler throughout the year.

Photovoltaic-powered electrical lights are a bad idea

Now, one thing you could do would be to try to do it with photovoltaic solar panels, and run electrical lights from them. The problem with this is that normal solar panels are only 16% efficient, and the luminous efficiency of a regular lightbulb is only 2%, a quartz-halogen bulb can reach 3.5%, compact fluorescents and LED lamps are typically about 10%, while sunlight is 13.6% (because only 37% of its light is within the visible band, and much of that is far from our photopic sensitivity peak). That means that every lumen of sunlight can only convert to about 16% × 10% / 13.6% ≈ 0.12 lumens of artificially generated light indoors. So instead of 5.7% of the roof space, you'd need about 48% of the roof space for solar panels for illumination alone, not leaving much space for anything else.

Lightpipes are a good idea

[Light pipes] (or light tubes, or lightguides) are like fiber optics, but thicker. Big ones can be silvered on the inside, like a thermos, and filled with air; small ones can be solid or water-filled. The light suffers a 4% Fresnel loss upon entry and upon exit, plus some absorption on the way down. (This absorption can be advantageous if you want to reduce infrared and ultraviolet in order to increase the illumination-to-heat and illumination-to-sunburn ratio; but ultraviolet absorption by Biosphere 2's regular glass roof resulted in ecological problems within, so beware.)

Typical lightpipes can carry 70% to 90% of the sunlight fed into them for many meters. Optical concentration (imaging or nonimaging) can concentrate multiple square meters of sunlight into a lightpipe whose cross section is a fraction of a square meter.

So, supposing that you want to illuminate a 50m² subterranean

apartment to conventional "natural lighting" levels. You can gather sunlight from a 50m² × 5.7% ÷ 80% ≈ 3.6m² area on the surface, stuff it through a 20cm-diameter 80% efficient lightpipe to carry it down to your apartment (leaving the infrared and ultraviolet up on the surface), and let the other 46.4m² of sunlight nourish your garden and park. Perhaps you can put the solar collector a couple of meters above the ground as a sort of artificial shade tree — the rotifer and snailshell sculptures mentioned in the introduction.

Needing 7.2% of your surface area (per underground story) is much better than needing 48% of it.

Illuminating the 190m² subterranean apartment in the illustration to this level will require shading almost 14m² at the surface. The rotifer sculpture mentioned at the beginning would have a mouth area of up to 19.6m²; the seven-meter-wide pond totals about 38.5m², and if the glass stones on its bottom cover 36% of the bottom, they would collect a similar amount of sunlight.

Nonimaging optics are limited to a concentration factor of $C_{max} = n^2/\sin^2\theta$, where n is the index of refraction at the absorbing aperture (1 if you're doing it just via reflection) and θ is the maximum angle from the optical axis at which you're gathering the light (the half-angle of the radiation cone apex). The rotifer sculpture might have a concentrating parabolic reflector of 2.2m radius at the mouth, concentrating down to a lightpipe throat of 75cm radius inside its sandstone-finish stem; that's a concentration factor of 8.6, which limits it to collecting sunlight from no more than 20° off-axis, or a total of a 40° arc through the sky, unless you turn the rotifer to track the sun a bit, or feed multiple sculptures into the house, each covering part of the sky. Note that the tropics are almost 47° apart, so you'll probably have to reorient the rotifer seasonally at least.

Note that if you can track the sun perfectly, the theoretical maximum without refraction is $\approx 1/\sin^2(0.54°)$, or about 11000 — about 11MW/m² or 1100W/cm².

You can trade off azimuthal field of view for elevational field of view for a given concentration, though; in the extreme of an east-west trough concentrating reflector, you could get the same 8.6-sun concentration by orienting the trough within 6.68° (or 6.68° - 0.54°, really) of coplanar to the plane of the sun's nearly-planar apparent motion.

Agricultural sustainability

The apartment described in our introductory anecdote occupies some 133m² just below the surface, although it has considerably more floor area than that because of its two stories. It could host a fairly large number of people; it's exceedingly spacious for just one or two people. It might become a bit of a pain to clean, in fact.

But the smallest number I've been able to convince myself of, for agricultural sustainability, is 50m² of cultivated area per person, using soybeans, dwarf corn, and ample soil amendments. In colder climates, even approaching this level of productivity requires greenhouses and similarly extreme measures. And if only some of the surface is gardened, in order to leave some of it for forests, brooks, and light collection, you need more space. And lower-labor agricultural systems like apple orchards are also lower productivity per hectare. (Mature tall-spindle apple orchards can yield 1000 bushels per acre per

year; at 40 pounds per bushel and 52 kcal per 100g that's 2331 kcal/m²/year (310mW/m²!) which is about ⅐ of the raw productivity of high-yielding conventional agricultural systems like corn. Supposedly netting and Tatura training can close most of the gap, but I'm skeptical, and anyway that moves the apples back into the high-maintenance intensively-cultivated category.)

Anyway, let's say you need 100m² per person for gardening. Then 150m² per person gives you some space for meadows and forests and whatnot, too. That's 6700 people per square kilometer; this compares reasonably to many current cities, such as Dalian at 7100, Rio de Janeiro at 6850, Bangkok at 6450, London at 5100, Athens at 5400, the Buenos Aires metropolitan area at 4950 (Buenos Aires proper is 14000), Moscow at 4900, Berlin at 3750, Accra at 3300, Quito at 3150, and Los Angeles at 2750.

Emergency escape

The plan described in the introductory anecdote features a number of heavy doors that close tightly. The door to the outdoors is like this in order to facilitate indoor climate control, but the others are that way for fire-escape reasons: you need to be able to reach a fire escape that's sealed off with a fire door without having to travel too far. So the door that appears to be laminated bamboo is actually a steel fire-door core with laminated-bamboo surfaces, so that fires or chemical releases inside one apartment don't render the escape route for the others unviable.

Medieval fortress defensibility scale

I ran into a fascinating discussion of medieval sieges the other day; one of the discussants said:

> There is usually a balance that prevents long long term sieges...a large population is capable of fully defending the walls and keeping the invaders out, but consume more resources and shorten the time that they can hide behind walls. A smaller force will consume less resources and hold out for longer, but they risk not being able to defend the walls fully due to lack of man power.

But of course a sufficiently large fortress doesn't suffer from this problem, because its ratio of arable land to walls becomes arbitrarily large; and this happens sooner if productivity per acre is high. Leaving aside motte-and-bailey-type fortresses where the food is grown *outside* the fortress in the bailey, what's the scale at which the lifestyle outlined in this scenario would become able to defend a hypothetical wall?

Suppose we need one defender per two meters of wall. Then a circle 300 meters across would have 942 m of wall around it, and also 471 × 150m² of land inside of it, and therefore be able to support 471 inhabitants, sufficient to defend that wall. 309 meters across would support 500 inhabitants.

This is a size sufficiently larger than Dunbar's number that you would probably need some kind of official power structure within it.

Clustering

In the example scenario, you have three apartments that access the surface through the same entry tunnel. In practice, you might want to cluster houses together more than that; there are great advantages to being able to borrow a hammer or some yeast from your neighbor

without having to walk 100 meters, and in particular there are advantages to serendipitous meeting and chit-chat with neighbors. If you cluster groups of ten such apartments together, and figure two inhabitants per apartment, everybody's gardens are a little further off (2000m², for the 100m² of gardens for 20 people, excluding parks, has a radius of 25 meters), but they'll encounter each other much more often, and forests and ponds can be proportionally larger; and in the fortress case, you can go slightly motte-and-bailey and actually locate the parks for the outside the fortress walls, leaving only the arable land inside.

This allows you to reduce your 309-meter-across circle by about 30 meters: the 14 or so clusters around the outside shrink to 2000m² each, leaving the other 11 or so clusters in the middle with 3000m², for a total area of 61000m² and thus only 279 meters of diameter, or only 877 meters of outer wall.

The Subway

I said there was an on-demand light rail. Specifically, what I have in mind is kind of like a horizontal elevator; a small capsule comes when you call it, and then takes you where you want to go, and is computer-controlled so it won't hit other capsules and you don't have to pay attention to driving it. Suppose, as above, that you have clusters of ten apartments containing 20 people, and your overall community is 309 meters across and 500 people, spread over a total of 25 stations. Each station, except the first, needs to be connected to at least one other station, and the stations are about 60 meters apart, so you need at least 1440 meters of tube. Say 1800 to be on the safe side, allowing for sidings and redundant loops. At an average of 5m/s you need 12 seconds to get to the next station and 60 seconds to get all the way across town. And you might have to wait 15 seconds for a spare capsule to come pick you up.

(Note that this 1800 is 3.6 meters per inhabitant, i.e. tiny in cost.)

The tube can be quite narrow. Suppose the capsules are designed to accommodate up to six people, two abreast, or one abreast if it's a wheelchair; the cabin can be two meters wide, 1½ meters tall, and three meters long. The tube can be 2½ meters wide and 2 meters tall, so the 1800 meters of tube suggested above work out to 4500m², or 9m² or 18m³ per inhabitant.

Also, the capsules, rails, and power cables (or shafts, or whatever) can be fairly light. Six people weigh 600kg or less, normally; accelerating 600kg to 11m/s over 30m takes about 6 seconds, which means it's about 1m/s² (a comfortable 0.1 gees), 600N, with a peak power of 6600W or a bit under 9 horsepower. Amazon sells a 1½-horsepower motor for pool water pumps for US$250 (the Hayward SPX2710Z1M); it weighs 27.7 pounds (12.6kg), so we can figure that a durable 9 horsepower would weigh 75kg and cost about US$1500. (Starter motors can be similar in power and weigh much less, but pool water pump motors are sold to run for hours continuously every day, not for a second or two a few times a month.)

So the whole capsule might weigh 800kg and need 12 horsepower of motors (to hit its target speed. That's ten kilowatts of electricity, which would be 21 amps at 480 volts — very easy to supply with no significant loss with a third rail. Given the short distances and the

availability of rails, you could maybe even use 48 volts at 210 amps, eliminating the risk of electrical shock, although you could still get creamed by a capsule on its way through the station.

A single capsule would need 84 round trips (168 minutes) to transport the entire population from one extreme of the town to the other, so you might need some ten capsules in total, one for every 50 people; this would allow 12% of the population to be in transit at any given time, if necessary. That's a total of US$30 worth of motor per person, and maybe another US$30 or US$100 worth of capsule construction.

I don't know how heavy train rails need to be to support a 800-kilogram mini-train. Standard axle loads are 19.3 tonnes per axle running on rails that weigh about 44.6 kg/m; here we're talking about 0.4 tonnes per axle, which (with linear extrapolation) would work on 0.92 kg/m rail, which is like a fifteenth of normal "light rail" rail. That would be a total of about 1700kg of steel for the system as a whole, or 3.4kg per inhabitant.

(In fact, you could go even chintzier: mountain bike tires are up to 57mm wide and can reasonably have a 15cm contact patch at 50 psi, so they can support up to 300kg each. Four wheels with mountain bike tires would work.)

If you were to scale a system like this one up, its 11m/s top speed would allow you to cross Buenos Aires, which is about 18km across at its widest point, in 27 minutes, plus half a minute to walk 30m to the nearest station and 10 seconds for a capsule to arrive. If you could double the top speed to 22m/s (79 km/h, 49mph; this would not require bigger motors, only accelerating for four times as long) then you could cut it to 14 minutes. Currently crossing Buenos Aires from Puente Saavedra to Villa Riachuelo in the bus takes 85 minutes on the 28 or 21 bus, which travel along the freeway. If you take the 76 and 150 through the city instead, it's 109 minutes. And often you have to walk for hundreds of meters to reach the bus stop and wait there for tens of minutes.

Given the advantages of this kind of transportation system, which would cost US$95 of vehicle, 3.4kg of steel rail, and 18m³ of tunnel excavation per inhabitant even at the low urban density of 6700/km², As urban distances go down, the cost of rail and tunnel should go down proportionally. So having built such a system in Buenos Aires, with its 14000/km² population, would have been enormously useful.

Gordon Mohr suggests that you could recharge at subway stations instead of having a third rail. 60 seconds at 3kW is only 180kJ; at the 18kJ/kg of current supercapacitors, you'd only need 10kg or so of them. If you could recharge as you zipped through each station, you'd only need 6 seconds, or 18kJ. Amazon will sell you 2.7V 10F capacitors for US$2.84; they can store 36 J, so 18 J of capacity would cost you US$1420, comparable to the motor.

The continuous-web press and the continuous press of the World-Wide Web

Kragen Javier Sitaker, 2017-03-20 (6 minutes)

I saw a continuous-web press in operation for the first time last night; by chance, I walked by the door of a newspaper at 2:30 in the morning and saw the morning edition being printed, cut, folded, and baled. And I was reminded about the twentieth-century saying, "I never quarrel with a man who buys ink by the barrel," originated by Charles Brownson, a Congressman from Indiana. I pondered this as I watched the awesome spectacle of one of the most powerful weapons of the twentieth century in full operation: a mass duplicator of information, the weapon that centralized control over public opinion in dictatorships and democracies alike.

It occurred to me to estimate the bit rate of this duplicator. A crude estimate of its speed would be about 2 meters per second, printing on a web that's roughly a meter wide. A similar newspaper we have here in the house has twelve columns across a two-page spread, perhaps 50mm from one column to the next, 3.8 mm per line. Here are ten representative lines of text from one such column:

nomía nos trajeron hasta esta
decadencia; las correcciones son
dolorosas y sufridas, y encima
Cambiemos suele prescindir del
vijo axioma de Raúl Alfonsín:
"Hacer política es hacer docen-
cia." El 70% de la población sabía
que marchábamos hacia Vene-
zuela y que la luz no podía costar
lo mismo que un café americano,

This is 317 characters of text, including newlines, in a 50mm × 38mm area, about 170,000 characters per square meter. If we figure that each character of text is 3 bits, which is about right for zipped text, this is 510,000 bits per square meter. This means that two square meters per second is roughly 1.02 megabits per second.

(We should perhaps correct somewhat for the fact that some of the paper consists of colors, even full-color photos.)

So, in the mid-twentieth-century world, a one-megabit-per-second web printing press could give you near-dominion over a small town, or a substantial position in the affairs of a large city or a nation; it would make a US Congressman fear you. Even today such an asset grants substantial influence, both because of its signaling value and because it allows its owner to reach the rapidly-diminishing population of people who still don't have computers.

But the US just elected Donald Trump as President in spite of every newspaper in the country endorsing Hillary Clinton. It seems that the apparatus of manufacturing consent is no longer effective. And I think that we can explain this largely in terms of these bit rates.

A web site in Macedonia can easily sustain a megabit per second, and any cellphone on the planet can read it.

To put this in a concrete current economic context, DigitalOcean currently offers a virtual private server (VPS) with 512MB of memory, a one-core processor, a 20GB SSD disk, and a terabyte of data transferred for US$5 per month or US$0.007 per hour (US$5.11 per month). A terabyte per month is three megabits per second — average, not peak. So DigitalOcean's smallest server is probably substantially higher bandwidth than the continuous-web press I saw.

Moreover, publishing something on a web site only requires you to send it to the people who want to read it, while publishing it in the newspaper requires you to make one copy per copy of the newspaper. So those megabits go a lot farther.

Of course, newspapers also offered anyone the opportunity to publish advertisements costed per page, although the cost was higher. The ability to have your message printed on the high-speed press wasn't what gave you power; it was your ownership, which allowed you to choose which message to print.

Today, a Raspberry Pi 3 costs AR$930 here in Argentina, which is US$58. It has a 100-megabit-per-second Ethernet port, which is probably a bit faster than you can get information out of it in practice; Jeremy Morgan found nginx was the fastest option, managing about 3900 transmissions of a 95,881-byte HTML file in two minutes, which is about 25 megabits per second. (The Monkey httpd was a bit worse, and lighttpd and Apache were several times worse in his high-concurrency test.)

So the capital cost of a machine to emit 25 megabits per second is about US$60, a bit over US$2 per high-speed continuous-web press equivalent, or maybe US$0.10 if you try to figure in how much of the newspaper each person reads. If you were duplicating data onto SD cards or something instead, you would probably get higher bandwidth.

By making the press itself abundant, we have not eliminated inequalities in power; we have merely shifted the bottleneck and corresponding power to elsewhere in the social system. The natural expectation might be that it would move to the organizations that control the physical infrastructure needed to distribute the copied information, and that could indeed happen — witness the failure of USA internet companies to penetrate into China due to its lack of net neutrality favoring domestic firms — but it seems that what more commonly happens is that power shifts to the institutions that have accumulated the data and interpersonal relationships to make the most addictive uses of these network links.

Digital noise generators

Kragen Javier Sitaker, 2018-10-28 (2 minutes)

The traditional approach to generating noise with a digital circuit is to use a maximal-length LFSR, which has the great advantage of using only a single bit operation per generated bit, although XOR is perhaps a somewhat more complicated bit operation than NAND or abjunction.

A crucial feature of the LFSR is that its state transitions are reversible; they do not lose information. Consequently its cycles form a partition of the state space; every state is the successor of some state, by a counting argument. In maximal-length LFSRs, there are two cycles: one of period 1, containing just the zero state, and one containing all the other states.

When thinking about generating digital noise on CPUs, it is interesting to think about other available reversible operations. For example:

- Rotating left or right by a constant number of bits.
- Adding or XORing a constant.
- Multiplying by an odd number.

- As a special case, 2's-complement negation.
- Permuting the bits or bytes of the state vector with a constant permutation.
- XORing any part of the state vector with the state vector, as long as no bits XOR with themselves, which is irreversible.
- Multiplying by a constant m modulo some other relatively prime constant n, iff the current state is less than n.
- Running an arbitrary substitution on the bit vector via a constant lookup table.

These are, as it turns out, the usual building blocks of symmetric cryptosystems and hash functions.

What if we investigate the periods and spectra of the functions comprised of different sequences of these operations? Perhaps we could find something that was fast to execute on a CPU, but also provided long-period white noise.

Such techniques are also useful for hashing to, for example, generate Perlin noise.

Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods

Kragen Javier Sitaker, 2019-08-17 (updated 2019-09-15) (15 minutes)

(Probably nothing in here is novel; it just documents my own exploration of the space of local search algorithms in vector spaces, which is well known, but not to me.)

When writing Rubber wheel pinch drive (p. 2912) I got confused with some basic trigonometry, trying to solve a triangle with the law of cosines† to find the intersection of two circles. So, impatient, I figured I'd solve the problem with brute force instead, so I wrote the following implementation of local search with random restarts for scalar functions of general vector spaces:

```
def search(f, p, restarts=30, steps=30):
    best = None
    for start in range(restarts):
        current = p()
        current_badness = f(current)

        for size in range(20):
            for i in range(steps):
                new = current + p() * 4**(4-size)
                new_badness = f(new)
                if new_badness < current_badness:
                    current, current_badness = new, new_badness

        if best is None or best[1] > current_badness:
            best = current, current_badness
```

Here `p` is a function that yields a vector from the domain of `f`, which returns a real.

At first this didn't work very well because I had erroneously provided a guess function `p` that was always non-negative, so each restart would progressively step from the neighborhood of 0 to the neighborhood of the correct solution and then get stuck. Nevertheless, it was able to find a reasonably good solution (and then I realized how to solve the problem in closed form without trigonometry).

† The law of cosines is $c^2 = a^2 + b^2 - 2ab \cos \gamma$, where γ is the angle opposite the side with length c.

Making local search in vector spaces more robust

Random restarts in general make metaheuristic search algorithms more robust; indeed, even the simplest possible metaheuristic search algorithm, "choose a random point", becomes workable with random

restarts.

In this implementation, the restarts aren't very random.

I tried to make the implementation somewhat robust against `p` functions of the wrong magnitude, as you can see; the algorithm tries a range of different exponentially-spaced sizes. Now that I'm using a non-broken `p`, this results in finding a solution correct to ten decimal places, which is pretty good for such a simple local search algorithm. But the particular orders of magnitude I chose are kind of arbitrary; basically I was just hoping they'd cover the right range.

It occurred to me that you can make it more robust against `p` guesses of the wrong order of magnitude by updating `size` incrementally, using a procedure like the following: when you find a step that improves the guess, try half that same step or twice that same step. If that improves the guess further, then multiply `size` by 2 or ½, respectively, before the next iteration. This way, if your step size is about right, `size` will experience a random walk around it, but if it's much too small (you're stepping around a locally flat linear region of the cost function) then `size` will grow exponentially, while if it's much too large (you're rocketing out of the basin with all the solutions in it) it will diminish exponentially.

By the same token, you could make it robust against a `p` function like the one I provided by trying a step of $-p$ when p makes the situation worse. That way, if you're in a relatively non-curved region, you can make progress by just shifting into reverse. Trying this actually gives you another crucial piece of information: if going both ways makes it worse, there's a good chance you're in a local optimum, using a step size that is too big to have a good chance of improving your position.

You could implement this as follows, though this code is a bit repetitive:

```
def climb(f, step):
    size, growth, here = 1, 2, step()
    cost = f(here)

    while True:
        yield here, cost  # This may be the same as last time

        where = size * step()
        new = here + where
        new_cost = f(new)
        if new_cost > cost:
            where = -1 * where
            new = here + where
            new_cost = f(new)

        if new_cost > cost:
            size /= 2
            continue

        where *= growth
        grown_new = here + where
        grown_new_cost = f(grown_new)
        if grown_new_cost < new_cost:
```

```
            new, new_cost = grown_new, grown_new_cost
            size *= growth
        else:
            growth = 1/growth

        here, cost = new, new_cost
```

This is able to find a good approximation of the intersection of two circles in "only" 128 iterations, using the following definitions, even when the answer is several orders of magnitude away from the starting step size:

```
def distance(p1, p2):
    return ((p1 - p2)**2).sum()**0.5

def circles(c1, r1, c2, r2):
    def badness(guess):
        return ((distance(guess, c1) - r1)**2 +
                (distance(guess, c2) - r2)**2)
    return badness

step = lambda: numpy.random.rand(2) - 0.5
```

Handling valleys (ridges), saddles, and higher-dimensional spaces

However, its adaptive step size will screw it in higher-dimensionality spaces, since when it's in a valley or saddle point where most directions are bad, it will tend to diminish the step size and find a point on the valley floor very precisely. Perhaps a better approach would be to diminish step sizes by a smaller amount that depends on the dimensionality, so that if there's at least one good direction, the step size will remain constant on average.

("Valleys" here are "ridges" in the usual hill-climbing metaphor, because here we're trying to *minimize* a cost function, while "hill climbing" is trying to *maximize* your altitude.)

To escape this trap, you could have different behavior when expanding the step size than when reducing it: keep increasing the step size without changing the step direction until the situation stops getting better. That is, walk along the line of the step by 2, 4, 8, 16, 32, etc., times the size of the initial step, rather than just 2 times, doing a crude line search once a promising direction is found. This will tend to ricochet you between the walls of a canyon, and eliminates the bias in the step-size random walk toward smallness, since any single lucky step in the right direction can increase the step size arbitrarily.

This is similar to the three-dimensional optimization strategy Dave Long tells me some bacteria use: flagella forward while things are improving, flagella backward (resulting in random tumbling) while things are getting worse.

In cases like those Adam and AdaGrad and the like are designed for, where the best step size varies enormously among different dimensions, you might want to use *hill climbing* — searching along one dimension at a time, so that you can use a separate step size for each dimension. This also potentially permits the use of Acar's

"self-adjusting computation" and similar generic incrementalization algorithms to speed up function evaluation. (See the section in More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) on incremental or self-adjusting computation.) Unfortunately, this means that you'll never make any further progress once you reach the floor of a diagonal valley. In *n* dimensions, there are $2n$ dimension-aligned directions a valley can descend in, but 2^n precisely diagonal orientations, so in some sense that's a much harder problem.

As an example of how relative scales on different dimensions matter, the above routine handles the following somewhat pathological problem reasonably well, although it takes it several hundred iterations; note the incorrect step function:

```
c = (3, 1e10, 4, 17, -5)
climb(lambda g: ((g-c)**2).sum(), lambda: numpy.random.random(5))
```

But it handles the following version much worse, requiring hundreds of thousands or possibly millions of iterations to solve it — it gradually exponentially converges on the right answer, but taking about 80'000 iterations per order of magnitude:

```
climb(lambda g: (((g-c)*(1,1,100,1,1))**2).sum(),
      lambda: numpy.random.random(5))
```

This induces a steep valley along the third dimension, and so the deltas in the other dimensions like the second and fourth dimensions suffer a drastically reduced step size, slowing their convergence enormously (from the outlandish values they took to get close to the optimum along the second dimension).

On one run, it finally found a solution accurate to two decimals on every dimension in iteration 886'803, after about 15 or 20 minutes of CPython interpretation:

```
886803 [  3.00416293e+00   1.00000000e+10   3.99999237e+00   1.70599240e+01
  -4.95000939e+00] 0.0177569891399
```

It goes about four times as fast with a non-buggy step function, converging to that same precision in only 207'804 generations:

```
207804 [  3.02129932e+00   1.00000000e+10   3.99999109e+00   1.70184720e+01
  -5.04976604e+00] 0.021740755647
```

The flagella-style variant described above improves on this by about a factor of 7:

```
28607 [  2.96086659e+00   1.00000000e+10   4.00023842e+00   1.69373547e+01
  -4.95732860e+00] 0.0155987598959
```

That's using the following implementation, which additionally is slightly simpler and only does one loss-function evaluation per iteration, instead of up to three:

```
def climb(f, step):
    size, here = 1, step()
```

```
    cost = f(here)

    while True:
        yield here, cost

        where = size * step()
        new = here + where
        new_cost = f(new)
        if new_cost > cost:
            size /= -2
            continue

        # We found a promising direction; swim!
        while True:
            yield new, new_cost
            where *= 2
            new_new = here + where
            new_new_cost = f(new_new)
            if new_new_cost < new_cost:
                new, new_cost = new_new, new_new_cost
                size *= 2
            else:
                break

        here, cost = new, new_cost
```

And this harness code:

```
from __future__ import division, print_function
import numpy

if __name__ == '__main__':
    c = (3, 1e10, 4, 17, -5)
    for i, (x, q) in enumerate(climb(lambda g: (((g-c)*(1,1,100,1,1))**2).sum(),
                                     lambda: numpy.random.random(5) - 0.5)):
        print(i, x, q)
```

As before, it takes four times as long if we leave out the `- 0.5`:

```
92241 [  3.04962626e+00   1.00000000e+10   3.99985342e+00   1.69648044e+01
  -4.97438500e+00] 0.00457665876023
```

Applied to the circle-intersection problem from before, it typically takes more iterations, like around 30 instead of around 10. (This is probably a somewhat smaller penalty than it sounds like, since the circle-intersection code from earlier is often doing two or three loss-function evaluations per iteration.)

It solves this geometric square model to a precision of 1e-6 typically in 1000 to 3000 iterations:

```
def square_constraints(points):
    p1, p2, p3, p4 = points[0:2], points[2:4], points[4:6], points[6:]
    side1 = p2 - p1
    side2 = p3 - p2
    side3 = p4 - p3
```

```
    side4 = p1 - p4
    return (side1.dot(side2)**2 + side2.dot(side3)**2 + side3.dot(side4)**2
            + side4.dot(side1)**2
            + ((side1**2).sum() - 5**2)**2
            + ((side2**2).sum() - (side3**2).sum())**2
    )

climb(square_constraints, lambda: 10 * (numpy.random.rand(8) - 0.5))
```

Without the fourth perpendicularity constraint, though, it converges very slowly, and the things it converges to don't look like squares. One sample result with the fourth perpendicularity constraint left out:

```
141071 [ 2.76119227 -2.36547768 -1.36787743  0.45423421 -1.35017868  0.48015388
 -1.33188753  0.50622078] 9.99823404211e-07
```

This has minuscule and nearly equal `side2` and `side3` (lengths about 0.032), whose dot product is consequently also very small even though they're very nearly parallel, being perpendicular to the nearly-parallel `side1` and `side4`. This allows `side1` and `side4` to minimize the function by becoming more and more nearly equal and opposite. It pays to be cautious when defining cost functions, since optimization algorithms will exploit whatever vulnerabilities they can find!

I haven't tried the per-dimension step-size approach above yet, though it would surely help for these examples.

Relationship to other kinds of optimization algorithms

See also Using the method of secants for general optimization (p. 1773) for a different generic derivative-free solver for scalar functions of general vector spaces, that one for zeroes instead of minima. I think both of these are only going to be reasonably fast for problems of low dimensionality, but I think hill-climbing suffers exponentially from high dimensionality, while the method of secants (like gradient-descent variants) will suffer only linearly from it.

Of course, you can find local minima of a computable continuous function by using automatic differentiation on it and using the method of secants to find a zero of its derivative.

Although the above implementations are not, hill-climbing and other kinds of local search are applicable to functions on discrete spaces without any kind of comparability between elements, such as graphs or strings of symbols. (That's the domain. The range still needs to be comparable.) The method of secants requires divisibility and zeroes. Hill-climbing also only requires comparability from its cost function — it takes no notice of its absolute magnitudes, just which values are higher and lower — and this *is* true of the implementations above.

Thoughts on quasi-Newton methods

For *regular* problems like the examples above, quasi-Newton methods would probably work better, but require differentiating the cost function. With the advent of automatic differentiation, this is no

longer a lot of work, but doing automatic differentiation on pure-Python functions like the above generally requires using forward-mode automatic differentiation, which is painfully slow. Reverse-mode automatic differentiation is dramatically faster for this sort of thing, but generally requires your program to be written differently.

As I said in Using the method of secants for general optimization (p. 1773), quasi-Newton methods require the maintenance of an approximation of the Hessian, and for functions of high-dimensional spaces, the Hessian is fucking humongous. A thing that has surely been tried, but that I haven't seen discussed, and which intuitively seems like it should work better for high-dimensional optimization problems, is using automatic differentiation to compute the gradient of the function to get a *direction* to move in, but then, rather than moving in that direction by an amount proportional to the *magnitude* of the gradient (as gradient-descent methods do), use automatic differentiation to compute the *second* derivative of the loss function *along that line*, which is a single number rather than a matrix of N^2 values (for a domain of dimensionality N) like the Hessian. Then you can use a Newton–Raphson step to figure out how far to move along that line: divide the first derivative (the dot product of the gradient and the direction) by the second derivative, thus extrapolating the distance to the point at which the gradient would fall to zero if the Hessian were constant over that region. (Alternatively, use affine arithmetic or reduced affine arithmetic to track down a precise zero along that line — see Fast mathematical optimization with affine arithmetic (p. 3163) for details.)

The appealing thing here is that gradient descent has linear convergence (i.e., the logarithm of the approximation error falls linearly with the number of iterations) while under appropriate circumstances Newton's method has quadratic convergence (i.e., the logarithm of the approximation error falls proportional to the square of the number of iterations). I'm not entirely sure whether Nesterov accelerated gradient descent, gradient descent with momentum, Adam, etc., achieve a better order of convergence, but I think they don't.

This would be big if true (see Things in Dercuano that would be big if true (p. 3136) and Top algorithms (p. 913)) which means that it, given how obvious it is, it probably doesn't work, or else I'm misunderstanding how quasi-Newton methods work, and they already do this. But it will be interesting to find out why not.

Very fast FIR filtering with time-domain zero stuffing and splines

Kragen Javier Sitaker, 2015-09-03 (updated 2015-09-07) (13 minutes)

It just occurred to me that maybe you can use splines to do convolution with large-support kernels without high-frequency components much more efficiently than using FFTs or time/space-domain convolution.

The underlying intuition here is that you can approximate the large kernel with a uniform spline of, say, second through fourth order, and then convolve that spline with the original data very efficiently.

This uses a series of inexpensive linear discrete-time time-invariant processing operations, specifically sparse-kernel convolution and boxcar filtering (simple moving average). But it does not fit into the standard FIR or IIR molds, so perhaps it's been overlooked so far. It is potentially an IIR filter, but the usual description of IIR filters in terms of linear combinations of past input and output terms does not yield an efficient implementation.

Splines

The spline curve through knots (0, 1) and (n, 0) for all other integral n approaches sinc as its degree approaches infinity.

XXX

Sparse-kernel convolution

A sparse convolution kernel is one that's zero at almost all points, except for a finite number of impulses. That is, the cardinality of its support is finite, and small compared to the bounds of its support. For example, in a discrete time domain, consider the kernel [-1 0 0 0 0 0 0 1 0 0 0 0 0 0 0 -1]. It should be apparent that, although this kernel covers 17 samples, you don't need 17 multiplications per sample to convolve with it without transforming to the frequency domain; you only need three. (And, in this case, even those happen to be trivial multiplications.)

A *recursive* version of sparse convolution, where the convolution kernel is causal and its output is added to the input, is the computational primitive of Karplus-Strong string synthesis, and digital delay-line audio synthesis in general.

In general, convolving a discrete-time signal with an N-impulse sparse kernel in the time domain can be done in N multiply-accumulates per input sample, regardless of the width of the kernel's support bounds.

In particular, the sparse kernels we will consider have impulses at the knots of some uniform spline; since uniform splines have regularly spaced knots [XXX is that the right definition?], the impulses in our kernel are also regularly spaced.

Boxcar filtering

Boxcar filtering is convolution with a "rectangular function", which is some arbitrarily scaled and shifted version of the "boxcar

function", which is 1 from -½ to ½ and zero elsewhere. This filter is also known as the "moving average" (or, to avoid ambiguity, "simple moving average"), "running mean", "rolling mean", "box blur", or "mean filter". This kernel and sinc are Fourier-transform duals.

Boxcar filtering of a discrete-time signal is very efficient: a boxcar-filtered signal is just the difference between terms a fixed distance apart in the signal's prefix sum (aka indefinite sum or antidifference), although this imposes a constant multiplication on you that you may wish to undo with a division. This means that you can calculate an boxcar filter of arbitrary width with one addition and one subtraction per sample, plus a big enough intermediate FIFO to cover the boxcar's length.

There's an inherent tradeoff between preserving step response and filtering out noise. Among linear filters with a given step response, boxcar filtering by itself is optimal for reducing independent independently distributed additive noise; for example, removing noise from a photograph while minimally fuzzing out the edges. Nonlinear filters like median filters can do better, but other FIR and IIR filters can't.

Repeated convolution of the boxcar function with itself yields the sequence of cardinal B-splines, which are successive piecewise-polynomial approximations to a Gaussian. Any uniform B-spline can be expressed as a weighted sum of these cardinal B-splines.

That is actually a well-known technique for efficiently approximating a two-dimensional Gaussian blur of an image.

Efficiently approximating a spline-kernel convolution

Because you can express any uniform B-spline as a weighted sum of cardinal B-splines, you can choose a regularly-spaced sparse kernel that will produce a given uniform compactly-supported degree-M B-spline through the knots when convolved with a fixed-width boxcar filter M+1 times.

Since composition of convolutions is not just commutative but also associative, this means that convolving your original signal with the N-impulse sparse kernel and then with a boxcar filter M+1 times will precisely convolve the image with an arbitrary N-knot degree-M uniform B-spline. This requires N multiply-accumulates and 2M+2 additions and subtractions per sample, M+1 FIFOs whose size is each the impulse spacing. In floating-point, the initial sparse kernel can be premultiplied by a small constant to compensate for the undesired amplification resulting from calculating from computing the boxcar filters without normalization; in fixed-point, most likely a bit shift in between stages of box filtering will be needed.

(I think this spline technique generalizes to a nonseparable multiple-dimensional kernel; if that is so, its computational advantage in two or three dimensions should be enormously greater.)

This approach is a fully general optimization for linear FIR filters used as bandpass filters, band-stop filters, and low-pass filters. It probably isn't useful for high-pass filters, because you will frequencies all the way up to Nyquist in your kernel, which means that your spline knots are necessarily a single sample apart.

However, because you can ensure that your filter (the one you implemented, not just the one you were approximating) is

linear-phase, you can subtract the filtered signal from the (lagged to zero-phase or π-phase) original signal to achieve some limited high-pass filtering.

(Note that in this case, since your sparse kernel is required to be even, you can use the folded FIR filter trick to cut the multiplications required by half again.)

I am SWAGging that this means that you need a number of multiplications per sample comparable to the Q of your filter if it's a bandpass filter, regardless of frequency. That is, for a Q of 20, you might need 11, or 21, or 41 multiplications per sample, but I doubt that you'll need 128 or that you can get by with 5. This, in turn, means that these spline-based filters should be very competitive with FFT-based techniques for all one-dimensional filtering outside the design space where Goertzel takes over.

(I thought maybe you could improve the Q further by composing the filter with itself, but it turns out that doesn't work: the Q improves by √2, but the computation time doubles. You have to actually include more signal samples under the kernel to efficiently get better Q.)

Designing the sparse kernel

I think you can totally just take a continuous FIR kernel and sample it at its Nyquist frequency, i.e. multiply it by a comb filter, and then convolve the result with the sparse kernel of coefficients for the fundamental spline you're using.

Spline definitions I'm confused about

https://en.wikipedia.org/wiki/B-spline says, "Any spline function of given degree can be expressed as a linear combination of B-splines of that degree. Cardinal B-splines have knots that are equidistant from each other. … A fundamental theorem states that every spline function of a given degree, smoothness, and domain partition, can be uniquely represented as a linear combination of B-splines of that same degree and smoothness, and over that same partition. … A cardinal B-spline has a constant separation, h, between knots. The cardinal B-splines for a given degree n are just shifted copies of each other."

https://www.cs.unc.edu/~dm/UNC/COMP258/Papers/bsplbasic.pdf seems better. It says splines are the linear combinations of B-splines. "'B-spline' refers to a certain spline of minimal support and, contrary to usage unhappily current in CAGD [computer-aided geometric design], does not refer to a curve which happens to be written in terms of B-splines."

Aha, and it explains that cardinal splines are the splines whose knots are at ℤ. I thought those were "uniform splines".

Related work

Unser, Aldroubi, and Eden's delightful 1993 paper [0] pioneered the use of the running-sum algorithm for linear-time B-spline filtering. On p. 827, they explain B-spline filtering:

> We propose the concept of B-spline filtering which is the process of applying a filtering operator to the continuous B-spline representation of a signal. When the operator is discrete, this procedure is rather trivial and does not seem to have any specific advantages: due to the linearity of all operations, one may as well apply the

filter to the discrete signal and avoid the unnecessary transformation step. Of greater interest is the case where the impulse response of the filter itself is represented by a B-spline of order *p*.

(By "represented by a B-spline", they mean "represented by a weighted sum of B-splines", as the equation not quoted here clarifies; Unser et al. regularly use "B-spline" to mean "weighted sum of B-splines", a usage which de Boor deplores.)

From this they derive that you can do a discrete convolution of the B-spline coefficients representing the signal and the filter kernel to get the (higher-order) B-spline coefficients of the convolution result.

However, it appears that applying this result to a discrete signal requires first deriving the B-spline coefficients from the discrete signal by a discrete convolution with the B-spline coefficients of the fundamental spline, and then after computing the convolution result in B-spline form, converting back to discrete-signal form by discrete convolution with the (higher-order, and thus longer-support!) sampled B-spline. This is a substantial amount of computation. Also, the Unser et al. algorithm requires the signal and the filter to be sampled (i.e. have spline knots spaced) at the same sampling rate, so it is no more efficient for a filter containing only low frequencies.

This restricts the applicability of the 1993 spline filtering algorithm.

The present work improves over the Unser et al. algorithm by avoiding the necessity to convert the signal as well as the filter kernel to and from the spline representation; and, furthermore, for filter kernels bandlimited to low frequencies, it can approximate the kernel with a high-order spline with much more widely spaced knots, resulting in much less computation.

Ferrer-Arnau et al. 2013 1 developed a filtering algorithm which superficially sounds very similar to the present one: they improved Unser et al.'s spline filtering algorithm by an approximate FIR filter. Upon further investigation, they developed a particular FIR filter to approximate the process of fitting a cubic spline to noisy data, rather than developing a spline to approximate an arbitrary FIR filter.

Vrcelj and Vaidyanathan 2001 [2] also uses FIR filters to approximately transform a signal into B-spline coefficients, rather than using B-spline coefficients to approximate a FIR filter.

CIC filters (Hogenauer 1980) are very similar indeed to the present work, consisting as they do of a composition of a cascade of running-sum filters ("integrators"), factored into a cascade of integrators, decimation, and a cascade of differentiators; or, for upsampling, a cascade of differentiators, zero-stuffing, and a cascade of integrators. Hmm, XXX if you stick a FIR filter in between two CIC filters running at a lower rate, is it the same thing? No; the CIC filter is *much more efficient*. The recommendation to put your compensation filter's cutoff below a ¼ of the first null frequency probably requires more FIR coefficients than I was thinking were necessary, but probably also applies to the present work!

Circle-portal GUI

Kragen Javier Sitaker, 2016-06-03 (11 minutes)

I was thinking about a zoomable, rotatable UI. In this world, there's some "world space" in which the scene graph exists, and your screen is an arbitrarily translated, rotated, and zoomed portal onto it, considered as a linear function in complex numbers: $y = mx + b$, where y is a point on the complex plane of world space, x is a point on the complex plane of screen space, and m and b are complex numbers that determine the translation, rotation, and zoom.

The world plane contains only one kind of object, which is mutable: portals.

A *portal* is a circle through which another part of the world plane is visible; like the screen, it consists of an (m, b) pair defining an arbitrary translation, rotation, and zoom, this time from the world plane onto itself. However, it also has a *clipping circle*, defined by a center and radius outside of which it is not visible, and a *background color*, which is an RGBA color that it renders underneath everything else seen through the portal.

Portals already existed (with that name) in Pad++ decades ago; in this system there are four differences:

- they are round, not rectangular;
- they can rotate as well as zooming;
- nothing else exists;
- they have a background color.

There is a total order among portals in the world plane, with portals earlier in the order being "painted on top of" portals later in the order. This may or may not result in the later portal being invisible because it's been obscured by an opaque background color.

Optimizations

Given the necessity to sample the world plane at pixel coordinates, you can do strength-reduction of the pixel-scanning operation; if Δx is the coordinate difference between pixels on the same row, you can compute $m\Delta x$ and scan the pixels on the row by repeatedly adding that.

To keep drawing quick, it's probably necessary to dynamically compute some kind of bounding volume hierarchy, which could be made out of circles or not.

As you move scan line by scan line down the image, you can use the midpoint algorithm (which incrementally updates an error accumulator $x^2 + y^2 - r^2$ as it changes x and y to walk along the circle) to incrementally adjust the start point of each circle.

You can cache parts of the world plane rasterized at some resolution, downsampling from there. However, it may be tricky to propagate updates.

Making things with it

First, of course, you can draw things by putting opaque portals on top of or next to each other. Those portals don't need to view anything in particular. At its simplest, you can use opaque black

circles all of the same size as if they were dot-matrix pixels, but you can also overlap a bunch of portals (either translucent or of different colors) to get a gradient, for example, or use two concentric circles of different colors and slightly different radii to get a curved line of some thickness.

Once you have a picture somewhere, you can add portals to it elsewhere in order to use it in more places. Changes you make to the original picture will be reflected in each of the copies. For example, you could draw a letter "C" in one place, add a portal to it, and add a crossbar on top of the portal, transforming it into a "G". Further modifications you make to the "C" — adding a serif, for example — will be reflected in the "G". If you draw glyphs for the letters "e", "t", "o", and "n", you can set up a series of portals to those letters to spell phrases like "no note on teen tenon tent to neon noon onto no tone". The rendering of the phrase will automatically reflect whatever changes you make to the original letterforms.

Furthermore, you can make a portal for a whole set of such pictures, such as an entire monospaced font, and use portals onto that portal to pull out individual letterforms. Then, if you redirect the portal to a different set of pictures, you have achieved a change of font. You could even have an area with several different font variants, such as plain, bold, italic, and bold-italic.

This works for monospaced fonts that don't differ too much in aspect ratio, and for proportional fonts that share the same font metrics, but it won't work very well for changing fonts between fonts with different metrics, including often changing between the plain and bold versions of the same font.

(You can make a crudely bolded version of such a font by making two overlapping portals to it that are shifted by less than a linewidth, thus thickening its lines.)

By putting portals within their own target, you can automatically generate fractals — which of course implies that the rendering code needs to handle infinite recursion gracefully.

User interface interaction techniques thus enabled

Since everything you see on the screen is a portal to "somewhere else", you can provide a command to jump to that other place, at which point you can zoom in or out as you wish. And you can add such a portal from anywhere to anywhere.

More commonly, you'd like to zoom in to look at a particular portal, without jumping through the portal. This should help a lot with the problem ZUIs have with constrained pixel displays, where things are almost always either too big or too small.

Conversely, you can display a set of "backlinks" to a place that are visual thumbnails in context of places that have a portal overlapping that place.

Because everything is a portal, in addition to jumping through it or moving it around, you can also drive it around the space it views, zooming, panning, and rotating.

Probably the usual way of making a new portal should be cloning an existing portal, after which you can start to make changes to it.

Minimal interactions necessary to use it

There are only a few basic actions:

- creating new portals;
- deleting portals;
- changing the background color of a portal;
- changing where a portal looks (its destination point, zoom, and rotation);
- changing where a portal appears (its location and radius).

For minimality of mechanism, the viewport portal should not require specially-implemented commands for it. It's just that deleting it or changing where it appears are inapplicable operations.

The usual map navigation actions are panning and zooming, and panning usually results from left-mouse dragging or finger-dragging. It would maybe be kind of unfortunate if left-mouse dragging did something to change the world, but of course that kind of conflicts with the desire for the viewport portal not to be special...

You might be able to get by with only jump-to rather than free panning and zooming: click on a portal to make it mostly fill your viewport. But that really only works for the viewport portal. Ideally (for minimality of mechanism) the viewport portal would be much like any other portal.

So that means that jump-to takes two different portals as arguments: the jump destination and the thing you want to cause to point at it (your "focus portal").

Even telling what you're clicking on may be a little tricky, since you can be looking at a portal that is viewing a zoomed-in view of another portal which is zoomed into a third portal, etc.

Practically speaking, you probably need to be able to copy portals so that you can make modified versions of them. But you can have two kinds of "copy relationships" between portals: a portal can simply be a view of another portal, or it can be a clone of it. It might make sense to start with a "create a view" command and then possibly later convert that into a "make a copy of the viewed scene".

At some point it may also be useful to push objects through a portal.

I'm thinking that probably when you click (or double-click?) on a portal a halo of buttons should appear around it offering you different options: one to change its size, one to move it around where it is displayed, one to delete it. Probably zooming and panning the selected portal should just be the usual mouse drag and scroll i

Prototyping

I've talked above a bit about techniques that might be useful for an efficient implementation of this system.

However, it should be possible to hack together a *simple* implementation of the system, enough to play with, much more easily... and so I spent a couple of hours on that in DHTML with `<canvas>`.

Real-time responsiveness

In the form described above, it's possible to require an arbitrary amount of computation per pixel; in fact, if the pixel happens to be a fixed point of a portal transformation, the amount is theoretically

infinite. This is intolerable for real-time user interface responsiveness.

To avoid this problem, I propose that we render portals each frame not from their *current* contents but from their *previous* contents, cached as a raster image from the previous frame. If no previous contents are available, use some placeholder texture that's easy to compute.

In the absence of alpha-compositing, this would guarantee that it's possible to calculate the screen image each frame with a single texture sample per screen pixel, plus some increment of work in updating offscreen texture buffers; if this increment is small, updates might take many frames to settle, while if it is large, they should settle quickly. This background increment itself has the same real-time pixel bound as the screen update. Normally you would expect the increment to be many times the size of the screen. For example, the VideoCore IV used in the Raspberry Pi claims a fill rate of a gigapixel per second, but only 2.1 megapixels of output screen resolution at most (and only one megapixel by default), so it should be able to compute almost seven screenfuls of offscreen texture updates per frame in the worst case.

To guarantee real-time responsiveness in the presence of alpha-compositing, partially-alpha-composited images should also be cached. Ideally you'd do this front-to-back, inverse-painter's-algorithm style.

Finally, it makes sense to schedule this offscreen texture updating to happen *before* the screen is painted rather than after, so that you'll only see lag in the case where there's more work to be done than can actually be done in a single frame time.

How inefficient is SNAT hole-punching via random port trials?

Kragen Javier Sitaker, 2018-04-27 (2 minutes)

Symmetric NAT is a tricky problem for peer-to-peer applications. Ierymenko says you can get 96% success in establishing connections if you do port prediction, but also that you can succeed eventually with random port trials because there are only 65535 ports.

The idea is that A and B send a pair of UDP packets to each other at the same time (on the mark of some third party) and have a 1/65535 chance of happening to guess the correct UDP port for the other. So if they do this once a second, they will succeed on average in 18 hours, at an average cost of 65535 packets per party. The time to success takes an exponential distribution.

I was thinking that perhaps you could increase your success by sending larger batches of packets, so that each packet has a larger "target size" to aim at, but that only makes sense for full-cone and address-restricted-cone NAT, which can be tackled by easier techniques anyway.

The purely random approach can still work faster than one packet per second. 16 packets twice a second should be feasible in most cases, which should take 2048 seconds on average. As long as this doesn't crash your NAT or disrupt your existing connections, which should be detectable, the expected bandwidth is (20 bytes IP header + 8 bytes UDP header) * 65536 = 1.8 megabytes, roughly the same as loading one extra web page.

3-D printing glass with continuously varying refractive indices for optics without internal surfaces

Kragen Javier Sitaker, 2016-10-06 (3 minutes)

For the "cloak of invisibility" using optical metamaterials, you don't actually need a negative refractive index; you just need to be able to precisely grade the refractive index throughout space. The approach they're taking is to fabricate nanostructures made of resonant components, but this has high dispersion, and so the invisibility fades as you use multiple wavelengths.

As an alternative, you could vary the mix of materials going into a block of glass. More lead oxide in one part, more silicon and aluminum oxides in another. But how can you achieve that? Depositing glass powders and then sintering them will leave you with a part that's full of voids. Voids are potentially problematic in structural parts (e.g. metal mounting brackets) but totally fatal in optics.

If instead of sintering the powders you fully melt them so that bubbles can rise, the bubbles will mix together the glass that they float through, and to a lesser extent the glass around it, especially if you put it under vacuum to degas it like in resin casting. Also, if the viscosity is too low, you may get convection currents.

Depositing the glass by FDM in air seems like it would hardly be any better.

A possible alternative would be to immerse the workpiece being built in molten lead oxide, using either selective powder deposition or FDM extrusion to deposit a higher-melting glass "underwater", thus avoiding bubbles; the molten lead oxide would fill any voids. The lead oxide would immediately begin to "flux" or dissolve the higher-melting glass, so tight temporal control of the process is critical. That same process of dissolution or diffusion can continue even below the glass transition, but more slowly, and is crucial to achieving a smooth gradient, but it also limits the strength of the gradient that can be achieved. It may be necessary to bake the finished workpiece in a solid state for some period of time after completion.

(The lowest-melting glass may not be pure lead oxide, but rather some mixture; ideally you'd use the lowest-melting glass for the immersion medium. Above the glass you could use a soft vacuum)

Speaking of gradients, one way to reduce the variability in such a process would be to maintain a vertical temperature gradient in the workpiece being built layer by layer, such that only the surface is above the point of lead oxide, while the layers below are below the glass transition temperature. This won't prevent diffusion, just slow it down, but it will stop slumping.

Optical systems built in this way, using gradients rather than surfaces, can entirely avoid the problems of stray light from unwanted

reflections from the surfaces of lenses, although total internal reflection is still possible, as in a graded-index optical fiber.

Optimization-based painting software

Kragen Javier Sitaker, 2018-04-27 (1 minute)

Optimization-based painting software are going to be a big deal.

What I mean by that is software that generates an image according to some kind of model of the image-forming process, controlled by a sketch made by the user. Perhaps at a reduced pixel count, or reduced coloring, or with added noise due to mouse, or whatever.

Perhaps the model involves lines, or wavelets, or gradients, or boundaries between areas, or three-dimensional objects, or people, or animals, or convolutional neural networks, or whatever. It's relatively straightforward to generate an image from such a model, and then you can compare the image to the image the user has drawn, using a metric that takes into account the kinds of errors people don't intend, in order to infer a highly probable underlying model — if not the most probable one given the whole set of possible models, which is probably infeasible to compute, at least a reasonably probable one. Then, given this underlying model, you can generate a high-fidelity image of what the user intended.

But that's just the beginning, because then you can modify the image in order to correct the model, you can select among a variety of images representing different models, and you can select among many images that potentially represent the same model.

How should we design a UI for a new OS?

Kragen Javier Sitaker, 2012-10-10 (updated 2012-10-11) (4 minutes)

I'm suffering quite a bit from trying to use Linux, Windows, and MacOS on current hardware. There's no reason, for example, for this laptop to spend thirty seconds or more to become ready for use when I want to use it. Its video display holds perhaps 3 megabytes of data, and it's capable of reproducing 60fps fullscreen 1024x600 video, which means it can draw the full screen contents, including running the video codec, in 16ms. 30 seconds is 1800 times longer than it ought to take to get to a useful screen.

There are responsiveness and performance problems all over the place. It's totally unacceptable that Ubuntu's pretty main menu takes three seconds or more to come up when I press the Windows key. Alt-tab between two windows that are already open has a noticeable delay, which means it's over 200ms. And, although the machine has a gigabyte of RAM, it frequently runs into OOM kills and memory-shortage kernel panics. Even on Ubuntu machines that aren't suffering from that particular problem, the machine often has to swap for a few seconds in order for the screen saver to display its password prompt.

And then there are things that just don't work. The trackpad stopped working (maybe when I rebooted with Ubuntu 12.04). The wireless disconnects and then won't reconnect without rebooting, a problem I also had with Ubuntu 8.04 on a Dell Vostro 9. The machine doesn't sleep when I close the lid, and when I sleep with the sleep key, it doesn't wake up reliably --- sometimes it gets into a mode where the screen turns on after every keystroke for 100ms or so.

I suspect that a lot of these problems are a result of the monolithic kernel design. This kernel has 43 modules loaded, including modules for the sound, the wireless, the mouse, the nonexistent parallel port, and the nonexistent Bluetooth interface. None of these can be restarted cleanly, and a bug in any of these subsystems can cause problems in the system as a whole, and although this is of course also the case with any driver that controls hardware that supports DMA, many pieces of hardware nowadays don't support DMA, or support DMA only in well-defined ways, e.g. via USBI UHCI.

Furthermore, although it's often possible to work around bugs in these subsystems by rebooting the machine, the kernel that gets rebooted is also the kernel that's running all your applications, so your applications lose their state too --- even though there's really no possibility that vi, Emacs, the GIMP, Firefox, or GnuCash has runtime state that's so tightly coupled with your video card that it can't be reasonably preserved across a restart.

On top of all this, sound often skips when playing MP3s if there's other stuff going on, like a compile or some web browsing.

So I propose a new system architecture for end-user free-software systems:

• a small hard-real-time hypervisor that's responsible for providing a trusted path to a low-latency user interface, protecting access to any DMA-capable hardware, and checkpointing and resuming virtual-machine images running under it;
• a display server running directly under the real-time hypervisor, handling the keyboard, mouse, and monitor, which is unavoidably part of the TCB because it provides the trusted user interface path;
• a Linux kernel, or several, running under the real-time hypervisor to handle other devices that need DMA; this is unfortunately part of the TCB.
• a separate Linux kernel, or several, running applications that don't need direct access to hardware at all; these can be checkpointed and resumed without knowledge of the applications.
• other Linux kernels to run applications that need direct access to hardware that doesn't do DMA. These can't be checkpointed and restarted, but they also aren't part of the TCB.

Topics

Circuit notation

Kragen Javier Sitaker, 2016-09-08 (updated 2017-04-18) (7 minutes)

(See also Graph construction (p. 3226).)

I was thinking there must be a way to write down circuit diagrams in an expression-like textual string in a compact way. This "example circuits and netlists" page gives the following example netlist for SPICE:

```
Multiple dc sources
v1 1 0 dc 24
v2 3 0 dc 15
r1 1 2 10k
r2 2 3 8.1k
r3 2 0 4.7k
.end
```

That defines two voltage sources, three resistors, and four nets (nodes). But it's a purely series-parallel circuit. If we use `|` for parallel composition, mere concatenation for series, `'` for inversion, and `[]` for grouping, we could write it as `V 24 R 10k [R 4.7k | R 8.1k [V 15]']`, which I think would be a huge improvement. Better still, without the component values, that's just `VR[R|RV']`.

You'd still need some way to handle circuits that aren't purely series-parallel, that aren't circuits, or that contain non-two-terminal elements. For example, further down, we have this bridge-rectifier circuit:

```
fullwave bridge rectifier
v1 1 0 sin(0 15 60 0 0)
rload 1 0 10k
d1 1 2 mod1
d2 0 2 mod1
d3 3 1 mod1
d4 3 0 mod1
.model mod1 d
.tran .5m 25m
.plot tran v(1,0) v(2,3)
.end
```

That's not series-parallel. But you could imagine defining a particular two-terminal chunk of it that occurs in more than one path through the circuit as `rload = R 10k;  V ac 15 60 [D rload D | D' rload D']`.

Alternatively you could do what we do in programming languages with gotos, where the named entities are not subgraphs we wish to traverse and return from (like functions) but labels for points in the control-flow graph. Suppose we mark them with an `@` suffix to distinguish them. Then we might write that circuit as `ra@ R 10k rb@;  V ac 15 60 [D ra@ D' | D' rb@ D]`, which is slightly shorter but maybe less clear. It's not quite clear what to do when you want a branch to *end* in such a label rather than to merely include it. This does, however, provide a more reasonable way to handle three-terminal elements.

In both of these cases, the stuff before a semicolon is special in that

it's in some sense mere definitions; it's what's after the last semicolon that gives the circuit.

Right now I'm looking at a diagram of an energy-harvesting circuit in a 2003 paper which could be written as follows:

```
q1@ [I ac | C] q2@; [D' q1@ D' | D' q2@ D' | C] S [D' | L [ C | [V'|R] R]]
```

which, as you can plainly see, is a capacitive (piezoelectric) current source feeding into a bridge rectifier powering a buck converter to charge a battery, with the buck converter controller being represented by a plain switch.

Without spaces, that would be the rather awful `q1@[Iac|C]q2@;[D'q1@D'|D'q2@D'|C]S[D'|L[C|[V'|R]R]]`.

It would be very nice to be able to render such expressions into schematics (and SPICE netlists) automatically.

Stack machines

An alternative approach would be to add circuit elements using stack-machine operations. In this approach, `R` is a stack operation which takes a node off the operand stack, attaches a resistor to it (of a specified value, if one is present), and returns a newly created node at the other end of the resistor. `D` and `D'` are stack operations which attach diodes in opposite directions.

Three-terminal devices fit comfortably — although there are more potential ways to define them, as their terminals could conceivably be assigned to inputs and outputs in 18 different fashions. The most general form is to merely push all of their terminals onto the stack as fresh nodes; given that and some stack manipulation operations, you can define the other 17 fashions in those terms.

How can we hook up circuit elements in parallel? We need to save the beginning of the parallel section on the stack with `[`, save the end of the first branch with `|` and return to the beginning, and then connect the two ends with `]` when we reach them. (Note that this implies that parallelism is of strictly two branches.) This suggests that `[` is just DUP and `|` is just SWAP, while `]` is a graph-construction operation that shorts two nodes together and then drops one of them.

In this interpretation, then, non-series-parallel circuits are merely circuits that don't respect the stack discipline on node access; they could be defined like Forth constants or PostScript variables, and whenever invoked, they short the node on top of the stack to their node (and leave it on the stack). Perhaps rather than `80 CONSTANT WIDTH` we should write something like `80 ]: WIDTH`, since if we're defining a node, we probably started by duplicating a node with `[`, and it's nice if the parens line up.

So then what does this previous circuit look like?

```
q1@ [I ac | C] q2@; [D' q1@ D' | D' q2@ D' | C] S [D' | L [ C | [V'|R] R]]
```

It becomes the following:

```
[ D' [ [ ac I | C ] ]: q | [ D' q D' | C ] ] S [ D' | L [ C | [ V' | R] R ] ]
```

However, in this version, we have a way to handle the special case of the implicit circuit around everything: an extra `[` at the beginning

saves the starting point, and an extra] at the end unifies them. So this becomes:

```
[ [ D' [ [ ac I | C ] ]: q D' | [ D' q D' | C ] ] S [ D' | L [ C | [ V' | R] R ] ∘
∘] ]
```

Or, if we use a more sophisticated tokenizer than Forth's:

```
[[D' [[ac I|C]]: q D' | [D' q D' | C]] S [D' | L [C | [V' | R] R]]]
```

Or, if we use more fashionable punctuation, maybe

```
{{~d {{ac i, c}}=q ~d, {~d q ~d, c}} s {~d, l {c, {~v, r} r}}}
```

I'm not sure if this is an improvement in readability over the previous expression, but the semantics are a lot less muddy! It lacks the feature the other version had, though, where reversing the direction of a circuit element was a general-purpose feature.

This version is strongly reminiscent of Binate, though, with its concatenation-for-series-and-comma-for-parallel, and I think it's probably possible to take the analogy further to the possible benefit of one or the other language. In particular, Binate's approach to "named terminals" is more readable, and Binate does handle converse orthogonally, but this thing's approach to "named labels" is cleaner.

Some musings on applying Fitts's Law to user interface design and data compression

Kragen Javier Sitaker, 2019-05-06 (updated 2019-05-09) (27 minutes)

Fitts's Law says MT = a + b lg(1 + D/W): we divide the distance to the center of the target by its width along the line of motion, add 1, take the logarithm (in base 2, by convention), multiply by some parameter b, and add some other parameter a, to get the movement time.

As described in Dercuano drawings (p. 64), I want to use Fitts's Law to design a bandwidth-limited drawing system for Dercuano. I can type about 72 bits per second if we count ASCII, or 24 bits per second if we use the gzipped weight of the text, or 45 bits per second if we consider the keyboard keys as being 5 bits each. Since I often have to stop and think while I'm typing, probably the bit rate for drawing should be somewhere in the neighborhood — maybe 5 bits per second, or maybe 500, but probably not 1000 or 10000. That is, some part of my mouse movements is basically random, and could be rounded off with no loss of intentional information. Fitts's Law can perhaps tell me what part.

We know from Fitts's Law that the imprecision of movement in a given time is proportionally greater when larger distances are being covered, although this flattens out for movements comparable to the target size. Solving for D/W as a function of MT, a, and b:

```
(MT - a)/b = lg(1 + D/W)
2**((MT - a)/b) = 1 + D/W
2**((MT - a)/b) - 1 = D/W
```

So, when MT = a, the start/stop time, D/W must be zero; when MT = a + b/2, you can reach targets about 0.414 of their width from your starting point (this is a bit silly, since you start inside of them!); when MT = a + b, you can reach targets 1W away (requiring you to move between 0.5 and 1.5 times their width in their direction); when MT = a + 2b, you can reach targets 3W away; when MT = a + 3b, you can reach targets 7W away; when MT = a + 4b, you can reach targets 15W away; and so on.

What does Fitts's Law suggest about the channel bit rate?

Consider a pixel-resolution pointing device, and suppose your starting point is surrounded by approximate circles of circular target buttons, each of radius 15W, thus containing about 47 targets each. If you move your mouse to the right, you cross the first of 8 circles of 2-pixel targets after 30 pixels, and there are 8 such circles, the last ending before pixel 46. Pixels 46 to 61 are divided into three-pixel-wide targets, pixels 61 to 77 into 4-pixel-wide targets, pixels 77 to 92 into 5-pixel-wide targets, and so on. By the time we

reach pixel 400 we have crossed 44 targets and entered a 45th; Fitts's Law suggests that we should have been able to select any of these 44 targets in time a + 4b. Moreover, since each of the circles has 47 targets arranged around it, we had a total of 2068 targets, all selectable in that same time: 11 bits of target. If b ≫ a (let's assume that for now), then that's 2.8 bits per b.

Now consider filling the same area with smaller targets, each of radius 31W, thus fitting 97 round targets around each concentric circle, and also about twice as many circles: 89 circles, say. So we have 8633 possible targets, which makes 13 bits, selectable in time a + 5b, which is only 2.6 bits per b.

This trend suggests that the highest possible bit rate would come from packing circles with the lowest possible D/W, which would be about 1. So your 2-pixel target is pixels 1 and 2, a 3-pixel target is pixels 2:5, a 9-pixel target is pixels 5:14, a 28-pixel target is pixels 14:42, an 84-pixel target is pixels 42:126, and a 252-pixel target is pixels 126:378, so in the same area as before, you have six "circles", each of which can contain about six targets. (You could probably do a bit better by staggering the circles to move the centers of targets further apart, but the improvement should be small.) So you have about 36 targets, 5 bits, selectable in time a + b, which would be 5 bits per b if a were small. Our rationale for assuming a is small has gone away, since we're no longer looking at the limit of large D/W, but it still seems likely that this is the best case.

Still, that's a much less variable bit rate than I was intuiting. In this tautochronic arrangement, every doubling of D/W adds 2 bits to the information content of the selection and adds b to the time. So if a = 1.5b (or perhaps a bit more, if the denser arrangements I mentioned pan out), the bit rate would stay fixed at 2 bits per b.

Of course, if unboundedly far-off targets are allowed, there is no limit to the bit rate. Instead of six "circles", you could have 12 "circles" of targets (the largest having targets 183708 pixels wide) or 24 (the largest having targets 97629963228 pixels wide — about 16000 km), and that would give you almost 7 bits per selection, which — according to Fitts's Law — would still take the same amount of time, MT = a + b. The number of bits per constant-time selection grows as log log D, though, and as you can see, that's effectively constant. Also I am going to go out on a limb here: I don't think you can actually move your mouse cursor 16000 km in the same time you can move it 84 pixels, even if your screen *does* scroll and anywhere from 9200 km to 28000 km *would* be close enough.

A different reductio ad absurdum of Fitts's Law (in this basic form) is that it has no term for the width of the target in the circumferential direction of motion. Above, I've considered the case where the width of the target is the same in all dimensions, but consider crossing-based user interfaces; in these, to activate a target, instead of moving the mouse to within a target and clicking on it, you just need to move the mouse across the border of the target, possibly without even stopping. Effectively, the "target" has infinite width in the direction of motion, which means D/W = 0 and MT = a + lg (1 + 0) = a + lg 1 = a + 0 = a. This would imply a constant time to select one of many targets that can be crossed in a straight line from where your mouse starts, regardless of how many such targets there are and thus how precise your angle has to be to hit the target you want, and also regardless of

how far away the targets are from the mouse's starting point. (The same argument would suggest that the time to select a known item from a pie menu is independent of the number of items in the menu if its inner and outer radii remain unchanged.)

Estimating the parameters from my handwriting

My handwriting is about 13 words per minute, which is roughly one letter per second. Each letter could be reasonably approximated by a couple of cubic Bézier curves, each of whose control points has an error in the neighborhood of, eyeballing, 10% of the distance from the previous control point, so perhaps D/W is about 7. Given the guess of 8 control points per letter and thus 125 ms per control point, this suggests that a and b are in the neighborhood of 30 milliseconds each; this in turn suggests a bit rate on the order of 64 bits per second for my handwriting. I write about half as fast with the mouse, so perhaps 32 bits per second.

This suggests that it should be safe to round drawing movement coordinates to about 64 bits per second. For explicit placement of anchor points with separate clicks, this is straightforward to apply: if the time since the last click is 250 ms, round it to 8 bits each of x and y for a total of 16 bits, but if it was 283 ms, use 9 bits each, and at 313 ms, use 10 bits each, etc. (4 Hz is about as fast as I can click with a mouse.)

I've rigged up a primitive experiment with the mouse and some SVG and JS to present me some circles to click on, and the data from the experiment is surprising. Fitts's Law does seem to hold, broadly speaking, but there's a lot of variability, like, a lot of residuals are on the order of half of the height of the trend line — variability gets bigger as task time gets bigger, maybe because I have a hard time hitting the tiny circles with the mouse or sometimes even seeing them. The residuals are far from normally distributed. A linear regression on 417 data points finds $a = 220$ ms, $b = 340$ ms, $R^2 = 0.7$; this means clicking on circles that appeared centered under the mouse took about 220 ms; circles whose center was one diameter away from the mouse took about 560 ms; circles whose center was three diameters away took about 900 ms; circles whose center was seven diameters away took about 1200 ms; and so on. What I did in R was this:

```
fitts.data <- read.csv('fitts-data-cleaned.csv')
fitts.data$fitts <- log(1 + fitts.data$D / fitts.data$W) / log(2)
model <- lm(MT ~ fitts, fitts.data)
plot(fitts.data)
plot(model)
plot(MT ~ fitts, fitts.data)
abline(model)
summary(model)
```

This is dramatically slower than I had anticipated! It suggests that my bit rate at moving the mouse to an area on the screen is closer to 6 bits per second than to the 32 bits per second I was hoping for or the 64 bits per second I get with a ballpoint pen.

(Further examination of the data suggests that the biggest residuals do come from the smallest circles, but in both upward and downward direction, so removing the smallest circles actually reduces the R^2 of the regression. *The Grammar of Graphics* §9.1.4.1 suggests applying a projective transformation to the data (MT, fitts) → (1/MT, fitts/MT) in order to eliminate its egregious heteroskedasticity, but I haven't tried that.)

On the other hand, a better workflow may be to sketch a whole freehand curve with the mouse or other input device, and then optimize an overall representation for it, in terms of lines, splines, and corners. I just opened Inkscape and scrawled "On the other hand, a better workflow may be to" in it, which took 163 seconds (4 wpm, a third of my speed with a pencil or ballpoint) and involved 37 glyphs (say this would require 300 control points), with rather larger errors (say D/W ≈ 3). This is about two control points per second with about 3b entry time (implying about 6 bits per control point, 12 bits per second) each, which is about 4 times worse than the estimate above from my normal handwriting, but still twice as good as the estimate from my SVG experiment.

Going further in that direction, maybe the right approach is to sketch things on paper, photograph them, scan in the photographs, and construct low-Kolmogorov-complexity approximations of the images. If I'm really getting 6–12 baud with the mouse, 45 baud with the keyboard, and 64 baud with a ballpoint pen, it would seem to make sense to just use the pen! Otherwise I could easily end up spending an hour and a half on a sketch that could have taken ten minutes — or, more likely, not making the sketch at all.

Vector encoding

If the objective is not to impede drawing but to minimize the Dercuano download size, it isn't sufficient to avoid mixing in a bunch of unintentional quantization noise; we also need to think about how to represent the displacement vectors that make up the drawing as bits.

8 bits per coordinate? What, with fixed fields?

Perhaps this could be a floating-point format with a sign bit, 2 bits of exponent (2^0, 2^1, 2^2, or 2^3 pixels per count), and a 5-bit mantissa. Exponent of 0 would be "denormalized" pixel counts: 0 is 0, 1 is 1, 2 is 2, etc., up to 31 is 31, but exponent of 1 and up would have an implicit leading 1, so 0x20 would be 32, 0x21 34, 0x22 36, etc., up to 0x3f, which would be $32+2\times31 = 94$, and then the exponent of 2 would similarly start at 0x40 for 64 and go up by fours: 0x41 for 68, etc. 0x7f in that scheme ends up being $256+8\times31 = 504$ pixels.

Truncated Golomb coding?

Golomb coding is a lossless encoding that concatenates an unary bucket identifier with a binary within-bucket index; it's the optimal prefix code for the geometric distribution. The buckets are (the intervals between) multiples of the bucket size parameter M; to encode a nonnegative integer, you do an integer division by M, encode the integer quotient q in unary (as, say, a series of q-1 1s followed by a 0), and then append the binary encoding of the remainder, using the number of bits necessary to encode all

nonnegative integers less than M. That is, the remainder is a fixed-length field for a given parameter M.

Suppose that we use M = 64 and truncate the result to fit in 7 bits. (We can, again, encode the sign bit separately.) Numbers less than 64 are encoded in binary as 0xx xxxx; numbers 64:128 are encoded with only 5 significant bits, thus rounding to even pixels, as 10x xxxx; numbers 128:192 are encoded with 4 significant bits as 110 xxxx, thus rounding to every fourth pixel; 192:256 are 111 0xxx, rounding to every 8th pixel; and so on until 111 1110 represents 384 and 111 1111 represents 448. Thus we have progressively worse resolution for large moves, rather than the fixed resolution Fitts's Law would suggest.

(You could omit the initial 1 of the unary code in this fixed-width context, but that doesn't overcome the overall problem.)

How about truncated Elias delta or gamma coding?

Gamma coding is a prefix code that represents an arbitrary positive integer as an excess-1 unary bit count (traditionally written as a number of leading zeroes, with no leading zeroes meaning the one-bit number 1) and then the number itself; so $5 = 101_2$, is written as 00101. Delta coding is "flatter"; it uses gamma coding to encode the number of bits in the number and then appends the number (without the leading 1), so the 5-bit number $10101_2 = 21_{10}$ is written as 001010101.

$127_{10} = 111'1111_2$ is the longest number whose bit count fits in three bits, and so it is delta-coded as 00'111'11'1111, or 001 1111 1111 in the traditional 4-bit groups. All larger numbers, and no smaller numbers, have three zeroes at the beginning. So the probability distribution for which delta coding is optimal is one where numbers larger than 127 are ⅛ of the total universe of numbers, numbers larger than 65'535 are half of that, numbers larger than 4'294'967'296 half of that (one out of every 32 numbers), numbers larger than 18'446'744'073'709'551'616 half of that (one out of every 64 numbers), and so on.

1 is delta-coded as 1: zero 0s indicating a 1-bit length field, which is 1, followed by the number in binary, omitting its leading 1, which leaves the empty string. 2 is delta-coded as 0100, and 3 as 0101, and that's all the 4-bit numbers. Then 4 is delta-coded as 01100, five bits, and thus up to 01111, 7. That's everything that begins with 01, 10, or 11, thus implicitly ¾ of all numbers, and then we're into the 001 territory that takes us all the way to 127.

So even though Elias delta coding is able to handle very large numbers with moderate overhead over fixed-width binary (unlike Elias gamma coding, which uses double), it squanders ¾ of the probability mass on numbers 1 to 7 inclusive, which is not helpful for our goal of representing coordinate pairs at 64 bits per second, which almost guarantees that often we'll want to encode relative coordinates in 4 or 5 bits.

Jointly encoding pairs

The Elias coding discussion didn't even consider where we're going to stuff the multiplier implied by the rounding, the one we earlier described as the exponent field of a floating-point format.

Fitts's Law suggests that the multiplier is almost independent of the resolution of the final result, in the sense that you could reasonably want 4-bit precision with a multiplier of 1, 2, 4, 8, 16, 32, or 64. However, there are a couple of dependencies. If you have 4-bit

precision, you don't really need all those options; 1, 4, 16, or 64 would work just as well, at the cost of reducing your effective precision to 3 bits at times. Also, on a pixel screen you probably don't want a multiplier of 1024 and a mantissa of 15, or for that matter a multiplier of 0.125 (though zooming in to clean up drawings may be useful at times). Moreover, if you have a fairly precise point where the mouse lingered long enough to give 8-bit precision, you don't really need multipliers like 32 or 64. And for compression it would be convenient to be able to make the ranges of the different precisions nonoverlapping, in the way the implied leading 1 does in non-denormalized floating point. These interactions all seem too complicated to find a simple solution to right now, though, so I'm just noting them.

Suppose we code the (logarithm of the) multiplier, shared between ΔX and ΔY, in a three-bit field, meaning a power of 4 between 1 and 16384; and we have another three-bit field (biased by 2) for the length of the ΔX and ΔY fields, represented in 2's-complement. Then a minimally precise data point would be something like 010'000'00'01, which means +4 in the Y direction, +0 in X, and that's 10 bits. The size field 000 means one data bit per coordinate, and the 10-bit data with this size field form a family of 4×4 lattices of exponentially varying sizes, covering the points (-2, -2), (-2, -1), (-2, 0), (-2, +1), (-1, -2), … (+1, +1), multiplied by their respective multipliers. All have the same (0, 0) point redundantly encoded.

These 10-bit-coded pairs have their worst-case error at vectors like (+2.5, +2.5), which is in between the (+1, 0) and (+1, +1) of the smaller lattice and the (+4, 0) and (+4, +4) of the larger lattice. This vector would be thus encoded as (+1, +1) with an error of 2.12 units, 60% of its magnitude; this level of error would be justified for movements so fast that they couldn't hit a target whose D/W was more than about 1.2, which is to say movements of under a + 1.2b, which I estimated above as about 66 ms. This gives a worst-case bandwidth for this encoding of about 160 bits per second, six times better than scrawling in Inkscape but almost three times worse than desired.

If we can manage to encode points less frequently, as the 250 ms example I mentioned earlier, we can hit 64 bits per second with 16 bits per pair. Those 16 bits might look like 000'011'00110'11011, which would be +6 in X, -5 in Y. The lattices of 16-bit-representable vectors overlap greatly, eliminating the holes in the 10-bit-representable values, and the worst-case relative error is $\sqrt{2}/32$, about one part in 45, i.e., D/W ≈ 45, so a + 5b movement time. With my pen handwriting guess figures, that would be 180 ms, but the four times worse time with Inkscape suggests more like 720 ms. So at this level our bandwidth is in the ballpark.

(Is three bits of $\log_4$ for the multiplier excessive? If we only had two bits of this exponent, the multipliers would be 1, 4, 16, and 64, which last would need only 5 bits of mantissa to reach the edge of the screen, and we'd improve worst-case bandwidth by 10%. Variable-length mantissas give us an escape hatch, though here they only allow us up to ±256.)

Successive approximations by alternately zooming in and out

What if we represented these vectors not with a single data point but a series of movements? If we're looking at a square picture divided into nine subpicture, we could indicate which subpicture to zoom in on with a number from 1 to 9, after which we can make another move, or we could indicate that we want to stop zooming with the number 0. This gives a base-10 prefix code that uniquely identifies any arbitrary recursively-divided square node.

The same digits in reverse indicate how to get back to the original viewpoint from the zoomed-in viewpoint, so such a code can also represent an arbitrary zoom out rather than in.

So if you want to indicate a sequence of points coupled with zoom levels, relative to some reference point, you could use a sequence of pairs of such codes: one to zoom out, then another to zoom in to the destination. The null movement case is 00; zooming in to the upper-right corner is, perhaps, 090; zooming out by one unit and then in to the lower-right corner is, perhaps, 5030.

Each digit takes 3.32 bits, so the minimal (null) movement is 6.64 bits, while the four-digit example "5030" is 13.28 bits. A movement that ends in a single zoom has a relative error of 0.5 either direction, i.e., D/W = 1, so the time is a + b, and each additional zoom (which must eventually be undone) gives you a factor of 3 (1.58 bits) extra precision in both X and Y, i.e., each extra 1.58b of MT adds 6.64 bits, or 4.2 bits per b, which is reasonably close to the 2 to 5 bits per b minimally needed. At my pen-based estimate of b = 30 ms, that's 140 bits per second, but again the Inkscape results being about four times slower would give more like 35 bits per second.

Maybe a better approach here might be just to specify the number of levels to zoom out, rather than the specific direction to do it in, which doesn't matter very much.

Quite aside from the problem considered here of encoding a mouse selection in a data file, this approach could be used to encode a mouse selection on the keyboard, too, and it would enjoy Fitts's-Law-like efficiency properties, which the conventional mouse-simulation approach of moving the pointer with arrow keys definitely does not. Maybe it could even be faster than using a shitty mouse. When I worked in a call center a quarter century ago, I was pretty quick on the keypad. I could always enter people's credit card numbers faster than I could convince them to say them. I haven't used keypads much since then, though, and in a quick typing test with typespeed(5) just now I was only able to reach about 1.49 digits per second; on a second trial I reached 1.66. which is about 5.5 bits per second, about the same as the 6-bit number I measured above for the mouse. (By comparison, typespeed measures me at 5.84 characters per second, 70 wpm, on English words; in actual text I'm closer to 90.) So maybe at least this wouldn't be much *slower* than an actual mouse.

Can we just punt to gzip somehow?

Dercuano is compressed for download as a gzipped tar file. What if, instead of coming up with an up-front hypothesis about the distribution of vectors in the drawings and then congealing it in a pile of bit-twiddling code, we just handle the rounding part, represent the vectors as bytes in some kind of straightforward way, and then let gzip handle the entropy-coding part? Gzip can also do things like recognize common patterns (if they repeat exactly) which we haven't

contemplated above. When it plows into the front end of the drawings, its entropy model is probably going to be attuned to HTML, but if all the drawings are together in the tar file, then it should have a pretty decent entropy model for drawings after a few kilobytes.

I don't know if this could actually work. I think the tricky part is really not the bit twiddling, but the decisions about which points should be in the "trellis" at each level of rounding.

Thredsnek: a tiny Python-flavored programming language

Kragen Javier Sitaker, 2017-03-20 (7 minutes)

I was thinking about making a tiny Python-like language, called Threadsnake or Thredsnek for the time being. The idea is to implement as much as possible in, say, 1.5KiB or 3KiB or 6KiB of code.

I think the most important linguistic reasons current Python is so effective are the following:

• The memory model is the Lisp-style object-graph, a garbage-collected heap.
• A small number of general-purpose, flexible-sized data structures (containers): specifically hash tables ("dicts") and dynamic arrays ("lists"). Pervasive mutability is key to Python's current flavor, but it clashes with the object-graph memory model in a lot of ways, so I think we could probably drop it. (Python also has tuples, sets, frozensets, namedtuples, deques, Counters, OrderedDicts, and defaultdicts, but these are less necessary.)
• "Duck typing": interactions between objects are indirected through interfaces, and so it generally doesn't matter what concrete type an object is, just what interfaces or protocols it supports. So, for example, keys in the built-in hash tables need not be strings; they can be any object that supports the `__hash__` and `__eq__` methods. (The original term for this was "object orientation", "message passing", or "late binding", but people got confused about what those terms meant; "duck typing" is the current term.) In particular, any code can define its own "types" which are really just wrappers that provide a duck-typed façade to dicts.
• As a special case, iteration indirects through an "iterator protocol" which allows for composable iterators, and there is a coroutine facility for this ("generators") which can be put to many different uses. (I am sympathetic to Alexandrescu's argument that maybe we should use a "range protocol" instead of an iterator protocol for this.)
• Errors are handled with exceptions. Ambiguity and implicitness is an error; there is very little DWIM. (Implicit variable declaration is an exception to this, and was probably a mistake.) Consequently, if your program runs and produces an answer instead of crashing, you can have a fair bit of confidence that the answer is correct.
• Reflection allows the in-language implementation of debugging facilities and transparent and semitransparent persistence facilities like ORMs.
• Tasteful and largish standard library ("batteries included"). It's very easy to, for example, run unit tests, split strings on whitespace, join together many strings with a separator (such as a space), concatenate strings, do formatted string interpolation, do integer and floating-point arithmetic, read a line from a file, read an entire file into memory, parse RFC-822 syntax, parse or emit JSON or XML or

CSV, do a substring search, extract a substring by indices, lowercase a string, remove leading and/or trailing whitespace from strings, display an unambiguous debugging representation of Python objects in HTML or in text, run binary search, round a number to a given number of decimals, search strings for regular expressions, collate the number of occurrences of each item in an iterable sequence and return the top items, sort and reverse lists, encode and decode UTF-8 and other common character encodings, and so on.

This is not as poetic as Tim Peters's *The Zen of Python*, but I think it might be more helpful.

Duck typing in particular means that all your data structures (heaps, sorted lists, whatever) and algorithms (sort algorithms, graph algorithms, whatever) are automatically polymorphic over whatever types are available, and that you can substitute persistent containers (in the disk sense) for nonpersistent ones transparently.

Python has some major shortcomings. The semantics of its procedure and class definitions make live code upgrade impossible; its efficiency in general is terrible; its semantics are so flexible that many errors cannot be caught until runtime even in principle; its absence of first-class lambdas or Smalltalk-style blocks has given rise to a steadily growing pile of kludges such as method decorators and context managers. But it remains immensely popular and immensely practical.

And this is in spite of its lack of many things commonly considered critically important in a programming language: encapsulation, structs, nested scoping (at least in old versions), a decent GUI library...

It's clearly impossible to implement a sizable standard library in a few K of code. But how much code would Thredsnek need to implement garbage collection, dicts and lists, duck typing (including for iteration), exceptions, and reflection? On modern machines, it would still be useful even with fairly inefficient approaches to these problems.

What kind of abstract machine would be needed to implement this? You need to be able to send messages (invoke methods), store and retrieve local variables (including parameters), retrieve constants, raise and catch exceptions, instantiate objects (including dicts and lists; possibly by sending messages to a class), and do reflection (possibly by sending messages to some kind of reflection object, which seems preferable to invoking magic non-implementable reflection messages on arbitrary objects). You probably also need control-flow and method-return operations.

For variable-length argument lists, like those used for instantiating lists or dictionaries, it might be useful to begin by pushing a stack mark and pass everything down to that mark as arguments.

As a point of reference, the Smalltalk-78 virtual machine for the NoteTaker was supposedly 6KiB of 8086 machine code. This used the Smalltalk-76 bytecode, which was simpler than the Smalltalk-80; according to Ingalls's 1978 paper on it, its high nibble selected the overall category of operation:

- 0x1x: load an instance field (implicitly limited to 16);
- 0x2x: load a local variable;
- 0x3x: load from the table of constants for this method;

• 0x4x: load *indirectly* from the table of constants (I think this was used for accessing classes and other global variables);
• 0x5x: load from a Context field (I don't understand this);
• 0x6x: load one of the universally common constants, -1, 0, 1, 2, 10, true, false, and nil;
• 0x7x: sends a message to the Context, but I don't know what for;
• 0x8x: sends one of SpecialMessages, which I assume are things like + and =;
• 0x90–0x97: jump forward up to 8 bytecodes unconditionally;
• 0x98–0x9f: jump forward up to 8 bytecodes if false;
• 0xa0 0xxx – 0xa7 0xxx: jump unconditionally up to 768 bytes back or 2047 forward;
• 0xa8 0xxx – 0xaf 0xxx: jump conditionally (by the same amount);
• 0xb0: discard stack top;
• 0xb1 0xxx: copy stack top into given location;
• 0xb2 0xxx: move stack top into given location (and pop it);
• 0xb3: return stack top as method return value.

The bytes denoting locations to store into were the same as the load opcodes.

The economics of solar energy

Kragen Javier Sitaker, 2008 (27 minutes)

Item #1 on the National Academy of Engineering's list of the most important engineering challenges of this century:

• Make solar energy economical. Solar energy provides less than 1% of the world's total energy, but it has the potential to provide much, much more.

Calculations of Limits

The detail page claims that the blurb is wrong; only 0.001% of the world's total energy usage is sold in the market, of which a fraction is fossil fuel. Additionally, although it's not mentioned in the page, many of the world's poorest people live entirely off of solar energy. It's just that the other 99.999% of the energy isn't easily used to drive mechanical engines at the moment.

Some of it is captured by plants in sugars and cellulose through photosynthesis, and that is called the planet's "net primary production". Peter Vitousek and others estimated in 1986 ("Human Appropriation of the Products of Photosynthesis") that humans consume as food or firewood 3% of its net primary production (including food for livestock) totaling 7.2 Pg/year of dry biomass, and "co-opt" another 19%, out of a total of 132.1 Pg/year.

7.2 Pg of carbohydrates is about 1.5 * 10^20 joules. 132.1 Pg of carbohydrates is about 27.7 * 10^20 joules. The US DoE EIA International Energy Outlook 2007 (PDF) reports that "world marketed energy consumption" was 447 quadrillion Btu in 2004, which is about 4.7 * 10^20 joules. This figure doesn't appear to include food sales.

A crude calculation (earthradius_equatorial^2 * pi * (1000 W/m^2) * 1 year in `units(1)` --- gosh, Unix is great!) suggests that the total solar energy falling on the earth is about 40000 * 10^20 joules per year. If Vitousek's figures are right, that means that the earth's ecosystem is about 0.07% efficient at converting sunlight into biomass, and therefore probably not more than 1.5% efficient at converting sunlight into anything but heat.

This leads to the conclusion that "world marketed energy consumption" is about 17% of the planet's net primary production, assuming that figure hasn't changed much since 1979, but that the planet's net primary production is only 0.007% of the energy received from the sun by the Earth. 17% of 0.007% is indeed about 0.001%, the figure from the original blurb.

At some point we'll have self-reproducing hardware, and the cost of manufacturing the solar cells will cease to be a problem; it will simply be a question of land use. To supply the 4.7 * 10^20 joules per year being currently sold in the market with the 40%-efficient solar cells in some labs today, we'd need to capture 11.75 * 10^20 joules per year of sunlight, which is 0.03% of the surface of the earth, including oceans. Matthias Loster made a lovely visualization of this and put it on Wikipedia.

If you were using 4%-efficient solar cells instead, you'd need 0.3% of the earth's surface area. Off-the-shelf inexpensive thin-film solar

panels are about 8% XXX efficient.

Calculations of Growth Rates

In 2005, the National Renewable Energy Laboratory published a FAQ on energy payback times of photovoltaic cells, which explained that at the time, multicrystalline photovoltaic cells produced more energy than had been used to make them in 2–4 years. Here are their references; I haven't read any of them:

E. Alsema, "Energy Requirements and CO_2 Mitigation Potential of PV Systems," Photovoltaics and the Environment, Keystone, CO. Workshop Proceedings, July 1998.

R. Dones; R. Frischknecht, "Life Cycle Assessment of Photovoltaic Systems: Results of Swiss Studies on Energy Chains." Appendix B-9. Environmental Aspects of PV Power Systems. Utrecht, The Netherlands: Utrecht University, Report Number 97072, 1997.

J. Mason, "Life Cycle Analysis of a Field, Grid-Connected, Multi-Crystalline PV Plant: A Case Study of Tucson Electric Power's Springerville PV Plant." Final report prepared for Tucson Electric Power, November 2004.

W. Palz.; H. Zibetta, "Energy Payback Time of Photovoltaic Modules." International Journal of Solar Energy Volume 10, Number 3-4, pp. 211–216, 1991.

The payback time is a representation of a sort of compound interest rate; a payback time of 2 years is a 50% annual percentage growth, 4 years is 25%. If you spend the produced energy on making new solar cells, those are the actual growth rates of your stock of solar cells (plus a bonus, in the form of compounding the interest more frequently, if you get the new cells into production in less than a year).

So consider Evergreen Solar's current situation. They're a small company with a market capitalization of US$917M as of their last annual report. Their current manufacturing capacity is 15 megawatts per year, and they've contracted to manufacture 125 megawatts in 2009, 300 megawatts in 2010, 600 megawatts in 2011, and 850 megawatts in 2012. Suppose a company of similar size were to invest its 300-megawatt 2010 production merely in making more solar cells, and that it had no non-energy costs. An annual growth rate of 50% --- that is, a 2-year payback --- would look like this:

```
In [3]: ["%d: %.1fMW" % (2010 + x, 300*1.5**x) for x in range(30)]
Out[3]:
['2010: 300.0MW',
 '2011: 450.0MW',
 '2012: 675.0MW',
 '2013: 1012.5MW',
 '2014: 1518.8MW',
 '2015: 2278.1MW',
 '2016: 3417.2MW',
 '2017: 5125.8MW',
 '2018: 7688.7MW',
 '2019: 11533.0MW',
 '2020: 17299.5MW',
 '2021: 25949.3MW',
 '2022: 38923.9MW',
```

```
'2023: 58385.9MW',
'2024: 87578.8MW',
'2025: 131368.2MW',
'2026: 197052.3MW',
'2027: 295578.4MW',
'2028: 443367.6MW',
'2029: 665051.3MW',
'2030: 997577.0MW',
'2031: 1496365.5MW',
'2032: 2244548.3MW',
'2033: 3366822.4MW',
'2034: 5050233.7MW',
'2035: 7575350.5MW',
'2036: 11363025.7MW',
'2037: 17044538.6MW',
'2038: 25566807.9MW',
'2039: 38350211.8MW']
```

The current 4.7 * 10^20 joules/year being sold in the market is 14 893 719 megawatts, which this curve crosses around 2037, and with the usual 5:1 ratio between peak watts and achieved watts (due to nighttime, solar angle changes, clouds, etc.) you don't reach it until 2041 or 2042. If you start with the 1744 megawatts that Evergreen says Solarbuzz said constituted the global solar power market in 2006, you gain about 8 years.

However, the *financial* payback time on solar panels is still dramatically longer, which is why they still haven't reached "grid parity" --- costing less per watt-hour than power from the grid. Solar panels still cost US$4-$5 per peak watt at retail. That's about US$20 per average watt, which is 8760 watt-hours per year; that's about US$0.87 of electricity at grid rates. That's a 23-year *financial* payback, and that doesn't include things like batteries, inverters, wiring, and installation.

Evergreen Solar

Evergreen's annual report suggests some reasons for this: the market is expanding at 42% per year, their own production capacity has to expand by a factor of more than 50 from 2007 to 2012 (this from a company that's already 13 years old). They had 276 full-time employees in manufacturing to reach their 15-megawatt-per-year capacity: 18 employee-years per megawatt. Their new 80-megawatt-per-year facility is expected to require another 410 employees (5 employee-years per megawatt). They are struggling to increase manufacturing capacity fast enough to keep up with demand, and apparently so are their "polysilicon" suppliers, because there's an industrywide shortage of polysilicon; building new polysilicon manufacturing facilities takes several years.

(I'm a little bit dubious about their terminology; I think the company's management may just not be very technical, or maybe not very smart. "Polysilicon" is short for "polycrystalline silicon", and silicon becomes polysilicon at the point that you crystallize it in a polycrystalline form in your furnaces. So the suppliers are supplying Evergreen with silicon; how many crystals are in each piece of silicon they supply is somewhat immaterial, since Evergreen melts the silicon

down and crystallizes it in polycrystalline silicon ribbons in their furnaces.)

They report that they had US$58M of product revenues in 2007, with US$53M "cost of revenue", which presumably includes things like manufacturing employee salaries, energy, and raw materials. They spent US$21M on research and development and another US$21M on "Selling, general, and administrative", and US$1.4M on "facility start-up", building a new plant to increase their manufacturing capacity from 15MW to 95MW this year.

So suppose they manufactured 15MW in 2007, as their annual report suggests. That would mean they got paid US$3.87 per watt on average, which is more or less in keeping with the US$4-$5 the panels cost at retail. They spent US$3.53 of that on their actual manufacturing costs. They explain:

> The main purpose of our Marlboro facility [where all of their manufacturing currently takes place] is to develop and prototype new manufacturing process technologies which, when developed, will be employed in new factories. As such, our manufacturing costs incurred in Marlboro are substantially burdened by additional engineering costs and also reflect inefficiencies typically inherent in pilot and development operations.

Elsewhere they explain that they use about 5 grams of silicon per watt; metallurgical-grade silicon costs about US$0.77 per pound , or US$0.0017/g.

They don't break out the costs of the silicon they buy from their suppliers, which might cost considerably more than the metallurgical-grade silicon it's made from. It appears that they have made prepayments and cash loans of, as I read it, about US$50M on a set of multi-year silicon supply contracts, although they only list US$23M in their "prepaid cost of inventory" line item; and elsewhere they say, "we have silicon under contract to reach annual production levels of approximately 125MW in 2009, 300MW in 2010, 600MW in 2011, and 850MW in 2012", for a total of 1875MW; and they say, "We believe future enhancements to our technology will enable us to gradually reduce our silicon consumption [from 5g/W] to approximately two-and-a-half grams per watt by 2012."

So suppose those 1875MW are to be made at an average of 3.5 g/W; that's 6600 million grams of silicon. And suppose the US$50M represents about half of the total price of that silicon; that would give us US$0.015 per gram of silicon. That's more or less in line with the raw silicon cost I estimated above for metallurgical-grade silicon --- it's higher, and by a factor of only about 2 --- which gives me some confidence that my guesstimate that the cost of the silicon is not yet a significant factor in the cost of the solar cells.

However, note that securing one of these long-term silicon supply agreements required selling about 15% of the company to the silicon supplier. The restrictions on that stock "will lapse upon the delivery of 500 metric tons of polysilicon to the Company", so we can guess that the total contract with that supplier is in the neighborhood of 1000-2000 million grams.

Also, they list $629M in "raw materials purchase commitments" among their "contractual cash obligations". This, plus the prepayments, is perhaps a ceiling on the amount of payment they may have committed to for the silicon; US$679M for 6600 million grams of silicon would be US$0.10 per gram, which would raise the cost of

silicon above from US$0.008 per watt to US$0.35 per watt. (It's possible that they have other raw materials purchase commitments, say for silane or hydrofluoric acid.)

In 2006, Evergreen and EverQ bought US$8M worth of silicon from REC, who I think was their sole silicon supplier at the time (unless DC Chemical was also a supplier?). During that year, they had $102K of sales. In 2007, Evergreen bought US$3M worth from REC, which is US$0.20 per watt if they produced 15MW.

Let's assume that their per-employee cost of labor on the factory floor is about US$120 000 per year. At 18 employee-years per megawatt, that's about US$2.2M per megawatt, or about US$2.20 per watt.

If we assume that the NREL numbers are applicable to their manufacturing, then each peak watt of panels required about 4kWh of energy; let's assume that costs US$0.10/kWh. So, per watt, we have:

revenue	US$3.87
gross profit	US$0.34
electricity	US$0.40
raw silicon	US$0.008
labor	US$2.20
OTHER	US$0.92

At present, they're also spending about half of their revenue on research and development. (That's part of why they're still losing money.) We can expect that the cost of labor per watt will decrease substantially in their 80MW non-pilot facility: 5 employee-years per megawatt would be US$0.60 per watt.

They also have been spending on the order of US$50M per year on capital expenditures, mostly equipment and facilities improvements. They report that their "fixed assets, net" are worth US$115M, including US$53M of "laboratory and manufacturing equipment", US$14M of "leasehold improvements", and US$67M of "assets under construction". They seem to expect that constructing the first 80MW/y production line in their new facility will cost around US$100M, although they don't really break it out that way in the report. That's about US$1.25/watt/year.

A capital cost of US$1.25 per watt/year of manufacturing capacity does not unavoidably contribute much to the cost per watt; after all, you can in principle amortize it over an arbitrary number of years. However, in an industry with a 42% annual growth rate, almost all cells will necessarily have come out of factories built within the last year or two, so it probably adds US$0.60/watt or more to the cost of the cells.

EverQ, a separate company that Evergreen owns a third of, had operating revenue of US$194M, cost of goods sold of US$160M, "other expenses" of US$27M, and assets of US$556M. I wish I had handy EverQ's manufacturing capacity numbers.

Nanosolar

Nanosolar claims an energy payback time of one month and a per-watt cost of 30 cents with their copper indium gallium diselenide

thin-film cells, in a November 2007 article on Celsias, although they had expected a cost in the sixties of cents per watt in a July 2007 interview. In the Celsias article, they also say they plan to reach 430 megawatts of production per year in 2008.

In the interview, CEO Martin Roscheisen also says:

> ...it is clear we are going to be manufacturing capacity limited for about as far out as we can see. There's presently really only two truly scalable solar markets in the world — Germany and Spain — and we do a lot there. Being a scalable market is today as much about feed-in-tariffs as about the administrative framework; tomorrow, with grid-parity PV systems, it is primarily about the latter.

Material Shortages

As I said before, Evergreen is experiencing an industrywide polysilicon shortage; however, the raw material silicon is extremely abundant, being the principal component of one of the most common minerals in the terrestrial crust.

However, the materials used in copper indium gallium diselenide (CIGS) thin-film cells like Nanosolar's are somewhat less abundant. Copper has been a precious metal since the Bronze Age, but indium, gallium, and selenium are all fairly rare.

As a point of comparison, after years of rapid increase, silver prices averaged US$13.40 per troy ounce in 2007, according to the USGS's silver report. That's US$430 per kilogram. About 20 700 tons of silver were mined in 2007.

Indium, by contrast, cost US$795 per kg in 2007, and averaged an even higher US$918 per kg in 2006, and only 510 tons were refined in 2007, making it 40 times rarer than silver and 85% more expensive. The USGS claims, "Thin-film ... CIGS solar cells require approximately 50 metric tons of indium to produce 1 gigawatt of solar power," which still makes it a tiny fraction of the total cost. (I am assuming the USGS is referring to peak watts at one sun, i.e. in direct sunlight without lenses or mirrors, and not average output or solar-concentrator output.) That's US$0.04 of indium per watt, so the price of indium would have to increase by a factor of 75 to increase the cost of thin-film cells by US$3 per watt. That would be about US$60 000 per kg. I think grid parity is somewhere around US$1 per watt, which would be around US$20 000 per kg.

At higher prices, you would expect new low-concentration sources of indium to become economic to refine, which would be nice, because current world indium production is only enough for about 10 gigawatts of CIGS per year. It's difficult to predict what kinds of improvements could occur and how much they could increase indium production. However, we can get a little bit of a clue by looking at the last several years. In 2002, indium cost only US$130 per kilogram, so we've already experienced a dramatic price increase, driven by dramatically increased production of LCD displays, which use indium tin oxide for thin-film transparent electrodes. So how much did indium production increase when the price increased by a factor of seven over four years? It increased from 335 tons to 510 tons. [XXX check that. probably slightly wrong.]

So, although it's error-prone to predict, the evidence suggests that indium production capacity will prove quite difficult to scale up over the next several years, which could limit CIGS thin-film solar cells to a small fraction of the overall energy market.

Gallium is only slightly more expensive than silver, at US$460 per kg. Supplies of gallium are even more limited than those of indium; the USGS report *estimates* world primary gallium production capacity at 184 metric tons per year, and actual production at 80 metric tons per year, making it 250 times rarer than silver. In the absence of the LCD demand that has caused indium's price to skyrocket over the last several years, its price has remained relatively constant 2002–2007 even as imports have more than doubled. This would seem to suggest that gallium's production could be increased considerably more easily than indium, but I suspect that this is not the case, as I explain below.

The gallium prices are stated for extremely pure gallium, with less than 0.1ppm impurities, because this is what is needed for its largest-volume use, high-performance integrated circuits made of gallium arsenide, largely for RF components in cell phones. The USGS also reports some information on "low-grade" 99.99% pure gallium:

> Prices for low-grade (99.99%-pure) gallium increased in the first half of 2007 from $300 to $350 per kilogram at the beginning of the year to about $500 per kilogram by midyear. Producers in China claimed that there was a shortage of supply, which was the principal reason for the increase in prices. Some were offering gallium at prices as high as $800 per kilogram, but little business was completed at this price level.

The reason I think gallium production will hit limits similar to indium production is that indium and gallium are chemically very similar, and they are both primarily refined from trace amounts (50 ppm or more, at present) found in zinc ores and bauxite, and consequently they are found as impurities in zinc. So I think it is unlikely that there are large amounts of easily recoverable gallium hiding somewhere without corresponding amounts of indium accompanying them.

Because of their chemical similarity, they are substitutable for one another in some semiconductor applications.

I believe CIGS contains equal numbers of atoms of indium and gallium, but I think the gallium is somewhat heavier. XXX I need to look at a fucking periodic table.

Selenium is also only found in trace amounts in the Earth's crust. I don't know how much it costs or how much is being mined.

Silicon solar cells are made from silicon, arsenic, boron XXX, and aluminum --- some of the most common elements on Earth. However, their processing XXX

Solar Concentrators

Everything above --- costs per watt, factory production capacities in watts, materials per watt, etc. --- is about solar cells in "one sun", i.e. the intensity of sunlight that naturally reaches the surface of the Earth, which is about 1000 W/m². Silicon photovoltaic cells can theoretically turn up to 31% of that into electricity, but the less expensive polycrystalline cells in common use are only about 12% efficient, with even lower efficiencies of 9–12% or so for thin-film cells and 6% for amorphous silicon cells. There are more expensive "multijunction" non-silicon cells available for sale now that are 34%

efficient, and 41%-efficient cells in laboratories that will presumably reach production soon; and there are quantum-dot and photonic-crystal approaches that could reach 60% in theory. (Some of these numbers are from the NREL report cited earlier, while others are from the National Academy of Engineering page cited earlier.)

However, these more-watts-per-unit-area approaches are very expensive per watt, so they are currently mostly only used in space missions --- to power satellites and the like.

Most types of photovoltaic cells continue to work in higher-intensity light, even working at higher efficiencies [XXX]. If you have mirrors that cost less per square meter than your solar cells, you can use mirrors to gather the same amount of sunlight onto a smaller area of expensive solar cell, for a lower overall system cost. This sort of thing is called a "solar concentrator", and there are some very-large-scale systems that don't even use photovoltaic cells at the focal point, instead using heat engines like an old-time locomotive, which can be more efficient at sufficiently high temperatures.

One experimental project uses a balloon, half of aluminized mylar, half of transparent mylar, to make a concave reflector for a small photovoltaic panel. In photos, it looks like it generates about "100 suns", or 100 times the normal intensity of sunlight. This means that "one watt" of solar panels, rated according to normal sunlight, can produce 100 watts or a little more [XXX confirm this], with the aid of a square meter or so of aluminized mylar, which costs on the order of US$2, and can be recovered abundantly from garbage in many areas. However, I suspect it needs some special cooling [XXX check this].

This kind of setup could theoretically be quite inexpensive and sturdy, but there are difficulties. Your hundred-sun system will suddenly become a zero-sun system if it's not pointed fairly accurately at the sun, so it requires control motors to follow the sun across the sky; this adds to the cost, and also reduces reliability. Your balloons will eventually deflate, and you have to reinflate them. And on cloudy days, your hundred-sun system is, at best, a one-sun system. So most of the production solar concentrators I've heard of have been large-scale thermal generators.

If your 1m² concentrating mirror cost US$5, your 100cm² 12%-efficient photovoltaic cell cost US$5, your motors and control system cost another US$20, and your cooling cost another US$20, you'd have a US$50 system producing about 120 watts, or about US$0.42 per watt. If you could upgrade to 24% efficient cells that cost another US$10 (I have no idea if this price is realistic), you'd have a US$60 system producing about 240 watts, or about US$0.25 per watt --- even though the solar-cell component of the system cost 50% more per watt, the system as a whole cost less per watt. In this way, photovoltaic concentrator systems can economically take advantage of more expensive photovoltaic materials, as long as the solar cells themselves are a small part of the cost of the system.

You would think that this kind of technology would have been adopted wholesale long ago, since it would appear to cost dramatically less per watt than fossil-fuel plants, not even counting the cost of the fuels. So there must be some difficulties that have prevented it from achieving the kind of efficiencies I've suggested above, at least scalably.

There are various experimental systems working on this principle: Solient's (see also the Technology Review article),

In summary: photovoltaic solar concentrators could, in theory, provide electrical generating capacity for US$0.05--US$0.50 per watt with current technology, and I don't know of any practical reason this potential won't be realized. But I also don't know why it hasn't already been realized, say ten or fifteen years ago, and there must be a reason; and maybe that reason still applies.

Incremental recomputation

Kragen Javier Sitaker, 2018-04-27 (12 minutes)

Let's solve cache invalidation, legendarily one of the two hardest problems in computer science.

Why is it hard? We can construct a hard example in three lines of code.

Suppose we construct a unidirectional data flow graph as follows:

```
x, y, z = Input(value=3), Input(value=4), Input(value=2)
p = Max(x, y)
for i in range(10000): p = Max(p, Subtract(p, z))
```

This constructs a directed acyclic graph of dataflow with 20004 nodes: three Input nodes, 10001 Max nodes, and 10000 Subtract nodes. If we increase y's value to 5, this changes the value of all of the Max nodes to 5 and all of the Subtract nodes to 3. By contrast, if we increase or decrease the value of x by 1, no other nodes have new values. How can we implement this efficiently?

There are a variety of different strategies you can use to evaluate such a dataflow graph, but most of them have serious pitfalls which can be demonstrated on the above graph.

To keep the scope of this note manageable, I'm only writing about algorithms for *static* dataflow graphs here, where the topology of the computation is independent of the data that flows through it, like an electronic circuit. To some extent, you can force conditionals into a static dataflow framework as conditional or multiplexing nodes, and iteration as array-valued values (as in TensorFlow), so this is somewhat less restrictive than it sounds.

Pure immediate mode

The simplest strategy is to calculate values on demand. To be concrete, you might have an `eval` method of no arguments which invokes the `eval` methods of the node's inputs:

```
def eval(self):  # for Max nodes
    return max(self.input1.eval(), self.input2.eval())
```

This is pretty much the approach I use in Pytebeat, for example, with values being arrays of 1024 numbers. On some dataflow graphs, this works fine, but on this one, it requires $4 + 2^{10001}$ calls to `eval`, which on my laptop would take about 10^{2995} years, at which point all the stars will have gone out and essentially all matter will be either iron or leptons, depending on whether protons are stable; this is not a practical way to evaluate this dataflow graph. The issue is that nodes whose output is used more than once will be evaluated more than once, which is exponential-time in such pathological cases.

(In Python it actually fails sooner than that by default because the default stack limit is not high enough.)

Topologically-sorted immediate mode

You can calculate values on demand in guaranteed linear time,

though. You begin by doing a topological sort of the nodes to construct a sequence such that each node comes before the nodes that use its value; then you can simply iterate over the sequence, storing the output of each node in an array or something.

This allows you to do the calculation several times for different input values without repeating the topological sort. In effect, you have compiled the dataflow graph into a branchless virtual machine program with a certain flavor of common subexpression elimination.

But, if you think about the standard topological sort algorithm, you will see that you could also do the equivalent of interpretation — you can evaluate the value for each node as you generate the topologically-sorted sequence.

(As it happens, in the example code, the nodes are necessarily created in a topologically-sorted sequence, because each node is constructed with its inputs as parameters. So in this case you can simply define `Max, Subtract, Input = max, operator.sub, lambda value: value` and never construct the graph in memory at all.)

Either way, this approach only touches each node once; on this graph it takes perhaps 100000 function calls, or about a millisecond for this graph, if you do it in Python with an existing in-memory graph.

This doesn't sound so bad, and in the case where you are evaluating some dataflow graph on all new inputs you've never seen before it's absolutely optimal and everything else we'll discuss in this note is slower, but in the case where you just changed x by 1, it takes 100000 function calls to tell you that nothing else has changed as a result. That's about three to five orders of magnitude slower than would seem reasonable. So let's look at incremental approaches to dataflow evaluation.

Invalidation propagation

I wrote about how you could treat the topologically-sorted sequence of operations as a sort of program. But this suggests that you could backtrack in it: if you have 50 operations, and input A isn't used before the 25th operation, the first 25 are guaranteed not to change their value just because input A changed. So you could just start the execution from operation 25, using the previously calculated values for operations 0–24, and then you don't have to do a bunch of redundant recalculation of values that are guaranteed not to have changed.

But this actually works a lot better with the "intepretive" topological sort, because it doesn't have to arbitrarily pick an ordering among nodes that have no actual data dependencies, so it can evaluate only nodes that changed data feeds into.

The way this looks is that changing an input works in two steps: first, you "retract" the current value, causing all the nodes that depend on it to also retract their current values; then, you assert a new value, causing all the nodes that depend on it to be recomputed. If a node gets an input asserted while some other input whose value it needs is still retracted, its output remains retracted. Only once all the required inputs are asserted can it assert a value.

In many cases, you can improve performance by retracting several things at once and then asserting their new values, instead of changing their values one at a time.

This approach is pretty broadly applicable, but it doesn't help for

our example graph; when we retract x=3, the invalidation propagates through 20002 nodes, and then when we assert x=2, the same value propagates through those same nodes again. It takes about twice as long as just calculating all the values from scratch without trying to be incremental.

Pull-based invalidation, or laziness

As I've described it above, invalidation propagation is eager — when you initially assert values for x and y, that pushes the Max node to compute their max, which then pushes the first Subtract node to compute a zero, which then pushes another Max node to compute a value, and so on. Computation is initiated by inputs and results in outputs.

It may happen that the end result of all this computation is, for example, to display a number on the screen, which can only happen at most about 60 times a second, depending on your hardware. But suppose you are changing x or y much more often than this — most of the values computed will never be used.

Now, if the value computed has to be available on a tight deadline, you need some kind of eager computation to store it ahead of time instead of computing it on demand. But what if it's okay to compute it on demand?

In that case, you can have nodes assert their outputs only upon request. In the case of our example graph, first you construct the graph, but don't calculate values for any of the nodes except x and y. Then, you request the output from the final p node. Since its inputs are retracted, it requests them to compute; whichever input tries to compute first finds that its inputs are also retracted, so it asks one of them to compute; and so on, until we are requesting the output of Max(x, y). Its inputs are asserted, so it computes its result (4) and asserts it; this allows a Subtract node to compute its result (2) and assert it; and so on.

This is roughly two thirds as efficient as the push-based approach in this case, and when we retract x later, it does the same invalidation propagation. The difference is that, when we assert x again, no further computation happens — nothing is currently requesting x's value. We can change x or y many times in between screen frames, cheaply.

However, it still has to recompute all 20002 computational nodes in order to discover that changing x doesn't change the final output value.

Change propagation

What if we don't have a separate retraction step, but just assert the new value of x? This helps a lot in this case — the Max node that depends on x can detect that its output values remains 4, so it doesn't need to propagate any change.

But what happens when we change y? If we change y to 8, the Max node updates to 8. This value needs to be sent to the next Max node and the Subtract node. Suppose we pick the Subtract node. Now its value (y-z) is 6, so it updates its value to 6. This gets pushed to the next Max node, which is now comparing 6 to 5, and so it asserts 6 on its output, pushing to two nodes. Later on, when the new value from the previous Max node reaches it, it must recompute a

second time. This kind of thing can result in an exponential number of recomputations, just as with pure immediate mode.

XXX hmm, maybe I need a better example to show the potential exponential behavior, because it peters out here

XXX does breadth-first propagation solve the exponential-time problem?

There's another problem, though, besides efficiency: "glitches" or "timing hazards". That second Max node's output was 4 at the beginning and 8 at the end. But for a moment in the middle, after its first recomputation but before its second one, its output was 6. 6 was never a correct value for max(max(x, y), max(x, y) - z)! If that value change results in your software system taking some action, you could be in trouble.

This happens at a very concrete level in digital logic circuits, in which "glitch" is a technical term for this kind of transient wrong answer. There, the standard solution is a clock whose edges trigger flip-flops.

Memoization

As an alternative to storing the current value of each node, we could instead store some set of previously computed values, according to the inputs that affect them. In the most direct form, of course, applied to a single node, this doesn't help much — computing the max of 3 and 4 is faster than looking up (3, 4) in a cache to return 4. But we could imagine, for example, memoizing a larger chunk of the graph.

The potential benefit of memoization, as opposed to the strategies described above, is that if part of the graph returns to a previous state, the result of that previous state can be retrieved from the cache — it isn't just a matter of "state unchanged" or "state changed".

Chunking

In fact, chunking the graph into smaller subgraphs — giant nodes that perhaps produce multiple values — is an approach that can be applied to all of the previous

Reduced affine arithmetic

Delta propagation

Honk development

Kragen Javier Sitaker, 2019-03-21 (2 minutes)

As I listened to a car honking its horn for a long period of time far away with no pause, I noticed that the quality of the sound changed subtly several times over the first second or two. I think this is a result of echoes: at first I heard only the incident horn, but after a short time it was joined by one, two, three, several echoes of the original horn. Depending on the particular details of the time delays, some of the harmonics in each echo interfered constructively with those in the original sound, while others interfered destructively.

Aside from what this implies about what we can learn about our built environment from analyzing the sound, it occurred to me as being a very easy effect to simulate; this took me about 15 minutes:

```
/* ./horn | aplay */
#include <stdio.h>
#include <stdint.h>

typedef uint8_t u8;

u8 wave(long long t)
{
  return (t & 128 ? 256 - (t & 255) : 128 + (t & 127)) >> 1;
}

u8 horn(long long t)
{
  enum { attack = 600 };
  int v = t < 0 ? 0 : t > attack ? 256 : t * t * 256 / attack / attack;
  return wave(t) * v >> 8;
}

int main()
{
  for (int a = 0; a < 32000; a++) {
    putchar(horn(a - 1000)
            + (horn(a - 6242) * 64 >> 8)
            + (horn(a - 8932) * 32 >> 8)
            + (horn(a - 12333) * 64 >> 8)
            + (horn(a - 3013) * 128 >> 8)
    );
  }
}
```

The waveform of the sound doesn't sound very much like a horn, but the changes in the tonal quality over time are similar to what I was hearing.

a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees)

Kragen Javier Sitaker, 2012-12-06 (updated 2013-05-17) (10 minutes)

Summary

There's an alternative to summed-area tables with a small, linear space cost and linear construction time and space, providing worst-case logarithmic-time reduction over arbitrary intervals under arbitrary semigroup operations, and which supports updates efficiently, unlike summed-area tables. The algorithm is like twenty fricking lines of code if you leave out the "update" and "small" parts.

I am surely not the original discoverer of any of this.

Introduction to abstract algebra

Abstract algebra is the study of what you can deduce from minimal sets of axioms about some set of things and operations on them. A lot of it seems to be taxonomic, assigning names to particular sets of axioms. This is cool because once you establish that, say, 32-bit bitstrings form a semilattice under the bitwise-OR operation, you can apply every theorem that anybody's ever proven about semilattices to 32-bit bitstrings and OR.

In particular, as I think Stepanov first realized, the correctness of an algorithm depends on these algebraic properties of the data it's manipulating. (Typically it also depends on operations being computable, and its efficiency depends on the complexity of that computation, which are perhaps unfortunately not within the purview of abstract algebra.)

A magma is a set associated with a binary operation that's closed over that set.

A semigroup is an associative magma. An example is the set of nonempty finite strings over some alphabet, with concatenation as the binary operation.

A semilattice is a semigroup whose operation is commutative and idempotent; in general a semilattice is a partially ordered set of some kind, with a unique smallest element, where the binary operation is the operation of finding the largest upper bound of the elements. Aside from the obvious examples of totally ordered sets like integers, things like 32-bit bitstrings under bitwise OR or AND form semilattices.

A monoid is a semigroup with identity. String concatenation is the usual example; the empty string is the identity element.

A group is a monoid where every element has inverse for every

element. It's sufficient to have a left inverse for every element; from that you can get identity (I think!) and right inverse.

Summed-area tables

Franklin Crow's 1984 paper, "Summed-area tables for texture mapping" calls them "summed-area tables", and Graphics Gems called them "sum tables". More recently, they're known as "integral images". In the one-dimensional case, they allow you to calculate the sum of values in an arbitrary interval in constant time by subtracting the values from the summed-area table at the ends of the interval: sum(f[m:n]) = -sat(f)[m] + sat(f)[n], where sat(f)[i] = sum(f[0:i]), assuming f's indexes start at 0.

N-dimensional case

You can compute an N-dimensional sum table; sat(f)[i0, i1, ... in] is sum(f[0:i0, 0:i1, ... 0:in]). In some interesting sense, more dimensions makes it more powerful: the set of queries that can be answered in constant time grows exponentially with the number of dimensions, while the constant-time factor only grows linearly with the number of dimensions.

Decimation

As an extension, you can use a decimated summed-area table, with values only present every (e.g.) 16th or 32nd index, without losing the constant-time property. You may have to consult the original array, but only up to 2*(16-1) or 2*(32-1) values of it, which is constant. If you needed to keep the original array around anyway, this dramatically reduces the space cost of the technique without slowing it down too much, which (I speculate) might actually make it faster.

N-dimensional decimation is nontrivial because you can't just store the values at the lattice points; to keep the constant-time guarantee, you have to store values for every point *at least one* of whose coordinates is a round number. This means decimation basically only saves you a linear factor of 16 or 32 or whatever, and you have to use a sparse-array representation to get any good out of it.

Generalization over operations

This problem, sum(f[m:n]), is a specific case of the general idea of " range queries".

Sum tables generalize beyond integer addition. Clearly they work fine for mod-N integer addition, vector addition, and the combination of the two (e.g. XOR). In fact, you can use summed-area tables over arbitrary groups, as long as the group operation and inverse are computable. (The range query is constant time only as long as those computations are constant time.)

(For the N-dimensional case, I think you may also need commutativity, but I'm not sure.)

A logarithmic-time alternative to sum tables for semigroups

But what do you do if you're interested in an operation that doesn't have a left inverse? For example, the "minimum" operation (or in general the meet operation of a meet-semilattice) can't have inverses of elements, because it's idempotent, so you can't compute it with a

sum table.

But you *can* compute it in logarithmic time with a tree. Let

```
mint(f, m, n) = nil if m == n
              = (m, n, min(f[m:n]), mint(f, m, floor((m+n)/2)),
                                    mint(f, floor((m+n)/2), n)) otherwise
```

You can compute this in linear time, assuming a constant-time binary min operation, as follows:

```
mint(f, m, n) = nil if m == n else
                (m, n, f[m], nil, nil) if m == n - 1 else
                (m, n, a, b, c) where
                    k = floor((m+n)/2) and
                    (_, _, a0, _, _) = b = mint(f, m, k) and
                    (_, _, a1, _, _) = c = mint(f, k, n) and
                    a = min(a0, a1)
```

Now if you precompute mint(f, 0, f.length), which is a balanced binary tree with 2*f.length - 1 nodes, not counting the nils, and which can be computed in linear time, you can compute min(f[m:n]) for arbitrary m, n in logarithmic time given that tree. That algorithm is straightforward:

```
tmin((a, b, c, d, e), m, n) =
    c   if a >= m and b <= n
    nil if a >= n or b <= m
    nmin(tmin(d, m, n), tmin(e, m, n)) otherwise

where nmin(a, b) = b if a == nil
                   a if b == nil
                   min(a, b) otherwise
```

This algorithm applies to any semigroup over the elements; it can be used to calculate sums as easily as it can be used to calculate minima, although less efficiently than a sum table.

Space reduction: decimation

Analogously to sum tables, if your leaf nodes represent spans of some 16 or 32 elements instead of 1, you get a dramatic space reduction without losing the logarithmic-time asymptotic performance.

Space reduction: array storage

The contents of the tree produced by the mint() function depends only on m and n, except for the min(f[m:n]); and if f.length is a power of 2, it is a full binary tree. A full binary tree can be stored, as in the classic binary heap, in an array a such that the children of the element at a[i] are at a[2i+1] and a[2i+2] (zero-based). So you can store the minima for the tree in an array (without decimation, of 2*f.length - 1 elements) rather than allocating numerous nodes on the heap.

This requires a slight enhancement to the lookup algorithm to recompute the same (m, n) as the construction algorithm, rather than looking them up in the tree.

Constant-space bottom-up construction

If you construct the tree recursively, in addition to the O(N) space for the results, you need O(log N) stack space. But that is not necessary. If you're using the array storage suggested in the previous section, you can fill the array starting from the end, so that the only auxiliary storage you need for the construction process is a simple counter.

Enhancement: updates in logarithmic time

If you update an element of the original array, you can update the tree nodes going back up to the root to reflect your update in worst-case O(log N) time. Appending or removing elements at the end of the array can be handled similarly, although sometimes appending an element will involve creating a new root node, which (in the array representation of the tree) is worst-case O(N), but amortized constant time.

This is a reason you might actually want to use these trees to handle range-sum queries rather than using sum tables: updating this tree takes O(log N) time, while updating a sum table takes O(N) time.

Enhancement: indices

In the case where the semigroup operation is exactly minimum or maximum over a totally ordered set, the value stored in each treenode will be the value of one of the items in the original array. In this case it is strictly more powerful to store the index of that item rather than its value. This may be useful if you have some other data that are indexed the same way.

This allows the algorithm to solve the "range minimum query" or RMQ problem, for which it is known as the "segment tree" algorithm. Danielp wrote a really awesome tutorial on RMQ on Topcoder.

The constant-time "sparse table" algorithm given in that article unfortunately only works for semilattices rather than general semigroups including arbitrary monoids.

N-dimensional case

This generalizes easily to quadtrees, octrees, etc., although the efficiency guarantees are not as good.

A constant-time alternative to sum tables for semigroups

A.C. Yao published one in 1982, "Space-Time Tradeoff for Answering Range Queries", but I don't know it. I think it's explained in the aforementioned really awesome tutorial on RMQ, involving a reduction to the least-common-ancestor problem, but I don't understand it yet.

Thanks

To John Cowan, Gian Perrone, and Seth David Schoen for discussion.

A tournament to decide which notes to devote attention to polishing

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

I should start publishing some of these notes. But how to select? There are 236 of them! Maybe read through four of them today, pick the two that seem to have the most potential, improve them, then repeat the process the next day, then do the same with the four winners.

To find some that are in the top, say, 10%, we need three or four such tournament levels. Four tournament levels look like this:

```
          Day 1: A B C D
          Day 2: E F G H
      Day 3:     A B E F
          Day 4: I J K L
          Day 5: M N O P
      Day 6:     I J M N
   Day 7:        A B I J
          Day 8: Q R S T
          Day 9: U V W X
      Day a:     Q R U V
          Day b: Y Z α β
          Day c: γ δ ε ζ
      Day d:     Y Z γ δ
   Day e:        Q R Y Z
Day f:           A B Q R
```

That should give two items that would, in the perfect-fairness case, be in the top 6.25% of the essays, with four revisions, at the cost of reading an essay 60 times (reading 32 unique essays) and doing 30 revisions. The two-of-four comparison system obviously deviates somewhat from perfect fairness, although, if the comparisons are reliable, it will find the best two; but the runners-up may not be the #3 and #4 best. (In the above example, C and D could have been the #3 and 4 best, but still be eliminated on day 1 because of having the bad luck of sharing the same day with A and B, if those were #1 and #2.)

Likely-feasible non-flux-deposition powder-bed 3-D printing processes

Kragen Javier Sitaker, 2015-09-11 (updated 2019-12-20) (49 minutes)

I just wrote this long thing in Flux deposition for 3-D printing in glass and metals (p. 1366) about a powder-bed 3-D printing technique that deposits a binder that's completely inert at room temperature, but upon firing the print in a kiln, becomes active. (See also 3-D printing by flux deposition (p. 466).)

I think there are a variety of other possibilities in powder-bed 3-D printing that have not yet been fully explored.

Powder-bed 3-D printing, *in general*, consists of depositing one layer after another of powder, alternating with selectively applying some kind of treatment to the top layer of powder which results in causing it to solidify. The classic inkjet-binder-deposition 3-D printing is one example, but selective laser sintering and selective laser melting are other processes in this category.

Magnesium oxychloride (Sorel cement) or zinc oxychloride

Sorel cement is a combination of highly water-soluble magnesium chloride (nigari) with highly water-insoluble magnesium oxide (milk of magnesia); it's a cement similar to Portland cement, but more refractory, less water-resistant (and won't harden underwater), and nearly twice as strong.

So, although I'd have to investigate more, I think you could use an aqueous solution of magnesium chloride to moisten a powder bed of sand and dry magnesium oxide to form a very strong mortar.

Zinc oxychloride might work in the same way: zinc oxide is insoluble, like magnesium oxide, while zinc chloride is so soluble it's deliquescent; and zinc oxychloride or zinc hydroxychloride formed in precisely this way was formerly used as a dental cement, like the zinc phosphate mentioned below. Zinc chloride, however, is acidic, corrosive, and a skin irritant, while magnesium chloride is free of these problems. In fact, Sorel investigated zinc oxychloride before settling on magnesium oxychloride!

Selective hammering

Instead of squirting binders onto a powder bed like an inkjet printer, you could bang the shit out of it with hammers like a dot-matrix printer, ideally under vacuum so that you don't generate explosive gas expulsions. The impact will stick together the particles in the vicinity, affecting a total mass of powder material similar to the total mass of the hammer. (This suggests that low-mass hammers are in some sense optimal.)

Selective electrical sintering

For beds of metal particles, instead of squirting binders, you could

touch the surface of the powder with an electrode and drive a large current into it, sintering the nearby particles together through joule heating of their contact points, like an old-fashioned coherer.

The electrode would probably have to be a carbon rod, since any other plausible material is likely to stop working due to surface oxidation.

This probably won't produce a strongly bonded part, but might be enough to produce a solid part that can then be solidified further by other means.

Cement precipitation by cross-linking with calcium or other polyvalent cations

A number of anions, such as phosphate, carbonate, and alginate, form water-soluble compounds with monovalent cations like those of the alkali metals (sodium, potassium) and ammonium, while forming water-insoluble compounds with divalent cations like those of the alkaline earth metals (calcium, magnesium). Calcium and magnesium also have highly water-soluble salts, such as their nontoxic chlorides. Phosphate is also water-soluble in the form of phosphoric acid.

This means that by mixing two liquids you can precipitate a solid through a double ion replacement reaction. This is used in molecular gastronomy spherification of foods, forming a flexible calcium alginate membrane around a liquid center with sodium alginate dissolved in it.

(I'm pretty sure this is because these anions are polyvalent and are strongly enough bonded to their cations that they are solvated together with them, rather than separately, so that once the cations are also polyvalent, the individual anions floating around with their individual cation harems are replaced by endless chains in which each cation links together different anions. But I'm no chemist.)

Candidate cements and fillers

Other polyvalent cations, like Cu_{2+}, Zn_{2+}, Fe_{3+}, Fe_{2+}, and Al_{3+}, should also work for this. Most of these also have relatively innocuous water-soluble salts; $ZnCl_2$, $Fe(NO_3)_3$, $Cu(NO_3)_2$, $FeCl_3$, and $AlCl_3$, as well as blue, white, and green vitriol, of course, which last are innocuous enough to use as nutritional supplements, but are subject to onerous reporting paperwork in places nowadays; acetates of calcium, magnesium, copper, zinc, and ferrous iron (II) are also all soluble, though acetate of zinc only a bit, and acetate of ferric iron (III) not at all. Ferrous citrate is also soluble.

So the plan is that you precipitate a solid cement in the interstices of an aggregate or filler, such as quartz, grog, carbon black, fumed silica, mullite needles, aluminum oxide crystals, rutile needles, zircon crystals, mica, chopped carbon fiber, chopped basalt fiber, chopped glass fiber, powdered graphite, powdered copper, powdered silver, hollow glass spheres, hollow steel spheres, chopped cellulose fiber (such as sawdust), silicon carbide, clay (especially finely dispersed bentonite), diatomaceous earth, etc.; or a mixture. If the cement is relatively inert, unlike the aggressively alkaline slaked lime and portland cement, a wide variety of fillers are possible that couldn't withstand the harsh chemistry of everyday building materials.

Different possible resulting cements include the following; I'm

including Mohs hardnesses as an imprecise but readily available and roughly accurate guide to strength:

• Aluminum phosphate — the rare mineral berlinite, with Mohs hardness 6.5, or, when hydrated, the unusual mineral variscite, with Mohs hardness 4.5, used as a dental cement; or, sometimes, aluminum triphosphate, aluminum hexametaphosphate, or aluminum tetrametaphosphate.
• Calcium phosphate — probably hydroxyapatite, like tooth enamel, Mohs hardness 5; can incorporate iron(II) and manganese substituting freely for calcium to form the equally hard graftonite;
• Calcium carbonate — calcite, Mohs hardness 3;
• Calcium alginate — a silicone-like insoluble, nontoxic organic water-gel-forming elastomer;
• Ammonium magnesium phosphate — the light, very soft (Mohs ≤ 2) mineral struvite, which might be formed if ammonium phosphate is the phosphate salt used;
• Magnesium phosphate is a GRAS food additive for buffering acidity, but I don't know anything about its mechanical properties;
• Magnesium carbonate — the soft mineral magnesite, Mohs hardness 3.5–4.5, which can be calcined at only 500–800° to magnesium oxide, or magnesia alba (periclase, as mentioned above), which doesn't melt until 2852° and is used as a stronger alternative to gypsum in drywall;

• Calcium magnesium carbonate — the mineral dolomite, Mohs 3.5–4, which probably will *not* form even if its constituents are available (because it's picky about crystallizing);
• Magnesium alginate ought to exist and be similar to calcium alginate;
• Copper phosphate — a blue-to-green insoluble copper salt;
• Copper carbonate — a bright blue to green pigment, depending on degree of hydration, occurring as malachite and azurite in nature (which differ in their degree of carbonation); "very sensitive to acids". Mohs 3.5–4.
• Zinc phosphate — one of the oldest and most widely used dental cements, so nontoxic and biocompatible, made in something like the way I'm suggesting here (mixing zinc oxide and magnesium oxide powder with buffered aqueous phosphoric acid); occurs naturally as the rare mineral hopeite (Mohs 3–3.5);
• Zinc carbonate — the mineral smithsonite (Mohs 4.5), one of the two minerals known as calamine (the other being zinc silicate);
• Ferric phosphate — non-toxic, except to mollusks, and sometimes used as an iron nutritional supplement, but almost insoluble in water; "heterosite" or "wolfeite"?
• Ferrous phosphate — the soft deep blue to bluish green mineral vivianite, used to kill garden slugs, Mohs 1.5–2;
• Iron carbonate — the dense yellow mineral siderite, Mohs 3.75–4.25;

• Manganese carbonate — the rose-red mineral rhodochrosite, Mohs 3.5–4.

So you should be able to get relatively high strength, almost as high as portland cement (whose strength comes mainly from belite, which is known as larnite in nature, Mohs 6), by precipitating calcium phosphate crystals from a water-soluble calcium salt such as calcium

chloride and a water-soluble phosphate salt such as monoammonium phosphate; you *may* be able to get a highly refractory bond by calcining the phosphate or carbonate of magnesium into magnesia; you can get an instant nontoxic aqueous elastomeric gel with calcium alginate; you can get biocompatibility (and guaranteed-working recipes) from zinc and magnesium oxides with buffered aqueous phosphoric acid; and there are thirteen other combinations that will probably work as well.

Further alternative polycations might include nickel, mercury, and vanadium ions, but these have some disadvantages (carcinogenicity, higher toxicity) and not much in the way of available information. Further alternative polyanions might include sulfate (which does have some insoluble salts, notably calcium sulfate (gypsum) and barium sulfate), oxalate, silicate (see below), sulfide (soluble with lithium, sodium, and ammonium, but should precipitate transition metals) and perhaps some carrageenans.

Iron sulfide in particular — fool's gold — is 6–6.5 on the Mohs scale, harder than apatite. It has the disadvantage of gradually oxidizing in air, though, with corrosive results, and of course the soluble sulfides are toxic.

Liquid tank systems

It might be advantageous to work with a mixture that is liquid until the cement is precipitated, rather than consisting mostly of a packed granular filler. This doesn't exclude the use of fillers; especially bentonite clay can remain in suspension in water up to fairly high concentrations of clay without solidifying the water. It might be worthwhile to mix a little sodium or potassium alginate in with the phosphate so that the initial introduction of the calcium donor will gel things in place in milliseconds and prevent the liquid from flowing further, even if the calcium phosphate or other cement takes some time to fully crystallize. (This might be useful to limit diffusion even in a powder-bed system.)

(The advantage of Newtonian or at least non-thixotropic liquids is that their surfaces are reliably quite flat and horizontal; they have no angle of repose.)

Other plant gelling agents such as pectins and carrageenans can also be precipitated into a gel by pH control and in some cases by polyvalent cations (though there are many different types of pectin and many different types of carrageenan, and they can sometimes react in opposite ways to pH changes), and aluminum sulfate precipitates insoluble, gelatinous aluminum hydroxide when the water is insufficiently acidic.

Nucleation control

It may be desirable to prevent homogeneous nucleation in order for the cement particles to be big enough to bridge the gaps between grains of filler. For of these most cements, if the temperature is kept high enough, cement particles will only nucleate on the surfaces of grains of filler; this may help to produce a solid mass. (More speculatively, pressure control is another possible lever to control nucleation, but this would probably require a liquid-filled chamber.) It may also be possible to solve this problem by making the precipitation mass-transport-limited.

Filler particles with more extreme aspect ratios — clays such as bentonite being the champion here, though a less expansive clay may be more practical for this use — should lower the critical percolation threshold needed to form a solid mass, thus placing less stringent demands on the nucleation process.

Densification

Once you have the "green" article made out of filler grains cemented together, you can use water to wash off the unhardened mixture of filler ("powder") and unprecipitated solute, as well as washing out leftover reaction products other than the cement. Densification may be needed after the initial precipitation, since when the cement precipitates from solution, the water and other solute remain. (For example, if reacting aqueous dipotassium phosphate (which dissolves 150 g per 100 mℓ of water) with calcium chloride to produce hydroxyapatite, you have potassium chloride and water taking up space in the result.) Densification can be carried out by passing a supersaturated solution of the same cement, or a compatible cement, over the printed object once it is removed from the powder bed; or it can be carried out by infusing the pores with a different material, perhaps a melt, again after powder removal.

Electrolytic injection of cations

As an alternative source of polyvalent cations, you could use small anodes of suitable metals (zinc, copper, manganese, or iron, although maybe it might be possible with a suitable alloy of calcium or magnesium) with a controllable current; this might allow you to switch on and off the cementing action with much higher precision and frequency than pumping solute liquids in and out of a pipette or inkjet, and would avoid the need for the extra water content to maintain those cementing ions in solution.

This approach should be especially suitable to introducing controlled amounts of impurities into particular places in the printed object — for example, copper or iron ions would probably produce a bright blue color, or manganese ions a rose-red color. You could probably get a wide variety of other colors by using other metals not otherwise mentioned here; cations introduced for the purpose of adding color need not be polyvalent or form physically strong compounds.

More generally, the precise control of mixing provided by the electrolytic mechanism can be used to produce precisely controlled gradients of material properties in the cementing material, for example to produce controllable optical or acoustic refraction.

In theory you could also use a sacrificial cathode that released anions such as phosphate or carbonate when electrolytically reduced, but that seems much more difficult; I know of no such material.

Alternative solvents

Water is a terribly convenient solvent for facilitating such double-metathesis reactions, since it's capable of dissolving a very wide variety of ions, it's fairly nontoxic, and it is liquid at room temperature. But it has the major disadvantage that it contains oxygen, so to metals like calcium, water is utter death. Other polar solvents might be feasible alternatives; for example, anhydrous ammonia at low temperature and/or high pressure, or molten-salt

mixtures like FLiNaK and FLiBe at somewhat higher temperatures, or the truly outlandish polar organic solvent systems used in current lithium-ion batteries.

Bicarbonate as a hydroxyl donor

Cyanoacrylates polymerize in the presence of hydroxyl ions; dripping cyanoacrylate onto $NaHCO_3$, stealing hydroxyl ions and converting it to sodium carbonate, is a well-known manual additive manufacturing technique which can probably be improved by adding filler to the $NaHCO_3$.

Bicarbonate as a CO_2 donor

Waterglass (sodium or potassium silicate) forms a silica gel rapidly upon exposure to CO_2; maybe you can use $NaHCO_3$ as a CO_2 donor for this purpose. Certainly you can harden it with acids instead, or with ethanol.

There are other materials that harden or recrystallize upon exposure to CO_2, most notably $Ca(OH)_2$, slaked lime, which produces calcium carbonate. Normally they harden fairly slowly once wet by absorbing CO_2 from the air, but maybe you could get them to harden faster by supplying them with $NaHCO_3$.

Metastable redox systems such as thermites

Rather than using chemicals that react immediately on contact, as in the above, or initiating some kind of interaction by slowly heating the entire powder bed after careful deposition, as in Flux deposition for 3-D printing in glass and metals (p. 1366) and 3-D printing by flux deposition (p. 466), it might be worthwhile to use chemicals that can react quite energetically, but which remain almost completely inert during the printing process; and, once the printing is complete, ignite them and allow the self-sustaining reaction to run to completion. The trick is to identify reactions that would produce enough heat to produce interesting materials, but without producing enough gas to blow the nascent object to bits.

Thermites, such as the classic aluminum-powder/magnetite system formerly widely used for welding, are one example; you could selectively deposit aluminum powder into a bed of magnetite, and then ignite the thermite once the printing is done (traditionally, using magnesium ribbon). This produces molten iron and molten (!!) aluminum oxide, which I expect would then quickly quench in the much larger body of magnetite, producing a solid object consisting of a magnetite shell around a core consisting of phases of iron and amorphous or cryptocrystalline corundum; plausibly both phases might initially be continuous, as in an open-cell foam, but the corundum would almost certainly fracture severely during cooling. With some luck, the purified iron thus produced will be sufficiently ductile to remain intact.

(The temperature is 2500° when the oxidizer is hematite rather than magnetite, but I think this is limited by aluminum boiling at 2519° rather than by the energy available.)

Magnetite has some disadvantages; it will melt onto the outside of the printed object, its own properties are not all that desirable, and it

adds iron (thus, weight) to the piece. Other oxygen donors might solve or at least ameliorate these problems. However, the traditional alternatives are hematite (red iron oxide), silica, diboron trioxide (boria), a mixture of manganese dioxide with manganese monoxide, lead tetroxide, cupric oxide (CuO, the toxic tenorite), and viridian. Of these, I think silica is the one with the highest melting point (1600°), and it has the benefit of being transparent; but the metallic silicon thus formed is even more brittle than corundum. Viridian and cupric oxide offer the fascinating prospect of 3-D printing in purified chromium and copper, but cupric-oxide thermite can be explosive. Additionally, chromite ($FeCr_2O_4$) might work — I think aluminothermic reduction of chromite is used for commercial chromium smelting.

Sometimes people use teflon instead of an oxygen donor, thus producing a metal fluoride (and carbon) rather than a metal oxide.

Typically when burning aluminum with quartz as the oxidizer, sulfur is included in an aluminum–sulfur–sand composition; WP claims this functions as an extra oxidizer to add energy, as well as to ease ignition. Sulfur is sometimes used with magnetite, aluminum, and barium nitrate to make "thermate," a higher-temperature thermite with mostly military uses.

Aluminum is not the only possible fuel metal, only one of the cheapest and safest; other possibilities include zirconium, calcium (!), zinc, titanium, silicon, boron, and magnesium.

Common fillers for thermite welding include high-carbon steel, cast iron, or pig iron, which melt and mix with the purified iron to produce a steel with the desired level of carbon.

Alternatively, at somewhat higher cost, you could attempt to make the oxidizer rather than the metal the limiting reagent — for example, depositing a small amount of magnetite powder in a bed of aluminum powder, rather than the reverse; then, the newly formed material will quench in the aluminum, acquiring an aluminum coating rather than a magnetite coating. This is very risky, though, because the aluminum powder burns fiercely in air. You'd need to do it under an inert or reducing gas, or in vacuum.

The reaction between zinc and sulfur, every chemistry teacher's favorite, is another candidate. The sphalerite or wurtzite thus produced is a reasonably strong mineral (Mohs 3.5–4). Other metals, such as aluminum and I think iron, have similar reactions, but the sulfides thus formed are less stable and tend to hydrolyze.

Some materials pricing

Looking at Mercado Libre here in Argentina this weekend (2019-12-13 to 2019-12-15) I found some vendors for most of the materials I mentioned above; today the dollar is around AR$62 bid, AR$67 ask; I'm using AR$64.50/US$ for the conversion. I've ordered the materials I was able to price roughly by price.

(Addendum 2019-12-20: the dollar is AR$73 today. I spot-checked three of the prices below; none of the three have changed, in pesos, although this means they have fallen by something like 10% to 15% in dollars. This clearly means that the error bars on these prices are like 20% or 30%.)

• Silica sand for construction (not very pure, but without stones or

salt) has costs that vary greatly by location, but are generally around AR$1200/$m^3$, which works out to about AR$750/tonne at 1.6 g/cc, or AR$0.75/kg (US$0.012/kg).
• Portland cement costs US$9.64/kg (US$0.15/kg).
• Calcium hydroxide (slaked lime) costs AR$7.8/kg (US$0.12/kg).
• Fine pine sawdust costs around AR$10/kg (US$0.16/kg) although prices vary by a factor of 2 or 3.
• Coke (carbon) costs AR$45/kg (US$0.70/kg).
• Magnesium sulfate (Epsom salt) costs AR$116/kg for beer brewing or AR$112/kg as medicine or AR$83/kg or as low as AR$60/kg as a hydroponics fertilizer (US$0.90/kg).
• Diammonium phosphate costs AR$150/kg as a hydroponic fertilizer or AR$60/kg in bulk (US$0.90/kg).
• Magnetite is I think AR$70/kg ("oxido de hierro magnetico color negro") but it isn't totally clear whether the AR$350 price is for a 5-kg bag or not. (US$1.10/kg)
• Sodium silicate solution (waterglass) costs AR$72/kg for waterproofing and surface-hardening concrete ("curador silicato", in this case Sikafloor CureHard 24). (US$1.10/kg)
• Quicklime, calcium oxide, costs AR$75/kg. (US$1.20/kg). Note that this is almost ten times the price of slaked lime, suggesting that either the slaked lime is adulterated or the safe handling of quicklime is very costly.
• Bentonite clay costs AR$232/kg or more when food-grade, but as clumping cat litter, only AR$83/kg (US$1.30/kg). The cat litter might be contaminated with other clays, with silt, or with sand, but for these purposes that might be acceptable.
• Aluminum in ingots costs AR$100/kg (US$1.60/kg).
• Calcium chloride costs AR$106/kg as a desiccant (US$1.60/kg), or AR$125/kg if you only buy one kilo. For beer brewing they charge AR$165/kg which seems like it might be purer. For bath salts, AR$155/kg with a purity of 77-80%.
• Calcium nitrate costs AR$111/kg as a fertilizer (US$1.70/kg). It's deliquescent above 50% humidity.
• Green vitriol costs AR$111/kg (US$1.70/kg) to AR$165/kg as a fertilizer.
• Sodium bicarbonate costs AR$129/kg (US$2.00/kg).
• Monoammonium phosphate costs AR$143/kg as a hydroponic fertilizer (US$2.20/kg)
• Lead in ingots costs AR$145/kg from BATERIAS INDIANAPOLIS in Burzaco. (US$2.20/kg)
• Trisodium phosphate costs AR$150/kg for industrial use. (US$2.30/kg)
• 85% phosphoric acid costs AR$495/liter for beer brewing, or AR$350/liter in bulk or as low as AR$170/liter. That's 1.6845 g/cc so that's reasonably close to being AR$495 or AR$350 or AR$170 (US$2.60) per kg of phosphoric acid.
• Alumina costs AR$298/kg from Alcoa, or, in bulk, as little as AR$194/kg (US$3/kg).
• Magnesium chloride costs AR$221/kg or AR$249/kg for food or nutritional supplement use, or as low as AR$195/kg for bath-salts use (US$3/kg).
• Brass filings from keys (probably mostly free-machining brass) can cost AR$230/kg, (US$4/kg) although the price seems to vary quite a

bit; another listing has it at AR$1500/kg.
• Scrap brass in ingots costs AR$230/kg (US$4/kg).
• Powdered sulfur costs AR$329/kg or AR$244/kg in bulk (US$4/kg).
• Potassium nitrate costs AR$245/kg (US$4/kg) to AR$289/kg as a fertilizer.
• White vitriol costs AR$258/kg (US$4/kg) as a fertilizer.
• Magnesium nitrate costs AR$262/kg (US$4/kg) as a fertilizer.
• Sodium carbonate costs AR$690/kg for bath-salts use, or AR$860/kg, or AR$280/kg (US$4/kg) in bulk. It's also available in small quantities in supermarkets mixed with sodium percarbonate for laundry use.
• Manganese sulfate costs AR$381/kg (US$6/kg) as a fertilizer.
• Chopped 4.5-mm glass fiber costs AR$381/kg (US$6/kg) ("Hilo De Fibra De Vidrio Cortada 4,5 Mm - 20 Kg Carga Placas", "Comercial San José", 12 blocks from the Tigre station), or in 3-mm cuts, as low as AR$337/kg ("mecha cortada", "chemia.com.ar").
• Copper sulfate costs AR$400/kg (US$6/kg) as a swimming-pool fungicide and algicide.
• Silicon carbide costs AR$420/kg (US$7/kg) ("Carbeto de silicio", in Portuguese, imported from Brazil, brand Imerys Fused Minerals.)
• Monopotassium phosphate costs AR$483/kg (US$7/kg) as a hydroponic fertilizer.
• Calcium citrate costs AR$520/kg (US$8/kg) as a nutritional supplement. Its solubility is a bit under 1 g/liter: 100x higher than calcium carbonate, but 1000x lower than chloride and nitrate.
• Zinc oxide costs AR$1600/kg to AR$3300/kg for cosmetics use, or AR$540/kg (US$8/kg) for use in paint ("purity 99.5%, contact with skin dangerous"). Also zinc phosphate dental cement is for sale for AR$2080 for 90 grams; presumably this is the zinc oxide and phosphoric acid mentioned above.
• Iron filings ("limaduras de hierro") cost AR$600/kg (US$9/kg) to AR$850/kg.
• Magnesium citrate costs AR$650/kg (US$10/kg) as a supplement.
• Powdered lead costs AR$700/kg, (US$11/kg) but see above about lead in ingots.
• Magnesium oxide costs AR$845/kg (US$13/kg) to AR$1040/kg in 99.9% USP food-grade form.
• Copper filings ("polvo de cobre puro") cost AR$850/kg (US$13/kg).
• Potassium chloride costs AR$996/kg (US$15/kg) as a salt substitute.

• Fine brass powder costs AR$1200/kg (US$19/kg).
• Potassium silicate solution costs AR$1450/kg (US$22/kg) as a fertilizer.
• Calcium acetate hypothetically costs AR$2000/kg (US$30/kg) but a lot of people complain about that vendor.
• Powdered zinc costs AR$2600/kg (US$40/kg).
• 97%-pure powdered aluminum costs AR$2900/kg (US$40/kg) though I've seen other listings at lower prices.
• 99%-pure powdered tin costs AR$3700/kg (US$60/kg).
• Sodium alginate costs AR$40000/kg. or as low as AR$10050/kg (US$160/kg) for culinary use.
• Nitrates of iron and copper are not available.

• Zinc chloride is not available.
• Potassium carbonate is not available, which is a shame, since it's much more water-soluble than sodium carbonate.
• Ammonium carbonate is not available, although it's used in some cookies here in Argentina.
• Aside from the possibility of prying them out of dead batteries, carbon electrodes are available for arc gouging: 4 mm diameter, 305 mm long for AR$83, 6 mm diameter of some unknown length for AR$43, 10 mm diameter of some unknown length for AR$72, or 13 mm diameter of some unknown length for AR$136.
• Several vendors sell bars of magnesium as sacrificial anodes for solar hot water heaters for a few hundred pesos, and there are a few magnesium firestarters like the one I had as a kid.
• Someone is selling "glass basalt fiber" for "SMC roving", for AR$100 for 1.5 meters. I have no idea if this is actually basalt fiber but I suspect it's just glass fiber.

Some candidate mixtures explored in more detail

Although there are of course a very large number of combinations drawn from the above that are likely to work, I thought it would be useful to work out some properties and approximate recipes for a few of the variants.

Although mostly I'm considering a binder-jetting process here, keep in mind that in fact the "binder" being jetted is in most cases just water, or water thinned with alcohol, and its only function is to solvate the actual cement grains so that they can react, and in some cases to drive the reaction kinetics toward water-insoluble cement products. In most cases, another polar solvent such as ammonia, or heat from a laser or arc, could be substituted for the water "binder".

Also, many of these mixtures would benefit from additional ingredients; the U Washington Open3DP project has published a number of recipes they found worked well. In many cases, for example, they added carboxymethylcellulose or a similar plant gum to provide both wet strength and green strength.

Cat-litter bentonite or other clay body by itself

If we jet water, perhaps thinned with a little alcohol, onto a powder bed made of clumping cat litter, it will clump. If left to dry, perhaps without even depowdering, it will form a dried unfired clay object. If some sand or grog is included, this object can even be strong enough to survive handling, and such additives will also reduce shrinkage on drying, as would non-expansive clays.

Quartz sand and calcium hydroxide

This is the classic *cal y arena* mortar, cured by absorbing carbon dioxide from the air, mostly in 24 hours. It has the attractive feature of being bright white. I think U Washington Open3DP has done some work with this recipe.

Quartz sand and portland cement

This is the classic hydraulic mortar; it sets up faster if you add some slaked lime.

Quartz sand, wood flour, cat-litter bentonite, diammonium phosphate, calcium chloride

Upon jetting water thinned with a little alcohol onto this dry powder-bed mixture, ammonium chloride and calcium phosphate are formed; bentonite crystals serve to provide extra nucleation centers for the precipitating calcium phosphate, to bridge gaps between precipitate crystals (especially initially, when they are small), to add tensile strength to the weaker calcium phosphate crystals, and to stop the propagation of cracks through the calcium phosphate. The highly soluble ammonium chloride remains in solution in the pore water; if desired, it can be leached out later by immersing the finished part in water. The quartz sand fills the majority of the material and provides mostly compressive strength. The wood flour serves to reduce density and provide tensile strength, like collagen in bone.

The mixture is kept dry and must be protected from air exposure when not in use, because the calcium chloride is deliquescent at ordinary humidities; even then, the ammonium has a limited shelf life, especially when warm.

The needle-like morphology of typical apatite nanocrystals is well-suited for bridging gaps between clay particles and other fillers, and would pose no barrier to further diffusion to carry the reaction to completion; even the platelet-like morphology that sometimes occurs with apatites and often with triclinic octacalcium phosphate would work well. The spherical morphology that occurs with amorphous tricalcium diphosphate (called tricalcium phosphate, TCP) would be pessimal, and when TCP precipitates from aqueous solutions, it always precipitates in amorphous form, requiring heat-treatment to crystallize. Apatite is favored at high pH; TCP is favored at more acidic pH; and OCP is favored in between, at a slightly acidic pH.

Calcium chloride is $CaCl_2$, with a molar mass of 111 and a solubility of 650 g/liter of water at 10°; diammonium phosphate is $(NH_4)_2HPO_4$, with a molar mass of 132 and a solubility of 575 g/liter of water at 10°. Hydroxyapatite, which is the mineral cement we are hoping for, is $Ca_5(PO_4)_3OH$, with a Ca:P ratio of 5:3 and a molar mass of 502; Wikipedia says it is commonly prepared as nanocrystals from a mixture of calcium nitrate and diammonium phosphate, including at non-stoichiometric ratios. So for every 5 moles (555 g) of calcium chloride we want 3 moles (396 g) of diammonium phosphate and get some miscellaneous products plus one mole (502 g) of hydroxyapatite, 10 moles of chloride ions, and 6 moles of ammonium ions, which I think will result in 6 moles of ammonium chloride (53.5 g/mol, so 321 g) and 4 moles of excess chloride. Also we have a couple of extra hydrogens floating around, so maybe we'll get hydrochloric acid or something; might be a good idea to include some calcium hydroxide or something if that's happening. (I should work out the side products in more detail; the formation of chlorapatite rather than hydroxyapatite may be a possibility, and seems guaranteed if you heat the result to dissociate the ammonium chloride.)

Solvating that amount of calcium chloride simultaneously would take 850 g of water, and of diammonium phosphate, 690 g of water, at 10°. So, dividing, for every gram of hydroxyapatite, we need 3.1 g of water, 1.1 g of calcium chloride, and 0.79 g of diammonium phosphate. Actually we might need somewhat more or somewhat less

water than that: more because some of the water molecules are tied up by the "pore walls" of the bentonite, or less because when hydroxyapatite precipitates out of solution, the water remains to solvate new calcium chloride and diammonium phosphate. It will gradually become saturated with ammonium chloride (solubility: about 240 g/liter at 10°) and lose its ability to solvate more calcium and phosphate so they can react.

I'm not sure whether you would expect such a water deficiency to also slow the formation of the calcium phosphate crystals, allowing them to grow larger, by limiting the speed at which calcium phosphate can diffuse to the crystal growth sites, or to result in smaller crystals because the solution is more fully saturated. Both seem worth a try. Also, though, the papers I've seen on hydroxyapatite wet precipitation, like Poinern et al. 2009, required hours for the crystallization to produce particles of tens to hundreds of nanometers, and ideally we'd like it to happen at subsecond time scales, or in minutes at most. (But Victor Chen's YouTube demo of reacting sodium phosphate with calcium chloride produced a solid and completed within a few seconds; similarly Arieus Alcide's reacting calcium gluconate with potassium phosphate produced a white precipitate instantly.)

(Carbonates or hydroxides might work to liberate ammonium from the solution, and would prevent the pH from dropping (Hielscher's sono-synthesis report says they tried to keep their pH around 10 with NaOH in order to get hydroxyapatite instead of a different calcium phosphate) but the chlorides they formed would also be soluble, except in a few problematic cases like chlorides of silver, thallium, lead (plumbous, II), mercury (I) (calomel), and copper(cuprous, I), all of which are alarmingly toxic, absurdly expensive, or both. Also, I suspect any of these would form soluble complexes with the ammonium ligands, leaving us back where we started. Perhaps it would help to use trisodium phosphate, which is pretty alkaline, in place of some or all of the diammonium phosphate.)

The apatite crystals can incorporate a little magnesium, which can transform them into whitlockite, but it is reported to inhibit apatite nucleation and growth, as does carbonate. Magnesium I think favors the precipitation of tricalcium phosphate, since β-TCP shares whitlockite's crystal structure.

So, if the amount of water is about right --- as set by the amount of pore space available for the reaction --- then every 5 kg (or, say, 5 nanograms) of pore space will produce 1 kg (or, respectively, 1 ng) of cement. Because hydroxyapatite has a density of about 3.2 g/cc, this means that the cement will fill up only about 8% of the pore space, so we'd better hope that we can get by with a smaller amount of water.

(8% was arrived at as follows: anhydrous calcium chloride weighs 2.15 g/cc, and undissolved diammonium phosphate weighs 1.619 g/cc, so the 5 g of solution that yielded each gram of hydroxyapatite actually occupied 4.1 milliliters before the water began to solvate the salts, and the gram of hydroxyapatite occupies 1 ml/3.2 = 0.31 ml, which works out to about 7.6%.)

How much pore space is there? Building sand weighs d = 1.52–1.68 g/cc (see also rfcafe), which suggests a void fraction of (1 - d /2.4) = 30% to 37%, 2.4 g/cc being the density of quartz; let's say one

third. The bentonite particles might occupy 50% of the remaining space, one sixth of the total, and the phyllosilicate bentonite crystalline material might have a density of 2 g/cc (I'm not sure). Let's forget about the sawdust for the time being. So we have one sixth of the space available as pore space.

For each 4.1 milliliters of pore space, we need 1.1 g of calcium chloride and 0.79 g of diammonium phosphate. So for each milliliter of powder, we need 270 mg of calcium chloride, 190 mg of diammonium phosphate, 1600 mg of construction sand, and 170 mg of bentonite cat litter. Or, per liter of mix:

Ingredient	Mass/liter	US$/kg	US$/liter
Sand	1.6 kg	0.012	0.019
Cat litter	170 g	1.30	0.22
$CaCl_2$	270 g	1.60	0.43
$(NH_4)_2HPO_4$	190 g	0.90	0.17
Total	2.23 kg		0.84

It's probably important to make sure that the formation of the calcium phosphate take place mostly between the bentonite grains. In the powder bed, the bentonite is I think unavoidably going to be aggregated into clumps of tens to hundreds of microns in size, and water, when wetting the powder, will reach the centers of those clumps last. But the centers of those clumps are precisely where the calcium phosphate is most needed --- in other places it runs the risk of forming crystals that don't attach to anything. I think the way to solve this is to thoroughly wet-mix the calcium chloride into the bentonite before drying the bentonite and breaking it into those clumps; then mix the clumps with the sand and the crystals of diammonium phosphate. That way, when the water wets the powder, it will first dissolve all the diammonium phosphate, then begin to diffuse into the bentonite clumps, where it can cement them by forming calcium phosphate there.

If the bentonite in question is not already a calcium bentonite, it may eat some of your calcium in this process, diffusing out sodium to replace it, so you may need to use somewhat more calcium than suggested.

We can see that if we were to replace all the sand 1:1 with sawdust, assuming 1 kg/liter, it would add US$0.16 to the cost and bring it up to US$1/liter. However, sawdust has much higher porosity than sand, so it would also increase the amount of bentonite and cement that could be included; perhaps the cost might increase to as much as US$2/liter.

Phosphoric acid is not a cheaper phosphate source but might permit denser cement

The diammonium phosphate mentioned above contains one phosphorus atom per 132-dalton formula unit, and additionally it needs more than its own mass in water to dissolve it. Phosphoric acid also contains one phosphorus atom per molecule, but its molecules are only 98 daltons, and it only needs a very small amount of water. So if diammonium phosphate costs US$0.90/kg, phosphoric acid could cost as much as $1.20/kg and still actually be cheaper. But in fact phosphoric acid costs US$2.60/kg.

Jetting 85%-pure phosphoric acid out of nozzles is not going to work; it's too viscous. But you could maybe use powdered solid

phosphoric acid. However, although it's not toxic, it's pretty caustic; most of the other chemicals described above are less dangerous.

Calcium nitrate is more expensive than calcium chloride

Rey, Combes, Drouet, and Grossin explain that the usual way to deposit apatites in lab wet synthesis, with also some use in industry, is by reacting calcium nitrate with an ammonium phosphate; one reason for this is that nitrate and ammonium groups are easily driven out of the reaction product by heating. Calcium nitrate at US$1.70/kg would seem to be very nearly the same price as calcium chloride at US$1.60/kg, but calcium chloride's molar mass is 111 (or 219 as hexahydrate), while calcium nitrate's is 164 (or 236 as tetrahydrate), so you get considerably less calcium for your money unless that calcium chloride is fully hydrated and the nitrate is desiccated.

The bigger issue is that nitrates are a certain amount of hassle to deal with, due to both their toxicity to the humans and ongoing chimpanzee dominance games the humans like to play.

There are presumably cases where the greater ease of driving nitrate residues out of the structure is a decisive advantage, however.

Berlinite-bonded alumina

Grover et al. at Argonne published a paper in 1999 on this, reporting a rather astonishing result: "We hydrothermally cured a mixture of Al_2O_3 and H_3PO_4 solution between 130°C and 150°C to form a hard and dense berlinite-bonded alumina ceramic." I would not have thought that phosphoric acid could attack sapphire so easily, much less that the result would be a low-temperature way to bond alumina grains. They got a "putty-like" gel of aluminum phosphates after heating alumina in aqueous phosphoric acid, which could dry (to a hydrated xerogel I suppose) and then redissolve in water; by heating it to 150° they drove off not only the water but also the remaining hydrogen, converting the water-soluble aluminum phosphates into berlinite, aluminum orthophosphate, $AlPO_4$, which is covalently bonded to the remaining alumina.

This is such an astounding development that I wonder why I haven't heard of it before; perhaps it has some fatal flaw not mentioned in the paper. The cement described would cost close to US$3 per kilogram and requires baking to cure, so it's not going to replace portland cement unless some material prices change dramatically, but it's both cheaper and presumably much stronger than common petroleum-based plastics, while sharing most of their advantages, although requiring a slow curing process to reach its full strength.

It might work for a variant of this binder-jetting process, too. Although the soluble aluminum phosphates are probably too syrupy to squirt out of jets, you can reportedly dry them to a hard, rocky form that dissolves again in water; squirting water onto it may be sufficient to stick particles of a filler such as sapphire together into a green body that can then be baked at 150°, perhaps with a preliminary aging step. And, like the processes described in 3-D printing by flux deposition (p. 466), it might be possible to bake the whole powder

bed, since the water is an essential reagent in the hardening process; if this works, it would make the green strength irrelevant, but might irreversibly cure the unused aluminum-phosphate binder. And of course you can use an FDM-like selective paste deposition process like those used for adobe and clay-paste "3-d printing".

More on this berlinite-gel process in Berlinite gel (p. 848).

The double-metathesis-type reactions described above might be a more comfortable way to precipitate aluminum phosphates *in situ* than pressure-cooking alumina in strong phosphoric acid for several days. For example, you could produce an aluminum phosphate by mixing solutions of aluminum chloride and diammonium phosphate --- even if the aluminum phosphates you get are water-soluble, they won't be nearly as water-soluble as the reagents, so you might get enough precipitation. But it seems likely that, without baking, you'll only get soluble aluminum hydrogen and dihydrogen phosphates.

Sawdust, diammonium phosphate, sodium bicarbonate, and calcium chloride

You should be able to make a kind of inexpensive waterproof fiberboard by precipitating apatite between the wood fibers in the same way described above, but a larger fraction of the resulting substance will be made of apatite, because you don't have sand grains taking up two thirds of the volume. Sodium bicarbonate can keep the combination alkaline, like trisodium phosphate above, which not only favors the precipitation of apatite rather than less-stable calcium phosphates, but also protects the wood fiber from acid. Bicarbonate will buffer the system, preventing it from becoming too alkaline, and additionally serves as a fire retardant.

The elasticity of the mix may pose problems for a powder-bed 3-D printer, since it will spring back after you compact it. You can compact the whole mass at the end of the process, squeezing both air and water out of the mix and causing the water to spread somewhat. The alternative of maintaining the bed under compression while you squirt binder onto it seems impractical. Just adding binders like carboxymethylcellulose won't help because it's the dry part of the powder bed that causes the problem.

A reasonable mix might be 500 g sawdust, 100 g sodium bicarbonate, 235 g calcium chloride, 165 g diammonium phosphate; this works out to US$0.80/kg.

Magnesium sulfate, sodium carbonate, and silica sand

These two soluble chemicals (Epsom salt and washing soda) ought to form magnesium carbonate (magnesite). Magnesium sulfate is US$0.90/kg and sodium carbonate is US$4/kg. I haven't worked out the stoichiometry, but probably the article of commerce is the heptahydrate, which will have an impact on that.

Green vitriol and trisodium phosphate

At respectively US$1.70/kg and US$2.30/kg, with some luck, these two highly soluble salts should react to make an insoluble basic copper phosphate, the deep green pigment pseudomalachite and its polymorphs ludjibaite and reichenbachite, $Cu_5(PO_4)_2OH_4$. Again, I haven't worked out the stoichiometry.

Spot-welding brass filings with a carbon or TIG

electrode

Brass filings can be bought as cheaply as US$4/kg. There are a couple of ways you could easily melt a controlled-size spot on the surface of a bed of brass filings using a carbon-rod or TIG electrode. First, you could charge up a capacitor and move the rod closer to the surface until there is an arc, with the rod being positive and the filings being negative; this will deposit most of the energy into the filings. Second, you could bring the rod into contact with the filings, run a current through the rod and an inductor, and then break contact, again inducing an arc, again with the electrons impacting the rod and the ionized air or other gas molecules impacting the filings. In each of these cases the spot size is controlled by the amount of energy built up in the energy-storage device.

Third, you could run an arc more or less continuously from the electrode to the bed, as in normal TIG welding or carbon arc gouging.

Lead particles in the powder bed might help with the sintering; I think molten lead can dissolve a signficant amount of copper, and I don't know about zinc (see Filling hollow FDM things with other materials (p. 2119) and A phase-change soldering iron (p. 2270) for more on related systems). If so, as described in 3-D printing by flux deposition (p. 466), it might be possible to later bake the finished piece to induce the lead to diffuse away from what were initially the sintering boundaries, thus preventing the evolution of any liquid until a substantially higher temperature.

Other powdered metals, such as copper, lead, stainless steel, steel, or aluminum, would also work to a greater or lesser extent, but steel and aluminum are relatively hazardous and would probably need to be done under an inert gas such as argon.

Groping toward a high-efficiency speaker driver

Kragen Javier Sitaker, 2019-04-02 (15 minutes)

How do you do a very simple but high-efficiency audio output circuit on a microcontroller?

The simplest possible approach is to connect a speaker between a GPIO pin and a power rail, then generate a signal on the GPIO pin. Digital outputs are quite low impedance when generating either a 1 or a 0, so very little power is wasted in the pin driver in the microcontroller.

This has wonderful linearity, but it has a few different problems: power, DC waste, impedance matching, and high-frequency noise.

Power: the GPIO pin is typically capable of sinking or sourcing 5–50 mA, sometimes at 5 V but often at only 3.3 volts. 50 mA at 5 V is 0.25 W, which is not going to be very loud unless it's in an earphone.

DC waste: the average value of the GPIO pin when it's emitting a signal that's symmetric around some zero value is going to be 2.5 V or 1.7 V, half the supply voltage. This DC component of the signal is going to draw current through the speaker coil without producing any sound. Worse, it will typically see a lower resistance than the speaker's nominal impedance.

Impedance matching: when you have a source with an internal impedance driving a load, the maximum power applied to the load is when the load's impedance equals the source impedance. If the load's impedance is too low, most of the voltage is dropped in the source impedance, and the voltage that actually reaches the load is too low. If the load's impedance is too high, all the voltage reaches the load, but only a fraction of the source's current-delivery capacity comes into play. To be concrete, driving 20 mA (ac!) through a garden-variety 8Ω dynamic speaker is only going to give you 160 mV (ac) across it, rather than the 3.3V or 5V your microcontroller can theoretically deliver.

High-frequency noise: GPIO pin voltage transitions are fairly sharp and so potentially have a lot of power in the ultrasound part of the spectrum. For directly driving a speaker, this may not be a problem, but under some circumstances the high-frequency signal can result in excessive heat dissipation in the speaker as well, especially once you solve the above power delilvery problems.

So I was thinking about these ideas:

First, how about just driving the speaker through an audio transformer? This ensures no dc reaches the speaker, allows the microcontroller to see an effectively higher speaker impedance (by the square of the turns ratio) and the waste of driving dc through the transformer's winding is potentially smaller than the waste of driving it through the hair-fine speaker winding. Transformers may even reduce the transmission of high-frequency noise, though probably not in a very well controlled way.

Second, how about using a transistor switch as an amplifier? An N-channel MOSFET or NPN transistor to ground would work, as

would a PNP BJT to a positive voltage supply. The MOSFET case can work with extremely high efficiency! A 2N7002 can switch 200 mA at up to 60 V with only 5Ω of on-resistance; in theory that would be up to 12 W of output, at which point it would be dissipating 1 W, requiring the TO-92 package for heatsinking rather than the SOT23-3L.

To solve the high-frequency noise problem, though, we need analog filtering — and we need it *after* the transistor switch, because if we do it *before*, we lose the efficiency that brought us here in the first place. If we use mostly LC filtering, rather than RC, maybe we can get high efficiency.

More elaborately:

Put a speaker in series with a capacitor to ground to block DC and stuff below, say, 20 Hz; this way the power dissipated by the speaker is almost all in the right frequency band to be turned into sound, even if the speaker's best-case efficiency is low, like 5% or so. Put another, much smaller capacitor in parallel with the speaker-capacitor combination in order to attenuate high frequencies, like above 20kHz or so. Put an inductor in series with the capacitor-speaker-capacitor combination in order to attenuate high frequencies further and prevent short-circuit currents. Put a Schottky clamping diode in parallel with the inductor-capacitor-speaker-capacitor combination, from ground up to the inductor's "input", to prevent inductive voltage spikes to large negative voltages. Drive the diode-inductor junction with a MOSFET to the positive voltage power supply — either a GPIO output from the microcontroller itself (which perhaps avoids the necessity for the Schottky diode), a logic-level-input P-MOSFET with its gate hooked up to the GPIO, a regular power P-MOSFET with its gate driven by a logic-level-input MOSFET or by a BJT, or maybe even a bootstrapped N-MOSFET.

Basically this is a buck converter driving a speaker through a DC-blocking capacitor.

So far so good, but there's one missing piece still: when there's a signal, the input has a positive DC level relative to ground, and there's no DC path to ground for it. So stick an additional humongous inductor in parallel with the original capacitor-speaker-capacitor combination in order to provide a non-dissipative DC path.

It might be more convenient to turn the whole passive-and-diode output part of the circuit upside down, hooking it up to the positive power supply rather than ground, so we can use an N-channel MOSFET to drive its input by shorting it to ground intermittently, rather than any of the annoying options for CMOS high-side switching.

Some rough numbers. Suppose the speaker is a standard 8Ω half-watt dynamic speaker. To make the whole mess feasible, let's use a 10:1 audio transformer to drive it; that way 1VAC 125mA on the output works out to 10V 12.5mA on the input, an impedance of 800 Ω instead of 8 Ω. The DC-blocking capacitor then shouldn't have too much more than 1kΩ of impedance at 20Hz ($1/\omega C < 1k\Omega$) which gives us 8μF, a blessedly quite feasible value. The parallel capacitor to short out stuff above 20kHz also shouldn't have too much more than 4kΩ of impedance, but at 20kHz, so 8nF is adequate.

The impedance of the whole capacitor-transformer-capacitor thing is going to be in the neighborhod of 2–3kΩ, so we want the input inductor to be in the neighborhood of that when we hit 20kHz; this requires a relatively large inductor of around 16mH in series. However, the much worse problem is that our parallel inductor to ground — the one that's supposed to drain off our DC voltage so we can keep running the circuit — is supposed to have an impedance in the neighborhood of 2–3kΩ for frequencies of **20Hz**. And *that* would require a humongous monster **16 HENRY** inductor.

So, what's the problem here? I think that maybe I've made the load impedance too high, requiring high-impedance capacitors (which are cheap) and high-impedance inductors (which aren't). Maybe I don't really need the transformer; then both the capacitors and inductors could be 100× lower impedance. That means the capacitors would need to be 800µF (annoying but fairly commonplace) and 800nF (totally normal), while the inductors would need to be 160µH (totally normal) and 160mH (also annoying but not exotic).

With ideal components, all the energy here would be dissipated either by the diode or the speaker. In practice, the inductors in particular will have significant parasitic resistance, depending on how much copper you're willing to lavish on them. One 150µH inductor I have a datasheet for here, the toroidal SMD PM2110-151K-RC from Bourns, has 0.049Ω of DC resistance; another, Bourns's "dual-winding SRF0703-151M" (really a transformer), has 0.986Ω. So the losses should be manageable.

Simulation shows reasonable results with these values and 100kHz PWM, though there's some serious harmonic distortion on the "negative-polarity" side of the wave at high amplitudes (presumably from the diode), and there's about 6 dB attenuation already at 8 kHz, and significant bleedthrough with a 40kHz PWM carrier. Probably a more judicious choice of component values would yield a sharper cutoff at a more appropriate frequency. It also seems to have rather large currents through the diode at times, not to mention the other passive components.

In Falstad's circuit format:

I was thinking that maybe I could use an electrolytic capacitor for the series capacitor for the speaker, since one end of it is periodically almost shorted to ground, but now I realize that won't actually work; the capacitor-speaker combination is in parallel with an inductor, which means its average voltage over time must be zero. (Otherwise the current through the inductor is growing without limit!) On the minus side, this means that you can't use an electrolytic capacitor. On the plus side, it means that by the same token, you don't need any capacitor, because the parallel inductor itself guarantees a zero DC component to the signal as seen by the speaker. And that, in turn, means that we don't really need such a large inductor; its impedance above 20Hz only needs to be large compared to 8Ω, not 20–30 Ω. (160mH at 20Hz gives us an impedance of $2\pi fL = 20.1\ \Omega$.)

Fuck inductors, though. We probably can't get by with *just* capacitors because any just-capacitor circuit of this sort is going to have a massive shoot-through current when it first turns on, and your MOSFET is maybe going to explode. But what if the only inductor in the system is a little choke that's there to stop that from happening? Maybe with a diode or capacitor in parallel with it to keep it from generating massive voltage spikes that blow up the transistor when we turn it off.

But then maybe we can use a capacitor in series with the speaker to high-pass filter the signal (at 20 Hz or so) and another in parallel with either the speaker or the capacitor-speaker combination to low-pass filter it (at 20 kHz or so). Maybe we'd like the time constant of the high-pass-filtering capacitor to be around 50 ms, and the low-pass filtering cap to be around 20 µs. Now we really do want to use a transformer, say 10:1, making the effective speaker impedance 800 Ω, so our high-pass-filtering cap in series with the transformer can be 68 µF (and either electrolytic or MLCC ceramic), while the high-pass filter in parallel with that can be 22 nF.

Let's say 100kHz PWM with a 50%-max duty cycle is our working assumption, and we're feeding the whole shebang from five volts. So the transistor is on for up to 5 microseconds, then off for at least 5 microseconds. And let's say we don't want more than, say, 200 mA going through the MOSFET, because it's a 2N7002 or something. How big should the choke be?

We want the current to ramp up to 200 mA in 5 microseconds when the choke sees all 5 volts, since that's probably the worst case. That's 125 µH. Let's use a capacitor in parallel with it to keep its voltage spikes limited without wasting any energy or introducing any nonlinearity; if we want the combination to resonate at 1MHz, we want the capacitor's reactance to exactly cancel the inductor's reactance at that frequency: $2\pi fL = 785$ ohms $= 1/(2\pi fC)$, giving 202 pF (and indeed 1 MHz ≈ (125 mH 200 pF)^-½). This does reintroduce the startup short-circuit path we were hoping to get away from, but now it ends 4000 times faster. However, in simulation, this only limits the inductive voltage spike to 140 V, which is still too

high. So we probably need some kind of more aggressive damping. A 4.7nF capacitor instead, in series with a 100Ω resistor, keeps the spike down to -23 V.

An interesting thing is that whatever the ringdown network for the choke is, whatever losses it has are mostly switching losses, i.e., they happen after each pulse, so using more pulses means more losses there. So to the extent that your normal filtering is adequate to keep your PWM or whatever out of your audio, you can lower the PWM frequency to reduce the ringdown losses.

If you wanted to keep the voltage spike down to 5 volts at 200 mA, you could use a 21.5Ω resistor in series with a regular silicon 700mV diode. Except that of course the resistor's voltage drop will fall as the current does, so it's more of an exponential decay than a linear one, and so it doesn't come close to stopping the choke current before the transistor turns back on. But maybe that's actually what we want? In simulation, it does keep the voltage spike to 4.6 volts.

Hmm, I just realized that maybe the body diode in the 2N7002 would have a similar effect. Maybe it points the wrong way, though.

Also I think the whole idea of capacitors on all the paths from power to ground is a dumb idea. Sooner or later all those capacitors are going to be charged up to 5V and then no more current will flow.

Relational modeling and APL

Kragen Javier Sitaker, 2019-05-20 (updated 2019-05-21) (5 minutes)

I think there's a kind of logic-programming or constraint-logic approach that preserves most of what's good about array languages, while adding the kind of multidirectional inference languages like Prolog and especially miniKANREN have.

I've noticed these notes are getting repetitive as I write down the same ideas over and over again, having forgotten them; I'll try to link them here.

I was thinking about object-oriented equational rewrite rules and IRC bots with object-oriented equational rewrite rules (p. 838) today or yesterday, thinking about how it would be nice to define properties like ".vol = π.r².h; .area = 2π.r(.h + .r)" so that "foo.area" would do a search for formulas that could be applied, and use that one if it happened that "foo" has properties .h and .r. (I vaguely handwaved in my head that some kind of namespacing could alias this to "foo.cylinder::h" so it wouldn't collide with, say, "foo.planck::h".) And it occurred to me that this is precisely the same thinking in A principled rethinking of array languages like APL (p. 1995) about array conformability. (And in OMeta contains Wadler's "Views" (p. 842), I opined that they were the same thing as Wadler's Views.)

A difference, though, is that in the rewrite-rule thinking, a single property can have multiple definitions, like methods overridden in different OO classes, of which normally only one is applicable, while in A principled rethinking of array languages like APL (p. 1995) no such merger was contemplated, except through explicit conditionals.

In IRC bots with object-oriented equational rewrite rules (p. 838) I'd suggested resolving conflicts through a specificity ordering, like CSS or Aardappel. But thinking of the rewrite rule as a *deduction rule* suggests another alternative. Suppose we read ".vol = π.r².h" as specifying an equation in the usual sense — a relationship that is known to hold in all situations where the variables are defined. In that case, it defines a *constraint*, which means that not only can we use it to compute .vol, but we can use it to compute .h if we happen to know .vol and .r from someplace else. That means that it's also an *assertion* — if we have a different computation of .vol from some other definition, the two values must agree, or we have discovered an inconsistency in our model!

So that's a different way of dealing with "rewrite rule" conflicts — crash the program if two conflicting definitions give different results.

(And Prolog, of course, considers conflicting definitions as equally valid possibilities, though there is a definite order to them; the second is only used if we backtrack out of the first.)

But we can get that without giving up the yumminess of implicit loops we get in A principled rethinking of array languages like APL (p. 1995) (and APL with typed indices (p. 3264) and Index set inference or domain inference for programming with indexed families (p. 1434)) by virtue of saying something like .r = [1mm 2mm 5mm 10mm], meaning that there are four situations of interest defined by different radii. And these "different cylinders" can all "inherit" a

common .h, have a .h that varies together with .r, or have a .h that varies independently of .r. The underlying logic is conditional deduction over various different situations.

I talked a bit about this connection in More thoughts on powerful primitives as well.

I wrote down almost exactly these ideas two years ago in Relational modeling (p. 1102).

By using the more powerful kind of relational programming miniKANREN provides, rather than the more limited kind used by Prolog, we may be able to solve more models. Also, for numerical relationships like the ones I used as examples above, interval arithmetic or affine arithmetic may be very useful for two reasons — first, in order to make progress toward solving or proving insoluble a system that starts out underconstrained (consider .x = exp(.x), which has no solution, or .x = exp(.x)/4, which has two solutions), and second, for determining whether two values of a numerical quantity reached through different computational paths are in fact equal or not. (Interval arithmetic can't prove that the values are equal, but it can reliably tell whether an apparent difference is too big to be due to rounding error.)

There's a potential conflict here between the use of implicit patterns of known values to distinguish situations where a property doesn't *exist*, like trying to find the radius of a cube, and where a property *isn't known yet*. I suspect that there may be different valid design choices one can make to resolve this conflict which lead to interestingly different languages that work for different purposes.

Microlens vibrating lightfield

Kragen Javier Sitaker, 2018-07-14 (updated 2018-07-15) (11 minutes)

Microlens arrays for 4D lightfield displays are now being shown publicly — more or less, a brute-force realization of "holographic displays". Essentially, this is garden-variety lenticular 3D, but with a computer screen rather than a printed image behind the lenses. But this places new demands on the underlying screen resolution. To reliably get human binocular vision at a distance of one meter, I think you need new images every 50 milliradians, half the distance between human eyes. With two dimensions of parallax and a radian or so of viewing angle, this works out to a few hundred images, let's say 256. For a 512×384 image, which I think is what the original Macintosh had, that means you need 50 megapixels.

(As a point of comparison, Thomas Burnett's FOVI3D display displays a 180×180 image with 50×50 viewing angles across 90° (10π milliradians), for a total of 81 megapixels, using 20 4K OLEDs tiled without very good brightness correction; another model uses 108 megapixels. He's doping all the pixels to yellow-green to get spatial resolution and brightness at the expense of color.)

It's challenging to fabricate so many pixels. One possible solution is to temporally multiplex a smaller number of pixels, scanning each pixel over a significant area with a vibrating or rotating mirror. DLP and inorganic LED pixels are capable of response times sufficiently fast to make this a viable option; LCD, CRT, and plasma pixels are not. DLP pixels are too close together, though, which leaves inorganic LED pixels as the only option. I'm going to consider only monochrome displays for now.

Doing this kind of thing with a vibrating or rotating mirror requires some kind of scanning pattern that scans the (image of the) physical pixel over all the spatial locations it's responsible for illuminating; the traditional approach from analog TV is a pair of sawtooth signals, a slow one (≈60Hz) for Y and a fast one (≈15kHz, with important harmonics up to, say, 105kHz) for X. Other scan patterns, such as Lissajous, are possible but do not remove the necessity for a rather high scanning speed in one dimension.

Vibrating or spinning a mirror at low speed is much easier than vibrating a mirror at high speed, especially if the mirror is large. Consider a small area of 393 216 spatial locations — this could be 512 lines of 768 spatial locations, 768 lines of 512 spatial locations, 128 lines of 3072 spatial locations, 48 lines of 8192 spatial locations, and so on. In the last case, supposing the Y dimension is scanned at 60 Hz, the X dimension will need to be scanned at 2880 Hz, which is considerably less demanding than 15kHz. At some cost in effective resolution and complexity of brightness control, you can use a sinusoidal scan for the X, avoiding the need for responsivity at higher harmonics such as 8640 Hz. Alternatively, you could use a spinning mirror such as those used in supermarket scanners and laser printers; a hexagonal mirror would give you a 2880 Hz scan at 480Hz or 28'800 rpm, which is challenging but feasible.

That is for a single LED; you need to position it at least 48 LED heights above the next LED below.

Ideally you'd like to be able to change all 50 megapixels for each frame, but even without that ability, you can make the display work for less-frequently-updated images. For example, you could assign a microcontroller to each 8192×48 area (512×3 macropixels), which it would have to refresh at least 60 times a second: 23'592'960 pixel outputs per second. This is within the capability of STM32F microcontrollers, which cost 59¢. Moreover, they can control 16 lines at a time at this speed, so a single microcontroller (and perhaps three associated 40¢ ULN2003 seven-Darlington low-side switching chips) can control a 8192×768 area (512×48 macropixels). Eight such microcontrollers would suffice for the whole 6144×8192 display (512×384 macropixels), with a total BOM cost of US$14.32 for the silicon, not counting the 128 tiny LEDs and 128 resistors, and actually wasting a bunch of the Darlingtons.

However, an STM32F0 microcontroller typically only has 4K of RAM. Rather than economizing so much on microcontrollers, it might make more sense to economize on mirror X scanning. For example, if we use 64 microcontrollers instead of 8, with 16 LEDs per microcontroller, we can control 1024 LEDs via 147 ULN2003s, and each LED only needs to cover an 8192×6 area rather than 8192×48, so the X scan on the mirror can slow from 2880 Hz (28'800 rpm with a hexagonal mirror) to 360 Hz (3600 rpm), which is much easier to achieve. Moreover, the signal to each LED need only change at 2'949'120 Hz rather than 24 MHz — this still poses signal integrity challenges but is dramatically simpler. You need 147 ULN2003s and 64 STMF0s, for a silicon BOM cost of $96.56.

(I should check the ULN2003 datasheet to see if it can handle a 3MHz or 24MHz signal.)

Note that this still only leaves you with 256K of RAM to hold the data to display on a 6144×8192 display, i.e. 192 pixels per byte. I think there are some items in the STM32 line with more RAM, up to 2 megabytes per chip. DRAM would likely be fast enough. Also, external RAM chips with their data lines connected to the driver inputs might work, as long as the drivers have a disable input. But it might be adequate to generate a single 8-kilobit scan line (1 kilobyte) on each scan, starting with some kind of heightfield model or something that you could reasonably rasterize a line of in 48MHz/360Hz = 133'333 32-bit CPU cycles.

By using the double-parabolic mirror trick used for the famous floating coin illusion, you can cause the microlens-array-generated lightfield image to appear to float in midair instead.

If we wanted to reduce this approach to an absolute minimum demoable product, maybe we could start with something the size of an 80×25 terminal with a narrow viewing angle. Let's say 80×5 = 160 macropixels horizontally and 25×8 = 200 macropixels vertically. And let's say we are willing to accept fewer viewing angles: 8 horizontally and 4 vertically, for example. And let's lower the refresh rate to a cinema-flickery 24Hz. And let's use a mirror that only scans in one dimension, horizontally. Now we need 800 fricking LEDs, but we can probably multiplex them a bit, because the whole matrix is only 1280×800, so we only need 61'440'000 pixels out per second, or 3'840'000 16-bit updates per second. If you run 32 of the LEDs at any given time using 5 ULN2003s, you can use 25 high-side switches (what are these called?) in, say, 4 chips. To get these 57 GPIOs you

might need, say, four microcontrollers, with very lax constraints on their output timing. This works out to 13 chips that collectively cost US$6. The 800 fricking LEDs may cost more than that, but probably not more than US$16.

The optics may be somewhat more of a problem. You only need 24Hz scanning (240 rpm) and possibly some kind of magnification in order to be able to use a manageably small scan mirror.

You might really want RGB LEDs and multiple brightness levels, which, at these speeds, are probably best achieved by linearly controlling current sources rather than PWM. These are probably achievable but may be difficult.

To investigate

• ULN2003 speed: Is 3MHz OK? 24MHz? The ULN2803A datasheet (the one with 8 Darlingtons instead of 7) says 130 ns propagation delay low to high, 20 ns high to low, which suggests it ought to be able to make it up to about 6MHz, but the ULN2003A gives a max of 1 µs for each of these, suggesting a limit of 500kHz, despite a typical propagation delay of 250 ns (thus 2MHz).
• Does the ULN2003 have chip enable? No.
• What's the high-side equivalent of the ULN2003? There used to be a UDN2891 but it's obsolete. As a sort of replacement, TI has come out with the US$1.81 TLC59123 and TLC59123A 8-input 500mA 13.2V latching synchronous high-side drivers, which claims it can only be clocked up to 1 MHz. It doesn't have a chip enable either. It also has 100–200 ns propagation delays, and requires clock pulses of at least 100ns, so you would think it ought to be able to do several MHz. There are other alternatives, like the US$2.52 Allegro A2982 (8 parallel 50V 500mA high-side drivers, but up to 10µs turnoff delay).
• Is PSRAM fast enough for framebuffers? The US$3.20 ISSI IS55WV51216EBLL-55TLI 8-megabit 16-bit-parallel 44-pin TSSOP PSRAM claims 55 nanoseconds, which is plenty fast enough, though the datasheet only claims 60ns; the US$2.10 ISSI IS62C1024AL-35QLI-TR is a 128K × 8 (1-megabit) real SRAM 32-SOP that claims 35ns.
• original Macintosh screen size: 512×384? No, 512×342.
• How much do SMD LEDs cost? How small do they come? 4.0¢ in metric 1608 packages (archaic 0603) in quantity 1000. These are the Rohm SML-D12x1 series, which come in five colors: V and U reds (630 and 620 nm), D orange (605 nm), Y yellow (590 nm), and M yellowish green (572 nm). They can withstand 100mA peak current (at 10% duty cycle 1kHz), 20mA continuous current, and 54mW power dissipation, with respectively 40, 63, 100, 100, and 30 millicandelas at 20mA. They drop 1.7–2.2 V. The Lite-On LTST-C191KGKT, another archaic 0603, costs 6.0¢; these can handle 30mA continuous, 80mA peak, and 75mW dissipation, and claim a max of 71 mcd at 20 mA instead of 30. These are binned by brightness and color. (But the min is only 18.) These LEDs (both types) turn off after dropping by about 200 mV; neither specifies a junction capacitance or response time in its datasheet.

Text relational query

Kragen Javier Sitaker, 2019-08-28 (10 minutes)

I talked a little about Lotus Agenda in Agenda hypertext (p. 1836). Today I want to explore a different related idea: a flexible tool for making relational views of text file contents, whether written by hand or generated by machine.

An Agenda file was, primarily, an unordered bag of text snippets. A lot of Unix utilities treat text file lines as sort of database records — roughly speaking, `sort` sorts the records, `uniq` eliminates duplicates and possibly provides you with a count, `grep` selects records matching a pattern, `cut` projects away some of the columns, `look` does a lookup in a sorted index, `join` and `paste` do relational joins, and so on.

These utilities are often the fastest way to get certain tasks done, but they're kind of hard to use (especially robustly), and they don't deal with ad-hoc-formatted text at all, which was Agenda's strength. However, Agenda's queries and views used a sort of tagging system that wasn't very powerful.

The basic idea: create relations by pattern-matching text lines

What if we had a system that also treated a text file as a bag of lines, but permitted relational queries on those lines, similar to how Sniki permitted relational queries on its link graph (see Prolog table outlining (p. 2837))? For example, consider these lines:

```
-rwxr-xr-x   1 user user     19096 Dec 30  2018 xshmucalc_fb
-rw-r--r--   1 user user       254 Dec 30  2018 erosion1d.c.~1~
-rwxr-xr-x   1 user user      8984 Dec 30  2018 erosion1d
-rw-r--r--   1 user user       534 Dec 30  2018 erosion1d-log.c.~1~
-rw-r--r--   1 user user      1122 Dec 30  2018 erosion1d.c
-rw-r--r--   1 user user      1362 Dec 30  2018 erosion1d-log.c
-rw-r--r--   1 user user     40055 Dec 30  2018 erosion1d-log.lst
```

Suppose you match them against this pattern, using two PCRE regexps:

```
-rwxr-xr-x 1 user user $size:\d+ $date:.* $executable
```

(`executable` gets the default pattern `\S+`; unquoted space matches any amount of space.)

This produces the following relation:

size	date	executable
19096	Dec 30 2018	xshmucalc_fb
8984	Dec 30 2018	erosion1d

The other lines don't match the pattern, so they don't enter into the result.

How about files that have an Emacs backup file, the thing with the version number between ~ marks?

```
$_ $_ $_ $_ $size1:\d+ $date1:.* ${fname}.~$v~
```

```
&$_ $_ $_ $_ $size2:\d+ $date1:.* $fname
```

This is a kind of self-join, joining the set of records with itself, but using two different patterns. They might both match the same line in different ways, but they each need to match some line for the query as a whole to succeed. Those lines may not be consecutive — in the above data they are not.

Inference rules or views

A better way to formulate that query is through a *view*, or inference rule. Here's an inference rule that factors out the common part of the above; it consists of a query, followed by one or more templates that transform the query results into inferred lines:

```
$_ $_ $_ $_ $size:\d+ $date:.* $fname
.: File $fname is $size bytes, modified $date.
```

This inference rule causes a panoply of inferred lines to implicitly spring into existence:

```
File erosion1d.c.~1~ is 254 bytes, modified Dec 30  2018.
File erosion1d is 8984 bytes, modified Dec 30  2018.
File erosion1d-log.c.~1~ is 534 bytes, modified Dec 30  2018.
File erosion1d.c is 1122 bytes, modified Dec 30  2018.
```

And so on. This allows us to write the self-join query from before much more conveniently, now matching these inferred lines:

```
File $fname $_:.*
&File ${fname}.~$v~ $_:.*
```

Such inference rules have the potential to produce infinite loops of inferring more and more lines:

```
GNU$stuff:.*

.: GNU's Not Unix$stuff
```

In general I think it is undecidable whether this is happening, so probably the best solution is to ensure that if it happens, it doesn't lead to disasters.

JSON?

This is messy, like the Unix shell utilities that inspired it — concatenating raw strings and then trying to parse the results is a recipe for disaster — so maybe inferring JSON and using destructuring matches like modern JS would be better than inferring text lines; then we only need to use text matching when it's part of the problem statement:

```
$_ $_ $_ $_ $size:\d+ $date:.* $fname
.: {fname, size, date}

{fname}
&{fname: "${fname}.~$v~"}
```

Here `{fname}` is syntactic sugar for `{"fname": "$fname"}`, and similarly for `{fname, size, date}`.

Grouping

Suppose you specify an aggregate operation on a field:

```
$perm   1 user user $size.sum:\d+ $_:.*
```

Aggregation implies that you need to do some kind of grouping in order to have groups to run the aggregation over. How do you do the grouping? Well, in SQL, if you use grouping, the only fields you can legally SELECT without an aggregate operation are the ones you're going to GROUP BY. (MySQL is historically lax about this.) So implicitly we could just use the fields that don't have an aggregate operation attached to them, so the above will group by permissions!

```
      perm    count size.sum
---------- -------- --------
-rw-r--r--        5    43327
-rwxr-xr-x        2    28080
```

Multiple aggregations on the same field don't fit easily into this approach, but they are rare.

A useful aggregation that makes sense in this context is `.join(sep)`.

Sorting

By default aggregation results should be sorted descending, but by which field? You should be able to tag a field in your query as the sort key; consider this data from `ps ux`:

```
user     28358  0.7  7.8 2114240 310916 ?      Sl   Aug22  59:20 /usr/lib/firefox
/firefox -contentproc -childID

user     28905  0.0  1.2 122440 49028 pts/2    S    00:49   0:04 xpdf.real sensor
s-18-00768.pdf
user     29260  0.0  0.0  22460  3516 pts/4    Ss+  Aug26   0:00 bash

user     29299  0.0  0.0   8340  1892 pts/4    T    Aug26   0:00 less sensors-18-
00768.pdf
```

You could match it with:

```
$uid $pid $_:.* $vsz:\d+ $rss:\d+ $tty $stat $start $cpu $cmd:.*
```

But maybe you'd like to sort by RSS:

```
$uid $pid $_:.* $vsz:\d+ $rss+:\d+ $tty $stat $start $cpu $cmd:.*
```

Or sort ascending instead:

```
$uid $pid $_:.* $vsz:\d+ $rss-:\d+ $tty $stat $start $cpu $cmd:.*
```

Of course more sophisticated sorting requires multi-field keys, specifying numeric versus ASCIIbetical versus locale versus mixed-text-and-numbers, field ordering in the key, and so on. But the simple case should be easy.

Non-equality criteria

The above allows you to select lines where a field is equal to a constant or to some concatenation that includes some other field value. So you can find your zero-byte files. But what if you want to find your files that are over a mebibyte? You need to be able to say something like this:

```
$perm   $nlinks user user $size[>1048576] $_:.* $name
```

Line sequences

Most text files aren't purely unordered bags, and if you can grok a bit of their structure, you can do much more useful things. There's a whole ladder of language power to ascend here — first strict sequences of line templates:

```
commit $commit
Author: $author:.*
Date:   $date:.*
```

Then some kind of vague contextual line-template thing for simple hierarchical structures with header lines at the top, where each occurrence of the *last* line in the template creates a row, but implicitly pulls in all the fields from the most recent occurrence of each of the others:

```
* $h1:.*
...
** $h2:.*
...
*** $h3:.*
...
${_:.*}<${url}>$_:.*
```

This would be especially useful for things like `ls -lR` output:

```
-rw-r--r-- 1 user user 1060956 Dec  2  2018 e0000ea7.au
-rw-r--r-- 1 user user 1060956 Dec  2  2018 e0000ffe.au

./whatsapp-mockup:
total 104
-rw-r--r-- 1 user user  1192 Oct 23  2016 camera.png
-rw-r--r-- 1 user user   591 Oct 23  2016 check.png
```

Here you want to use a pattern something like this, so that you can know what directory each file is in:

```
${dir}:
total $dirtotal
...
$perm   $nlinks $user $group $size $date:.* $filename
```

Alternatively, you could tag some kind of thing onto the end of the line pattern that asks for the *most recent* matching line, without implying a hierarchical structure.

Then some kind of regular expression system for line templates, then a full grammar system (which is getting into Tagging parsers (p. 208)), which could also extend down into the lines themselves, so that you can do things like parse the ingredients out of "Neapolitan ($17): Ham, tomato, garlic, and mozzarella". The only trouble with that is that an AST isn't very similar to an N-ary relation.

Web scraping

Probably the largest current source of structured data that needs to be parsed out of big text files, and for which regexps are currently the best choice.

Data entry

If you were writing a file to be parsed by such a query system, you could imagine a text editor that would make it very easy by offering syntax highlighting and contextual autocomplete — maybe any word that was the same as in the line above it would be grayed out, and TAB at the end of a line that was shorter than the previous line would copy down whatever text was the same on those two lines. So for example at the end of this:

```
Barbara is Joanie's mother.
Joanie is Ryan's mother.
Ryan
```

TAB would insert a grayed-out "is", taking you to the next "field", at which point an autocomplete dropdown combo box thing would suggest that you might want "Joanie" or "Ryan". (Maybe it could guess that the two data columns were the same type and suggest "Barbara" too.)

CIC-filter fonts

Kragen Javier Sitaker, 2017-06-28 (1 minute)

The traditional way to compose the graphical things that make up fonts, whether as outlines or as strokes, is to concatenate sequences of lines, arcs, and Bézier curves.

I've thought about alternatives including decomposing those shapes into splines and sine waves. Now it occurs to me that maybe CIC filters would also be a reasonable kind of way to decompose those shapes.

The idea is that the path of a paintbrush painting the letter is some kind of f(t) = (x, y) parametric curve, and CIC filters are capable of producing fairly interesting parametric curves at pretty low computational expense. Maybe stroke width should also be part of it.

Salt slush refrigeration

Kragen Javier Sitaker, 2017-08-22 (updated 2019-10-08)
(12 minutes)

Salt depresses the freezing point of water. When you freeze salty water, the behavior depends on whether you're at, above, or below the eutectic point, -21.1° and 27% NaCl. If less saline than the eutectic point, first you get ice crystals sucking up heat and growing without much salt until the remaining brine is at the eutectic point, at which point it freezes. If more saline than the eutectic point, instead you get salt crystals sucking up (much less) heat and growing without much water until the remaining brine is at the eutectic point, at which point it freezes.

On the other hand, if you have salty ice and you melt it partway, the part that melts first will be the eutectic phase, leaving the remaining phase (either water or salt) more concentrated in the remaining crystals. At this point you can mechanically separate the two with an arbitrarily small energy input.

I was thinking that you could use this behavior somehow to get a refrigerator, but now I'm not sure you can. It seems like the movement of mass into the eutectic phase is kind of unrecoverable by freezing and melting. Maybe you could separate them with a pressure swing or by distillation.

Frozen salt water as a freezer thermal reservoir

(This comes from a discussion with SpeedEvil on Freenode.)

But suppose you have a conventional freezer, cooled using a conventional refrigeration approach like the compression-condensation cycle or an ammonia-absorption cycle, and you'd like some resilience against problems --- either power outages, as in Balcony battery (p. 2377), or mechanical failures. A phase-change thermal reservoir inside the freezer is one way to achieve this.

However, just putting water bottles in the freezer is suboptimal. Normally the freezer is at -20° or so, and the water bottles won't melt until 0°, which means that all your food also heats up to 0°, possibly allowing it to spoil or get soggy. A lower-temperature phase-change material would work better, ideally something that melts just above the freezer's normal temperature, like about -18° or so.

You could try using just near-eutectic NaCl salt water, but you run the risk that, with repeated freeze-thaw cycles, it will separate --- I didn't understand this until SpeedEvil explained it to me.

Suppose it's a little lower in salt content than the eutectic 27%. Low-salt-content crystals will freeze first, concentrating the salt in the remaining solution, and at -20°, you will be left with a large amount of lower-salt-content crystals floating on top of the remaining very-nearly-eutectic solution at the bottom. If this system (because "mess" sounds too unappealing) melts, the higher-salt-content water is denser and thus will tend to stay at the bottom, although there will be a small amount of diffusion at the boundary layer. If it then refreezes, the same thing will happen again, but this time the

initially-freezing crystals will be even lower in salt content, and thus will freeze at an even higher temperature.

Repeated cycles of this will eventually separate the mixture into a large amount of very-nearly-eutectic mix at the bottom, which never freezes, and a small amount of very-nearly-pure water at the top, which freezes far too easily, separated by a very thin diffusion layer.

I think one possible cure is to make it a little *higher* in salt content than the eutectic 27%, so that the crystals that freeze first are higher in salt content than the eutectic, concentrating water in the bottom. (I'm assuming that the crystals will still be water crystals and not salt; if not, this won't work!) This way, when the system melts again, the denser, saltier water liberated from the crystals at the top of the solution will not be stable in that position --- it will produce convection cells that carry it back toward the bottom of the tank. This should provide some mixing, but I'm not sure if it will be enough.

Another possible cure, of course, is to use an impeller or a spoon to mix the liquid when there is liquid.

A third possibility is to immobilize the whole solution in some kind of gel, such as agar, so that the crystals cannot float or sink. This way, the physical distance between the different phases of crystals remains small enough to prevent diffusion. Over time, though, I think crystal formation in repeated freeze cycles will cut the gel matrix to shreds.

A fourth possibility is to use a Peltier cooler on top of the salt-water tank inside the freezer to drop it an extra 2° relative to the rest of the freezer. This is a relatively small temperature difference and a small heat flux, so the Peltier cooler should be relatively efficient, although its waste heat does add to the freezer's load.

A fifth possibility is to find another material whose aqueous solution has a slightly warmer eutectic point, one toward the bottom end of the freezer's normal temperature range. There are an abundance of inexpensive and nontoxic salts, acids, and bases that might work. Surely there is a database of their eutectic points somewhere.

A sixth possibility is to just run the freezer a bit cooler, perhaps cooling the brine tank directly and arranging things so that heat from the outer walls diffuses first through the food and then into the brine tank, thus keeping the food a bit warmer than the brine tank.

Candidate eutectic systems

If $NaCl{\cdot}nH_2O$ is barely unacceptable, what might work better? Ternary aqueous salt systems (e.g. NaCl, KCl, H_2O) are probably going to have *lower* eutectic temperatures rather than higher ones. For example, according to a paper by Hall, Sterner, and Bodnar in 1988 on "Freezing point depression of $NaCl–KCl–H_2O$ solutions", this system has a eutectic at -22.9° at 74% water, 20.5% NaCl, and the remainder KCl. (I think those are weight fractions, not mole fractions.) So we can probably mostly restrict our attention to binary systems of water plus a single solute.

For storing in conjunction with food we probably want something nontoxic and non-caustic; even nitrates, bromides, or soluble hydroxides would be questionable. I think this mostly restricts us to soluble chlorides, acetates, formates, phosphates, bicarbonates,

carbonates, and sulfates of potassium, sodium, magnesium, calcium, and perhaps ammonium and aluminum, plus nontoxic water-soluble organic compounds like urea.

Material Eutectic temperature with water
$CaCl_2$ −51°
$MgCl_2$ −33°
KCl −11° at 19.5% (plus additives)
Or −10.8° at 19.1% in Willem van der Tempel's 2012 thesis on "Eutectic Freeze Crystallization"; eutectic given as 19.4 wt% KCl.
Urea
(NH_2CONH_2) −12°, Frisbeetool (plus additives)
Na_2SO_4
(mirabilite) −1.24° I think at about 3.98%
$CaSO_4$ Insoluble, that's plaster, dude
$MgSO_4$ about −5° at about 19%
NaH_2PO_4 about −10° at about 35%?
$NaNO_3$ −17.45° at 37.93% (Holmberg, 1968, AE-340)
Na_2CO_3 −2.06° at 5.70% (Holmberg)
KNO_3 −2.87° at 10.29% (Holmberg)
K_2SO_4 −1.59° at 6.48% (Holmberg)
NH_4Cl −15° (Frisbeetool)
$AlCl_3$ caustic and somewhat toxic, but also I don't know
Sodium acetate
(CH_3COONa) about −18° at about 22%
CH_3COOK −60° at 49%
$NaHCO_3$ −2.23° at about 6.2%
Na_2CO_3 −2.13° at about 5.5% (same source)
$NH_4H_2PO_4$
(monoammonium phosphate) −4.15°?
$Al_2(SO_4)_3$ No freaking idea

From this I think we can conclude that potassium chloride is a very promising choice, despite the dozens of other compounds I haven't investigated yet; and you could probably use urea, ammonium chloride, or sodium acetate. (Urea might require some extra measures to prevent bacterial growth; ammonium chloride might outgas ammonia, perhaps eventually exploding if sealed.) Ternary eutectics involving some of the salts in the −10°–0° range might be interesting, too — perhaps they could either combine with one another or with something like potassium chloride to give a more ideal eutectic point.

Some of these systems have a serious supercooling problem — sodium acetate is famous for this property. If the solution is sufficiently capable of supercooling, you might be able to cool it to the freezer's minimum temperature of −20° or whatever while the reservoir remained entirely liquid — and then, if it started freezing, it would *heat the freezer back up* to its eutectic temperature until it finished freezing. I think some of the "additives" mentioned above by Frisbeetool are actually for nucleation sites to prevent supercooling. You'd think boiling stones would be a sufficient solution to this problem, but maybe not?

Non-aqueous solvents such as propylene glycol might be worth investigating, but giving up water's enormous enthalpy of fusion of 333 kJ/kg seems like a sacrifice that's probably not worth making. Amusing thought: heavy water has both a larger enthalpy of fusion

and smaller freezing point depression, and it's not sufficiently toxic to rule it out for this purpose; it's just far too expensive at present.

System sizing

The worst power outage I've had to endure was three weeks at Christmas, in the worst heat of the summer. Suppose that a normal refrigerator requires about 220 W, as suggested in Household thermal stores (p. 1533), so a normal chest freezer might require 300 W, or perhaps 100 W if superinsulated. Three weeks of 200 W is 360 MJ, so keeping food frozen through such an outage would require on the order of one tonne of salty ice — half a tonne if you could hit the 100-W figure, or only 256 kg or so if you could insulate all the way to 50 W. By contrast, keeping food frozen for an extra day (at 200 W) would require only 17 MJ or 50 kg of ice, and keeping it frozen during the night when the solar panels are off would require only about 25 kg of ice.

At the tonne level, the cost of the phase-change material becomes significant, potentially hundreds of dollars for the salt.

Why freezer thermal stores are important

Solar photovoltaic energy is on track to be by far the cheapest source of energy to date, but energy storage — especially kilowatt-scale energy storage — is not cheap. If you can run your freezer only on sunny days, when energy is abundant, you can save yourself or your municipality the need to use scarce cloudy-day or scarcer nighttime energy to keep your food cold. The kind of phase-change thermal reservoir discussed above is about two or four orders of magnitude cheaper than batteries, which are still US$100 to US$200 per kilowatt hour (US$30 to US$60 per megajoule).

Why do I say such a thermal store would be cheaper? According to Thermodynamic systems in housing (p. 2804), water's heat of fusion is 333 kJ/kg, so 3 kg per megajoule — at the US$0.58/k$\ell$ cost for expensive reverse-osmosis water from Sorek cited in Calculations about desalination in Israel (p. 2827), water costs US$0.0017 per 3 liters and thus per megajoule. Adding a controlled amount of salt might add a bit to that cost, but I don't think it's more than an order of magnitude. According to A minimal-cost diet with adequate nutrition in Argentina in 2017 is US$0.67 per day (p. 3206), supermarket salt cost AR$41.65 per kg in 2012 when AR$16 was US$1, so that's almost US$3 per kg, or US$1 per 3-kg megajoule; but I'm pretty sure bulk rock salt is at least one order of magnitude cheaper than that.

A freezer designed for use in this way would probably be a bit larger than the freezers we currently use.

Pattern matching and finite functions

Kragen Javier Sitaker, 2017-05-10 (14 minutes)

What if we unified function definition, pattern matching, and dictionaries?

Consider this table:

```
| Input | Output |
|-------+--------|
|     1 | "st"   |
|     2 | "nd"   |
```

In JS or Python, we could encode it as a hash table: `{1: "st", 2: "nd"}`. This has the advantage of being "just data" and therefore easily changed, for example to add more items, and more easily optimized, for example by using a hash table.

But we could also encode it as code instead of data; in JS, for example, `x => x === 1 ? "st" : x === 2 ? "nd" : null`. OCaml has a syntax that allows us to encode it as code while we omit the variable name: `function 1 -> "st" | 2 -> "nd"`.

All of these cases benefit from having a fallback:

```
|   Input | Output |
|---------+--------|
|       1 | "st"   |
|       2 | "nd"   |
| (other) | "th"   |
```

In Python, we can write this, more or less, as `collections.defaultdict(lambda: "th", [(1, "st"), (2, "nd")])` (although `defaultdict` has a fatally bug-prone interface; you shouldn't use it). As code, this function could be written in JS as follows:

```
x => x === 1 ? "st"
   : x === 2 ? "nd"
   :           "th"
```

Or, in OCaml, as follows:

```
function
    1 -> "st"
  | 2 -> "nd"
  | _ -> "th"
```

The OCaml approach works by pattern-matching the argument against each of the "patterns", potentially binding variables (just as in passing arguments to a function) that can then be used in the consequent of that pattern match. In this case, there happen to be no variables either on the left or the right side.

Really simplified overview of type

inference in OCaml

OCaml does type inference to figure out what the argument type — which is to say, the domain of the function — should be. To simplify things and avoid subtyping relations, normal ML type inference requires that the domain be a known type, not some arbitrary collection of values. Consequently, the first example above produces a warning:

```
# let suffix = function 1 -> "st" | 2 -> "nd" ;;
Characters 13-43:
  let suffix = function 1 -> "st" | 2 -> "nd" ;;
               ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^
Warning 8: this pattern-matching is not exhaustive.
Here is an example of a value that is not matched:
0
val suffix : int -> string = <fun>
```

However, OCaml's type inference algorithm has been extended in ways that do require subtyping, including "polymorphic variants" and objects with methods. Here's an example with polymorphic variants:

```
# let rec int_of_peano = function `Z -> 0 | `S(x) -> 1 + int_of_peano x ;;
val int_of_peano : ([< `S of 'a | `Z ] as 'a) -> int = <fun>
# let rec peano_of_int = function 0 -> `Z | n -> `S (peano_of_int (n-1)) ;;
val peano_of_int : int -> ([> `S of 'a | `Z ] as 'a) = <fun>
# peano_of_int 11;;
- : [> `S of 'a | `Z ] as 'a =
`S (`S (`S (`S (`S (`S (`S (`S (`S (`S `Z))))))))))
# int_of_peano (`S (`S (`S (`Z)))) ;;
- : int = 3
# int_of_peano (peano_of_int 11) ;;
- : int = 11
```

Note that the return type of `peano_of_int` is not quite the same as the argument type of `int_of_peano`:

```
([> `S of 'a | `Z ] as 'a)
([< `S of 'a | `Z ] as 'a)
```

That's because the argument type is an upper bound, while the return type is a lower bound. It's valid to pass a value of a subtype, for example only `` `Z ``, as an argument; the types don't have to match exactly. Similarly, it's valid to pass the return type into a context that could handle some wider array of possibilities, perhaps `([`S of `a | `D of `a | `Z] as a)` if we want to support efficient binary representation through both successors and doublings. But the converse operations are not valid — we cannot pass `` `D (`Z) `` to `int_of_peano`, because it will crash, and we cannot use `peano_of_int` in a context that can only handle `` `Z ``.

Of course, it's not just a matter of the polymorphic variant tag matching; the type of its argument has to unify, too:

```
# int_of_peano(`Z (`D (`Z)));;
Characters 12-26:
  int_of_peano(`Z (`D (`Z)));;
```

```
              ^^^^^^^^^^^^^^
Error: This expression has type [> `Z of [> `D of [> `Z ] ] ]
       but an expression was expected of type [< `S of 'a | `Z ] as 'a
       Types for tag `Z are incompatible
```

Making it work with infix operators

In OCaml, the `|` and `->` tokens are not infix operators; you cannot make expressions with them alone. They are part of the `function` and `match` productions in the grammar. But what if they were infix operators? What if we want the following expression to parse as infix, work by pattern-matching, and evaluate the function outlined above?

```
  1 -> "st"
| 2 -> "nd"
| _ -> "th"
```

Or, using operator tokens that make it look like JS or Python data:

```
1: "st", 2: "nd", _: "th"
```

The first is fairly straightforward: `x -> y` is, more or less, JS's `x => y`, a λ-abstraction. It's a function that takes `x` as an argument and returns `y`, evaluated on a context augmented with whatever names are bound in `x`. But we kind of want it to be able to *fail*, either at compile-time or at run-time, so that we can union `1 -> "st"` with `2 -> "nd"` and get `1 -> "st" | 2 -> "nd"`. And, for this kind of case, we really want the failure semantics to be *ordered* — we don't want to return `"th"` for everything, just everything not otherwise covered.

Leaving aside the very interesting type inference question for now, let's consider what this gives us. We have a single symbol here for defining pattern-matching lambda-expressions that can fail, and a second one that extends it to pattern-matching ordered conditionals, which also work as dict literals. This (plus some syntax for applying a function to an argument) is already more than enough for Church numerals, and so we're already past the Turing-completeness line; but can we make it more convenient?

In Perl, Python, and especially JS and Lua, it's very common to use dicts as general-purpose data structures. But here our "dicts" are functions (whose domain we perhaps have some way of computing, or at least conservatively approximating). Can we pattern-match on those dicts?

In ES6, pattern-matching on a "dict" (called, confusingly, an "object") looks like this:

```
const {a: b, c: d, e: f} = {c: 1, e: 2, g: 3};
```

This binds the variables `d` and `f` to `1` and `2`, and the value `b` to `undefined`. We could imagine that, given the option to declare a failed match, the missing value for `a: b` would cause the pattern match to fail, but the missing binding for `g: 3` would not — the point of storing your data in dicts in the first place is so that you can add new properties to it without breaking existing code, which is how email

headers have remained backwards-compatible for forty fucking years.

If the "dict" you're matching is a function (that can fail), this corresponds to the pattern-match requiring it to succeed on some finite set of arguments mentioned in the pattern. And those semantics are straightforward to implement, although maybe inefficient.

This means that to try to invoke a function, you're taking the function that is its argument and trying to invoke it (possibly several times) with the keys in the argument pattern. This sounds like it's going to be an infinite regress, but presumably at some point you will bottom out in symbols and other atoms, which, say, cannot be invoked as functions.

If we try to keep our syntactic noise to a minimum, we could declare that lowercase barewords are symbols and variables need uppercase (as in Erlang), use the `:` and `,` symbols from Python/JS instead of `->` and `|`, and use the infix-syntax and function-application-by-juxtaposition syntax from OCaml. So then our `peano_of_int` function ends up as:

```
Peano_of_int = 0: z, N: (s: Peano_of_int (N-1));
```

And then its counterpart should look like this:

```
Int_of_peano = z: 0, (s: N): 1 + Int_of_peano N;
```

And the example we started with would be written:

```
1: "st", 2: "nd", _: "th"
```

Arguments first!

At this point, we start to want local variables or let-expressions.

But let-expressions are just, in some sense, syntactic sugar to paper over the unfortunate fact that in `(λx.some long thing involving x)3`, the `x` argument and the `3` are spatially far apart, and we want them to be close together. That is, we have the order `x Y 3`, and we want `x` and `3` to be adjacent. Of the six possible orderings of the three items, only `x Y 3` and `3 Y x` do not have them adjacent, and `let` rewrites that to `x 3 Y`, omitting the literal tokens.

But there are three other orderings that would also solve the problem, which are `Y x 3`, `Y 3 x` and `3 x Y`. Since `Y` is an expression written in terms of `x`, it's desirable for readability for `x` to precede it and be adjacent to it, so `3 x Y` would perhaps be the clearest order.

Which is to say, perhaps arguments should precede functions in a function application expression, as, in a sense, in the ς-calculus and other object-oriented languages — even though, in this case, the functions are first-class values rather than merely selectors.

This leads us to write our examples above as follows, with a needless Dijkstra-like `.` introduced to improve familiarity:

```
Int_to_peano = 0: z, N: (s: (N-1).Int_to_peano);
Peano_to_int = z: 0, (s: N): 1 + N.Peano_to_int;
```

This pants-on-head syntax now gives us the sugar to avoid let-expressions in programs like this:

```
Sort = nil: nil,
    (car: P, cdr: Xs):
        Xs.(P.Lt.Filter).(Lesser:
        Xs.(P.Ge.Filter).(Greater:
        Lesser.Sort.((car: P, cdr: Greater.Sort).Append)));

Filter = F: (nil: nil,
            (car: X, cdr: Xs): X.F.(true: (car: X, cdr: Xs.F.Filter),
                                    false: Xs.F.Filter));

Append = nil: (Ys: Ys),
         (car: X, cdr: Xs): (Ys: (car: X, cdr: Xs.Ys.Append));
```

Here my `Filter` and `Append` functions are curried, and I'm presuming that `Lt` and `Ge` are curried primitives such that, for example, `4.Lt` evaluates to a function that returns `true` for arguments that are less than 4.

If you could arrange for the `X/Xs` destructuring pattern-match to fail in `Filter` when `X.F` doesn't return `true`, maybe you could get a cleaner program. I am not clear that there is a way to do that within the semantics I have described.

If we wanted it to be more Prolog-like, we could use ; instead of ,; to be less Prolog-like, we could interchange the sense of upper and lower case, or use Ruby-like prefix colons for literal symbols instead of case, or interchange = and :. And we could potentially dispense with the . for function application. Four of the 11 other possibilities arising thus:

```
sort = Nil: Nil,
    (Car: p, Cdr: xs):
        xs (p lt filter) (lesser:
        xs (p ge filter) (greater:
        lesser sort ((Car: p, Cdr: greater sort) append)));

Sort = nil: nil;
    (car: P; cdr: Xs):
        Xs.(P.Lt.Filter).(Lesser:
        Xs.(P.Ge.Filter).(Greater:
        Lesser.Sort.((car: P; cdr: Greater.Sort).Append)))

sort: Nil=Nil;
    (Car=p; Cdr=xs):
        xs (p lt filter) (lesser:
        xs (p ge filter) (greater:
        lesser sort ((Car=p; Cdr = greater sort) append)));

sort = :nil: :nil,
    (:car: p, :cdr: xs):
        xs.(p.lt.filter).(lesser:
        xs.(p.ge.filter).(greater:
        lesser.sort.((:car: p, :cdr: greater.sort).append)));
```

Yeesh, that last one looks unparseable.

Raph Levien's Io language used, approximately, -> and a right-associative ; where I am using .(and :, thus avoiding the pileup

of right parentheses at the end. If we tried that approach and terminated each alternative in the pattern match with . (that being the only symbol whose precedence in prose is lower than ;), we might end up with something like this:

```
sort = Nil; Nil.
    (Car; p. Cdr; xs);
        xs -> (p -> lt -> filter) -> lesser;
        xs -> (p -> ge -> filter) -> greater;
        lesser -> sort -> ((Car; p. Cdr; greater -> sort) -> append.
```

This does not seem more readable to me.

Backtracking, generators, and binary relations

All of the above is predicated on the idea that a function produces at most one value — so, for example, `_ -> "a" | _ -> "b"` will never return "b" because the first match will never fail. But a natural extension of the approach is to allow any expression to yield any number of values, as in Icon, rather than just zero or one. (Partly by coincidence, Icon uses | to do something closely analogous to chaining together cases of a pattern-match.)

This, in effect, means that we are no longer talking about functions; we are talking about binary relations. With an order imposed on their pairs, perhaps.

There is a rather nice algebra of binary relations; they form a lattice (considering them as sets of (input, output) pairs with the usual set operations), a monoid (under composition), and they have a nontrivial isomorphism — the converse or inverse, which, unlike function inverses, is defined for all binary relations.

One approach to programming with general binary relations would be to attempt a binary-relation-based pattern-matching version of miniKANREN, abandoning the ordering of the possibilities. And that would be cool.

Another approach would be to follow Icon (and Python and JS) in using these generators for iteration. Io does this using no new operations, just a little bit of syntactic sugar for continuations. Python, JS, and Icon do not allow multi-shot continuations; Python and JS, like Io, reify the suspended generator, while Icon usually does not, instead identifying the generator with the expression. I'm not sure how many operations you really need to control the backtracking, but there are at least two: one that prevents further backtracking (Prolog's cut) and one that backtracks repeatedly until no further backtracking is possible, then continues.

Illumination cost

Kragen Javier Sitaker, 2017-05-31 (3 minutes)

Went on a trip to Carrefour the other day and walked down the residential illumination aisle. A 500W 118mm halogen tube went for AR$25 (US$1.60) with no visible indication of its brightness, the same price as 300W, 150W, and 100W versions. An OSRAM 13W LED bulb using 13 watts, supposedly equivalent to 100W incandescent, providing 1350 lumens, was priced at AR$289 (US$18), while OSRAM compact fluorescents using 20W, supposedly equivalent to 85W incandescent, cost AR$90 (US$5.60) and provide some illegible number of lumens which I suppose is about 1150. (The iPhone Notes app peremptorily downrezzed my photos and destroyed the information I was trying to acquire.)

If we assume a luminous efficacy of 18 lm/W for the halogen, it should be 9000 lm.

Historically, the most inexpensive way to do lighting has been with straight fluorescent tubes, like the T8 size. I didn't happen to see these at Carrefour, but DMX SRL in San Nicolás in Buenos Aires is offering 58W GE T8 tubes for AR$59 (US$3.70). These are F58T8 tubes; one such on GE's site has 4900 mean lumens. Additionally, for these, you need a ballast; Tienda de LED in Chacarita offers a two-tube RTM electronic ballast for 58W T8 tubes for AR$75 (US$4.70), or US$2.35 per tube.

type	US$	W	lm	lm / W	lm/US$
halogen	1.60	500	9000	18	5625.
LED	18	13	1350	103.84615	75
compact fluorescent	5.60	20	1150	57.5	205.35714
T8 fluorescent	6.05	58	4900	84.482759	809.91736

#+TBLFM: $5=$4/$3::$6=$4/$2

The very low cost of the halogen bulbs surprises me, but it seems like it might make feasible a project I've been thinking about for some time, which is making a daylight booth in my house for mood control. Direct sunlight is about 100klux, while indirect daylight is in the 15klux range. In a reflective-walled booth, like an indoor-growing apparatus, almost all of the light would be absorbed by my skin unless the booth got very large; my skin absorbs about ⅓ of the light that falls on it, and has a body surface area of about 2m², so effectively I absorb about 0.7m² of light. Illuminating 0.7m² with 15klux requires a bit over 10klm, which means one or two of these 500W bulbs would be totally adequate. I'd need three if I were black.

Now, 1000W of illumination will require a certain amount of cooling and fire-danger attention. You could get the same 18klm out of LEDs with only 173W, but you'd need 14 bulbs like the one I saw, costing US$240 instead of US$3.20.

Free space optical coding gain

Kragen Javier Sitaker, 2019-05-08 (updated 2019-05-09) (4 minutes)

I was thinking about Wi-Fi and infrared remote controls for TVs and air conditioners today. (Did you know there used to be infrared 802.11 access points too?) Remotes don't work if you don't point them at the air conditioner (or TV or whatever), although the infrared light they emit is pretty bright, as bright as a bright flashlight. But it's modulated at a barely ultrasonic frequency; the first TV remote controls were in fact ultrasonic chimes pinged with a hammer, and bizarrely manufacturers have continued using the same frequencies despite using a completely different medium.

A remote-control receiver receives about -54 dBm of signal

I'm not totally sure, but I'm guessing that these remotes use infrared LEDs with a forward drop of about 1.5 volts, a current of about 40 mA, and an efficiency on the order of 4%. (Typical LEDs have a luminous coefficient around 3%, although modern illumination white LEDs can reach 25%, but I'm assuming that these advances haven't translated to the infrared LEDs used in remotes.) That would work out to 2.4 mW of light energy, or +3.8 dBm, which is then emitted with an "antenna gain" of about 6 dBi (thus EIRP ≈ 6.2 dBm) spread over a sphere of perhaps two meters radius (50 m² of surface) and detected by a phototransistor of radius perhaps 8 mm (5e-5 m²), so the received signal should be about 60 dB below the EIRP, or about -54 dBm.

But Wi-Fi works with orders of magnitude less than that

Wi-Fi often achieves sustained, consistent data transmission despite signal levels below -70 dBm, sometimes below -100 dBm. GPS receivers detect even weaker signals.

What does the optical environment look like for that kind of thing?

What if you used the spread-spectrum coding-gain approach used by GPS receivers and Wi-Fi receivers, but for local optical communication? You can easily modulate ordinary LEDs at over a megahertz, and now that CRT TVs are dying out, I think there aren't many sources of megahertz-range optical noise in households. Common illumination and taillight LEDs are typically pulsed, but only on the order of 100 Hz, in order to reduce switching losses; I think their 10,000th harmonic is going to be very weak, precisely because of those switching losses (aside from having a very low duty cycle even if the switching were perfect).

There *is* still the problem that direct sunlight is 100 kilolux, and even indoor room lighting is 50–500 lux, while the light you're able to transmit from an infrared LED is also only about 100 lux a few dozen millimeters in front of the LED, maybe 1 lux or less at the

sensor. Even if the infrared light coming in an open window is effectively constant over microsecond-scale time periods, it still gives rise to shot noise at your infrared sensor. We usually think of shot noise as going away as signal levels rise, but actually it increases; it's just that it increases proportional to only the square root of the signal, so the signal increases even more. But in this case the sunlight "signal" carries no information, and an increase in shot noise proportional to its square root could eventually swamp the information-carrying signal.

In the 1000-ms response time of a conventional remote control, you could transmit literally a million bits, giving you the possibility of up to 60 dB of coding gain. (I think? I'm kind of guessing about the limits of coding gain here. I should go back and really understand information theory.)

The key problem with light is that it is easily blocked, and even when multipath transmission can get it around obstacles, it's heavily attenuated. But, by the same token, there's no need to share bandwidth or avoid interfering with reserved bandwidth.

Some notes from playing 20q.net

Kragen Javier Sitaker, 2007 to 2009 (22 minutes)

Summary: 20q.net seems to do badly at choosing questions. It was able to guess the axolotl and the domestic cat; but it missed the sailboat, a gallon bottle of milk, one million, basil, a knife-sharpening stone, methyl ethyl ketone, Che Guevara's corpse, Mare Imbrium, and a leather high-heeled tango shoe.

Q24. I am guessing that it is an axolotl (Mexican salamander)?
Right, Wrong, Close
23. Can you find it in a house? Sometimes.
22. I guessed that it was a largemouth bass? Wrong.
21. Is it soft? Yes.
20. I guessed that it was a tadpole? Close.
19. Does it have a tail? Yes.
18. Does it have an exo-skeleton? No.
Is it tasty? Unknown.
17. I guessed that it was a cichlid (tropical freshwater fish)? Wrong.
Can it cheer you up? Unknown.
16. Is it larger than a pound of butter? No.
15. Does it weigh more than a duck? No.
14. Is it ferocious? No.
Does it bring joy to people? Unknown.
13. Does it live in the ocean? No.
12. Does it go in your mouth? Doubtful.
11. Does it live in salt-water? No.
10. Can it be hunted? Yes.
9. Do you know any songs about it? No.
8. Does it live in fresh water? Yes.
7. Is it a wild animal? Yes.
6. Is it an appliance? No.
5. Is it larger than a microwave oven (or bread box)? No.
4. Can it live out of water? No.
3. Does it swim? Yes.
2. Does it have whiskers? No.
1. It is classified as Animal.

Yes, it was:

You were thinking of an axolotl.
Can it live out of water? You said No, 20Q was taught by other players that the answer is Yes.
Can it be hunted? You said Yes, 20Q was taught by other players that the answer is No.
Does it bring joy to people? 20Q was taught by other players that the answer is Yes.
Can it cheer you up? 20Q was taught by other players that the answer is No.
Is it tasty? 20Q was taught by other players that the answer is No.
Contradictions Detected
The opinions of the 20Q A.I. are its own, and are based on the input of players. 20Q's answers reflect common knowledge. If you feel that 20Q is in error, the only way to correct it is to play again!
Similar Objects
a tadpole, a cichlid (tropical freshwater fish), a largemouth bass, a newt, a salamander, a paramecium (protozoa), a guppy (fish), a bullfrog, a trout (fish), a koi (fish), a leech, a Siamese fighting fish.

Well, it's hardly surprising that it had so much trouble guessing in that case. I had two "wrong" answers.

Still, it doesn't seem like 20Q is doing the best possible job of choosing questions. How often is an animal an appliance, and how often does an animal that doesn't live in salt-water live in the ocean?

I'm pretty sure that it can only live out of water if given an iodine injection to induce metamorphosis.

Thinking of a tango shoe (leather, high-heeled):

Q30. I am guessing that it is a camera?

Right, Wrong, Close
29. I guessed that it was a sneaker? Close.
28. Is it human powered? Yes.
27. Is it an absolute state? No.
26. Is it comforting? No.
25. Can it be used for recreation? Yes.
24. Is it brown? Sometimes.
23. Would you give it as a gift? Yes.
22. Would you find it on a farm? No.
21. Does it taste good? No.
20. I guessed that it was vomit? Wrong.
19. Does it open? No.
18. Can you smell it? Yes.
17. I guessed that it was a steak (beef)? Wrong.
16. Can it be painted? Doubtful.
15. Is it round? No.
14. Is it found on a desk? No.
13. Can it fit in an envelope? No.
12. Do you make something with it? No.
11. Is it living? No.
10. Does it have eyes? No.
9. Does it live in the jungle? No.
8. Is it smaller than a loaf of bread? Yes.
7. Does it live in salt-water? No.
6. Does it have a shell? No.
5. Can you play games with it? No.
4. Can it climb? No.
3. Is it black? Sometimes.
2. Is it heavy? No.
1. It is classified as Animal.

Eventually:

You were thinking of a high-heeled shoe.
You said it's classified as Animal, 20Q was taught by other players that the answer is Other.
Can you smell it? You said Yes, 20Q was taught by other players that the answer is No.
Can it be used for recreation? You said Yes, 20Q was taught by other players that the answer is No.
Is it human powered? You said Yes, 20Q was taught by other players that the answer is No.

Thinking of Mare Imbrium:

Q30. I am guessing that it is an angel?
Right, Wrong, Close
29. I guessed that it was the Moon? Close.
28. Does it contain a liquid? No.
27. Can it help you find your way? Doubtful.
26. Does it produce gas? No.
25. Would you use it daily? Doubtful.
24. Can it affect you (cause an effect to you)? Yes.
23. I guessed that it was a coral reef (marine habitat)? Wrong.
22. Can it be stolen? Doubtful.
21. Is it considered valuable? Yes.
20. I guessed that it was a snow man? Wrong.
19. Is it brown? No.
18. Is it used for entertainment? Doubtful.
17. Can you use it 24 hours a day? No.
16. Does it bring joy to people? Yes.
15. Is it hard? No.
14. Can you put something into it? Doubtful.
13. Can you smell it? No.
12. Does it make noise? No.
11. Is it larger than a microwave oven (or bread box)? Yes.
10. Do people sit on it? No.
9. Does it provide shade? No.
8. Is it stationary (movement)? Yes.
7. Is it orange colored? No.
6. Would you eat its fruit? No.
5. Is it found in mines? No.
4. Is it a geological feature? Yes.
3. Is it a metal? No.
2. Does it weigh more than a duck? Yes.
1. It is classified as Mineral.

It wasn't able to get it.

Thinking of Che Guevara's corpse:

Q30. I am guessing that it is a mermaid?
Right, Wrong, Close
29. I guessed that it was a skeleton? Close.
28. Can it be hunted? No.
27. Does it have a backbone? Yes.
26. Can you see it in a zoo? No.
25. I guessed that it was an angel? Close.
Can any age group use it? Unknown.
24. Does it like to clean itself? No.
23. I guessed that it was a composer? Close.
Can it affect you (cause an effect to you)? Unknown.
22. Does it live in the forest? No.
21. Does it like to run? No.
20. I guessed that it was Superman (fictional)? Close.
19. Is it worth a lot of money? Doubtful.
18. Can you smell it? No.
17. I guessed that it was Spiderman (superhero)? Close.
16. Does it bring joy to people? Yes.
15. Is it tall? Yes.
14. Do you find it in the sky? No.
13. Is it outside? Yes.
12. Is it cold? No.
11. Does it come in different colors? No.
10. Does it have teeth? Yes.
9. Does it have four legs? No.
8. Does it like to be petted? No.
7. Is it spotted? No.
6. Do you find it in space? No.
5. Is it useful? Yes.
4. Is it dangerous? No.
3. Is it larger than a microwave oven (or bread box)? Yes.
2. Can it growl? No.
1. It is classified as Animal.

Thinking of methyl ethyl ketone:

Q30. I am guessing that it is a stick of gum?
Right, Wrong, Close
29. I guessed that it was air? Wrong.
28. Does it make music? No.
27. I guessed that it was electricity? Wrong.
26. Is it used for communications? Yes.
25. Does it communicate? No.
24. Is it human powered? No.
23. I guessed that it was energy? Wrong.
22. Do you clean it regularly? No.
21. Can you make sounds with it ? Yes.
20. I guessed that it was mineral water? Close.
19. Does it contain words? No.
18. I guessed that it was water? Close.
17. Would you find it in an office? Yes.
16. Can it be used for recreation? Yes.
15. Would you use it daily? Yes.
14. Does it bring joy to people? Yes.
13. Is it hard? No.
12. Does it have a hard outer shell? No.
11. Can it be placed on your head? Yes.
10. Do you eat it with Thanksgiving dinner? Sometimes.
9. Is it tasty? Sometimes.
8. Is it usually sliced or carved? No.
7. Can you walk on it? No.
6. Does it flower? No.
5. Can you add it to a salad? Yes.
4. Can you use it with your friends? Yes.
3. Is it larger than a pound of butter? Irrelevant.
2. Is it decorative? No.
1. It is classified as Mineral.

Thinking of a rectangular knife-sharpening oilstone:

Q30. I am guessing that it is lipstick?
Right, Wrong, Close
29. I guessed that it was an electric toothbrush? Wrong.
28. Does it have a hole in it? No.

27. Is it made out of wood? No.
Is it pleasurable? Unknown.
26. Is it larger than a microwave oven (or bread box)? No.
Can it cheer you up? Unknown.
25. Would you find it in an office? No.
24. Can it bend without breaking? No.
23. I guessed that it was dill? Wrong.
22. Is it straight? Yes.
21. Is it worth a lot of money? No.
20. I guessed that it was a piccolo? Wrong.
19. Is it connected to a wire? No.
18. Does it cut? No.
Can you play games with it? Unknown.
17. Do you wear it? No.
16. Would you wear it on your wedding day? No.
15. Does it come in a pack? No.
14. Does it get shorter from using it? Yes.
13. Would you use it daily? Yes.
12. Would you give it as a gift? Yes.
11. Does it smell sweet? No.
10. Does it bring joy to people? Sometimes.
9. Does it come in many varieties? Yes.
8. Can you walk on it? No.
7. Is it made of crystals? Yes.
6. Can it blink? No.
5. Does it come in a box? Yes.
4. Is it round? No.
3. Is it used to make jewelry? No.
2. Do you hold it when you use it? Yes.
1. It is classified as Mineral.

Thinking of basil:

Q30. I am guessing that it is breakfast?
Right, Wrong, Close
29. I guessed that it was lunch? Wrong.
28. Would you find it on a farm? Yes.
27. Do you use it at night? Sometimes.
26. I guessed that it was marmalade? Wrong.
25. Would you find it in an office? Doubtful.
24. Is it a specific color? Sometimes.
23. Does it go inside other things? Sometimes.
22. I guessed that it was dinner? Wrong.
21. Does it contain a liquid? Yes.
20. I guessed that it was ballet? Wrong.
19. Can it be used for recreation? Sometimes.
18. I guessed that it was an ear of corn? Wrong.
17. I guessed that it was salad? Close.
16. Does it smell sweet? Yes.
15. Does it live in the forest? No.
14. Is it flat? Sometimes.
13. Is it red? No.
12. Does it bring joy to people? Yes.
11. Does it get really hot? No.
10. Is it colorful? Yes.
9. Is it used in Oriental cooking? Yes.
8. Does it taste good with butter? Yes.
7. Is it a leafy vegetable? Yes.
6. Does it have a backbone? No.
5. Is it round? No.
4. Can you peel it? No.
3. Does it come in different colors? Yes.
2. Is it crunchy? Yes.
1. It is classified as Vegetable.

However, apparently my opinion of basil is different from most people's:

You were thinking of basil.
Is it crunchy? You said Yes, 20Q was taught by other players that the answer is No.
Does it come in different colors? You said Yes, 20Q was taught by other players that the answer is No.
Is it used in Oriental cooking? You said Yes, 20Q was taught by other players that the answer is Doubtful.
Is it colorful? You said Yes, 20Q was taught by other players that the answer is

No.
Is it flat? You said Sometimes, 20Q was taught by other players that the answer is No.
Does it smell sweet? You said Yes, 20Q was taught by other players that the answer is No.
Can it be used for recreation? You said Sometimes, 20Q was taught by other players that the answer is No.
Does it contain a liquid? You said Yes, 20Q was taught by other players that the answer is No.
Do you use it at night? You said Sometimes, 20Q was taught by other players that the answer is No.
I don't know what kind of people think that basil doesn't smell sweet and isn't used in Oriental cooking.

Thinking of a gallon bottle of milk:

Q30. I am guessing that it is a phone book?
Right, Wrong, Close
29. I guessed that it was a cigarette case? Wrong.
28. Do you open and close it? Yes.
27. I guessed that it was a tissue box? Wrong.
26. Is it white? Yes.
25. Is it black? No.
24. Is it round? No.
23. I guessed that it was a bottle of water? Close.
22. Would you use it in the dark? Yes.
21. Do you put things in it? No.
20. I guessed that it was a revolver (hand gun)? Wrong.
19. Would you give it as a gift? No.
18. Can it be refilled? Yes.
17. I guessed that it was a notebook (paper)? Wrong.
16. Can you use it with your friends? Yes.
15. Does it have writing on it? Yes.
14. Is some part of it made of glass? No.
13. Does it have a cable? No.
12. Is it used by the police? Yes.
11. Is it used for entertainment? No.
10. Do you use it at work? Yes.
9. Is it alive? No.
8. Can it fit in an envelope? No.
7. Does it dig holes? No.
6. Can it be used to put things together? No.
5. Is it small? Yes.
4. Does it have short fur? No.
3. Is it brown? No.
2. Can you see it in a zoo? No.
1. It is classified as Animal.

Q17. I am guessing that it is a domestic cat?
Right, Wrong, Close
16. Does it have a long tail? Yes.
15. Is it small? Yes.
Does it come from something larger? Unknown.
14. Does it live in large populations? Sometimes.
13. Do you know any songs about it? Yes.
12. Is it a carnivore? Yes.
11. Can it be trained to obey commands? Doubtful.
10. Does it eat fish? Yes.
9. Is it spotted? No.
8. Is it a herbivore? No.
7. Does it usually live on a farm? No.
6. Does it come from space? No.
5. Does it serve a purpose? No.
4. Is it awake at night? Yes.
3. Is it a small mammal? Yes.
2. Can you find it in a house? Yes.
1. It is classified as Animal.
You were thinking of a domestic cat.
Does it live in large populations? You said Sometimes, 20Q was taught by other players that the answer is No.
Does it come from something larger? 20Q was taught by other players that the answer is No.

Thinking of the number 1 000 000:

Q30. I am guessing that it is cyberspace?
Right, Wrong, Close
29. I guessed that it was a language? Wrong.
28. Is it printed? Sometimes.
27. Is it used during meals? Irrelevant.
Can it add? Unknown.
26. I guessed that it was information? Close.
25. Is it healthy? Irrelevant.
24. Is it used by the police? Yes.
23. Can you buy it? Irrelevant.
22. Can it be used for recreation? Yes.
21. Does it have cash value? Irrelevant.
20. I guessed that it was knowledge? Close.
19. I guessed that it was mathematics? Close.
18. Is it taught in school? Yes.
17. Can it live out of water? Irrelevant.
Does it involve contact with other humans? Unknown.
16. Can you read it? Irrelevant.
Was it invented? Unknown.
15. Is it used for entertainment? Yes.
14. Does it have a title? Yes.
Is it man made? Unknown.
13. Is it something you bring along? Irrelevant.
12. Do you look at it? No.
11. Does it move? No.
10. Is it used to calculate? Yes.
9. Is it mechanical? No.
8. Do you use it at work? Yes.
7. Does it need love? No.
6. Does it have a cold nose? No.
5. Can it be heard? Irrelevant.
4. Is it small? No.
3. Does it get wet? No.
2. Do you hold it when you use it? Irrelevant.
1. It is classified as Other.

Thinking of a sailboat:

Q30. I am guessing that it is a power boat?
Right, Wrong, Close
29. I guessed that it was a boat? Close.
28. Can it float? Yes.
27. Would you pay to use it? Sometimes.
26. Is it mechanical? Yes.
25. Is it very large? Sometimes.
24. Do you hold it when you use it? Sometimes.
23. Was it used over 100 years ago? Yes.
22. Does it have four wheels? No.
21. Does it open? No.
20. I guessed that it was an outboard motor (motorboat engine)? Close.
19. Does it roar? No.
18. I guessed that it was an accordion? Wrong.
17. Does it move? Yes.
16. Do you use it at night? Yes.
15. Does it roll? No.
14. Would you find it on a farm? Sometimes.
13. Does it have lots of buttons? Sometimes.
12. Does it have buttons? Yes.
11. Can it be heard? Yes.
10. Is it black? Sometimes.
9. Is it connected to a wire? No.
8. Does it break if dropped? Yes.
7. Does it have a trunk? No.
6. Does it grow in the Southern U.S.? No.
5. Is it larger than a microwave oven (or bread box)? Yes.
4. Is it used for entertainment? Yes.
3. Is it flat? No.
2. Is it something you bring along? Yes.
1. Is it hard? Yes.
It is classified as Unknown.
You were thinking of a sailboat.
You said it's classified as Unknown, 20Q was taught by other players that the answer is Other.
Is it something you bring along? You said Yes, 20Q was taught by other players that the answer is No.
Is it black? You said Sometimes, 20Q was taught by other players that the answer

is No.
Can it be heard? You said Yes, 20Q was taught by other players that the answer is No.
Does it have buttons? You said Yes, 20Q was taught by other players that the answer is No.
Does it have lots of buttons? You said Sometimes, 20Q was taught by other players that the answer is No.
Would you find it on a farm? You said Sometimes, 20Q was taught by other players that the answer is No.
Do you hold it when you use it? You said Sometimes, 20Q was taught by other players that the answer is No.

At this point it has played 64 million games.

TV oscilloscope

Kragen Javier Sitaker, 2017-04-10 (updated 2017-06-20) (4 minutes)

Electronics hacker "GreatScott!" made a video using a TV CRT as a "crude" oscilloscope.

In the video he shows that the horizontal scan normally runs at some 15kHz, and its return at the end of the scan is not very clean. He demonstrates visualizing waveforms of a few times that frequency.

One difficulty is that the deflection coils in a TV CRT produce a deflection that's proportional to their current, but he's driving them with a voltage signal, and they are primarily inductive loads — one consequence is that they more strongly attenuate higher frequencies, but another is that they produce frequency-dependent phase shifts (of nearly 90°) and thus badly deform the waveforms.

It seems like a straightforward solution to this problem is to drive the coils from a current source rather than a voltage source, so that up to some potentially fairly high voltage the magnetic field will faithfully reproduce the desired signal.

Scott's TV originally used a -42V to +30V signal for the horizontal scan at a bit over 15 kHz (with a voltage waveform that was a distorted square wave, thus producing a distorted triangle wave of current for the scan), with a 600mΩ resistance and 210μH of inductance. The vertical scan used -10 to +40V at 43 Hz, with 21Ω resistance and 20mH of inductance.

In both cases there were strong harmonics in the signals.

It seems to me that if you want to make this a useful oscilloscope tube, your best bet is to turn the screen sideways, because the "vertical" deflection of your signal basically always needs to have higher frequency components than the "horizontal" scan. If a ±40V signal is adequate to recognizably reproduce a deflection of some 150kHz, then by using a current source with compliance up to 40kV, we should be able to successfully reproduce 150MHz. The coil probably would not survive 40kV, though, as special coil construction is needed to handle voltages over a few hundred volts, so we could probably only reach a few MHz in practice without rewinding the coil.

At the 15kHz fundamental, the 210μH inductance represents about 20 ohms (making its 0.6Ω real resistance insignificant at that frequency or above), so getting a full deflection requires on the order of an amp or two through the coil.

Purpose-designed oscilloscope tubes differ in a few ways: they use electrostatic deflection, which I think is not a thing you can retrofit to the tube afterwards; are longer so that smaller angles are feasible; and have an axial voltage gradient to progressively accelerate the beam so that the electrons are moving more slowly as they go through the deflection plates than when they hit the screen. (In part this is to compensate for some disadvantages of electrostatic deflection: it deflects fast electrons less than slow ones, so the speed must be relatively low and consistent across all the electrons in order to get a large and consistent deflection. Magnetic deflection does not have these problems; the radius of the electron track depends only on the magnetic flux density, not on its speed.)

A computer monitor might be more promising. This TV had only about 350 lines per scan and a very low refresh frequency, so it could get by with a low horizontal scan frequency. By contrast, the LG 710e monitor someone threw out the other day is reported to support 1024×768 at 85Hz. This means that its normal horizontal scan must run at at least 65kHz. I don't know if it uses a higher voltage than ±40V or not; it would seem like using a coil with half as many turns would give you a quarter the inductance but also half the field, which would be a win.

(See also files VCR oscilloscope (p. 213), Laser printer oscilloscope (p. 449), and CCD oscilloscope (p. 1861).)

Topics

Full res globe

Kragen Javier Sitaker, 2014-02-24 (1 minute)

Suppose you want to make a globe with outrageously high resolution. Maybe you want to map every street in the world, or every car. How much space do you need?

The Earth is almost exactly 40 000 000 meters around (the small error in this number is due to long-ago measurement mistakes), and to see every street, you need no worse than, say, 15-meter resolution — which you can get from, say, Landsat. OpenStreetMap may be a more interesting data source.

40 million divided by 15 gives you 2⅔ million pixels around your globe. If you're using a regular 600dpi laser printer, your globe is 370 feet in circumference, or 18 meters in radius, 36 in diameter. Your globe will be about 14 stories tall.

To reduce that to a single story tall, you'd need to reduce the size by 16×, to 9600dpi. At this resolution, your pixels are only 2.6 microns wide: within the range of what you can see with a light microscope, but not easily.

However, 9600dpi is somewhat difficult to achieve. 2400dpi is supposedly achievable on high-end inkjet printers, and you might be able to use photographic reduction processes to reduce them 4:1.

Scriptable windowing for Wercam

Kragen Javier Sitaker, 2018-10-26 (updated 2019-07-24) (26 minutes)

One of the designs I'm thinking of for window systems for BubbleOS (see Speculative plans for BubbleOS (p. 2128)) is sort of based on MGR, the Blit, and Plan 9, with some ideas from NeWS (as filtered through the UNIX-HATERS Handbook), Bitcoin, eBPF, and Dan Luu's studies of user interface latency. It's also partly inspired by thinking about might-have-beens about the VT100, the H19, and the Datapoint 2200 from the 1970s.

However, see also A nonscriptable design for the Wercam windowing system (p. 3092).

Basically, the issue is that user interface latency is a really big deal when it comes to the "feel" of an interactive system, and modern computer software design is making our user interface latency suck shit, to the point that most modern computers are dramatically less responsive than an Apple //e. The Apple //e takes 30 ms to get a keystroke on the screen, while a typical modern machine takes 100–160 ms, and a tuned modern machine takes 60 ms. And this gets worse rather than better when we try to operate our systems over long-latency links, which are, despite all predictions, increasingly common in today's world, despite the concurrent proliferation of low-latency links.

One approach to the link latency problem is the Lotus Notes strategy: partially replicate the application state on different nodes, including some as close to the user as possible, and reconcile the occasional conflicting update after the fact. This is more or less the modern AJAX strategy, but it doesn't help much with user-interface latency as such.

A different approach, which is sort of the original use case for JS, is to put a small amount of application-specific code as close as possible to the client to react quickly to input events, while delegating more complex processing to the client application. As Don Hopkins explains:

> At the mere mention of network window systems, certain propeller gheads who confuse technology with economics will start foaming at the mouth about their client/server models and how in the future palmtops will just run the X server and let the other half of the program run on some Cray down the street. They've become unwitting pawns in the hardware manufacturers' conspiracy to sell newer systems each year. After all, what better way is there to force users to upgrade their hardware than to give them X, where a single application can bog down the client, the server, and the network between them, simultaneously!
>
> The database client/server model (the server machine stores all the data, and the clients beseech it for data) makes sense. The computation client/server model (where the server is a very expensive or experimental supercomputer, and the client is a desktop workstation or portable computer) makes sense. But a graphical client/server model that slices the interface down some arbitrary middle is like Solomon following through with his child-sharing strategy. The legs, heart, and left eye end up on the server, the arms and lungs go to the client, the head is left rolling around on the floor, and blood spurts everywhere.
>
> The fundamental problem with X's notion of client/server is that the proper division of labor between the client and the server can only be decided on an application-by-application basis. Some applications (like a flight simulator) require that all mouse movement be sent to the application. Others need only mouse

clicks. Still others need a sophisticated combination of the two, depending on the program's state or the region of the screen where the mouse happens to be. Some programs need to update meters or widgets on the screen every second. Other programs just want to display clocks; the server could just as well do the updating, provided that there was some way to tell it to do so.

The right graphical client/server model is to have an extensible server. Application programs on remote machines can download their own special extension on demand and share libraries in the server. Downloaded code can draw windows, track input eents, provide fast interactive feedback, and minimize network traffic by communicating with the application using a dynamic, high-level protocol.

As an example, imagine a CAD application built on top of such an extensible server. The application could download a program to draw an IC and associate it with a name. From then on, the client could draw the IC anywhere on the screen simply by sending the name and a pair of coordinates. Better yet, the client an download programs and data structures to draw the whole schematic, which are called automatically to refresh and scroll the window, without bothering the client. The user can drag an IC around smoothly, without any network traffic or context switching, and the server sends a single message to the client when the interaction is complete. This makes it possible to run interactive clients over low-speed (that is, slow-bandwidth) communication lines.

From a security point of view, the idea of uploading arbitrary application code to the window server is somewhat alarming. What if it hangs the window server, or makes it run slowly or unresponsively? What if one application uploads a malicious version of a widget used by another application?

Putting a small amount of application code into the input event handling path is also the approach taken by BPF for packet filtering: tcpdump uploads a tiny bytecode program into the BSD kernel to discard uninteresting packets *in interrupt context*, forwarding the interesting packets to the user-level program. This avoids context-switching to the tcpdump process for every network packet, which was seriously important in 1992 when BPF was designed, and even more important in 1980 when its stack-machine predecessor, CSPF, was designed.

BPF's instruction set has 22 instructions and two registers, but only supports forward jumps, so it cannot express loops. eBPF, which includes things like functions and user-accessible data structures, is now used by Linux not only for packet filtering, but also for sandboxing processes (a purpose for which MacOS uses a tiny Scheme), inserting debugging and performance probes into the kernel, XXX

Uses of scriptability in Wercam

Suppose that application programs can upload event-handler scripts for a similar virtual machine into the Wercam window server, which then compiles and runs them. Then maybe those scripts can provide quicker responsiveness than the applications themselves, because they're running in the process that directly draws into the framebuffer. Indeed, maybe at some point we can move that process out of the time-sharing operating system the applications are running on, into a real-time executive like the one in RTLinux, or even onto dedicated display-handling hardware. Then we can get the latency of user interface responsiveness down into the submillisecond range where the delay really is undetectable by humans.

But to guarantee this kind of responsiveness, especially without rewriting major parts of your application in this strange virtual

machine, we must limit the amount of context available to the event-handler script; and it might not produce the ultimately correct display immediately. In a lot of cases, this is probably okay. Mosh does something similar with typing: when you type a printable character, it immediately adds it to your screen, and then it reconciles the screen image with the remote host, so if the character didn't get echoed by the application there, it disappears.

What kinds of things might you reasonably add?

Input event selection

Well, one simple example is that you can specify which events you would like the window server to send to the client. Don's example of how some applications would like all mouse movement, while others just want clicks, is the simplest example. You can implement it easily if your event-handler script is in charge of sending the events back to the client; it can simply return without doing anything when the mouse-button state hasn't changed since the last event. This mechanism is more complicated than the X11 mechanism:

```
/* Apparently StructureNotifyMask is what you use to get MapNotify
 * events? */
XSelectInput(w->display, w->window, KeyPressMask
             | KeyReleaseMask
             | ButtonPressMask
             | ButtonReleaseMask
             | PointerMotionMask
             | StructureNotifyMask
);
```

But it's probably a lot easier to debug!

Bit gravity

X11 has a "bit gravity" feature which modifies window resize handling. If the bit gravity of a window is set to, for example, `NorthEastGravity`, then when a window is resized, the previous window contents are in the upper right corner of the screen ("northeast" in the conventional mapping of compass directions to maps). This matters because there is a span of time between the window resize on the server and when the application may be able to respond by redrawing the window. Indeed, when X was designed in the 1980s, window redraws often took several video frames, even when there were no issues of system load.

Input event translation

A more interesting example — and this is where we get into MGR and Blit territory — is that if the client's event-handler script is responsible for sending the events to the client, maybe it can also determine the form of those events. Like, maybe you could add a mouse-compatibility layer in front of some program written for a character-cell terminal, just by defining a few event handlers.

Application-to-display stream parsing?

Of course, that suggests that the event-handler script could *also* be in charge of the handling of data *from the client*. And then maybe you could, as the Blit does, start out in a glass-tty mode with some default

event handlers that provide glass tty behavior, and then upload new event handlers with escape sequences.

That's probably not actually ideal, for a couple of reasons. First, graphical applications can easily involve sufficiently massive data volumes that we want to minimize the number of copies of that data. (I'm typing this on a 1920×1080 32bpp 60Hz screen, which multiplies out to 497,664,000 bytes of pixel data per second. mpv can actually reliably get that data on the screen, using OpenGL. We probably don't want that data flowing through an unaligned FIFO, and we probably don't want client bytecode to be in charge of parsing it, because despite the potential advantages of XXX

It's probably better to maintain the application-to-display protocol fixed, but include in it the ability for the application to directly invoke previously-uploaded event handlers, including event handlers that won't fire on any window-system-generated events.

Vertical sync for tear-free redrawing

Another interesting example is the unfortunately-named† XSYNC extension, intended to provide tearing-free and flicker-free double-buffering for X11, as well as audio/video synchronization. It was proposed in 1991 but the Linux implementation still lacks access to the vsync signal needed to make it work, despite some work on this in 2003. XSYNC works by corking up the pipeline of drawing requests from a given client until some condition becomes true, such as a given timestamp passing, a counter incrementing, or the monitor going into vsync. Then the pipeline gets uncorked and updates the screen during the vertical blanking interval (VBI) or renders the next animation frame or whatever.

† "Unfortunately named" because an almost, but not completely, unrelated core X11 function is called `XSync()`.

Aside from the clumsy special-casing in the `XSyncWaitCondition` struct (which you can read about in the docs if you're interested), implementing vertical synchronization just by uncorking a drawing request pipeline excludes many optimizations we would like to do. Consider what Massalin said about terminal emulation in Synthesis:

> The numbers in Table 7.5 can be used to predict the elapsed time for the "cat /etc/termcap" measurement done in Section 7.2.2. Performing the calculation, we get 3.4 seconds if we ignore the invocation overhead and use only the per-character costs. Notice that this exceeds the elapsed time actually observed (Table 7.2). This unexpected result happens because Synthesis kernel [sic] can optimize the data flow, resulting in fewer calls and less actual work than a straight concatenation of the three quajects would indicate. For example, in a fast window system, many characters may be scrolled off the screen between the consecutive vertical scans of the monitor. Since these characters would never be seen by a user, they need not be drawn. The Synthesis window manager bypasses the drawing of those characters by using fine-grained scheduling. It samples the content of the virtual VT100 screen 60 times a second, synchronized to the vertical retrace of the monitor, and draws the parts of the screen that have changed since the last time. This is a good example of how fine-grain scheduling can streamline processing, bypassing I/O that does not affect the visible result. The data is not lost, however. All the data is available for review using the window's scrollbars.

This kind of optimization — which, incidentally, improves predictability and reduces user-interface latency — can't be done simply by uncorking a drawing pipeline at a predetermined time. You have to avoid sticking useless drawing operations into the drawing pipeline in the first place.

It would, on the other hand, be easy to implement this drawing approach as an event-handler script, although not without some kind of looping capabilities. Note that in this case the loop indexes over the terminal screen contents, which is a finite-size data object, and so it's amenable to worst-case execution-time guarantee calculation — just not in such a straightforward way as BPF's loop-free virtual-machine instruction set. (And you could limit execution time by, for example, inserting an Ethereum-style gas check before each backward jump or potentially-recursive function call, although a static check seems perhaps more desirable, since it moves the error reporting to a client request instead of a failed window redraw.)

(Despite the complaining in the links above, it's actually reported to be possible to get tear-free redraws under X11; GLX is reported to be adequate when used properly, but I think I do see tearing in mpv using an OpenGL visual.)

Terminal emulators may be a somewhat unusual case, though. The "source" contents of a terminal window is small (typically a few kilobytes) and bounded, so it's safe for a window server to traverse it during the VBI; and it's much smaller (typically 200× smaller, though this varies by font size and pixel depth) than the pixel data in the window, updating the "source" is inherently much cheaper than updating the pixel data; and the source may suffer massive quantities of updates while it's not visible. Other kinds of applications (hypertext browsers, movie players, PDF viewers) might not have all these properties.

So it may not be ideal to design Wercam around what's best for terminal emulators.

However, tear-free vertically-synced redrawing is desirable for many applications.

Window-server-side text editing

However, modern GUI programs are full of text fields, and each text field is a full-fledged text editor. Much of the time, the app doesn't care about the intermediate values of the text field, only its eventual value. Rather than simply doing local echo of keystrokes, ideally the vast majority of keystrokes and mouse clicks could be handled by the window server without any interaction with the application process at all, until it wants the contents of the text field, or the user sends some keystroke that the text field doesn't handle.

This requires the window location and shape, font metrics, font glyphs, and buffer contents to be all maintained in the window server, where they're accessible to the client-sent event handlers. The font glyphs in particular are a potential problem, given the rendering time and total size of full Unicode fonts, so probably some kind of glyph-rendering-on-demand is needed, with some kind of placeholder displayed for not-yet-loaded glyphs.

With Unicode, combining characters and bidirectional text rendering are another big ball of hassle that is probably best not uploaded in tiny event handlers.

But even handling the most basic actions with low latency — cursor positioning with the mouse or arrow keys, inserting characters, deleting characters with backspace — would go a long way to reducing the latency of user interaction with text fields.

Keyahead and mouseahead for menus

One of the benefits of Don Hopkins's implementation of pie menus in the window server in NeWS was "mouseahead": since mouse movements that followed the click that brought up the pie menu weren't processed until the pie menu was already active, there's no window of time during which a too-fast click or release will be lost. This is analogous to how you can "key ahead" or "type ahead" in keyboard-driven menu or data-entry systems; you don't need to wait for the application to display a menu before selecting from it, or to move the cursor to the next field before typing into it. The same sequence of actions will always have the same result regardless of details of timing or how fast the application manages to respond, which makes the system feel better, allowing the user to control it quickly with open-loop control.

A very simple event-handler script is adequate to track the user's position in a menu tree and navigate it by mouse movements.

"Keyahead" is a rather old term, appearing for example in the TRS-80 Model II DOS manual:

Keyaheads

TRSDOS allows keyaheads of up to 80 characters. This means that you can type in the next command while previous ones are being executed.

Note: A keyahead will not be displayed until TRSDOS or the application program is ready to interpret it.

Unfortunately I don't know of a modern term for the phenomenon.

MATE, the desktop environment I'm using at the moment, has a serious failure of both keyahead and mouseahead. It has a Microsoft-Windows-95-style "Start" menu, which can be activated either by clicking the menu button or by pressing the Microsoft Windows key on the keyboard. When it hasn't been used for a while, though, it gets slow (presumably relevant stuff needs to be read from disk) and subsequent keys or mouse actions are captured by whatever the foreground application window is, rather than being routed to the menu. This means that, even when the menu opens quickly, you have to wait for it to appear before starting to select things from it.

Animation, compositing, and filtering

It's beneficial for filtering (for e.g. text drop shadows) to run in the display server rather than the app.

Other protocol considerations

Applicaiton embedding (e.g. a Flash player or movie player in a web browser) will really benefit a lot if there's a way to avoid copying all the pixel data first from one application to the other, then to the server.

Tentative protocol design

The primitive unit of drawing is a 32×32-pixel tile in premultiplied 32-bit RGBA format with the bytes in that order. This representation is chosen for a few reasons:

• It's 4096 bytes, the usual memory page size on i386 and amd64 systems. That means that in theory you should be able to transfer tile buffers between clients and servers on the same machine without copying them, just by remapping memory, at least if they're properly aligned. It may have undesirable cache effects for operations on

corresponding pixels in multiple tiles, but typically these are done on only three or four tiles at a time, and all modern L1D caches are at least four-way set-associative.

• A single scan line of it is 32 pixels, which is 128 bytes. This is larger than, and divisible by, the cache line size on currently popular desktop CPUs, which is 64 bytes. It's also larger than any of the SIMD registers in current popular CPUs, which max out at 512 bits (64 bytes). A single color plane of it would be only 32 bytes, which would be smaller than a 512-bit AVX512 register, but would fit in the more commonly used 256-bit SIMD registers.

• It's smaller than typical L1D cache sizes (≈64 KiB), so you can fit several tiles in the L1 cache at once.

• It's large enough that most pixels (87.9%) are interior pixels, not border pixels.

• It's large enough that unaligned blitting from one tile to another will still only run into tile boundaries every 16 pixels on average.

• It's small enough to keep wasted space in tiles that run off the edge of a window to a tolerable level. To take a random window size that would fit on this display, a 949×1067 window is 30×34 tiles, or 31×35 tiles if none of its edges are aligned on tile boundaries. That's a total of 1,111,040 pixels, while the window as such contains 1,012,583 pixels, so you have 9% waste. Windows I actually have open on this display have sizes like 800×482, 656×362, and of course 1920×1080. Many of these are divisible by 16; some are even divisible by 32.

• It's the pixel format this video system uses. Most video systems, in fact. And it's easy to work with. And it has alpha. It has the great disadvantage that it's twice as big as the 16-bit and 15-bit formats common in mobile phone displays and video formats.

Tiled images can efficiently support filtering and rescaling operations, which, like alpha-compositing, are fundamental to currently fashionable GUIs.

There are two ways to draw things: either send a tile from the application to the display server, sticking it into a tile-aligned position on some pixmap, or blit some pixels from one pixmap to another. Blitting uses the premultiplied version of the Porter–Duff "over" operator to modify the destination pixmap with the source pixmap, as in Plan9's 8½ or the usual use of the XRENDER extension.

Blitting coordinates can exceed the boundaries of the source pixmap, which is not an error; instead, the pixmap wraps. Destination pixmap coordinates are clipped as you would expect.

Note that this leaves out the "hold out of" and "add" Porter–Duff operations, as well as the possibility of using an alpha channel from another source, which are present in the XRENDER Composite request.

When the application creates a thing, such as a pixmap, a data buffer, or an event handler, it specifies the identifier it will use in the future to identify that thing. This eliminates the round trips that would be needed if the display server were to be responsible for allocating these identifiers, as in X11 and 8½. The application must first request resource allocations to be used by these later creations; the resource allocation may be denied, but if it is granted, the creations are guaranteed to succeed precisely when they do not exceed the allocated quantity.

Duplicate tiles are not coalesced in the memory of the display

server, as they are in XRENDER. This is because, in any case, this could not be visible to applications, for security reasons. Reducing the charge against the application's pixel quota would make applications unstable in a difficult-to-debug way; they would fail to allocate sufficient pixels only when certain other applications were running. Pixmaps are writable, and Wercam is designed to provide guaranteed real-time responsivity, which means that even copy-on-write tile sharing is probably a bad idea, because it means that writing a pixel might vary in speed by orders of magnitude depending on whether that tile was shared. (And this is a side-channel information leak if the timing is observable to the application, which it surely would be.)

Another desirable property of the system is that you should be able to capture and replay a protocol stream, as you can with ttyrec, and in particular that it should be possible to generate a "checkpoint" containing just the protocol messages necessary to get the window into the current state, so that a checkpointed application can be reconnected to a fresh window server, if desired.

Event types:

- VSync
- Timer expiration
- Mouse events
- Keyboard events
- Touch events (start, end, move)
- Screen resize
- Error
- Window close

$1 recognizer diagrams

Kragen Javier Sitaker, 2019-08-11 (updated 2019-10-24) (15 minutes)

I read the 2007 "$1 recognizer" paper the other day. It describes a simple "unistroke recognizer" you can implement in 100 lines of code or so to experiment with pen-based gestures, like PalmPilot Graffiti; they report on a user study on an Itsy (or rather an iPAQ) where it compared reasonably well to a couple of other stroke recognition algorithms popular in the research literature.

It occurred to me that something like the $1 recognizer might be a viable solution to my problem in Dercuano drawings (p. 64), namely, how to illustrate the notes in Dercuano without using either too much of my time or too many bytes.

The $1 recognizer algorithm

For the $1 recognizer, a pen gesture consists of a sequence of (x, y) points; its task is to match this sequence against a collection of "template" gestures and provide a list of gestures that match most closely.

The first point in the sequence is where the pen first touched the tablet, and the others are samples of the pen's position taken over time until it is lifted. These trace out some kind of more or less continuous curve on the display, but the position of each individual point along that curve is just a matter of how far the pen had gotten when the sampling clock fired.

So, the first thing the algorithm does is resample the curve to a uniform point spacing, using a fixed, predetermined number of points that is the same for every gesture. They found that numbers in the range 64–256 worked best. The resampling algorithm they used is fairly naïve, just linearly interpolating between points. This step normalizes the drawing speed and the relative phase of the sampling clock and the drawing operations, so that exactly the same curve traced at different speeds will result in very nearly the same set of points.

People are also not absolutely precise about the angle, position, scale, and aspect ratio of their pen gestures, so the next steps in the algorithm are to try to normalize out these features. The points are rotated around their centroid so that the gesture starting point is at 0 degrees. The X and Y coordinates are then given independent affine transforms to fit them into a predefined 1×1 bounding box, thus eliminating variations of position, scale, and aspect ratio. Finally, this normalized sequence of points is compared against each (normalized) template by calculating the average Euclidean distance between corresponding points — not once, but with a series of different candidate rotations using golden-section search, based on their observation that the rotation-distance function had no local minima on correct matches.

Remarkably, they reported 99% accuracy on a vocabulary of 16 unistroke symbols in their tests, varying very little with stroke speed; the fastest strokes were around half a second, so this amounts to around 8 bits per second of input bandwidth.

The nature of diagrams

Diagrams have a few freehand lines, but are mostly symbolic — aside from textual labels, they mostly consist of many repetitions of a relatively small number of different symbols, at different positions, orientations, and sometimes scales or aspect ratios. So bubble charts contain bubbles, connecting lines, and arrowheads; circuit diagrams contain resistors, capacitors, inductors, grounds, horizontal and vertical wires, rectangles representing chips, junctions, and so on; various kinds of diagrams contain different kinds of boxes. Some of these kinds of symbols can be freely rotated, while others cannot. Other variations between different instances of the same symbol are usually random and need not be stored.

Also, diagrams commonly contain significant topology, quite aside from their possibly significant geometry, and often it's helpful to "snap" certain connection points together, and if a symbol is later moved, to update connected symbols so that they remain connected.

Diagrams in such a form can be quite reasonably represented as a set of references to symbols, each associated with a position, orientation, scale, and possibly aspect ratio. The symbols themselves can possibly be shared between multiple diagrams or embedded in one diagram.

Drawing diagrams with pen gestures

It occurs to me that a pen gesture interface is probably one of the most straightforward ways to create diagrams; it offers the possibility of smoothly scaling from a pure sketching interface to a much more formal interface. The basic idea is that you put a series of strokes on a canvas, and the system (initially devoid of symbol definitions) tries to figure out which strokes belong to the same symbol, using something like the $1 recognizer; when it gets it wrong, you correct it after the fact.

By translating, rotating, and scaling the graphic for each symbol to match the original stroke you input it with, the system redraws your diagram. By remembering all of your strokes, it gradually improves the definition of each symbol, improving the appearance of your diagram, without overly interfering with the sketching process.

Furthermore, you can explicitly edit symbols; for example, in a circuit diagram, you might want your ordinary wire symbols to be only horizontal or vertical, so you might want non-rotatable horizontal and vertical line symbols. A small vocabulary of such non-rotatable symbols (boxes, ellipses, lines, arrowheads) would be adequate for many quick diagramming tasks. You might want to add or move attachment points, add synonym templates, toggle rendering of noise, add additional rendered decorations you don't need to sketch explicitly (including other symbols, as in Recursive curves (p. 1948)), and so on.

If you were to write text in such an interface, it would ideally discover the relatively small number of letters you were using and represent your "diagram" as a list of letters and their positions.

Aside from the above fuzzy spectrum between defining symbols and freehand drawing, you'd probably want the usual kinds of drawing operations: undo, redo, move, rotate, scale, multiple selection, and so on.

Doing it on hand-computer touchscreens

Realizing such a fluent interface with the non-ideal hardware available is a substantial challenge. In practice multitouch cellphone touchscreens are what I have available, and these have relatively crude touchstart and touchend resolution, although they're fairly precise during the touch (and some of them are even fast, like 60 Hz, while others are more like 10 Hz); moreover, they have major finger occlusion problems.

Using the quasimodal multitouch ideas outlined in Interactive calculator (p. 2771), Two-thumb quasimodal multitouch interaction techniques (p. 1765), and Interactive geometry (p. 508), I think this can be overcome: a transparent virtual stylus projects from your finger upon first touch, and a button elsewhere on the display starts the ink running out of it. This allows you to reposition the stylus before you start drawing and stop drawing before you lift your finger, and it greatly reduces the finger-occlusion problem. It also conflicts less with the now-standard one-finger-drag scrolling gesture.

Rounding

For Dercuano, as mentioned in Dercuano drawings (p. 64), I want to round off coordinates to reduce the amount of space they take up in the rendered output, although more bloat can be accepted in the source code. Symbol definitions that have been drawn many times offer a way to do this: the Platonic location of a point whose drawn location is highly variable the various times I drew the symbol can be safely rounded to any convenient precision that doesn't take it too far outside the zone where it's being drawn. Moreover, maybe we should weight that point less heavily when we're matching templates. The user should have the option as to whether to draw that point with per-symbol-instance noise or not.

Other points whose position can be interpolated to reasonable precision (either with a spline or with a line) also do not need to be stored for graphical display.

The problem of coming up with a minimal-length description of a polyline that stays within the usual limits of drawn instances of the symbol is an optimization problem that can be solved using the usual kinds of search approaches for offline optimization problems.

Repetition

If you draw the same symbol several times in a row, perhaps in a linear or circular path with systematic variation in position, angle, or size, it's possible that you would like to continue drawing more of it; since the system is categorizing each stroke as a symbol and redrawing it, a reasonable thing for it to do in such a case is to offer further repetitions, perhaps in a different color, with a slider to accept one or more of those repetitions.

Interpolation

One of the attractive features of resampling all the strokes to a uniform number of points is that it makes it easy to interpolate between them, for example, linearly. In drawing editing, this could be used for several different things:

• By defining a subspace from two or more templates, you can draw a stroke that indicates simultaneously a location in that N-dimensional subspace as well as a location, rotation, scale, skew, and stretch in the

display space. In this case, the final operation from the $1 recognizer of calculating the sum of Euclidean distances to measure the distance from a stroke to a template is replaced by projecting your stroke onto that subspace, then measuring its distance from that projection.

• By using two or three templates to define a subspace of one or two dimensions, you can map an area of the display to a subspace of the many-dimensional stroke space. By dragging around this subspace, you can explore variations within that space to instantiate in your drawing.

• By drawing a path through such a subspace, you can define an *animation*. This may work better with a K-nearest-neighbors kind of interpolation so that you can place more than three templates into a two-dimensional space. This path might be drawn synchronously as a draft animation plays — unlike the stroke used for stroke recognition, its timing *is* important.

• Of course you can also do animations morphing strokes with standard tweening functions such as ease-in/ease-out and linear interpolation.

• When doing repetition, as described in the previous section, if the repetitive strokes map onto one of the one-dimensional subspaces found between existing templates, they could indicate a gradual transition; for example, a series of curved lines gradually becoming more straight could indicate a morphing progression that could be continued to straightness and possibly beyond.

Improving the $1 recognizer

Alternative template matching algorithms

The $1 recognizer mostly tries to normalize rather than using search, but even so, the researchers apparently found it necessary to use search for angular alignment to get competitive results. In some cases, they seem to have used fairly fragile statistics in order to keep the algorithm accessible to mathematically naïve users: the normalization of X and Y coordinates using the bounding box means that noise in the X coordinate of the single leftmost and rightmost points will be distributed across all the points, and the linear-interpolation resampling scheme guarantees that such noise will occur.

The search used for the optimal rotation is the old-fashioned golden-section search algorithm, which has the advantage of being derivative-free, but has quite slow convergence (slower than binary chop!) and also makes rather strong assumptions about the input.

(An alternative way to match against a template that is insensitive to translation, scaling, and rotation, though not aspect ratio, would be least-squares linear regression in $\mathbb{C}$, the complex-number field. I've never done linear regression in $\mathbb{C}$, but I think it's a straightforward extension of linear regression in $\mathbb{R}$.)

One approach to improving the algorithm would be to use more robust statistics. For example, you could use the standard deviation or quantiles to determine the X and Y scaling factors, and you could use an angle that depends in some way on all the points instead of just the first point to get the initial rotation.

Perhaps a simpler approach, though, is to use a generic optimization algorithm. The function to optimize is already present: it's the

average Euclidean distance from the points of the transformed input stroke to the corresponding points of the template stroke. The objective is to find the transformation that minimizes it; the translation in X and Y, rotation around some arbitrary center, and scaling in X and Y, form five continuously variable parameters out of the six in an arbitrary 2-D affine transformation. (The sixth missing parameter is diagonal shear, and I'm not sure it should be omitted.) With modern automatic differentiation, it should be straightforward to use a generic optimization algorithm like Adam or a quasi-Newton method to search this parameter space for the best fit. This would probably result in a much simpler algorithm, and possibly a faster one as well.

This also allows extreme aspect ratios and rotations to be penalized in a smoother fashion than the original $1-recognizer algorithm.

Using a better resampling algorithm would probably help somewhat as well.

Indexing

Another issue with the algorithm is that it doesn't really permit any kind of indexing of the templates; if you are matching each new unistroke against a database of 10,000 64-point templates, it is going to take 640,000 Euclidean-distance computations.

The above hacks don't help much with indexing, but perhaps absurdly-downsampled versions of the gesture and templates could be used to get a linear speedup on to searching a large index of candidate glyphs — like 4 or 8 points. Some kind of interval-arithmetic categorization or something is needed if you're going to get a superlinear speedup — some way to put a lower bound on the best distance to any template in a given group, so that you can avoid iterating over the templates in the group.

Alternatively, you might be able to use linear-algebra techniques to speed up the search; if a smallish number of low-dimensional subspaces nearly contain most of the templates (as determined by PCA on subsets of the templates), you can project a user stroke onto each of those subspaces to find out which are plausible candidates (and which are too far away), then perhaps use a k-d tree on the remaining principal components.

You're pretty much fucked if you want to build an oscilloscope on the AVR's ADC

Kragen Javier Sitaker, 2013-05-17 (3 minutes)

An oscilloscope is a crucial tool for serious circuit hacking. The minimum serious oscilloscope input bandwidth is 20MHz, which is to say, it attenuates 20MHz signal components by 3dB (and probably phase-shifts them), 40MHz signal components by 9dB (and phase-shifts them more), 80MHz signal components by 15dB, and so on; so on a "20MHz" oscilloscope you should still be able to *see* if there's an 100MHz signal, even if you can't measure it very well or see what its shape is.

It would be nice if it were possible to improvise a 20MHz oscilloscope out of inexpensive electronics.

Suppose, though, you're trying to work with an AVR ATMega328. This chip can only run at a max of 20MHz clock, and its ADC can only manage some 77000 conversions per second, and those at 7.5 bits of resolution. It would seem that you're pretty much fucked for seeing anything above 35kHz, which is some 500 times slower than you would like, and 500 times slower than the processor's own clock. That is, you're not going to diagnose much of anything related to an AVR with another AVR, right?

Well, consider this. It's common, although far from universal, for the 1MHz or 3MHz or 10MHz signal you're interested in to repeat many times. So if you can figure out its period, you can sample different points from many waves, then reassemble them into a picture of what one period of the wave looks like. Each sample-and-hold cycle should take place in well under a microsecond, and a faster external sample-and-hold circuit can be built, perhaps with an op-amp on its input to raise the input impedance.

(You probably can't show more than about 1000 samples horizontally on the screen at a time anyway, and you can't do that more than 60 times a second.)

Suppose, though, that it doesn't repeat many times? There's not a whole lot you can do about that if you don't have some way to store the analogue signal until you have a chance to digitize it. All the options I know of (Williams tubes, magnetostrictive delay lines, acoustic delay lines) seem improbable.

As for guessing the period, you can bandlimit your input signal with an analog input filter, sample the waveform at more or less random intervals, and then seek the period that provides the best continuity.

That won't give you a 20MHz oscilloscope but it should give you a 200kHz oscilloscope. One order of magnitude down, two more to go.

The Suburbean: a minimally-mobile dwelling machine with months of autonomy

Kragen Javier Sitaker, 2019-11-24 (updated 2019-12-03) (32 minutes)

Suppose we take seriously Le Corbusier's idea that a house is a "dwelling machine"; what would it look like? I propose the Subur-bean or Suburbean, a sort of immobile or minimally mobile alternative to a submarine, designed to give the humans maximal control over their living situations. Previous notes on this subject include Thermodynamic systems in housing (p. 2804).

I have been careful in this note not to rely on any novel technology that the humans do not have working already; it's all just a straightforward application of known, working processes to the problem.

My Vanagon experience

The moment in my life when my house was the most convenient was the three months in 2006 when I lived in a Volkswagen Vanagon with Beatrice, which we dubbed the Magic Bus. This is sort of counterintuitive: you would think that living in such a tiny space would be very inconvenient, and indeed accessing some kinds of things was somewhat inconvenient, requiring disassembly of the bed for example; but the day-to-day tasks in it were quite convenient. At first we had a terrible time finding things, but after a few days we got into the habit of always putting things away as soon as possible, and it became *easier* to find things than in a larger house, which allows you to get into bad habits.

I say it was a tiny space because it was a little under two meters wide, about four meters long, and about a meter and a half tall; I couldn't stand up inside unless we cranked up the pop-top, which raised the roof to a height of over two meters in the center portion of the vehicle (say, 1.5 meters by 1 meter), also providing access to another bunk up there that was two meters by 1.5 meters long, about 0.8 meters tall. (This two-meter length included the 1-meter hatch from below, which you would close with the second half of the bed if you were going to sleep up there, which we never did.)

Many camper Vanagons had the front "bucket" seats mounted to swivel around toward the back, so that when it was parked, you could turn them to face the center of the interior. Ours was an aftermarket conversion that didn't have that, so the front driving area was nearly partitioned off from the main interior area, making it even smaller than it would be otherwise. So the only seating in the main living area was the vinyl-padded bench seat that the bed folded down into, which could seat about three people.

As a vehicle, the Vanagon was a terrible piece of shit, but as a house it was wonderful. Unfortunately we drove it a lot in kind of an abusive way and thus had to spend a lot of time fixing it.

It had a vinyl awning or canopy that could be rolled out from one side of it to provide a shaded area to set our chairs in.

One thing it couldn't provide internally was sewage facilities; for this we relied on external bathrooms or, occasionally, Gatorade bottles. And of course the external scenery was usually gorgeous and changed often.

So the inner sanctum of the Magic Bus was about 12 cubic meters, much of which was storage cabinets (and the refrigerator, sink, stove, and batteries), and there were another couple of cubic meters of machinery mounted below, including the hundred-kilowatt air-cooled boxer engine, wimpier than many modern motorcycle engines; and the additional bunk was about 2.4 cubic meters more. The canopy occasionally enclosed another 10 cubic meters or so, and another 12 cubic meters or so were needed for access to the back lift gate.

And this was very comfortable and convenient for two people nearly 24 hours a day for several months, with occasional breaks. Without, it should be emphasized, any drugs other than the occasional ibuprofen or beer for one of us, or any particular level of spiritual enlightenment, since of course drugs or enlightenment can make you comfortable under almost any circumstances.

There was something very empowering about having everything you need within arm's reach, and it also had very nice acoustics and a seriously nice sound system.

Cars are comfortable

Back when I had cars, I often enjoyed sitting in them listening to music. Bucket seats in cars are more comfortable than many chairs, though not all, and acoustics inside of cars are generally much better than in houses, offices, or classrooms, largely due to the necessity of damping engine and road noise; although false-ceiling acoustic tiles help significantly, it's very expensive to buy and install the tens or hundreds of square meters of acoustic foam needed to give really good acoustic characteristics to a house, office, or classroom. If the car engine is running and you have an air conditioner, you have tens of kilowatts of power available for heating or cooling the interior, so within a minute or two you can get the temperature to a comfortable level, whatever your preference is.

Small spaces are more controllable, but large spaces are more efficient

When larger spaces go out of control and become unlivable, it happens more slowly than in smaller spaces; and bringing them back under control takes longer.

CO_2

For example, consider CO_2 homeostasis. Mina's bedroom is 36 cubic meters, three times the size of the Vanagon, and in Reducing nighttime bedroom CO_2 levels (p. 478) I calculated that if Mina and I are in there for 12 hours without any airflow, we could raise the CO_2 levels from their default 400 ppm to 14000 ppm; it would take us 20 minutes to double the CO_2 level. Her whole apartment is 14 m × 3 m × 4 m, or 168 m³, so if it were sealed, it would take us 90

minutes to double the CO_2 levels. By contrast, in the Vanagon, it would take only 6 minutes. So if you manage to seal the Vanagon up too tightly, you'll notice within minutes that it's getting uncomfortably stuffy, and you'll be able to tell within a few minutes if improved ventilation measures are successful.

Climate control

Similarly, if the air conditioner in Mina's apartment breaks, it may take a few hours for temperatures to reach the level where you realize this has happened; and if the house has gotten too hot while you were out, it can take half an hour or so for the air conditioner to bring the temperature down to a livable level.

Per-person efficiency

However, larger spaces generally require more energy and more material to remain under control, although as the scale increases, many of the things you might want to control become more efficient to control.

Acoustic conditioning

There is an example above of acoustic tiles: a single-person listening booth of 0.8 m × 0.8 m × 1.5 m has a total surface area of 6.1 m², which works out to 6.1 m² of expensive acoustic materials per person. By contrast, a 5 m × 5 m × 3 m listening room has a total surface area of 110 m² and can hold about 35 people, so it needs only about π m² of expensive acoustic materals per person.

Climate control per person

A more extreme example has to do with climate control.

A minimal private bunk, like the upper level of the Magic Bus, might be about 2 m × 1 m × 0.8 m, with a surface area of 8.8 m². (This is a bit cramped; this body is 0.95 m high, seated; but we can imagine that there's a bit of ceiling height variation to accommodate such things.) If you're trying to maintain an insulated tent of this size at 22° at a time that the outside temperature is 0°, and your insulation is 100 mm of 0.04 W/m/K insulation (typical for insulation materials; see Air conditioning (p. 1665)), you have roughly 10 m² of effective surface area, so you need 88 W and 1 m³ of insulation, both per person.

If, by contrast, you have a sort of barracks with two stories, each 2.4 m tall, containing a 5-m-long corridor whose walls are covered with three levels of 0.9 m × 0.7 m doors leading into such capsules --- sort of like a morgue or mausoleum, but for the living, like a Japanese capsule hotel --- the overall building is 5 m × 5 m × 5 m, not counting the 100 mm of insulation around the outside. Its surface area is about 160 m², so under the same conditions it loses about 1400 W and needs 16 m³ of insulation. But it holds 48 people (assuming the last meter of corridor is used for travel between the levels and whatnot) so this 29 W and 0.33 m³ of insulation per person, one third of the individual tent. In fact, if occupancy is over about 30%, it won't need active heating; it will need cooling.

There is no limit to this kind of increase in efficiency from scale, assuming the whole interior can legitimately be at the same temperature.

Lighting

Another example has to do with lighting. As described in Illuminating yourself with 10 kilolux of LEDs to combat seasonal affective disorder (p. 527), a few years ago you could supply artificial daylight (10 kilolux) to an individual human in a sort of tanning booth or SAD-treatment pod at a cost of about 200 watts and US$150 of LEDs. But obviously illuminating a normal-sized living room with 200 watts will not come close to daylight. (More information about lighting costs is in Illumination cost (p. 1242), including an option that uses many times more energy but uses only US$3.20 of quartz-halogen bulbs; notes on using lightpipes instead are in Can artificially-lit vertical farming compete with greenhouses? (p. 2064), Subterranean glazing (p. 1126), and Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566).)

Indoor pot growers often use portable closets illuminated in such a way to daylight levels, sometimes with low-pressure sodium bulbs; modern high-efficiency LEDs are also apparently considerably better than the ones I mentioned above. (See Can artificially-lit vertical farming compete with greenhouses? (p. 2064).)

The outline of the Suburbean

The Suburbean is a self-contained living space capable of months-long autonomous habitability for three people under a wide variety of external conditions, much like a nuclear submarine, but with the objective of bringing habitability to urban rather than marine environments. It is built into a standard-width refrigerated "high-cube" TEU shipping container, 6.1 m × 2.44 m × 2.90 m, so that it can be easily loaded onto a truck, train, or ship for moving, although it's better not to do this while people are inside of it. The refrigeration system is used to maintain the interior at a comfortable temperature chosen by the inhabitants, rather than a temperature suitable for preserving food. The Suburbean has very limited autonomous mobility --- it's more of an autoimmobile than an automobile.

Unlike a nuclear submarine, the Suburbean does need access to external air, at least to exhaust its waste products into and usually also to burn its diesel fuel with. When no external power is available, its refrigeration unit and other internal energy consumption is powered by two 1-kW onboard diesel engines, providing some 2 kW of mechanical or electrical power.

The whole Suburbean weighs some 20 tonnes, well short of the 30-tonne limit for a loaded TEU. This means that when lifting itself vertically with its six built-in winches with its 2-kW-output generator engine running at 100% duty cycle, it can rise only about 10 mm/s, although when running off batteries or external power, it can manage about 130 mm/s, limited only by the 25 kW of the winches. In horizontal or downward movement, when it need only overcome friction, whether suspended in the air by its winch cables or running on wheels, it may be able to move several meters per second over limited distances under its own power. This is what I mean by "very limited autonomous mobility".

How realistic is this?

Amazon lists a 6 horsepower (=4500 W) winch for US$320. eBay

lists a bunch of 1kW handheld portable generators for around US$200 to US$300, but they all run on gasoline; diesel generators seem to start around US$1200 and 7kW. A plain TEU-sized shipping container seems to cost around US$2000, but refrigerated ones seem to cost around US$6000, or up to twice that new.

Thermal homeostasis

Like some refrigerated shipping containers, the interior of the Suburbean is superinsulated with vacuum insulated panels (< 8 mW/m/K) to reduce the power necessary for refrigeration; it uses 50 mm of them in two staggered layers, reducing the interior dimensions by 100 mm in addition to the 200 mm or so consumed by corrugation, to about 5.7 m × 2.04 m × 2.5 m (32.3 m³, of which 20 m³ is air). Over the effective surface area of 70 m² or so, this works out to about 11.2 W/K, so over the 0° to 44° temperature range, only a maximum of 250 W of forced heat flow is needed at steady state, or about 85 W electric to power the heat pump with its CoP of 3, which works out to about 210 W of diesel fuel. If three people are actually present inside, this adds about 300 W of forced heat flow when the outside temperature is too hot rather than too cold, increasing these numbers to 550 W of heat flow, 180 W electric, and 460 W fuel.

The usual wooden flooring of a shipping container is not present, since the vacuum insulation layer includes the floor as well, requiring a rigid protective support surface to prevent damage to it.

The air conditioner's CoP of 3 is achieved by liquid-cooling its condenser coils with antifreeze that is circulated through pipes that heat the metal outer walls of its entire 35-m² lateral area, providing a large surface for radiative and convective cooling. When the air conditioner is operated in heating mode as a heat pump from outside to inside, this operates as liquid-heating the evaporator coils with the same antifreeze circulated through the same pipes, where they absorb heat from the environment.

When the Suburbean is being heated rather than cooled, the diesel generators' exhaust is routed through a heat exchanger to transfer the heat they produce to the interior as well through a closed-circuit heat-transfer fluid, the same way that car heating systems typically work. This reduces the energy demand of the heat pump, possibly to zero.

What existing reefers are like

The Container Handbuch says that typical power consumption for cooling a ThermoKing Smart Reefer TEU is around 3.6 kW, which is about 43 times what I've calculated above; EPRI's "Electric Refrigerated Container Racks: Technical Analysis" says that diesel reefers have 2-liter engines with 30 to 40 horsepower, or in modern units, 20 to 30 kW. Container Handbuch section 3.1.1.2, "Container design and types, Part 2", suggests perhaps unintentionally that typical mechanically powered refrigerated containers are *not* insulated, and that insulated containers typically use 50–100 mm of polyurethane foam, reducing heat conductance to 0.4 W/m²/K (type code H5) or 0.7 W/m²/K (type code H6). Instead, the 50-mm thickness of VIPs described above would have heat conductance of some 0.16 W/m²/K. This explains a discrepancy of about 3.4, leaving another factor of 13 or so from my calculation above, to be explained by people using uninsulated containers (!?) and/or the much lower temperatures.

It seems that self-powered refrigeration units are (or recently were) dominant in land transport, but plug-in electric refrigeration units (three-phase 400VAC) instead are dominant for sea transport. Carrier and ThermoKing make all the refrigerated container machinery for sea transport.

I found a "Technical Specification for Refrigerated Container Model No. SS1WN1" of half a TEU from Shanghai Reeferco. It claims they use a Carrier refrigeration unit and their insulation is 63–80 mm in thickness everywhere except on the floor where it ranges up to 135, and that the heat transfer rate U_{max} is 20 W/K at 20°C. Its surface area is about 43 m² so that works out to 0.47 W/m²/K, which is in the range of the Container Handbuch numbers above. Yet the Carrier 69NT40-541-300 it ships with can do 3.2 to 10 kilowatts of cooling with inside-outside temperature differences of 67° (3.2 kW) to 36° (10 kW). You would think that with a temperature difference of only 36° you would only need 720 W, not 10 kW. Maybe it's shipped with this huge air conditioner for the initial pulldown?

Energy storage and solar panels

The Suburbean carries half a tonne of diesel fuel, which weighs 0.832 kg/ℓ and provides 43.1 MJ/kg, so this occupies 0.6 m³ of the 32.3 m³ available and stores 21.6 GJ. At the outdoor high-temperature extreme of 44°, when it needs to use 460 W of diesel fuel to maintain thermal homeostasis, this provides almost 18 months of autonomous operation before needing to refuel, as long as it has access to oxygen from air and somewhere to release exhaust.

The Suburbean also includes half a tonne of lithium-ion batteries, which at some 500 kJ/kg amounts to 500 MJ, about 2% of the energy content of its diesel fuel tank. Still, at the 180 W electric needed to maintain thermal homeostasis at extreme temperatures, this amounts to a bit over a month of autonomy without access to air; for example, during a flood or while buried under rubble, although assumptions about external temperature and insulation may be called into question in such circumstances. Lithium-ion batteries have a self-discharge rate on the order of 2% per month, which is insignificant in this context.

The batteries are rated for a discharge rate of 5C (12 minutes), which is lower than the 15C discharge rate (4 minutes) used for quadcopters and the like, but higher than the lowest-end batteries. At a conservative discharge rate of 3C (20 minutes), the Suburbean can muster a peak output power of some 400 kW, a bit over 500 horsepower; for example, for arc welding.

To recharge the batteries without consuming diesel fuel when sunlight is available, 6 m² of the 15-m² roof of the Suburbean contains 22%-efficient SunPower Maxeon Gen II monocrystalline solar panels under an openable protective cover. This provides nominally 1300 W peak of solar power, providing 260 W as a 24/7 average, at a typical 20% capacity factor. Moreover, the back of the cover is mirrored, and it is positionable under motor control, permitting higher capacity factors than are possible with statically positioned panels, and potentially even providing over 1300 W at times.

Atmospheric life support

See also House scrubber (p. 248) and Notes on a possible household air filter (p. 1961).

Of course, when air is available from the outside, the Suburbean will use it, after appropriate filtration and temperature control. But above, it is explained that the batteries can provide a month's worth of climate control without air for the diesel engine. So, what about air for the humans inside in such a situation?

Oxygen

Remaining human-habitable without access to air requires very roughly 600 g of oxygen per person per day, which is the amount in about 2 m³ of air (2.4 kg) or 0.4 m³ of oxygen, at 1.429 g/ℓ. You'd think you could generate oxygen on demand in such situations through electrolysis of water, and although that does work, it turns out to be very expensive, about 250 MJ/kg O_2 (see Why you can't run a diesel engine on water and diesel fuel with electrolysis (p. 345)), which at 600 g/day/human works out to about 1700 W per person, a large energy drain which also adds to the cooling load when the situation is hot. The 20 m³ of air contains enough oxygen to last only 10 person-days, or 3 days with 3 people, and storing compressed air at ordinary pressures such as 15 atmospheres (1.5 MPa) would only give you 15 normal m³ of air per m³ of compressed-air storage.

Instead, the Suburbean stores oxygen as relatively nontoxic sodium chlorate, $NaClO_3$. Aircraft decompression masks are supplied from sodium-chlorate chemical oxygen generators; a 63-mm-diameter, 223-mm-long canister (0.0007 m³) generates enough oxygen for two humans for about 15 minutes, which suggests you'd need 1 m³ per person per month, which is closer but still too bulky. A simpler chemistry is used in chlorate candles, which are mostly sodium chlorate (2.5 g/cc) but with iron powder to produce heat, and provide 6.5 person-hours of oxygen per kg, which works out to 110 kg per person-month or 330 kg per 3 person-months.

However, the Suburbean's sodium chlorate is not mixed with a fuel in this way, so there is no risk of an oxygen-candle explosion. Instead, heating the sodium chlorate to the requisite 300° is done with an electrical heating element. This produces NaCl and 48 daltons of oxygen per 106.4 daltons of $NaClO_3$, so the 55 kg of oxygen required for three person-months of autonomy require only some 122 kg of $NaClO_3$, occuping 49 ℓ.

(I think it should be possible to run the diesel engines from stored sodium chlorate and diesel fuel, but the amount of sodium chlorate required is rather large, and the reduction to NaCl consumes some of the energy; 106.4 daltons of $NaClO_3$ yield 48 daltons of oxygen, which can oxidize only 14 daltons of diesel, so you need 7.6 kg of sodium chlorate for every kg of diesel, so you only get 5 MJ/kg from the total mixture (minus whatever the endothermic chlorate decomposition energy is), and only 1.5 to 2 MJ/kg of exergy. Still, that's three or four times the exergy density of the batteries, and it might provide a viable approach to multi-month underwater autonomy. See Underwater energy autonomy (p. 1662) for more.)

The Suburbean generates its own sodium chlorate, when water and energy are abundant, from electrolysis of an aqueous solution of NaCl, with some HCl to lower the pH, at 90°. Because this reaction also produces some hydrogen, the reaction chamber is outside the

interior space, so that if there is a hydrogen leak it dissipates into the environment rather than making the internal atmosphere explosive. Normally the hydrogen is fed into the diesel engines through a secondary injector to burn it, or burned in external air with a spark igniter if the diesel engines remain off for too long. If there is no external air, the hydrogen is just released into the environment.

CO_2

It isn't enough just to add oxygen to the atmosphere, though; CO_2 must also be removed. I reviewed the possibilities in House scrubber (p. 248); the Suburbean's CO_2 scrubber uses six small beds of high-surface-area caustic magnesium oxide to absorb the CO_2, which it regenerates by heating them to 450° by recirculating a stream of CO_2 through the bed and through a heating element. One person-hour of CO_2 is 25 grams, if the figures in Reducing nighttime bedroom CO_2 levels (p. 478) are correct; MgO weighs 40.3 daltons; $MgCO_3$ weighs 84.3 daltons; CO_2 weighs 44 daltons, which is the difference. So each bed is sized to be able to hold 75 g of CO_2 during its active hour, which makes the conservatively 150 g of $MgCO_3$ (2.96 g/cc, so 50 cc) which becomes 71.7 g of MgO after heating. Excess CO_2 is vented to the environment.

(Hmm, I'm not sure this is actually the right solution; I can't find any notes about anyone using MgO as a CO_2 scrubber, and Wikipedia's CO_2 scrubber article says the Space Shuttle's metal-oxide-adsorbent scrubber was regenerated with 10 hours of 200° air through the "Metox Canister", which it turns out actually used *silver* oxide, perhaps in a thin layer on the surface of some kind of inert support material that comes with a high surface area. More recent design proposals use solid amine adsorbents and Fe_2O_3 but I don't know if they've flown or if they're suitable for the Suburbean.)

As a backup in case all of this fails, the Suburbean is also equipped with lithium-hydroxide curtains which provide a few days of autonomy before needing to get access to air.

Other contaminants

As mentioned in House scrubber (p. 248), there are other contaminants that must also be removed, and a variety of means to remove them.

Subdivision into compartments

The reason there are six separate CO_2 scrubbers is that the Suburbean is divided into two compartments with a hermetically-sealed bulkhead between them, connected through an airlock; experience with the ISS has shown the importance of being able to isolate the effects of accidents such as fires and refrigerant leaks to only part of the environment.

If the air quality in one compartment is becoming bad because of a broken or inadequate pollution control system rather than because of a polluting accident, the inhabitants can open the airlock to allow air to flow.

Doors and connectivity

Of course, the Suburbean has the usual big doors that are the entire rear end of the shipping container. But it has some other features as well.

The Suburbean is stackable; each of its two independent compartments has a hermetically-sealed hatch in one corner of the top surface and the bottom surface, making it possible to connecting multiple Suburbeans into a single larger dwelling-machine by stacking them on top of one another and twistlocking them together, then opening the hatches and sealing them together. ISO 1496(1) requires that TEUs be tested for stacking nine containers high, but that's only safe when the doors are closed! The Suburbean has extra bracing just inside those rear doors, part of which is the hatch shaft itself, so that it can safely support that amount of weight even with the doors open.

This allows you to construct an ad-hoc autonomous minimally-mobile hermetically-sealed apartment building with space for up to 26 people to live comfortably, assuming you use the rear compartment of the bottom Suburbean as a common entry and exit.

When no other Suburbean is atop yours, these hatches can also serve as entry and exit, if you either have a way to get on and off the roof, or space underneath. Unlike the rear doors, the hatches cannot be locked by people outside, only by the Suburbean's computer systems, ensuring that escape is possible in an emergency (even if the rear compartment is on fire) and preventing outsiders from locking the doors as a way to apply coercion to the inhabitants.

The shaft connecting the top and bottom hatches is also hermetically sealed from the compartment it runs through, with a door providing access to the compartment. A positive-displacement ventilation pump runs only when air-quality sensors report that the air in both the shaft and the compartment are not contaminated. This means that air-contamination incidents in compartments do not discourage you from traveling vertically past those compartments in a stack of three or more Suburbeans. It also makes it possible for the inhabitants of a compartment to lock it against access from their neighbors, while still allowing those neighbors to pass through.

If there are stable high points to attach the winches to, no separate crane is needed to stack the Suburbeans; once some winches are attached, the upper Suburbeans can move themselves into position. The winch cables can also guy the stack of Suburbeans to points on the ground or elsewhere to reduce the risk of falling in wind. (See Bootstrapping rope bridges and other tensile structures with UHMWPE-bearing drones (p. 2950) for one way to bootstrap the winch rope attachment.)

If your Suburbean is hanging from its winches out of reach above you, you can command it to descend to within reach and open a bottom hatch so that you can enter; then, once you have entered, you may want to command it to ascend again.

Both of the hatch shafts are on the right side of the Suburbean if you're facing its nose; this means that if you're facing the rear door, the rear hatch shaft is on your left. This means that if one Suburbean is yawed 90° on top of another, one twistlock point and adjacent hatch shaft can dock, but it's the *rear* hatch of one connecting to the *front* hatch of the other. With some additional support beyond that provided by the twistlock points, this design permits the assembly of much larger and more stable ad-hoc hermetically-sealed interconnected Suburbean Voltrons.

Flotation

Because the Suburbean is hermetically sealed and has a volume of 43 cubic meters, but a gross weight of only 20 tonnes, it floats if it falls into water as long as it doesn't leak, like other shipping containers.

The sensation of space: it's done with lights, mirrors, fans, and acoustic foam

Humans who feel that they're in a small, cramped space for a long period of time will be unhappy. So within the Suburbean there are areas with "infinity mirror" illusion ceilings and parallel mirrors on the walls to create the illusion of a large horizontal space. Extra acoustic foam on the other walls and behind holes in the mirrors provides the acoustic sensation of being outdoors; fans silenced by baffles followed by laminar ductwork provide a breeze.

Garbage and sewage

These are potentially a big issue, as they are in space travel and nuclear submarines.

Stereographic map app

Kragen Javier Sitaker, 2018-12-02 (2 minutes)

Maybe a stereographic projection, or Ptolemaic planisphere, would be a fun way to display a local map on your cellphone. You'd still have different possible zoom levels, but all of them would show the whole world on your screen, except for an arbitrarily small area just around the point of projection. You could move the point of projection as you moved around.

Planisphere projection has many interesting properties. It's conformal, which is to say that it's locally planar — it doesn't distort the shapes of small objects — but it's not isometric or equal-area, which is exactly what would seem to offer the possibility of making a potentially useful local map that includes the entire planet.

There's the question of how to orient things. You can try to orient the map with north at the top, or you can try to orient it according to the cellphone's compass, but either way you have a contradiction. Suppose you orient it with north at the top. In the center of the screen you have the antipodes, and around it the rest of the world, and you are positioned at the point at infinity. Suppose you're in a cul-de-sac with a street leading out to the north. Does this street appear at the top of the screen or the bottom?

If it appears at the top of the screen, the more northerly points on the street are further down the street. The least northerly point, the end of the street where you are, is at infinity. More and more northerly points are further down the screen toward the antipodes, until finally the street ends. So in fact north is down.

Consider, though, a parallel street far enough to the west that its end appears on your map, which also ends in a cul-de-sac just to the west of you, and proceeds north from there. On *this* street, more northerly points are further up the screen — until they start to curve in towards the center of the screen, and then start to curve back down, and north is down again.

Interval filters

Kragen Javier Sitaker, 2015-09-17 (2 minutes)

What if we consider the particle-filtering problem from the perspective of interval arithmetic? Instead of approximating a multidimensional prior probability distribution using an exponential number of particles, we could approximate it with an exponential number of irregular partitions of the multidimensional space, and then subdivide the high-probability partitions and fuse the low-probability ones in order to give each partition equal probability, then do a Bayesian update. It seems like this could work and might be more broadly applicable (and rigorously justifiable) than the Monte-Carlo approach.

Like raw particle filters, this won't work well on high-dimensionality spaces, but perhaps it can, like them, be extended to work on such spaces.

Interval arithmetic can be used to efficiently calculate that the posterior probability of being inside a large region of the space is negligible.

Often, divide-and-conquer algorithms are more efficient when the division is by three instead of by two — dual-partition Quicksort being one notable example — and I suspect that might be the case here too. If combined with random rather than optimal positioning of the partition, in particular, it would help with the case where we really do kind of need particles — where there is a tiny local maximum probability lost in a large, low-probability partition. Eventually, random choice of three-way partitioning will happen to snag the tiny local maximum between its pincers, and have a chance to track it down further.

You could store for each partition not only the total probability (or, equivalently, average probability density) of the partition, but also the average slope or derivative of the probability density inside of it. This would dramatically reduce the error in the estimate of the PDF that all the intervals comprise together.

An algebra of textures for interactive composition

Kragen Javier Sitaker, 2019-05-08 (4 minutes)

I was thinking about the problem of composing graphical textures in a user interface, and it occurred to me that a neat formulation was possible using just functions of the form $\mathbb{R}^2 \to \mathbb{R}^2$, which I will call "textures". The whole system functions by composing textures out of more primitive textures.

(Perhaps I should recast this as functions of the form $\mathbb{C} \to \mathbb{C}$? That would conveniently provide rotation and a wide variety of conformal mappings, and it would substantially reduce the number of functions needed, though it would require the redefinition of ×, ÷, and ** (and compensating additions of their elementwise variants), and probably I should be renamed Z.)

Visualization on the screen

The idea is that the inputs to a texture are coordinates representing the position on the screen, and the outputs represent in some sense a color. To fully specify an RGBA color, you need two textures (I suggest using HSVA with one texture for HS and the other for VA, or YUVA with a YA/UV split), but you can quite reasonably visualize individual textures by using a constant for the other texture.

Atomic textures

The most basic textures you start with are numeric constants, I, and T. Constants such as 0.3 are interpreted as having that value everywhere for both components: λ(x, y) → (0.3, 0.3). I, or meshgrid, is the identity function: λ(x, y) → (x, y). T, or transpose, is almost the same, but returns the coordinates in reverse order: λ(x, y) → (y, x).

The standard functions abs, ln, exp, sin, cos, tan, asin, acos, and atan are also available as atomic textures, and they also apply elementwise; e.g., sin(x, y) = (sin x, sin y).

You could imagine loading in (channels of) image files as additional atomic textures.

Binary or combining operations

Two special shunting operations are provided: composition, written backwards with tightest precedence with ".", and joining, written with loosest precedence with a comma, ",". Composition A.B is just λ(x, y) → B(A(x, y)), while joining combines values from the different functions; if A(x, y) = (ax, ay) and B(x, y) = (bx, by), then (A, B)(x, y) = (ax, by). The opposite combination can be achieved by composition with the aforementioned T texture, as (A.T, B.T) = (ay, bx). (For convenience, we could define textures X as (I, I.T) and Y as (I.T, I), so you can write A.X to get just the X output of A on both channels.)

A fairly standard list of binary arithmetic operations apply pointwise: +, -, ×, ÷, //, %, &, |, &^, ^, **. That is, given that a(x, y) = (xa, ya) and b(x, y) = (xb, yb), (a ** b)(x, y) = (xa**xb,

ya**yb), (a & b)(x, y) = (xa & xb, ya & yb), etc. In this way you can compute, for example, 3 + 4 * 5 * I % 1. % is the modulo operation, // is integer division as in Python, ** is exponentiation, ^ is XOR as in C, and &^ is the and-not, set-subtraction, or abjunction operation, as in Golang. Binary operations are applied to fractions as binary fractions.

Comparison operations are also provided: ==, >=, <=, >, <, != all apply pointwise to textures and produce answers of 0 or 1, representing, respectively, true or false, as in C. So, for example, (3, 4) < (3, 5) produces (0, 1).

Finally, four-dimensional simplex noise is provided with the # binary operator.

Interactive user interface

For playing with these textures, it occurred to me that you could probably usefully compile them into GLSL shaders for real-time display, and use an RPN-calculator approach like rpn-edit or autodiffgraph to provide instant feedback on each new atomic texture as it's created; the multitouch approach described in Interactive calculator (p. 2771) might be more usable on hand computers.

Additional atomic textures t, the current time, and M, the mouse coordinates, would facilitate simple interactive animations. Multitouch puppetry could be handled in a variety of ways, the simplest of which is something like variables t0, t1, t2, t3, t4 for the first five touches.

Some notes on the landscape of linear optimization software and applications

Kragen Javier Sitaker, 2019-08-21 (updated 2019-08-25) (35 minutes)

I started auditing an "operations research" class at the UBA this quatrimester. It's largely focused on linear programming, which is to say, optimizing linear functions subject to linear constraints, but the class also covers some other non-linear-programming topics.

I'm particularly interested in optimization algorithms, as I've said a few times before, because they potentially raise the level of abstraction in programming — rather than specifying how to compute something, you just specify how to recognize if something is the thing you wanted to compute, and then let some kind of generic solver figure out how to solve the problem. That's what earned them such a prominent place in More thoughts on powerful primitives for simplified computer systems architecture (p. 1895). And it turns out that linear-optimization solvers, as they're called, are the most developed family of optimization algorithms out there.

Other useful overviews of the space can be found in the NEOS Server Optimization Guide and the GLPK Wikibook.

I'm paying as little attention as possible to proprietary software here, but unavoidably need to mention it periodically simply because it has played such a central role in this space.

Overview of linear programming

Linear programming is a particularly popular subset of mathematical optimization because there are well-known algorithms for solving it that scale to fairly large numbers of decision variables (the variables the optimization algorithm is allowed to decide on a value for to reach the optimum), and it provides a useful approximation for many economically important problems. It's so popular that sometimes it overshadows the rest of mathematical optimization — many books purportedly about mathematical optimization consist almost entirely of material on linear optimization, with perhaps a short section at the end on nonlinear optimization.

I've tended to be a bit prejudiced against linear optimization because the real world is never perfectly linear and because I felt that linear constraints weren't very expressive. But, now that I'm taking this class, I'm starting to appreciate the astounding expressiveness of linear programming — especially "mixed integer" linear programming ("MIP" or occasionally "MILP"), an extension of pure linear programming in which some of your decision variables are constrained to integer values, which is more expressive but enormously more difficult to solve.

As the lp_solve documentation summarizes it:

The linear programming (LP) problem can be formulated as: Solve $\mathbf{A}\cdot x >= V_1$, with $V_2\cdot x$ maximal. $\mathbf{A}$ is a matrix, x is a vector of (nonnegative) variables, V_1 is a vector called the right hand side, and V_2 is a vector specifying the objective

function.

An integer linear programming (ILP) problem is an LP with the constraint that all the variables are integers. In a mixed integer linear programming (MILP) problem, some of the variables are integer and others are real.

(Some formulations additionally specify that all x_i are nonnegative, which turns out to matter very little.)

There are several algorithms known for solving linear optimization problems, of which the oldest and most-widely-used is George Dantzig's "simplex algorithm", despite its worst-case exponential complexity. Many newer solvers instead use the "interior-point method", which has worst-case polynomial complexity for continuous linear optimization. (Most mature solvers support both.) However, for mixed integer linear programming, they all must fall back on exponential-time search procedures, usually "branch-and-cut" procedures (also known as "branch-and-bound").

The software landscape

Typically, as an end-user, you solve linear optimization problems by writing your problem in an "algebraic modeling language" such as GNU MathProg or "GMPL" (a dialect of a popular proprietary modeling language called "AMPL") or ZIMPL; the model translator compiles your model (including data files, which it might pull from a database) into a standard format (such as "MPS", "LP", or `.nl` — see below), generally expanding it considerably, and submits it to a "solver".

Unfortunately, the most popular model translators and solvers are all proprietary; proprietary CPLEX, now owned by IBM, is the most popular solver, with proprietary Gurobi and proprietary SCIP second and third, and proprietary AMPL is the most popular model translator; there is an excellent AMPL book by Brian Kernighan (et al., but "Kernighan" is a sufficient recommendation) which also serves as an introduction to linear programming. Both CPLEX and SCIP are gratis for institutional academic use (we are using SCIP in the class) but not to independent researchers; I don't know about AMPL. So we can forget about these.

On the NEOS server, anyone can use most of this software in batch mode for free, for optimization jobs of up to 16 megabytes of input, 3 GB of RAM, and 8 hours of run time, thanks to the Wisconsin Institute for Discovery at UW Madison; the NEOS server has AMPL, ZIMPL, CPLEX, SCIP, CLP, CBC, Gurobi, CBC, and SYMPHONY, but not including GLPK or lp_solve, perhaps because it doesn't consider them "state of the art".

XXX I really need a diagram!

Modeler–solver interfaces (MPS, Osi, `.nl`, and LP)

Often the model translator talks to the solver through a file in some standardized file format; MPS is the most popular such format, a punched-card-based format originally designed for IBM's Mathematical Programming System/360. LP, sometimes called "CPLEX LP" because of its origins in CPLEX, is a more-readable but less-widely-supported format; and AMPL, a popular but proprietary algebraic modeling language (compatible with GLPK's MathProg), defined its own `.nl` format, mentioned earlier, that has been interfaced to a wide variety of solvers.

Linear-programming solvers have been around considerably longer

than algebraic modeling languages, so both MPS and LP are designed for humans to write, but MPS is designed badly.

(There are actually two different, incompatible MPS formats: the original fixed-field MPS format from the 1960s, and a slightly less bletcherous "free-form" 1980s version.)

Here's a small LP file that GLPK and CBC are able to accept and solve (the optimum is z = 1, y = 0.33...).

```
Maximize
 x: + 2 y + 3 z
Subject To
 a: + 2 z + 3 y <= 3
Bounds
 0 <= y <= 4
 0 <= z <= 1
End
```

You can save that in `foo.lp` and solve it with GLPK by running `glpsol --lp foo.lp -o foo.out`. You can transate it to MPS with `glpsol --check --lp foo.lp --wmps foo.mps`.

Most solvers, including GLPK's, also have bindings that allow you to call them from your program without preparing an input file for them to parse; and the COIN-OR project has written a standard API called "Osi" for doing this with many different solvers.

GLPK (modeling language (GMPL/MathProg) and solver)

GLPK, a C library, is the thousand-pound gorilla of linear optimization systems; Octave is built with it, and there are bindings to it in Java, Python, and R. The GLPK package includes the model translator for the popular algebraic modeling language GNU MathProg (*aka* GMPL), and also solvers for the revised simplex method, the primal-dual interior point method, and the branch-and-bound method.

MathProg is a subset of the AMPL language mentioned above, including nearly all the facilities of AMPL for defining optimization problems, but without statements like `include`, `model`, and `data`.

It supports MPS and LP format files for both input and output, and can even translate between them, as well as generating them with the MathProg model translator.

GLPK was originally released in 2000, but has been under active development ever since; there is a Wikibook about it, linked above in the introduction.

Here's a MathProg version of the example LP file above, with additional directives to solve it and display the results:

```
var y >= 0, <= 4;
var z >= 0, <= 1;
maximize x: 2*y + 3*z;
subject to a: 2*z <= 3 - 3*y;
solve;
display x, y, z;
end;
```

If you save this as `min.mod` you can run `glpsol -m min.mod` to get the

solution, or `glpsol -m min.mod --wlp min.lp` to get a slightly expanded version of the LP file above. Pitfall: if it's gzipped, like most of the examples that come with GLPK, `glpsol` will uncompress it to run it, but at least the version I have dies with a spurious "read error".

This example is somewhat freer-form than the LP file (there's an inequality with decision variables on both sides, for example), but to really show the advantages of an algebraic modeling language like MathProg, we need a bigger model. For example, here's an integer-linear-programming sudoku solver I wrote this afternoon:

```
param N default 9; set S := 1..N; param SW 'square width' default 3;
set G 'givens' default {};
param givenrow {G}; param givencol {G}; param givenchoice {G};

var X { S, S, S } binary;

maximize pleasure: 69;

rows {col in S, choice in S}: sum {row in S} X[row, col, choice] = 1;
mutex {row in S, col in S}: sum {choice in S} X[row, col, choice] = 1;
cols {row in S, choice in S}: sum {col in S} X[row, col, choice] = 1;
squares {bigrow in 0..SW-1, bigcol in 0..SW-1, choice in S}:
    sum {row in 1..SW, col in 1..SW}
        X[bigrow * SW + row, bigcol * 3 + col, choice] = 1;
givens {j in G}: X[givenrow[j], givencol[j], givenchoice[j]] = 1;
```

`glpsol --check --wlp sudoku.lp -m sudoku.mod` translates this 12-line MathProg model into a CPLEX LP file of 2000+ lines, beginning as follows:

```
\* Problem: sudoku *\

Maximize
 pleasure: 0 X(1,1,1)
\* constant term = 69 *\

Subject To
 rows(1,1): + X(1,1,1) + X(2,1,1) + X(3,1,1) + X(4,1,1) + X(5,1,1)
 + X(6,1,1) + X(7,1,1) + X(8,1,1) + X(9,1,1) = 1
 rows(1,2): + X(1,1,2) + X(2,1,2) + X(3,1,2) + X(4,1,2) + X(5,1,2)
 + X(6,1,2) + X(7,1,2) + X(8,1,2) + X(9,1,2) = 1
 rows(1,3): + X(1,1,3) + X(2,1,3) + X(3,1,3) + X(4,1,3) + X(5,1,3)
 + X(6,1,3) + X(7,1,3) + X(8,1,3) + X(9,1,3) = 1
```

There's a SciTe-based IDE for GLPK called Gusek I haven't tried. I've often had a lot of trouble debugging my MathProg models, and I wonder if it might help.

ZIMPL (modeling language)

ZIMPL, the Zuse Institute Mathematical Programming Language, is a modeling language from the same academic research institute, the Zuse Institute Berlin, that wrote the solver SCIP, but ZIMPL is free software, while SCIP is not. It's mostly compatible with GNU MathProg. It started out as Thorsten Koch's Ph.D. thesis in 2004, ZIB-Report 04-58, "Rapid Mathematical Programming".

("Mathematical programming" is a synonym for "mathematical optimization".)

The ZIMPL language appears to be more or less at the same level of abstraction as MathProg, but with arguably nicer syntax. So for example in ZIMPL you might say

```
minimize cost: 12 * x1
    + sum <a> in A : u[a] * y[a];
subto oneness: sum <a> in A : u[a] == 1;
subto nonnegative: forall <a> in A : y[a] >= 0;
```

while in AMPL/MathProg you would say

```
minimize cost: 12 * x1
    + sum {a in A} u[a] * y[a];
subject to Oneness: sum {a in A} u[a] = 1;
subject to Nonnegative {a in A}: y[a] >= 0;
```

It can produce MPS and LP files, as well as something called "Polynomial IP". Beware, it generates the name for its output file from the name of the input file, and so it will overwrite any existing file of the corresponding name.

Here's a translation of the tiny model used as examples earlier into ZIMPL:

```
var y >= 0;
var z >= 0;
maximize x: 2*y + 3*z;
subto a: 2*z <= 3 - 3*y;
subto ym: y <= 4;
subto zm: z <= 1;
```

If saved as `foo.zpl`, you can convert it to LP format with `zimpl foo.zpl`, writing the output to `foo.lp`.

Since ZIMPL and MathProg are so similar in their capabilities, but MathProg is bundled with the popular GLPK solver, I don't know what the advantage of using ZIMPL would be — except that the proprietary solver SCIP has ZIMPL built in, and so it's more convenient to use SCIP with ZIMPL than with MathProg.

The biggest difference I've found so far between ZIMPL and MathProg, actually, is that MathProg lets you specify things to do after the solution is found, at least when you're using the GLPK solver. This way you can present the solution in a more readable form. My Sudoku solver above, for example, has half a page of code tagged onto the end to display an ASCII-art Sudoku board. To do the same thing with SCIP and ZIMPL, I ended up writing a Python script to match regexps against the SCIP output.

CMPL (modeling language)

CMPL is another algebraic modeling language from the COIN-OR project, GPLv3 licensed, bundled with an IDE called Coliop; it can use the CBC or GLPK solvers, as well as proprietary solvers. It also includes Java and Python interfaces, presumably as a sort of embedded DSL. The project mailing list seems consistently very low traffic since 2011.

I haven't tried it yet, although it looks like it might address some of my annoyances.

MiniZinc (modeling language)

MiniZinc is a constraint modeling language that is not limited to linear constraints; it can use CBC as a solver, as well as MinisatID, proprietary SCIP, and over a dozen other solvers. I haven't tried it yet.

libisl (ILP solver)

The documentation says:

> isl is a library for manipulating sets and relations of integer points bounded by linear constraints. Supported operations on sets include intersection, union, set difference, emptiness check, convex hull, (integer) affine hull, integer projection, and computing the lexicographic minimum using parametric integer programming. It also includes an ILP solver based on generalized basis reduction.

I have it on my laptop because GCC depends on it, apparently for a newish loop optimization framework internal to GCC called Graphite. It sounds scarily powerful. Unlike the others, it's specifically intended for *integer* optimization, with no support for continuous-domain optimization.

Needless to say, it doesn't interoperate with the others.

COIN CLP/CBC/SYMPHONY (solvers)

The COIN project is an Apache project for making operations-research results reproducible by basing them on open-source software. It includes the solvers CLP, CBC, and SYMPHONY; CBC and SYMPHONY require an underlying linear-programming solver like CLP; it also defined an API called "Osi", the Open Solver Interface, as an alternative to the file-format interfaces described earlier. I haven't yet figured out how to use SYMPHONY yet.

These three solvers are the only free solvers I've found on the NEOS server.

I've been able to solve minimization MPS problems with CLP using `clp foo.mps` but solving maximization problems or seeing the actual results requires a slightly more elaborate command:

```
$ clp solar.mps -maximize -dualsimplex -solution solar.solution
```

If you apply this to an MPS file containing an integer-programming problem like the Sudoku solver given above, you get garbage, because CLP finds a continuous solution instead of an integer solution. There is a similar `cbc` executable which has an `-branch` option to avoid this:

```
$ cbc sudoku.mps -dualsimplex -branch -solution sudoku.solution
```

This finds an answer which appears to be correct, using binary variables as Garns intended, in about half a second. By contrast, with GLPK, `glpsol --mps sudoku.mps --output sudoku.sol` finds a solution in 4 seconds. The CBC user's guide explains in detail how CBC supports integer variables but does not explain how to use the `cbc` executable; Prof. Haroldo Gambini Santos wrote a short separate CBC command-line guide in 2011; it recommends the simpler

```
$ cbc sudoku.mps solve solu sudoku.solution
```

which seems to be equivalent. Without the "solve" command (or the lower-level `dualsimplex` and `branch` commands in the version above), `cbc` will still be happy to write `sudoku.solution`, but it may contain no solution, or only a solution of the linear relaxation of the problem.

On a more complex problem, unfortunately, I got CBC to dump core with this command. The other command worked better but I think it may not have actually given the right answer.

A nice feature of CBC is that if you kill it with ^C it responds by displaying information about the process it's made so far on the problem (and then, as you would expect, exiting).

CBC also accepts input in CPLEX LP format.

It seems that CLP, CBC, and COIN-OR in general have stagnated somewhat since John J. Forrest, the primary author of CLP and CBC, has retired from IBM Research around 2005; there's mojibake in the CLP User Guide and the CBC User Guide, for example. CLP and CBC are primarily intended to be invoked via an API, but they support MPS input.

CLP, and perhaps COIN-OR as a whole, descends from a proprietary IBM product called OSL, "Optimization Solutions and Library", which had its last release in 2000 and was withdrawn in 2003 with a recommendation that users switch to COIN-OR:

> For those customers considering options in the area of Optimization, IBM is strongly recommending the use of the open-source COIN solution. Much of the IBM Research Division's efforts in Optimization for the past few years (along with effort from many others in the open-source community) have gone into developing and enhancing COIN. It has progressed to the point where IBM Research feels that COIN is equal or superior to OSL in most respects....and COIN is very competitive functionally and from a performance viewpoint with other commercially available Optimization offerings.

According to the user guide, running `make unitTest` builds an executable called `clp` which can be used as a standalone solver with MPS input. Presumably the `cbc` executable is similar.

(I suspect IBM acquired ILOG and thus CPLEX around 2003; the announcement above suggests that it was maybe a bit after 2003, since it doesn't mention CPLEX.)

DSDP (solver)

The abstract of the DSDP tech report (ANL/MCS-TM-277) says:

> DSDP implements the dual-scaling algorithm for semidefinite programming. The source code if[sic] this interior-point solver, written entirely in ANSI C, is freely available. The solver can be used as a subroutine library, as a function within the MATLAB environment, or as an executable that reads and writes to files. Initiated in 1997, DSDP has developed into an efficient and robust general purpose solver for semidefinite programming. Although the solver is written with semidefinite programming in mind, it can also be used for linear programming and other constraint cones.

Apparently semidefinite programming is some kind of generalization of linear programming:

> All linear programs can be expressed as SDPs, and via hierarchies of SDPs the solutions of polynomial optimization problems can be approximated. ... A linear programming problem is one in which we wish to maximize or minimize a linear objective function of real variables over a polytope. In semidefinite programming, we instead use real-valued vectors and are allowed to take the dot product of vectors; nonnegativity constraints on real variables in LP (linear programming) are replaced by semidefiniteness constraints on matrix variables in SDP (semidefinite

programming).

The paper that introduced semidefinite programming gives further context.

> Semidefinite programming unifies several standard problems (eg, linear and quadratic programming) and finds many applications in engineering. Although semidefinite programs are much more general than linear programs, they are just as easy to solve. Most interior-point methods for linear programming have been generalized to semidefinite programs.

This all sounds great, but, to me at least, it is not at all apparent how to use the `dsdp5` command to solve a linear program. The documentation is all for the library's C API, and so are the examples.

NLopt (solver)

NLopt is a *non*linear optimization library, so it probably doesn't really belong in this list, but in theory it should be able to solve linear optimization problems too, as a special case; it will be interesting to compare it. It has bindings in C, C++, Fortran, Octave, Python, Guile, and R.

Octave (programming environment)

Although Octave is mostly a matrix computation system, it includes support for linear programming, as well as quadratic programming, general nonlinear programming, and linear least-squares solution of matrices.

Sagemath (programming environment with modeling embedded DSL)

The Sage math programming environment has a mixed integer linear programming module which provides an embedded DSL in the Sage environment for constructing MILP optimization problems. It looks a little clumsier than MathProg. It can use GLPK, CBC, CVXOPT, PPL, or some proprietary solvers.

It *also* has a semidefinite programming module, using CVXOPT as the default (and by default only supported) solver.

I haven't tried it.

Parma Polyhedra Library "PPL" (solver)

The GPL C++ Parma Polyhedra Library provides a kind of generalization of mixed integer linear programming that I don't fully understand, especially suited for static analysis of hardware systems, with APIs in C, Java, OCaml, and Prolog. I haven't tried it. The comprehensive user guide says a lot of things like this:

> Note: The affine dimension *k* <= *n* of an NNC polyhedron P in Pn must not be confused with the space dimension *n* of P, which is the dimension of the enclosing vector space R^n.

CVXOPT (modeling embedded DSL and solver)

CVXOPT is a GPL3+ library for Python under active development since 2004; it is intended for convex optimization but provides a lot of general numerical functionality, including interfaces to GLPK, plus its own solvers for linear and quadratic optimization (under the rubric "cone programming"), as well as nonlinear optimization and semidefinite programming. I haven't tried it but I assume it is suitable for writing your models in too.

Pyomo (modeling embedded DSL)

Pyomo, formerly "Coopr", is an algebraic modeling language like ZIMPL or MathProg, but realized as an embedded DSL in Python, or perhaps more accurately, a Python API, with the concepts closely matching those of ZIMPL or MathProg. It supports linear optimization and also quadratic optimization, general nonlinear optimization, etc. It's able to read model parameters from data files in MathProg format, but not to read MathProg models.

Pyomo can use GLPK, CBC, or some undocumented set of other solvers.

FLOPC++ (modeling embedded DSL)

FLOPC++ — another part of the COIN-OR project — is, similarly, an algebraic modeling language realized as an embedded DSL in C++. I haven't tried it but it looks like roughly the same level of pain as Pyomo. It can at least use CBC.

Google OR-Tools (solvers and embedded DSLs in multiple languages)

Google has a set of free-software "operations research tools" called OR-Tools, including a linear optimizer called Glop, licensed under the Apache license 2.0, with bindings in Python, C++, Java, and C#. Glop doesn't seem to support MIP, but the bundle also includes a constraint solver and a SAT solver, as well as interfaces to external MIP solvers (they recommend SCIP). I haven't tried any of them yet.

lp_solve (solver)

lp_solve is a simplex-method solver, using branch-and-bound for mixed integer programming, which supports the MPS file format. Early versions were proprietary, but recent versions are free software.

I had some trouble getting it to interoperate with GLPK or ZIMPL. I *did* eventually get it to read an MPS file generated by ZIMPL, and I think I know why the GLPK-generated version was failing; my example problem (given in MathProg and LP format above) is a maximization problem, not a minimization problem. Upon translating it to MPS with `zimpl -t mps min.zpl` (see below), ZIMPL issued the following warning:

```
--- Warning: Objective function inverted to make
             minimization problem for MPS output
```

And then lp_solve was able to solve it with `lp_solve -mps min.mps`, and indeed the value of the objective function was -3.66...7 rather than 3.66...7. So I guess that the problem was that MPS doesn't have a way to say you're trying to maximize the objective function, not minimize it.

With this in mind, I was then able to solve the free-form MPS file I had generated with `glpsol -m min.mod --wfreemps min.fmps` by using `lp_solve -max -fmps min.fmps`, `-max` being an `lp_solve` flag to override this. GLPK can also generate fixed MPS files lp_solve can read with its `-mps` flag.

lp_solve has its own "LP format" which is not the same as the CPLEX LP format used by GLPK, ZIMPL, CLP, and CBC, leading to much confusion on my part. The documentation does explain this:

The lp-format is lpsolves [sic] native format to read and write lp models. Note that this format is not the same as the CPLEX LP format (see CPLEX lp files) or the Xpress LP format (see Xpress lp files)

I was able to translate the file from MPS to this incompatible LP format with `lp_solve -max -fmps min.fmps -wlp min.lps.lp`:

```
/* min */

/* Objective function */
max: +2 y +3 z;

/* Constraints */
a: +3 y +2 z <= 3;

/* Variable bounds */
y <= 4;
z <= 1;
```

This can be reduced to the following, a format which is quite reasonable for writing by hand, and still work as input to lp_solve:

```
max: +2 y +3 z;
a: +3 y +2 z <= 3;
y <= 4;
z <= 1;
```

Unfortunately nothing but lp_solve supports this format. (But I think it can translate it to MPS format.)

In theory lp_solve supports CPLEX LP format with the flags `-rxli xli_CPLEX` to read or `-wxli xli_CPLEX` to write, but I think the Debian package failed to include the relevant module, so this doesn't work. (If you really needed to do this, you could use GLPK to translate from LP to MPS so lp_solve can handle it.)

lp_solve even supposedly has an "xli" to read MathProg, presumably linked with GLPK.

lp_solve seems to be much weaker than GLPK's solvers; I have an underconstrained 9x9 Sudoku puzzle, using the above solver, here that GLPK can solve in 4.1 seconds, but lp_solve chewed on it for 22 hours without solving it before I killed it. The two projects started about the same time, but GLPK has seen continued development. I suspect that any current interest in lp_solve is largely because GLPK is GPL, so you can't build proprietary software with it, while lp_solve is LGPL, so you can.

Like GLPK, lp_solve also has an API as well as file formats — in C, Java, and Free Pascal.

Hacks to expand what you can do with a linear optimizer

The description from lp_solve makes linear optimization sound really weak and limiting:

Solve $\mathbf{A}\vec{x} \geq \vec{\mathrm{V}}_1$, with $\vec{\mathrm{V}}_2 \cdot \vec{x}$ maximal.

And, in some ways, it is; but as I'm learning in this class, there are standard hacks for turning a much larger variety of problems into linear problems. Some of these are done for you automatically by

model translators for algebraic modeling languages, while others aren't.

Minimizing vs. maximizing

The simplest hack is switching between minimizing and maximizing. The lp_solve definition above might suggest that you can't minimize things, but of course when $\vec{x}$ is chosen to make $\vec{V}_2 \cdot \vec{x}$ minimal, then $(-1\ \vec{V}_2) \cdot \vec{x}$ is maximized. Moreover, its maximal value is precisely the opposite of the minimal value for $\vec{V}_2 \cdot \vec{x}$; so if your solver wants to maximize, you can just flip the sign on its objective vector and the objective result, and you can minimize.

As mentioned earlier, ZIMPL will do this when generating an MPS file, since apparently MPS can't express whether you want to maximize or minimize your objective function, and so given just an MPS file, GLPK, lp_solve, CLP, and CBC assume you want to minimize.

Mixing ≥ with ≤

Similarly, $\mathbf{A}\vec{x} \geq \vec{V}_1$ suggests that all your constraints must have decision variables on the left side of a "≥". But that's silly; the constraint $2y \geq 4$, for example, is equivalent to $-2y \leq -4$. So by flipping the signs on a row of the matrix and the corresponding limit, you can effectively get both ≤ and ≥ constraints in the same matrix. And that's how you can get criteria like $1 \leq 2y + 3z \leq 2$.

Indeed, even the CPLEX LP format supports this directly for decision variables:

```
Bounds
 0 <= y <= 4
 0 <= z <= 1
```

Decision variables on both sides

Similarly, if you have a criterion like $2y \leq 3z + 1$, you might think that doesn't fit into the $\mathbf{A}\vec{x} \geq \vec{V}_1$ mold. But all you have to do is subtract $3z$ from both sides — $2y - 3z \leq 1$ — and Bob's your auntie!

Equality constraints

Similarly, if you have an *equality* criterion like $3p = 4q - 2r$, you can convert it into two *inequalities* — $3p \leq 4q - 2r$ and $3p \geq 4q - 2r$ — which can only be simultaneously true when strict equality is satisfied. This reduces the dimensionality of your feasible region below the full dimensionality of the decision-variable space, though that's not a problem for the simplex method.

Binary gates with big *M*

A common nonlinearity that can be handled fairly easily by integer linear programming is a sort of "something-or-nothing" criterion; for example, with solar panels, the amount of power you can produce at a site (and thus money you can make) is proportional to the amount of panel area installed at the site, but to produce any power at all at the site, you need to run power lines to the site, which has some fixed cost.

If you have some upper limit M on the power you can produce, you can multiply that upper limit by a binary variable W that encodes

whether or not a site is active; for example, in MathProg notation:

```
param M {s in Sites} := available_area[s] * power_per_area;
var W {s in Sites}, binary;
subject to power_installation {s in Sites}:
    0 <= panels_installed[s] <= W[s] * M[s];
```

When W_s is 0, this forces `panels_installed[s]` to also be 0; when W_s is 1, `panels_installed[s]` can have any value at all, as long as it's less than M, which was chosen to be large enough not to be a restriction in practice. (Solvers can suffer precision problems if M is too many orders of magnitude larger than the actual values of the variable, though.)

Then, you can use this variable W in your objective function to take into account the installation cost.

(I mean "gate" in the sense of something that can block something else from happening, not in the sense of a NAND gate.)

Absolute values

A much cooler trick that doesn't even require dropping back to integer linear programming is encoding absolute values. Suppose one of the terms of an objective function you're trying to *minimize* is the absolute value of some linear function f of your decision variables, $|f(\vec{x})|$. That's not linear, or even differentiable, because it changes direction abruptly when $f(\vec{x}) = 0$, so you can't solve it directly with a linear solver. What you can do is replace $|f(\vec{x})|$ with a new variable t which is constrained to be greater than or equal to $|f(\vec{x})|$ using two new constraints: $t \geq f(\vec{x})$ and $t \geq -f(\vec{x})$. This ensures that $t \geq |f(\vec{x})|$, which, in conjunction with the minimization criterion, forces $t = |f(\vec{x})|$, and again, Bob's your auntie!

When you're trying to *maximize* a sum including $|f(\vec{x})|$, which is a more unusual thing to do, this becomes trickier; you must drop back to mixed integer programming and introduce a binary variable W and maximum M bound and use a variant of the binary-gate trick to prevent t from ever being strictly greater than $f(\vec{x})$, with $t - f(\vec{x}) \leq WM$ and $t - (-f(\vec{x})) \leq (1-W)M$.

Mutual exclusion

As demonstrated in the Sudoku example above, you can use a simple sum condition to require that precisely one of a set of options be chosen: $W_1 + W_2 + W_3 = 1$.

Piecewise-linear functions

Mutual exclusion allows you to use piecewise-linear functions in your linear constraints and objectives. You can't do this in the obvious way — $W_1 f_1(x) + W_2 f_2(x) + W_3 f_3(x)$, with the f_i being the linear pieces — because it wouldn't be linear. But you can introduce new "abscissa" variables z_1, z_2, z_3 that are gated by the W_i and restricted to their own regions: $3W_1 \leq z_1 \leq 6W_1$, for example, restricts z_1 to $[3, 6]$ when $W_1 = 1$, and 0 otherwise. Then $f_1(z_1) + f_2(z_2) + f_3(z_3)$ gives you the piecewise-linear function you wanted, and $z_1 + z_2 + z_3$ gives you its abscissa, which perhaps you want to constrain to be equal to x.

This is a variant of the binary-gate trick that requires no big M.

(I've written it here with single scalars z_i, but you can extend it to

piecewise-linear functions of multiple variables in a few different ways.)

This has the disadvantage that if your piecewise-linear function is discontinuous, it ceases to be a *function* at the discontinuities; it can take two different values.

(I think there's also a way to make a *convex downwards, continuous* piecewise-linear function out of absolute values without involving integer linear programming, in the case where you're minimizing, but I haven't seen it worked out yet.)

Ratios between linear forms where the denominator has known sign

¿Qué necesito para relación de pareja?

Kragen Javier Sitaker, 2016-03-09 (6 minutes)

¿Qué necesito en una relación de pareja?

Supongo que lo más básico es el amor: la aceptación incondiconal de otra persona, el reconocimiento psicológico de la naturaleza ilusoria de la separación entre las personas: que la diferencia entre mi bienestar y tu bienestar es una ilusión.

Pero el amor sólo, como emoción o estado psicológico, no es suficiente. Es igual o más importante el respeto para la autonomía de la otra persona: si bien no hay una diferencia real entre los estados del mundo que son buenos para mí y los que son buenos para vos, hay otras cuestiones. Cada une tiene su propia información acerca de sus propias necesidades — sé cuando tengo hambre y que tan importante es para mí ver a mi mamá, lo sé más que sabés vos, mientras que vos sabés más cuando vos tenés hambre. También, cada une tiene su propio sendero de desarrollo y crecimiento.

Más que nada, para mí, el rol de la relación de pareja es apoyar y habilitar este crecimiento de cada une. Para eso se necesita un respeto profundo y una alta priorización de ese bienestar y también tal crecimiento: a veces esto implica interrumpir otras cosas (reuniones, trabajo, viajes, sueño) para cuidar a la pareja, y a veces (más difícil) resulta necesario soltar algún mambo de cada une para lograr la capacidad de estar presente para le otre. Por ejemplo, si estoy muy apegado a mi concepto de que soy súper empático, me puede costar mucho reconocer los momentos que no logré empatizar, y eso me puede obstaculizar en prestar más atención al tema y tener la humildad para escuchar que había equivocado.

Con el traspaso de los años, cada une puede hacer a le otre más fuerte y capaz, a través de enseñarle cosas, pero también a través de hacer cosas que le otre no logró. Si sé hacer un cappuccino y vos no, te lo puedo enseñar, o te puedo hacer un cappuccino cuando lo querés. Así volveremos más fuertes en equipo que solos.

Otro aspecto de trabajar en equipo (cosa que veo como fundamental de la pareja) es compartir perspectivas. Ya que cada une tiene su propia perspectiva acerca de cualquier cosa que experimentamos, al consultar a le otre, tendremos una perspectiva más completa, y podremos actuar más inteligentemente juntes que separades.

Al unir recursos y negociar soluciones mutualmente agradables para las situaciones que enfrentamos, podremos lograr mucho más juntes que soles. Si vos querés pasar unos años en la universidad, poder vivir conmigo mientras estoy ganando plata será mucho más conveniente que intentar ganar plata mientras estudiás; al cocinar juntes, siempre que nos podemos poner de acuerdo en qué comer, tendremos mucho mejor y más comida por menos esfuerzo.

En otros casos, hay muchas ventajas de que estamos en dos cuerpos distintos, no el mismo cuerpo; más allá que los placeres del sexo (cosa que nos nutre emocionalmente de una forma profunda) poder estar en dos lugares distintos a la vez nos permite hacer cosas que no podríamos

hacer soles: mirar el doble de las cosas, llevar cosas acá y allá, etc. Eso solo resulta ventajosa para les dos mientras tenemos una relación igualitaria; si no, vuelve un suerte de explotación, en lo cual la pareja más débil está sirviendo a le otre, y así tiene mucho menos energía y tiempo para sus propias cosas.

Eso vuelve a la cuestión del reconocimiento de la unidad de intereses: nuestra habilidad de colaborar así siempre está sujeta a las limitaciones impuestas por nuestro egoismo. Mientras siento que lo que te hace bien también por eso me hace bien, puedo pesar los dos bienes dentro de mí; mientras que no, llegamos a las negociaciones, donde te ofrezco hacer algo que me cuesta si vos hacés algo que a mí me importa pero te cuesta a vos. Para mí, los dos aspectos, negociaciones y amor, siempre existen en cualquier relación real. La negociacion es necesaria para convivir con otro ser que no es perfectamente altruísta o no confía que sos perfectamente altruísta.

Pero yo. ¿Qué necesito yo?

Pero todo lo anterior tiene que ver con que pienso que cualquiera necesita en una relación de pareja. No hablé mucho de lo que necesito yo en particular, que tal vez otras personas no necesitan.

Necesito mucho cuidado y suavidad en cuanto navegamos los conflictos. Hay personas que pueden bancar palabras duras, criticándolas agudamente con ataques contra su carácter y naturaleza, y después perdonar con el excusa de que esas palabras eran motivadas por enojo y no representaban una manifestación verdadera de lo que veía le otre. Yo no. Una vez que me decís que soy insincero o estúpido o lo que sea en un momento de enojo, por más que negás creerlo mil veces, siempre después me preguntaré cuál es la verdad y cuál es la mentira de tu creencia: me mentís ahora que piensás que no soy estúpido porque tenés miedo que la verdad me lastimaría, o me mentiste cuando estabas enojade para lastimarme?

Necesito mucha honestidad, en general. No banco muchas mentiras.

Necesito inteligencia. Estuve en relaciones antes con personas de baja inteligencia, y por más que eran personas muy lindas y cuidadosas y honestas, no podía conectarme con ellas a un nivel para formar un buen equipo, mucho menos un buen equipo igualitario.

Necesito la libertad de estar en relaciones íntimas con otras personas.

Necesito, creo, una conexión sexual activa y fuerte.

Energy storage efficiency

Kragen Javier Sitaker, 2019-07-30 (4 minutes)

From https://news.ycombinator.com/reply?id=20561792&goto=threads%3Fid%3Dkragen%2320561792

Indeed, I think the finite amounts of existing dams are the reason people are looking to batteries.

Your point about the efficiency is interesting, although I didn't understand it at first. I think you're saying that the capital cost of the lithium-ion battery storage is partly defrayed by the higher efficiency of the storage system? Like, for each kilowatt-hour of Li-ion storage (with, let's say, a round-trip efficiency of 95%, although I think that's too high), you "get back", say, 0.25 kWh every time you use it, that you would have lost if you'd stored that energy in pumped storage instead? So over, say, 15 years, you "get back" US$82 or so, at US$5.48 per year?

https://electrek.co/2018/11/20/tesla-gigafactory-battery-cells-made-cost-advantage-panasonic-lg-report/ claims that the battery cell cost is US$111 per kWh at the moment (though other manufacturers are still stuck around US$140), so that would work out to about a 5% annual IRR if the cells were the only cost; I think that in fact they are on the order of half the cost (though Tesla's blog post here doesn't actually list prices!) and so that would be a 2.5% or so IRR. Not enough to justify the battery investment on its own, but it would definitely be a significant boost to the project's ROI.

I have a couple of objections to that line of reasoning, one trivial and one serious.

The trivial objection is that the wholesale cost of electrical power, although it varies a lot, averages about half of the 6¢/kWh you're imputing. https://www.zmescience.com/ecology/climate/cheapest-solar-power/ talks about the just-signed Atacama project at 2.9¢/kWh, which I think includes the cost of some storage. So the numbers are more like 1.25% IRR rather than the 2.5% I suggested above or the 5% you suggest.

The more serious objection is that, when you're filling up your utility-scale storage during hours of excess power production, you're not paying 6¢/kWh or 2.9¢/kWh. In fact, due to non-dispatchable "baseload" plants like coal and nuclear, it's common right now for *the power plant to pay you* to take the power, with the price typically around -4¢/kWh, which is the cost of burning it up in giant resistors. When instantly-dispatchable solar plants come to dominate power production, we can expect to see a price floor of 0¢/kWh. Maybe if a storage-plant operator is paying a solar-plant operator to leave their PV plants running, they'll have to pay 0.01¢/kWh or 0.1¢/kWh. But they won't be paying anywhere close to the average price of electrical energy. They'll be paying the *marginal* price of generating electrical energy *when it is cheapest*.

So that means that the amount of money you make from a utility-scale energy storage plant isn't going to be determined by how

much energy you need to charge it up. Your round-trip energy efficiency could be 10% or 5% and you still wouldn't pay a significant percentage of your revenues to obtain that energy. What determines your revenues is *how much energy you can release* once you are selling energy rather than buying it. (And the quality of your trading strategy, of course; if you decide to wait to sell your energy until your LMPs go above US$45/MWh, and they sit at US$42/MWh all night long, you don't make any money.)

Round-trip energy efficiency only matters *at all* in the sense that it diminishes your effective storage capacity — if theoretically you have "1 MWh" stored, but when you turn it on, only 0.9 MWh flows to the grid, you only get paid for that 0.9 MWh, and that's what you need to pay your capex and opex with. But it only matters very marginally whether you had to buy 1.1 MWh or 2 MWh or 5 MWh or 10 MWh to charge up your storage facility.

Service-oriented email

Kragen Javier Sitaker, 2017-06-20 (updated 2017-06-21) (15 minutes)

What would a REST or REST-plus-invalidations system for my mail look like?

You could plausibly argue that this is the wrong question to ask, because really the right architectural style is something else — something more like Kafka, which gives you a way to safely resend operations that may have side effects, and to incrementally replicate large databases. But let's leave that aside for the moment.

At the bottom of the stack, we have three kinds of resources: a mbox file (which we probably need invalidation notifications, quick ETags, and byte-range fetches for), some kind of metadata store for tags and marks, and an index listing all the mboxes. Everything else is built on top of that.

The mbox-file resource can be provided by a service that keeps open an ssh connection and sends commands over it, or several ssh connections, or with rsync, or local file access, or whatever. Probably the most sensible way to do it would be to tunnel REST requests over an ssh connection to a remote REST service accessing a local file.

The metadata store is probably local and probably can be a simple key/value store.

A layer up, we convert blocks of the mboxes into resources of their own. The interface here is something like

```
GET /size?url=foo/bar/baz
GET /block?url=foo/bar/baz
          &start=180052992
          &bytes=1048576
```

/size and /block are cacheable stateless microservices that merely transform ordinary GET requests into GET-with-byte-range and HEAD requests.

Ideally the mbox blocks would be large enough to be large compared to the bandwidth-delay product, but small enough to amount to a tolerable delay when they are fetched. This is infeasible when my latency is 200+ ms, so I probably have to hide the latency as much as possible with parallelism and prefetching. Specifically, my ping time to canonical.org is currently 175–177 ms, my bandwidth at the office is about 1.5 megabytes per second, and a tolerable delay is 100 ms, which means that we want to ensure that 95%+ of our requests can be served from a local cache, which implies very aggressive cache prefetching. Or sucking it up, I guess.

The bandwidth-delay product is about 256 kilobytes, coincidentally almost exactly the bandwidth-delay product of a spinning-rust disk (though about 64 times that of an SSD being read). So, with chunks of 256 kilobytes, we could maintain full bandwidth usage with a parallelism factor of 2; with 128 kilobytes, a parallelism factor of 4; or with 64 kilobytes, a parallelism factor of 8. Probably the best overall compromise is a parallelism factor of 8 and 128-kilobyte chunks. Then, on the rare occasion that we have to suck up a cache miss, the size of the 128-kilobyte chunk will add 85 ms of

latency on top of the 175 ms already inherent in the link — not insignificant, but not the main bottleneck.

My current mailbox is 4.3 gigabytes, which will take about 45 minutes to initially download at 1.5 megabytes per second.

Given the blocks, we need to find the messages within, and the message boundaries ("\nFrom " or "\AFrom ") might cross block boundaries. For this we use a stateless boundary-parsing service:

```
GET /bloxparse?url=/block?url=foo/bar/baz%26start=180052992%26bytes=1048576
```

This returns three items: an array of (potentially many) byte offsets where definite message boundaries within the block are found, an array of byte offsets before the beginning of the block which could potentially be message boundaries (containing zero or one item; this is if the block begins with something like "rom "), and an array of byte offsets just before the end of the block which could potentially be message boundaries (similarly, containing zero or one item, for cases where the block ends with "\nF" or something.)

If I run this locally, it should be cached pretty aggressively, because I have 181490 message boundaries in those 4.3 gigabytes, so a single 11-byte decimal number or 8-byte binary number stands in for 23 kilobytes of data. This very minimal summary, which can be generated in about 10 CPU seconds (with the bsdmainutils from command, for example), occupies about 2 megabytes and can avoid transferring 4.3 gigabytes.

This /bloxparse service is invoked by an /mboxparse service which manages some amount of concurrency and reconciles the possible offsets near the ends of blocks.

(In a more generalized sense, they aren't so much possible offsets as sets of candidate finite state machine states: if the finite state machine is in state 3 or 5 at the beginning of this block, then it has found a message boundary; at the end of the block it is in state 2. More generally it is a mapping from input states to output states. But maybe that level of complexity isn't needed here, since the message-boundary-parsing service is very simple.)

The /mboxparse service takes the same parameters and provides the same result format as /bloxparse, but also takes optional blocksize and nprocs parameters.

However, it isn't necessary to parse the whole mailbox in order to start parsing message headers and contents from it and processing queries. We can chain two calls to the /block service to fetch a message, the second-invoked one fetching a 128k-aligned block and thus more neatly cacheable, and the other one extracting a message from it according to /mboxparse.

Somewhere nearby we should have a service that reformats /mboxparse results into lists of links to messages, and perhaps another that maps somewhat simple links to messages into redirects to the double-chained /block resource mentioned above:

```
/msg?mbox=foo/bar/baz
    &start=180053082
redirect to
    /block?url=/block?url=foo/bar/baz
        %26start=180052992
```

```
    %26bytes=1048576
&start=180053082
&bytes=20330
```

It would be nice to be able to somehow incrementally list the messages that have been parsed so far, like with some kind of re-rereadable message queue, like Kafka. Lacking such a thing, we can prefetch stuff in the background, I guess.

Once we have some message URLs, we can start parsing those messages so we can index them, both with full-text indexing and with traditional database-column indexing. Perhaps we maintain cached index segments corresponding to segments of the mailbox, and cache merge results for those index segments, re-merging index segments on demand.

A parse request might look like

```
GET /parse822?url=foo/bar/baz
```

where foo/bar/baz is something like the /msg? URL mentioned above. It returns some kind of parsed representation of the message headers, perhaps encoded using FlatBuffers; this parsing can be cached. (Maybe /hdr is better?)

A query process might fetch index segments (computed on the fly if necessary) for ever-larger sections of the mailbox, starting from the end, running sort-merge joins on them, perhaps ceasing once it has enough results to fill the screen (or a bit more), and perhaps maintaining a couple of different query frontiers open at once — full-text index segments and header index segments, for example.

The desire to be able to move various kinds of processing to the storage server suggests that it would be best for the service identifiers like /parse822 to be mapped not to processes on machines but to pieces of code, perhaps bundled up with some kind of handle to a persistent state for the services that aren't purely stateless. Then a sort of query optimizer can try running the service locally, and if that's taking a long time (e.g. >10ms), try running it remotely as well and use whichever one gets faster results. Some kind of standardized bytecode would be one way to handle such mobile-code services. (Also you could hide this behind a process-on-machine resource.)

All of this somewhat abstracts away the question of bandwidth usage, treating it as an implementation detail of the services, when it kind of isn't really — if I have a bunch of useless local jobs sucking up all my uplink bandwidth, it's going to make anything else I try to do slow. You could conceivably pass in a handle to an accounting resource to the service when you invoke it for it to charge its bandwidth and even CPU usage to, which would have the ability to cut it off and cause it to fail fast if it went over its resource limits or if you just no longer cared about the results.

All of this is about reading mail. Sending mail is a different matter; we want to ensure that mail gets sent exactly once. If the client has a private namespace on the server (/outmail/myhostname) it can peremptorily allocate message-IDs within there, assuming it hasn't suffered an attack of amnesia due to some kind of virtual machine checkpoint and restart (which could cause it to reuse the same

message ID), and PUT messages there. As long as PUT is atomic then it's all good; retries are safe. In HTTP, PUT also has an If-None-Match: * option which can be used to ensure that you never overwrite an existing message, but what do you do in that case? (I guess you can GET the message to see if you previously PUT the same message and forgot about it, or whether it's a collision.) If there's some kind of collection indexing, then a mail-sending process on the server can watch the collection index for changes, passing the mail to Postfix or whatever when it sees a new message.

That is, Kafka-like topics aren't necessary for reliable exactly-once mail sending. HTTP semantics are more than adequate.

Other useful stateless services:

```
/mime?url=foo/bar/baz
```

Gives you an index of the MIME structure of the RFC-822 message; the links add more parameters and contain enough data to do the parsing efficiently.

```
/col?parser=/parse822
    &col=subject
    &items=/msglist?foo
```

Passes the message URLs in /msglist?foo through /parse822?url=$url and extracts URL-subject pairs (the "subject" "column") from them.

```
/invert?from=bar
    &to=baz
    &data=/col?foo
```

Invokes /col?foo and inverts it, converting values to keys and keys (such as message URLs) to values, and sorting by the new key. Excludes rows whose keys are outside the range from bar to baz. (Maybe the exclusion should be elsewhere?)

```
/union?data=/a
    &data=/b
    &data=/c
```

Merges some sorted sequences of key-value pairs. Note that applying /invert with a range to /union gives you a single-field query over a merged index.

```
/join?data=/a
    &data=/b
    &data=/c
```

Given some sequences of key-value pairs, this returns one row for each key that occurs in all the datasets, with the values for each dataset concatenated.

By applying /join to some /inverts applied to /inverts with ranges applied to /unions of the appropriate /cols, you can get a multi-field query. If you leave out the /inverts, you get a message index.

Ideally every service should be self-describing in that if you invoke

it without all the mandatory parameters, it gives you IDL for how to call it, an HTML form or equivalent. Also, we need some way of assigning media types to URLs and URL input fields to make it easy to plug things together, and a better invocation syntax with less noisy parameters, and supporting URL nesting. Something like Clojure keyword syntax.

Also, both requests and responses should be able to contain capabilities, in order to avoid confused-deputy attacks.

An interactive prompt should promiscuously prefetch stuff as you are composing your request so you can see what you're doing, since GET is safe. If you do some interactive exploration, you should then be able to go back and factor out some parameters from your script, then turn it into a new microservice.

Minimal implementation

Of course I don't need all this shit to be able to try it out, and I do need my mail pretty soon. A mini HTTP server with a small number of simple scripts (parse message starts, provide mailbox size and mailbox blocks) that I can tunnel over ssh should be pretty doable. I'd need some special-purpose caching logic but nothing really special. Also mapping some URLs to ssh-tunneled URLs and others to local scripts seems like it should be pretty doable.

In terms of data formats, I can probably get by with space-separated URL-encoded fields with newline record terminators for now. Or Excel CSV, which is probably just as easy, but doesn't sort properly.

Sorting and caching is probably pretty easily done with LevelDB or maybe Redis. Or both. LevelDB on my laptop can handle about 300k record insertions per second, so about half a second to sort the subjects of all my messages. /bin/sort sorts my 100k-line ~/netbook-misc-devel/bible-pg10.txt in 770 ms, or 420 ms with `LANG=C`, which is the same speed (even with `-S 1G`). It seems like it should be possible to go faster since that file is only 4.4 megabytes; `LANG=C wc` takes 100ms.

As another sample computation, `time grep -a '^Subject: ' adjuvant-mbox.1g | wc` finds 43893 subject lines in 1073741824 bytes (1 GiB) containing 41630 message starts in 11.5 seconds. Oh wait, it takes 740ms if it's already in memory, then another 740ms if I pipe it through sort. The total time for `grep | sort | wc` drops to 1000ms with `LANG=C`, which mostly affects sort.

HTTP/2 supports out-of-order responses over a single connection, so using HTTP/2 would avoid the need to use multiple HTTP connections. The quasi-required encryption would probably hurt performance, but it isn't really required in the standard.

I should check out Hyper the Terminal and see if it has anything interesting (no, not for this). And maybe Spark and Samza.

Literate programs should include example output, like Jupyter, but Jupyter is imperfect

Kragen Javier Sitaker, 2018-04-27 (3 minutes)

For decades, I've appreciated the aspiration of literate programming, to produce software that can be pleasantly and easily read as literature. However, notably, for decades, literate programming has remained unpopular. I think the biggest reason for this is that literate programming as we have practiced it so far omits one of our most powerful tools for understanding programs in practice: running them.

That is, standard literate programming tools like CWEB or noweb include nothing in the readable text that is contingent on what the program actually does when you run it. Typical literate programs don't even include unit tests, which implicitly make claims about what *would* happen if the program were to be run — if the author tells you the unit tests succeed, then you can suppose that that is what actually does happen. In cases like tests written with Python `doctest`, the test case shows the actual output from the program.

The Mathematica-derived "notebook" interface of IPython/Jupyter seems like a promising step forward, because it does show example output. Peter Norvig is working on a set of such notebooks called pytudes to demonstrate some challenging problems.

Jupyter notebooks are pretty awesome, but they have some limitations. To wit:

Because Python is an imperative language, the interpreter state (and thus the results of cell evaluation) depends not only on the contents of the notebook, but also the order in which the cells have been evaluated — and, potentially, even the number of times each cell has been evaluated, and previous cell contents that were evaluated, even if they no longer exist.

Perhaps worse, there's no way to "export" a class, function, or value defined in a notebook so that it can be used from elsewhere. Each notebook is relatively self-contained — for better or worse. You can't use a notebook as a way to present and document one module of a larger system, although you can use them as a way to document how to *use* such a module. (There is the somewhat primitive `%run` mechanism, which I think is analogous to C's `#include`.)

Jupyter notebooks are also less than ideal for multiuser use. There are a variety of ways you could imagine a multiuser notebook working — for example, all the users could all be editing a single shared document, or each one could have their own document that imports certain cells from other documents, or some combination.

The flatness of Jupyter notebooks makes them hard to navigate once they're over a certain size. Hyperlinks and folding could help.

However, it's important to point out all the ways the Jupyter notebook interface is vastly superior to traditional command prompts, REPLs, and source code editing environments and even, in most cases, traditional literate programming tools:

• Typography: headers, equations, bold and italics;
• Collapsible output (i.e. you can hide the output of a cell, and actually the whole cell, if you like);
• Multimedia output — plots, raw HTML, tables, equations.
• Pywidgets provides interactive experimentation with variable values.

Heating my apartment with a plastic tub of hot water

Kragen Javier Sitaker, 2018-06-17 (3 minutes)

My apartment receives hot water from a shared hot-water heater, and taking a hot shower warms up the 100 m³ apartment noticeably. So I filled up a large plastic tub and dragged it into the living room.

This plastic tub is 330 × 300 × 600 mm, more or less, and it's full of 40° water while it's 15° outside. This is about 60 kg of water, which has the thermal mass of about 120 kg of air, and about 1500 kilocalories or 6 megajoules. If this tub takes 6 hours to cool off, which seems plausible, it's heating the apartment at almost 300 watts on average during that time.

To heat the apartment with the hot water supply at the 2000 W or so it really needs, I would need about 19 milliliters per second of water, or about 70 liters per hour, considerably below the shower's output of some 300 mℓ/s. The hot water flow would need to be intermittent, because the first liter that comes out of the faucet is cold, and the first ten or twenty liters are noticeably below maximum temperature — drawing water continuously at 19mℓ/s would just warm up the pipes in the wall, not the interior of the apartment.

Refilling one of two 35-ℓ hot water tanks every half hour would take about 2' out of every 30', with the final result being equivalent to a 90-minute shower every day.

So my shower is heating my house at 300 mℓ/s · 25° · 1 kcal/kg/° · 1 g/cc = 31 kW. That's pretty respectable, especially given that the electrical service is only 66 amps, 16 kW. Too bad that, in its current form, the shower also raises the humidity uncomfortably high.

The hot-water tanks could take the form of tall cylinders with hot water at the top, cold water at the bottom, and a heat exchanger in between, driven either by thermosiphon action or by an actual pump. At 140 mm diameter and 2.5 m tall, they would hold 38.5 liters and thus 4 MJ of heat at $\Delta T = 25°$. By separating the cold water from the hot water in the same tank, they would avoid the need to have double the tank capacity to separate hot from cold, or to put air into the tanks between emptying and refilling, which can promote rusting.

However, if you just left them uninsulated and didn't use a heat exchanger, the result could be adequate with a bit more work. Each tank as described would have a surface area of 1.1 m², and at 40°, a black body radiates 545 W/m², so this would be about 600 W of heat emission per tank — counterbalanced by absorbing 430 W from the environment, so only 170 W net. This is about an order of magnitude too low, suggesting that you could get the right result by flattening the tank out to be an order of magnitude thinner and thus wider.

Cobstrings

Kragen Javier Sitaker, 2015-08-21 (updated 2015-08-31) (5 minutes)

COBS ("consistent overhead byte stuffing") is a byte-stuffing method for avoiding NUL bytes in your packets so that you can use them for framing which has some interesting virtues. You take your packet

```
f o o\0\0\1\0 x y z\0\7
```

append a NUL to it so that it's a concatenation of NUL-terminated strings, then compute the lengths of all the NUL-terminated strings:

```
f o o\0\0\1\0 x y z\0\7\0
3       0 1   3       1
```

Now you convert the NUL-terminated strings to counted strings with the counts starting at 1.

```
f o o\0\0\1\0 x y z\0\7\0
3       0 1   3       1
\4f o o\1\2\1\4 x y z\2\7
```

So now your packet is the same length as before but contains no NULs, if we count the terminating NUL we added, through a reversible transformation that eliminates the NULs.

But that's impossible, by the same pigeonhole principle that shows that file compression has its limits. And indeed we run into the standard problem with counted strings: you run out of counts. What do you do if you have more than 254 bytes between NULs?

COBS solves this by reserving \xff for a 254-payload-byte prefix block, which does not have a terminating NUL; so a COBS string in general consists of a sequence of zero or more \xff-prefixed blocks followed by an excess-1-count-prefixed block, which may be empty.

It occurred to me that this representation for in-memory strings has some advantages:

• Like C strings, it only requires a single extra byte of overhead, at least in the cases where C strings are a good idea.
• Like C strings, you can cut a string into tokens in place by overwriting separators in it with metadata. (This requires moving around later parts of the string if it's long, though.)
• Unlike C strings, it's 8-bit clean; it can store any byte, including NUL bytes, avoiding security holes, among other problems. This means COBS strings can be safely nested!
• Unlike C strings, appending to a long string (of a few kilobytes) is reasonably efficient, as is taking its length; so `stpcpy` is unnecessary. And Boyer-Moore search is plausible.
• Unlike C strings, you can copy it several bytes at a time.

It has a couple of disadvantages compared to C strings: code implementing fundamental string operations is a bit more complicated; you can't compute a suffix of a string without mutating it, which means that a number of standard library functions need an

extra "start index" argument; and copying data into and out of the string requires special consideration for possible chunk boundaries.

Here, I'm eliminating as unhelpful in this context the constraint to not use NUL bytes, so a \0 length byte is an empty string, a \1 length byte is a single-byte string, a \xfe byte is a 254-byte string, and the \xff byte prefixes 255 bytes of payload data.

So a long string might look like this in memory:

```
FF C O B S ( " c ... s oSPFF t h a t ... s t a rFF t i
 n g...SPSPBE / * c o bSP c h u n k ... \nSPSPSPSP}\n
```

with the \xBE at the beginning of the final block both signaling its length and

I think these functions may be correct, but I have not tested them.

```
void cobcpy(unsigned char *dest, unsigned char *src)
{
   while (src) {
      memcpy(dest, src, cobclen(src) + 1);
      dest += 256;
      src = cobcnext(src);
   }
}

void coblen(unsigned char *s)
{
   size_t n = 0;
   for (; s; s = cobcnext(s)) n += cobclen(s);
   return n;
}

void cobcat(unsigned char *dest, unsigned char *src)
{
   while (src) {
      while (cobcnext(dest)) dest = cobcnext(dest);
      cobaddbytes(dest, cobcbody(src), cobclen(src));
      src = cobcnext(src);
   }
}

/* returns index of first c in cob, or coblen if not found */
size_t cobchr(unsigned char *cob, char c) {
   size_t n = 0;
   while (cob) {
      unsigned char *m = memchr(cobcbody(cob), c, cobclen(cob));
      if (m) return n + m - cobcbody(cob);
      n += cobclen(cob);
      cob = cobcnext(cob);
   }
}

int cobcmp(unsigned char *a, unsigned char *b)
{
   for (;;) {
      int n = cobclen(a), nd = cobclen(b) - n;
```

```
      if (nd < 0) n += nd;
      int d = memcmp(cobcbody(b), cobcbody(a), n);
      if (d) return d;
      if (nd) return nd;
      if (n != 255) return 0;
      a += 256;
      b += 256;
   }
}

/* append n bytes starting at src to cob */
void cobaddbytes(unsigned char *cob, unsigned char *src, size_t n)
{
   while (cobcnext(cob)) cob = cobcnext(cob);
   int available = 255 - cobclen(cob);
   int to_copy = (n < available ? n : available);
   *cob += to_copy;
   memcpy(cobcbody(cob) + cobclen(cob), src, to_copy);

   /* copy any remaining bytes into a new chunk */
   cob = cobcnext(cob);
   if (cob) {
      int tail = n - to_copy;
      *cob = tail;
      memcpy(cobcbody(cob), src + to_copy, tail);
   }
}

/* cob chunk next; returns NULL if there is no next chunk */
unsigned char *cobcnext(unsigned char *s)
{
   return (cobclen(s) == 255 ? s + 256 : 0);
}

/* cob chunk length */
int cobclen(unsigned char *s)
{
   return *s;
}

/* cob chunk body */
unsigned char *cobcbody(unsigned char *s)
{
   return s+1;
}
```

Steampunk spintronics: magnetoresistive relay logic?

Kragen Javier Sitaker, 2013-05-17 (15 minutes)

I thought it was possible to do high-speed digital electronic computation with 19th-century materials and fabrication techniques, using the (ordinary) magnetoresistive effect and differential circuits to obtain nonlinear amplification. This document explains why I thought it was possible.

However, now I think it's *not* possible, because it involves using iron or otherwise ferromagnetic wires to carry the signals that need to be switched, and those wires, in addition to being magnetoresistive, are extremely self-inductive; the consequence is that they can only practically carry very slowly varying signals (1Hz or worse). You could try to balance the heavy self-inductance with a coaxial sheath to add capacitance, but I'm not convinced that will work adequately.

The rest of this document was written before I knew about this problem.

Electromechanical relays

Electromechanical relays are a relatively simple invention, once the idea is pointed out: an electromagnet pulling a springy bit of metal into or out of electrical contact, opening or closing an electrical circuit. You can make one with a little fuss if you have some wire and ferromagnetic metal, and one version was invented in 1840 by Samuel F.B. Morse for his Telegraph. They are sufficient for building Boolean logic devices to perform arbitrary digital computations, as shown by Claude Shannon in his thesis and extensively exploited for telephone switching in the early 20th century. Indeed, since they're fairly close to ideal switches (very unlike bipolar transistors), logic circuits built using them are quite simple, using only one or two relays per gate or flip-flop, even without any elaborate mechanical tricks.

However, for digital computation, relays have some serious drawbacks. Modern silicon semiconductor devices can operate comfortably in the 4GHz range (i.e. 250ps per cycle) at room temperature; at higher cost, germanium, silicon germanium, gallium arsenide, ECL, and/or further cooling can push speeds higher, past 10GHz (100ps).

By contrast, electromechanical relays typically can't operate faster than about 100kHz (10 μs, 10 000 000 ps). This is a pretty big disadvantage, and it's the reason relays have been out of favor for digital logic since the 1940s. The basic problem is that the metal contacts are macroscopic objects full of baryons, so you have to move an awful lot of electrons through one set of contacts to produce enough energy to move another set of contacts. The vacuum tubes that replaced relays in the 1940s move only electrons, which have three orders of magnitude less mass per unit charge, and semiconductors share this advantage.

(Relay coils also have substantial inductance which limits the speed at which current in them can rise and fall.)

(Semiconductor devices also have the advantage of being very small, speeding up the timescale of anything, but this advantage could in theory be reproduced by other kinds of devices as well.)

A digression: relay logic circuits

A normal single-pole double-throw relay has five terminals:

- `C1` and `C2`: two terminals on the coil;
- `A`, an armature terminal;
- `NO`, a normally open contact which gets connected to `A` after a delay when there's current flowing through the coil; and
- `NC`, a normally closed contact which is connected to `A` except (after a delay) when there's *no* current flowing through the coil.

There are any number of possible ways to do digital logic using relays. This one is among the simplest.

Let's us a kind of "open-collector" convention: we represent logic 0 as a low-resistance path to ground, and logic 1 as the lack of a low-resistance path to ground. In that case, you can construct a basic inverter as follows, with V+ being the power supply rail that doesn't represent logic 0:

```
X' = Not(X): Relay(C1=V+, C2=X, A=gnd, NC=X')
```

This inverter is more than it appears: the normally-open contact `NO` is actually available as a buffered copy of the input `X`, and any number of outputs can be connected to the inverter's input and will be implicitly ANDed, providing fan-in, the ability to combine different pieces of information. That is, this isn't just an inverter; it's a single-relay combination N-ary AND-NAND gate, or a buffer.

(You can safely stick a resistor in series with the coil of each relay operated this way, since the coils are never placed in series with each other.)

You can put together an RS latch in the usual way:

```
Q, Q' = RS(R', S'): Q' = S' = Not(R'); Q = R' = Not(S')
```

That is, you hook up the two inverters in a loop, each inverting the other's output — wire-ANDed with an active-low asynchronous reset or set input. This gives you a bistable circuit whose state you can change, which gives you memory, making sequential circuits possible.

The fanout of this kind of relay logic will be limited only by the number of coils whose current can be run through a single set of relay contacts before the resistance of the point of contact creates a substantial voltage drop. Typically the fanout provided in this way is very large. As long as the fanout is greater than 1, you can build circuits that do universal computation.

There are two more features crucial to digital logic: level restoration and inversion.

Level restoration means that, if the input to an inverter only barely qualifies as a logic 1, the output needs to be a logic 0, but not "only barely" — it needs to be a better 0 than the input was a 1, or if the input was barely a 0, the output needs to be more-than-barely a 1. That is, you need a kind of "range compression" between the input and output. Relays make this really easy: when the contacts are open,

the resistance across them is some 20 orders of magnitude higher than when they are closed.

Inversion is the ability to get a zero from an all-ones input, or a one from an all-zeroes input. Some kinds of digital logic used in the past were capable of producing various combinations of AND and OR using only diodes and resistors, but not inversion, which requires some kind of amplifying element.

So whatever kind of thing you use for digital logic will need memory, fan-in, fanout, level restoration, and inversion.

The magnetoresistive effect

Kelvin (alias William Thomson) discovered what is now known as the "magnetoresistive effect" in the 1850s:

W. Thomson, "On the Electro-Dynamic Qualities of Metals: Effects of Magnetization on the Electric Conductivity of Nickel and of Iron", Proceedings of the Royal Society of London 8, 546–550 (1856–1857). http://archive.org/details/philtrans05965210 http://zapatopi.net/kelvin/papers/on_the_electro-dynamic_qualities_of_metals.html http://archive.org/stream/philtrans09842257/09842257#page/no/mode/2up

He found about an 0.5% change in the resistivities of ferromagnetic metals when a strong magnetic field was applied, depending on whether the field was parallel to the current or at right angles to it. Importantly (and necessarily for the P-symmetry of the electromagnetic force), the resistivity change doesn't depend on whether the magnetic lines of force run in the same direction as the electrical current or the opposite direction.

0.5% is a pretty small change, and Thomson had difficulty measuring it accurately. (Wikipedia claims he got up to 5%, but I'm not seeing that in the papers he published. Other sources claim you get 5% with a 90% nickel, 10% iron alloy, but I'm not clear on how sensitive that mixture is to impurities.)

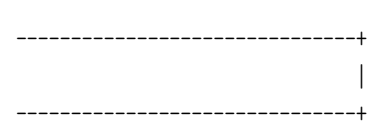
Speculation: ordinary magnetoresistance provides amplification

But I speculate that you can *almost certainly* use this "ordinary magnetoresistance" effect to produce a solid-state "relay" that provides amplification, using 1850s technology! Better yet, you can produce a kind of low-quality radio detector, which was the crucial invention that made radio transmission of audio possible, replacing the electromechanical coherer invented in 1890.

This speculation depends on the crucial assumption that the current running through the magnetoresistive element does not produce a magnetic field that tends to diminish the resistance — that is, that the magnetoresistive effect does not diminish at higher current densities. If this assumption is wrong — and I'm still not sure, because I don't understand the physics — then it may not be possible to use a magnetoresistive element to control a larger amount of power using a smaller amount of power.

I argue that this assumption is reasonable for two reasons.

First, consider a long, thin, flat, wide insulated metal tape, folded in half the middle:



An electrical current through this tape will produce magnetic fields that very nearly cancel, but the magnetoresistance (produced by an externally applied magnetic field) of each half of the tape should still be nearly the same as before you folded it in half.

Second, resistivity is typically greatest when the current flows *parallel* to the magnetic field. But in that case the magnetic field from the current is at right angles to the applied magnetic field, and so will not affect it in any way.

These are not ironclad arguments: the "cyclotron orbits" pursued by the electrons inside the metal might still produce magnetic fields in unexpected orientations.

Balance: Wheatstone bridges to amplify output

There's still the issue of the 0.5%, though. If the difference between zero and strongest magnetic field you can provide changes the resistance of your magnetoresistive element by only 0.5%, then your current will vary by only 0.5%, or less still, which means that if you just use that current directly to create another magnetic field, that other magnetic field will vary by only 0.5%. Which is to say, you completely fail at amplification.

But that's not the only thing you can do with a variable resistance. If you balance the resistance of your magnetoresistor with a similar-sized resistor in a Wheatstone bridge configuration, the voltage across the middle of the bridge will be zero when the magnetoresistor is at its reference resistance, but nonzero when its resistance is perturbed by a magnetic field. To be specific, if its resistance varies by 0.5%, the voltage across the middle of the bridge can be around 0.25% of the total voltage applied to the network.

That doesn't sound like much, but that low voltage can be (by my assumption above) providing an arbitrarily large amount of current — current which can be used to energize another coil to an arbitrarily strong field, a field which will be zero when the bridge is balanced.

This means that you can get amplification, which translates into the necessary overunity fanout. Your amplification is limited only by the precision to which you can balance the Wheatstone bridge.

Magnetoresistive radio detectors

As mentioned earlier, the perturbation in resistance depends on the absolute value and orientation of the magnetic field, not its direction; that means that the perturbation induced by a coil is symmetric around zero in the current applied to the coil. You have some kind of slight resistance bump, up or down, centered on zero.

Typically, this takes the form of "Kohler's rule", which says the extra resistance is proportional to the square of the applied magnetic field.

That's a significant nonlinearity! That means that the average resistance in the magnetoresistor is not the resistance in the magnetoresistor at the average current in the coil. If you have a pure-AC current in the coil, that can still produce a significant magnetoresistive effect, which means you can demodulate AM radio.

Level restoration

How can you do level restoration with magnetoresistive logic? One way is to exploit the symmetry around zero (and indeed the zero derivative at zero implied by Kohler's rule) mentioned in the previous section. You can improve the zero level a bit further by biasing the minimum a bit with a permanent magnet, as described.

You could use a cascade of two inverting magnetoresistive "relays" to restore both the 0 level and the 1 level, but there may be easier approaches; for example, magnetoresistance in many materials saturates at some flux density, and flux density in ferromagnetic materials saturates at some applied magnetomotive force. (Every material tends to relative permeability of unity, in the limit of sufficiently large field strength.)

Inversion

If the bridge is balanced so as to have zero potential difference and so zero current across the middle at zero applied field, you don't have inversion. But if you balance it a little differently, you can have a potential difference at zero applied field, which shrinks to zero at the applied field corresponding to logic 1, then starts to grow again. Alternatively, you can bias the field using a permanent magnet rather than the resistors, giving you a nice zero derivative in the neighborhood of logic 1. Either way, you get inversion.

Fan-in

How can you connect multiple inputs to a single output? One fairly inconvenient way — analogous to what we do in TTL and the like — is to physically colocate multiple coils, driven by different inputs, to produce magnetoresistance in the same magnetoresistor.

Memory

Aside from the usual feedback approach with a couple of inverters eating each other's tails, you might be able to use high-hysteresis, low-coercivity materials for a sort of ferrite core memory, with a nondestructive readout. I'm not entirely sure how you'd erase it, though; perhaps you could saturate your magnetic storage core in either direction, but take the reading at a point where a permanent magnet interferes with the field, either constructively or destructively?

Mayonnaise

Kragen Javier Sitaker, 2019-03-19 (updated 2019-06-10) (10 minutes)

Basically, homemade minipimer mayonnaise is a fucking miracle. From 200 mℓ of oil (US$0.18), an egg (AR$35 for half a dozen, US$0.15 per egg), 20 mℓ of lemon juice (AR$100 for 500 mℓ, I think, so US$0.10) and a pinch of salt (say US$0.01), you get about 300 g of mayonnaise customized to taste. Not counting depreciation on the minipimer and the 40 kJ of electrical energy, that's 44¢, and the whole process takes under 4 minutes, including getting the ingredients out and washing the dishes. And the result keeps even without refrigeration, though beware of circumstances where it can get diluted with water, lowering the acidity and salinity to levels where bacteria and fungi can grow.

The recipe is, as explained in that Twisted Sister song, huevos con aceite y limón. In more detail:

Mayonnaise recipes

https://www.fifteenspatulas.com/homemade-mayonnaise/

- one egg
- .25 cups oil
- .5 tsp ground mustard
- .5 tsp salt 30 seconds add another cup of oil over 60-90 seconds
- 2 tbsp lemon juice

https://www.inspiredtaste.net/25943/homemade-mayonnaise-recipe00/#itr-recipe-25943

- one large egg
- 1 tbsp dijon mustard
- 1 tbsp red or white wine vinegar
- .25 tsp kosher salt
- 240 mℓ (1 cup) oil (grapeseed, safflower, or canola)
- 1 tsp lemon juice

add oil incrementally while blending

https://www.epicurious.com/recipes/food/views/mayonnaise-24108003

- one egg yolk
- ½ tsp dijon mustard
- ¾ cup oil
- 1 tsp wine or cider vinegar
- 1½ tsp lemon juice
- ¼ tsp white pepper

add oil incrementally while whisking; add the salt and pepper at the end

use room temperature eggs

http://dish.allrecipes.com/making-mayonnaise/

- two yolks from large eggs

- 2 tsp lemon juice or vinegar
- 1 cup oil (light olive, grapeseed, or canola)
- a pinch of salt

  add oil incrementally while whisking
  add the salt at the end
  use room temperature eggs
  don't use bottled lemon juice
  add more yolk on emulsification failure
  for aioli add a very finely minced clove of garlic
  maybe try tarragon (estragón)

http://www.cookingforengineers.com/recipe/43/Homemade-Mayoonnaise

- 2 large egg yolks
- 3 tbsp lemon juice
- ¼ tsp salt
- pinch of white pepper
- 1 cup oil

  whisk in oil drop by drop after whisking other components
  freeze unused egg whites in ice cube trays
  https://aseasyasapplepie.com/homemade-mayonnaise-30-seconds/

- 1 egg (cold)
- 200 g sunflower oil (cold)
- 2 tbsp vinegar or lemon juice
- ¼ tsp salt
- 1 tsp dijon mustard

  warns not to break the yolk (!)
  use an "immersion blender" and it'll be easy; hold it still 10 seconds to get the emulsification started
  https://cooking.nytimes.com/recipes/12459-mayonnaise

- 1 large egg yolk
- 2 tsp lemon juice
- 1 tsp dijon mustard
- ¼ tsp kosher salt
- 1 tsp cold water
- ¾ cup oil (safflower or canola)

  whisk slowly
  slowly dribble in the oil

https://www.jamieoliver.com/recipes/eggs-recipes/my-beautiful-mayo/

- 2 egg yolks
- 1 heaped tsp dijon mustard
- 500 mℓ mixed oils
- 1–2 tbsp white wine vinegar
- ½ lemon
- sea salt

  add oil slowly
  add vinegar after most of the oil

Notes from my experience

Since noting the above, I've made mayonnaise about 20 times. My experiences:

• With a 600-watt minipimer ("immersion blender") there is very little you can do to keep the mayonnaise from emulsifying properly in less than a minute; I managed to do it once by not having enough egg in there, so I added another egg.
• This is true regardless of how much or how little oil you are including or how warm or cold anything is.
• Alioli — aioli in French — is fucking amazing. Including a clove of raw garlic — without bothering to mince it, because the minipimer takes care of that — makes a magical gel of deliciousness that can be applied to any food.
• Lower-power minipimers are less reliable at emulsification and much slower, so if you're using one of those you may actually need to wait to add some of the oil. You still don't need to do the thing where you carefully add the oil in a tiny trickle to keep it from separating out, which apparently you do have to do if you're mixing it with a fork or a whisk. The longer time probably produces more wear and tear on the minipimer.
• A bit of raw onion in the mayonnaise instead of garlic produces a result very much like sour cream with onion.
• Both vinegar and bottled lemon juice are fine, but I like the flavor of the lemon juice a bit better.
• The mayonnaise thus made separates a bit over the course of a few days if not eaten first, forming a sort of hardened grease on the top and up the sides of the mixing bowl.
• I've been using bargain-basement sunflower/soy oil mix (AR$33 per 900 mℓ last time I bought it, although then US$1 was AR$41, and now US$1 is AR$45) and can't tell the difference from pure sunflower oil.

I'm using cut-off bottoms of Coke bottles as mixing bowls. These are somewhat annoying to actually get the mayonnaise out of, because of the five smallish projections around the bottom, but I suspect those help a bit with the mixing part, by virtue of allowing the minipimer to spin very close to the bottom without actually touching it. Miraculously, neither of the minipimers I've used for this so far have the geometry to cut up the bottle bottom.

Minipimers are also much easier to wash than whisks are; you stick the end of the minipimer into a bowl of water and turn it on. The emulsion nature of mayonnaise helps here, dispersing the oil in small micelles. The PET of the Coke bottle is somewhat less accommodating; although the oil doesn't soak into it the way it does with polyethylene and polypropylene, really getting it off the plastic requires copious detergent and hard work with a sponge. Fortunately, this is unnecessary if you just rinse the mixing bowl with water and then make more mayonnaise in it as soon as you run out.

So far I haven't gotten salmonella from my homemade mayonnaise. Wikipedia tells me that large salmonella outbreaks in mayonnaise are invariably associated with inadequate acidity, with pH of 5 or even 6, while pH in the 3.6 to 4.1 range prevents spoilage. Unfortunately I don't have litmus paper handy, so I don't know what the pH of my mayonnaise is, and I don't carefully measure the acid as I add it.

You can turn the mayonnaise into a super lazy egg salad by adding a couple of boiled eggs, and optionally black or white pepper and a slice of raw onion, and chopping for just two to ten seconds with the same minipimer before washing it. If you have the eggs boiled beforehand, this is an excellent antidote to the urge for expensive convenience food.

Failed mayonnaise rescue by defecation

A couple of times using an underpowered minipimer I've failed to get the mayonnaise to mayon at first. In each case, after failing to solve the problem by adding more egg yolks, I let it sit covered in the fridge for an hour or two, and a substantial amount of bright yellow oil separated at the top; after pouring this off, it was relatively easy to get the less-oily remainder to gel, and it could then assimilate the oil that had been poured off. I suspect that what's happening is that the egg is being reduced to separated droplets floating in the oil, and further stirring is not effective at getting them to join up, though perhaps it makes them smaller, and certainly it keeps them from settling.

This process of separating immiscible liquids, or a liquid and a solid, by allowing the heavier one to settle out, is known as "decantation" or "defecation". Do not attempt to instead separate the mayonnaise after digesting it.

Presumably the aqueous phase of a successful mayonnaise is continuous, and that is the difference; I don't know if its oil phase is discontinuous, separated into droplets, or if the two phases form interpenetrating open-cell foams. The aqueous phase of the failed mayonnaises is definitely discontinuous, though, because tiny droplets of it remain suspended in the oil after it separates.

Is it healthy?

Aside from the concerns about salmonella, mayonnaise has a lot of calories; it's more than 70% pure fat. Eating fat is probably good for you (the late-20th-century conventional wisdom to the contrary has been shown to be false) but eating calorically dense foods is not. So it should be used as an ingredient in a more diverse food, such as a salad, not eaten by itself. Commercial mayonnaise is unappetizing enough that you have to be Michael Hart (peace be upon his blessed soul) to eat it by itself, but this stuff is tasty enough that I'm at risk of just eating it with a spoon.

If you're eating a low-carbohydrate diet, perhaps a ketogenic diet, maybe you shouldn't eat commercial mayonnaise, because it invariably contains modified food starch as a thickener. But real mayonnaise, made from egg, oil, and either lemon juice or vinegar, contains only traces of carbohydrates; lemon juice is about 6% carbohydrates (according to the bottle I have here) and the mayonnaise is about 5% lemon juice, so each 100 g of mayonnaise might contain 300 mg of carbohydrates from the lemon juice.

Surrealist code

Kragen Javier Sitaker, 2016-10-11 (3 minutes)

It occurred to me that you could maybe produce random deep-sounding or epic-sounding surrealist things with a dictionary substitution, which is to say a code, applied to ordinary English sentences, respecting the same parts of speech. For example, take this ordinary sentence by Thomas Ptacek:

If I were in charge of Russia, I would not want to get caught hacking the US.

Tag it by parts of speech and inflection:

If(conj) I(pron) were(v, 1st person singular subjunctive) in(conj) charge(n, plural or mass) of(prep) Russia(proper noun), I(pron) would(modal v taking infinitive) not(adv) want(v, inf) to(prep) get(aux v taking past participle) caught(v, past participle) hacking(v, present participle) the(article) US(noun).

Now, likely, you can make a substitution of other words that are the same part of speech while leaving it nearly grammatical. Some of the words — the ones in closed classes like conjunctions, prepositions, and modal verbs, and the ones that determine the inflection of other verbs — might be best to leave unchanged. For the ones you substitute, you could have a boring choice:

If I occurred in things of English, I could maybe take to have tagged making a sentence.

But maybe if you pick words with great emotional resonance instead, you could end up with something that sounds poetic, surrealist, or deep instead:

If I exalted in stone of suffering, I should deeply have danced flying the blood.

There are lists of "emotionally powerful words", "trigger words", "power words", or "high emotion words" going around for two-bit hustlers to spice up their sales pitches with. If I pick some words at random from one of these lists, I get this instead:

If I banned in insiders of Eva, I would stoically get satisfied controlling the miracle.

Another one quotes Churchill approvingly, "We have before us an ordeal of a most grievous kind." If I use the uncommon words from the Churchill quote, I get this:

If I struggled in ordeals of God, I would not wage to get surpassed suffering the tyranny.

The list of "317 power words" underneath gives results that are not as evocative, perhaps because the author is a two-bit clickbait hustler and not Winston Churchill, producing this instead:

If I collapsed in meltdowns of IRS, I would not worry to get cautioned smashing the mistake.

If I instead pick an arbitrary page of the Silmarillion for my words, I get this:

If I lay in lands of Beleg, I would not stay to get spoken asking the tree.

Notes on 3-D printing a mechanical LUT

Kragen Javier Sitaker, 2014-04-24 (3 minutes)

I tried 3D-printing a mechanical LUT on Julian Cerruti's Prusa Mendel the other day. The idea is that you position a probe in X and Y to set the input, then drop it down to see how far down it can fall before hitting the LUT to get the output.

It didn't go well, for several reasons.

First, I was trying to print at high resolution, both horizontally and vertically.

Vertically: my model had a 1/32 solid part at the bottom, and rose to a max height of 15/64 above that; these units were scaled to √2 centimeters, so the minimum thickness was √2 cm/32 = 0.044 cm = 0.44 mm, which worked okay (the first layer thickness was set to 0.35 mm, and subsequent layers 0.2 mm); the total thickness then would have been 17 √2 cm/32 = 3.76 mm. But note that 3.76mm is only 18 layers of plastic, which is close enough to the nominal LUT's desired resolution of 16 thicknesses that there could be aliasing problems. It would be better to double the thickness and align it precisely with the layers: two layers of solid, plus two layers per LUT level, for a total of 34 layers: (+ .15 (* 34 .2)) = 6.95 mm.

Horizontally: across the √2 cm width of the model, I had 15 intervals between grid lines, or 0.94 mm per interval. While the Mendel is perfectly capable of positioning the print head with precision well below a millimeter, the extruded plastic is substantially wider. Measurement of the infill lines on the bottom surface shows them to be spaced about 1mm to 1.5mm apart. Corner radius seems to be about 0.5mm. This means you can't practically make a positive feature with a total width below 1mm, with the software stack Julian's using, anyway (slic3r and pronterface, I think).

I think it's possible to achieve this with 1mm to 1.5mm horizontal spacing. It should be possible to make *holes* much narrower than 1mm, as long as they don't have to be too close together.

This brings me to the second problem: discontinuous layers. FDM machines typically print in horizontal slices to avoid crashing the print head into already-printed stuff, but they have various kinds of trouble when those horizontal slices contain discontinuities. At a minimum, they pull threads of plastic between the different places they visit; but also, the process of switching the pinch wheel between forward and reverse seems to be fairly undependable. So it might be desirable to add material *in between* grid points so that each layer is a single continuous piece. If the object is still a heightfield, this continuous-piece constraint simplifies to "no local maxima".

A third potential problem — which didn't show up in this case, but did in previous prints — is horizontal surfaces over infill. This requires the infill to be nice and solid to support the surface well; otherwise it can end up with holes in it.

Editor buffers

Kragen Javier Sitaker, 2015-07-15 (updated 2015-09-03) (16 minutes)

A text editor buffer is a potentially very large mutable string which you may want to make persistent, in the sense of storing to disk. One engineering problem, a less serious one than it once was, is how to implement this data structure efficiently, given that it needs to efficiently support arbitrary insertion and deletion, string search near the cursor, reading the region near the cursor, and moving the cursor to previous (or arbitrary) positions.

Text editor buffers also often contain associated metadata, including "markers" that you can efficiently jump the cursor to, which stay with the text they are attached to even when there are insertions and deletions elsewhere in the buffer. This means it is not sufficient to merely store an integer offset into the buffer as a marker; you must, at least, update that offset when there are insertions or deletions before it. There may be a pretty large number of markers, like, one per 16 bytes or so. You probably also need to be able to find the markers in a region of the buffer, like, for the purpose of storing line numbers. (Emacs markers only offer a subset of this functionality, because other primitives offer the other parts of it.)

This is also a reasonable description of the functionality a filesystem must provide, except that filesystems often do not support insertion and deletion in the middle of files efficiently. Nearly all, however, support appending to the end of files.

You could imagine a software system that elided these distinctions to some degree — where all your data was, conceptually, in a single sequence, into which you could insert data at any location, and which you could search through with impunity. Maybe you could even make it more efficient than current systems.

A byte array

The simplest data structure here is simply a contiguous byte array, reallocated when growing is needed. This used to be unusably slow, but now CPUs can `memmove()` 5 gigabytes per second, so now you're doing OK up to about 100 megabytes without doing anything special — you can `memmove()` 100 megabytes after every keystroke with barely detectable latency.

Gap buffers

A refinement of the raw byte array approach is the "gap buffer" approach, used by Emacs, where you leave a gap in the middle of the array where the cursor is. Moving the cursor (or, rather, inserting or deleting text in a new location) involves moving the gap, or rather moving text from one side of the gap to the other, but inserting or deleting text at the gap generally just involves adjusting the gap size. This means you only have to `memmove()` the 100 megabytes after every thousandth keystroke or whatever. (At the moment, my Emacs buffer gap is 1737 bytes.) This is quite fast, and it's from the at least 1970s (and may date back to Expensive Typewriter), although in the 1970s it was 80 kilobytes instead of 100 megabytes that you could move without the user getting annoyed.

As usual with things that are amortized cheap but occasionally expensive, you can make gap movement incremental at the cost of more memory usage and complexity. You need to keep track of a set of edits pending integration into the buffer (because the gap hasn't reached them yet), move the gap incrementally towards those edits (during idle time and during each keystroke), and include special cases in anything that *reads* the buffer to check the edits-pending-integration. Nobody does this, because instead they break things up into smaller pieces:

A single level of indirection

Supposing that your 100 megabytes or whatever are not enough (I have 16 gigabytes of RAM on my laptop, and plenty of files bigger than that). The next thing to try is to divide the buffer into a linear sequence of pieces, managed with, say, an array of pointers, or an array of structs. (For example, each piece's struct might contain a start pointer, a gap start offset, a gap end offset, and a total length. On a 64-bit machine, it would be reasonable for the first to be 8 bytes and the others to be 4 bytes, for a total of 24 bytes with padding.)

This is basically what the STL deque class does. It's also the approach taken by Finseth's editor Mince.

How many pieces to use? The general rule for this kind of thing is that you can reduce things that take O(N) work to O(√N) by dividing them into O(√N) pieces, so that the indirection table is about the same size as the pieces. In this case, if you have, say, a 128-gibibyte buffer, you could divide it into 2-mebibyte pieces, and there will be 65536 of them, and so your array of piece descriptors will take up about 1.5 mebibytes. This means that moving the buffer gap in any one of the pieces will take at most (2 mebibytes / 5 gigabytes per second) ≈ 0.4ms; moving a piece will take the same; and splitting a piece additionally involves inserting into the middle of that 65536-item array, which could take up to another 0.3ms or so. So the worst case is 0.7ms, and the average case (assuming the gap moves randomly) is half of that.

This is more or less the optimum piece size for this size of buffer. If you use smaller pieces, like 1 mebibyte, then moving the gap in a piece or splitting a piece will take less time, but updating the indirection array will take more time — a total of 0.8ms worst-case in that case. If you use larger pieces, like 4 mebibytes, updating the indirection array will take less time, but splitting the piece or moving it will take more time — a total of about 1ms worst-case in this case. Both of these numbers are worse than 0.7ms, but the threshold where this starts to matter to interactive response is where it becomes a significant fraction of a 17ms screen refresh.

Probably splitting pieces is much less common than moving the buffer gap a long way, so you might want to use somewhat smaller pieces in the interest of improving average-case response at the expense of worst-case response.

You can, of course, divide smaller buffers into smaller pieces.

If you're dealing with on-disk data instead of in-RAM data, you have to deal with both lower data rates and high latency. Reading or writing 2 mebibytes of data on spinning rust takes about 35ms, and seeking to it takes another 8ms or so, so the piece-splitting operation mentioned above that takes 0.7ms in RAM might take 90ms on

spinning rust. Worse, some disks are bigger than 128 gibibytes.

To deal with that kind of horror without nosing up into human-detectable operation times, we need to do better than O(√N). We need O(log N), and for that we need multiple levels of indirection:

B-trees, or multiple levels of indirection

B-trees are usually explained as an N-ary version of balanced binary search trees, a kind of ordered dictionary that's more amenable to sequential access than red-black trees and whatnot. But you can also use them for things that are just plain sequences. Each child pointer carries with it the total length of the sequence below it, so that you can index through the child pointers of a node until you find the pointer that contains the position you're interested in.

How many levels do you need? For spinning-rust usage, you probably want your B-tree nodes to be around half a mebibyte (so that you don't waste most of your time waiting for the head to seek to them); if your pointers and sizes are 40 bits, then a node holds about 48000 pointers, for about 23.4 gibibytes of child nodes, or 1.17 tebibytes of grandchild nodes. So basically with *two* levels of indirection you can get anything in two seeks and insert anywhere in three seeks and a mebibyte and a half.

For in-RAM usage, like for a traditional editor buffer, you probably want a lower branching factor and correspondingly deeper tree. For example, if we take our node size to be nominally 512 bytes and pointers to be 8 bytes, then our nodes have 64-way branching, or 32-way if they include the child weights. 128 gibibytes of buffer is 256 mebi-leafnodes, so you have up to five levels of branching, and about 1/31 of your RAM is taken up by internal nodes.

The leafnodes could still, if you wish, use buffer gaps. But it's no longer essential. Copying up to 512 bytes after every keystroke (and updating up to six ancestor weights) is not very expensive.

For more usual buffer sizes, you need less levels of indirection. 8 megabytes is only 16 kibi-leafnodes, so 528 internal nodes in a three-level tree suffices.

Compressed RAM

With the increasing gap between RAM speed and CPU speed, and the advent of new very-high-speed compression algorithms like LZ4, it's becoming reasonable to compress in-RAM data that isn't immediately being used; it's often faster to spend the CPU to decompress it than it is to take the locality hit of copying it from main memory.

Ropes

You'll note in the discussion about on-disk data structures that there was little discussion of locality of reference for writing, no discussion of fragmentation, and no discussion of crash recovery. We blithely assumed that updating in place presented no problems. Similarly, in the discussion of updating ancestor weights in RAM, there was no discussion of concurrency. And undo, of course, was taken for granted.

In practice, of course, these problems are ubiquitous. One way to

solve them (at the cost of unpredictable memory usage) is to *never modify data in place*: instead, always write new copies of the data, and eventually garbage-collect the old data once it's no longer used. This makes your data structures "persistent" in the functional-programming sense — you can reference their old state simply by keeping a reference to it, which makes undo quite simple — and allows you to choose where to write the updates to, which helps with fragmentation and write bandwidth. This is the approach behind the NetApp WAFL, behind Ousterhout's Berkeley LFS, and also behind the "rope" data structure from Xerox PARC's Cedar, which made its way into the SGI STL in a reference-counted form.

If you strictly follow these rules for B-trees, every byte you insert or delete involves creating a whole new set of treenodes up to the root. In our 128-gibibyte-buffer-with-six-levels-of-treenodes case, this is 3 kibibytes of data — plenty fast enough for keystroke response, but 3072 times bigger than the keystroke being written. It's going to give your garbage collector a headache, even though it won't trip any write barriers. There are a variety of different ways of solving this, including zippers.

The standard rope approach to this is to use unbalanced binary trees rather than B-trees, so that you only need a couple of small treenodes gluing together the parts of your buffer you aren't editing with the new string you're inserting. This way you need, say, 40 bytes of freshly allocated data to record each new keystroke, instead of 3072.

One of the simplest approaches, though, is to batch up a pending update until it's big enough to be worth it.

Update logs

In transaction processing, this is sometimes called a "side file": you log the inserts, updates, and deletes in a small file "to the side of" your main database. Any query must take care to ensure that its results take the changes in the side file into account, which typically involves traversing the side file sequentially; or you can maintain an updated version of the relevant part of the database in non-immutable memory.

This is more or less the approach that WAFL originally took to keep its disk write bandwidth manageable: it would buffer changes (in battery-backed RAM) until the once-per-second timer fired and it wrote a snapshot to disk.

In the case of a text editor, it would seem that a gap-buffer representation for the particular part of the buffer you're currently modifying should enable modification to proceed with very high efficiency; once the modifications are complete and you move elsewhere, they could be recorded in new B-tree nodes.

Markers

All of the above, however, disregards the problem of markers. If you have 128 gibibytes of text in your editor buffer, you might have 8 gibi-markers. It's no good if adding a character to your 512-byte leafnode is efficient if that requires you to increment 4 billion markers!

It's not obvious how to solve this problem scalably. But there is a way.

If you take the Mince approach, an array of separate 2-mebibyte gap-buffer pieces, maybe you could associate a separate marker table with each piece, containing the marker's physical position in that piece. This requires up to 65536 lookups to find a marker, and updating up to 131072 marks when the gap moves. (You'd probably want to doubly-index the marker table so that you can usually update fewer.) These sound like ridiculous numbers, but they're probably in the same ballpark as the cost of moving the gap normally.

In a mutable B-tree, though, there's a much more interesting possibility. Suppose a mark stores the addresses of all six of the nodes on its path down from the root, plus the byte offset into the leaf node. A mutation to nodes on that path might alter the offset within the node at which the pointer to the child is found, but it won't alter the value of that child pointer, so the mark remains valid. Only if the leaf node is mutated, or if a node it traverses is split so that the child is no longer present, will the mark need updating. And we could index the marks by these addresses so that we can find the marks that need updating when we're splitting a node.

We could go further, though. Suppose every node has a parent pointer. Now, the mark can simply consist of a pointer to the leaf node that it points into and an offset into that leaf node, and that leaf node can have a list of marks associated with it. No mutations higher in the tree will require updating the mark; updating the leaf node may require updating the mark, but finding it is easy.

This is THE SOLUTION to the scalable editor buffer problem.

Passively safe solar hot water

Kragen Javier Sitaker, 2012-10-15 (updated 2012-10-16) (6 minutes)

Suppose we want a solar hot-water-heating panel to never heat above 49 degrees under normal circumstances, so that the water it heats never becomes dangerously hot. "Normal circumstances" might involve a temperature of, say, 35 degrees outdoors. One way to do this would be to have a thermal resistance between the panel and the environment that allows a heat flux equivalent to the absorbed sunlight once there's a 14-kelvin difference: given, say, 800 watts per square meter, you need a U-factor of 800 watts/14 kelvin square meters, or an R value of 14 kelvin m²/800 W, or R = 0.018 K m² / W; that's about equivalent to an inch of concrete. However, typical outdoor air film values are around R = 0.03 K m² / W --- on each side, so 0.015 on both sides together.

If that wasn't enough thermal conductance, you could reduce the sunlight by angling the panels or painting them gray or shading them or whatever so that they only collect 400 W/m² or something, and then you should be fine. But there's another problem, which is that that 14-kelvin difference above ambient is still a 14-kelvin difference above ambient when ambient drops to 0 degrees, which will give you 14-degree "hot" water.

That's not really acceptable! To have a passively safe design that still provides adequate heat in winter, you need some kind of more consistent heat sink than the air. Maybe radiating to the sky could work: you use some insulation to keep from losing heat to the nearby air, and radiate your extra heat as infrared into deep space.

For this, you would have enough insulation to permit the difference from ambient air to be up to 50 degrees or so (R = 0.06 K m² / W, which should be achievable with nothing more than some trapped air spaces) while permitting infrared radiation to get to space, in particular around the ten-micron wavelength. Transparent polyethylene film trapping air spaces will apparently work for this (see patent http://www.google.com/patents/US5493126), but it photodegrades rapidly enough that it would need replacement every few months. Acrylic (plexiglass) transmits near infrared; I think it transmits thermal infrared (LWIR) as well, but I haven't tested. FT-IR spectra on the web for polyethylene terephthalate http://deepblue.lib.umich.edu/handle/2027.42/32476 suggest that it, too, transmits LWIR well, and it can survive solar ultraviolet for a long time.

Anyway, then, you just need to angle the panel so that it will be sufficiently coupled to the part of the sky that doesn't have the sun in it to shed the heat it acquires from the sun.

A nice thing about this kind of radiative cooling is that the power transmitted is proportional to the fourth power of the temperature. So if you're transmitting 800 W/m² at 49 degrees (322 K), at 43 degrees (316 K) you'll be transmitting 740 W/m², and at 30 degrees (303 K) you'll only be transmitting 627 W/m² --- you'll have a whole 173 W/m² pushing you toward your target temperature. Unfortunately this is still not enough to be very robust against efficiency losses in picking up the heat. arccos(627/800) is about 38

degrees (of arc!), and arccos(740/800) is only 22 degrees --- so whenever the sun is further than 22 degrees from at right angles to the panel, it won't be able to heat the water above 43 degrees C. Which means, at best, 3 hours a day.

But that's for a flat panel! If the collector isn't flat (for example, if it consists of multiple flat panels at different angles), it will absorb heat from the sun at a more consistent rate throughout the day. That solves the intermittency angle problem. (The requirement that the thermal emission equal the sunlight at the maximum safe temperature can be met, as before, by adjusting the angle of attack to the sunlight.)

The big problem with that approach is its low efficiency. Heating from 0 degrees to 43 degrees, you start off with about 48% efficiency (1-(273/322)^4) but end up with 7% efficiency (1-(316/322)^4). That means you end up with panels covering many times more area, for safety, than you would need simply to gather the appropriate amount of energy, simply because the vast majority of the energy gathered is re-radiated immediately.

There might be a way to avoid this problem: creating a sufficiently selective surface. Blackbody radiation has a fairly sharp cutoff at its top frequency, and absorption bands in plastics also have fairly sharp cutoffs. It might be possible to put together a blend of transparent plastics that block essentially all radiation longer than, say, 8000 nanometers, but have one or two orders of magnitude more transmissivity for shorter wavelengths. A black surface covered with such plastics would have an emissivity that jumped sharply (from, say, 0.001 up to 0.1 or 0.2) upon reaching a target temperature. A sufficiently large radiator of such a surface, backed by sufficiently good heat transport, would maintain a narrow range of temperatures over a wide range of heat flows.

Window systems

Kragen Javier Sitaker, 2018-10-26 (1 minute)

I have several notes on window systems:

Cached SOA desktop (p. 2229) is about a REST architecture applied to a windowing system, with each 16×16 tile being a separate resource, using a cache invalidation protocol for redraws.

Speculative plans for BubbleOS (p. 2128) talks briefly about Wercam, a secure windowing system.

What does a futuristic OS look like? (p. 2163) talks about what I think a "cool" or "futuristic" OS should look like, or rather what "outdated" OSes look like.

A minimal window system (p. 1545) talks about how to make a windowing system use a minimal amount of code, considering different design alternatives.

Pixel stream (p. 617) talks about a protocol for windowing systems.

Real time windowing (p. 891) asks about how to make windowing systems guaranteed responsive.

Three-stack generic macro assembler (design sketch)

Kragen Javier Sitaker, 2019-04-30 (8 minutes)

IBNIZ is viznut's bytebeat and display-hack virtual machine; it uses a stack-based instruction set, and when it's in run mode, it's constantly executing the program as you edit it. The program runs repeatedly on the same stack, and whatever it leaves on the stack is interpreted as pixels to paint the screen contents. (Audio works similarly.)

I was just reading Longo's *Introduction to DECSystem-20 Assembly Programming* and thinking about how the DEC assemblers and the assembler described in Nova RDOS (p. 1724) didn't have even the machine's fundamental opcodes defined internally; they were defined as manifest constants and macros, but basically almost all the assembler did by default was put numbers into memory and build a symbol table, which always seemed like a really cool idea to me. (And it was fundamental to how Gates, Allen, and Davidoff wrote Microsoft BASIC, by incrementally hacking the DEC machine into emulating an 8080.)

The first example program in Longo begins as follows:

```
EXAMPLE 1, ADDING TWO NUMBERS
I:    3    ;I=3
K:    2    ;K=2
J:    0    ;save a spot called J
```

This assembles three numbers into memory and sticks three entries into the symbol table.

Now, symbol tables are awesome and really flexible, but it would be even simpler if we could do without them, at least at the fundamental level. And some constructs — notably nestable conditionals and loops — are somewhat awkward to write in macro assemblers using labels. I mean, it's not that the labels stop you, but they don't help.

It occurred to me that maybe a stack-based assembler that filled the object file the way IBNIZ fills the screen could work.

How it would work

If the assembler interprets the input `3 2 0`, it would first push 3 on the stack, then 2, then 0. If that's the whole input, those stack contents are, in some encoding, the contents of the binary file it will write out. Similarly, if the input contains `"ABC"`, some representation of that string gets pushed onto the stack — maybe 65 66 67 3, the UTF-8 values of the string and then its length, for example. But then you could define "macros", little functions that would pop things off the stack, change the state of the interpreter, and push more things back onto the stack. For example, you might have a `MOV` macro that would push the encoding of a MOV instruction onto the stack, popping off an appropriate number of operands.

(Such an assembler designed for AMD64 machines would need to

work in bytes, while a SPARC assembler might be easier if it worked in 32-bit words. You could in theory do the conversion at the end of the process.)

Advantages; the landscape

Nestable control structures — the whole raison d'etre of this goofy idea — would use a third stack for their jump addresses, in addition to the operand stack that's accumulating the output file and the macro execution stack that keeps track of which macros are invoking which. And adding some peephole optimization would be pretty trivial, although you'd have to be careful with variable-length instruction encodings, and you might want to have some kind of low water mark that prevented such rewriting, since you wouldn't want to invalidate a jump destination. (Your macros could still inspect the previously emitted code, though.)

You'd still have a symbol table, of course, so you can call named functions. It would just be built and maintained by macros.

Although you'd probably want to use some kind of RPN syntax, there's no reason the macros would have to be programmed at a FORTH-like level, except perhaps as a bootstrappability exercise. On the contrary, the compile-time macro data world can be garbage-collected, dynamically-dispatched, pattern-matching, backtracking, theorem proving, SAT solving, whatever is most convenient for writing bits of compiler macros. PostScript and Factor are not the limit.

If you gave the compiler macro language the ability to read from its own input stream — the way FORTH immediate words do in order to read the name of a word to define, for example, or the way PostScript programs do to incrementally read and render bitmap data — you could convert your macro assembler into a compiler for arbitrary languages by providing different preludes. It might not be a good idea, but you could do it.

What's the difference from emitting binary from whatever random high-level language? The smooth incremental path from manually typing in (or hexdumping) some binary data to refactoring parts of it to enable you to generate more of it.

Self-bootstrapping

Maybe also the smooth incremental path of building more capable assemblers. This might be a way to do something like StoneKnifeForth that gradually adds features from one stage of the language to the next, without ever requiring a backwards-incompatible language leap. The most basic bootstrap compiler could handle nothing more than converting binary to decimal, while valid input to it could remain valid for all later versions. Here's a somewhat small, though surely not minimal, implementation of such a basic bootstrap. This is for AMD64 Linux, and it doesn't check its input for validity.

```
## Convert space-separated decimal numbers to binary

## You know, I think this is almost the same as the i386
## system call interface, but maybe with different registers?
## Also, different system call numbers!  On i386 %eax=1 is
```

```
        ## _exit().

        .globl _start
        ## First, read a byte:
_start: xor %edi, %edi          # fd 0
        mov $buf, %esi          # into buf
        xor %edx, %edx
        inc %edx                # 1 byte
        xor %eax, %eax          # _NR_read is 0
        syscall

        test %eax, %eax         # quit if error or EOF
        jle done

        ## Only if we've got a space, write out the number:
        mov (buf), %eax
        cmp $32, %eax
        jne keep_converting

        ## We got a space, so we should write out our byte:
        mov %ebx, (buf)         # store byte into buf
        xor %edi, %edi
        inc %edi                # fd 1
        mov $buf, %esi          # write from buf
        mov %edi, %edx          # 1 byte
        mov %edi, %eax          # _NR_write is 1
        syscall

        ## Then repeat:
        xor %ebx, %ebx          # clear accumulating number
        jmp _start

keep_converting:
        imul $10, %ebx
        mov (buf), %eax
        and $15, %eax
        add %eax, %ebx
        jmp _start

        ## Got EOF or error, so exit.
done:   xor %edx, %edx
        mov $231, %eax          # _NR_exit_group in unistd_64.h
        syscall

        .data
        .align 8
buf:    .byte 0
        .byte 0
        .byte 0
        .byte 0

        .byte 0
        .byte 0
        .byte 0
        .byte 0
```

This can reproduce its own 119 bytes of machine code (well, of an earlier version of itself) given this input:

```
echo 49 255 190 96 1 96 0 49 210 255 194 49 192 15 \
5 133 192 126 55 139 4 37 96 1 96 0 131 248 32 117 26 49 255 255 199 137 \
28 37 96 1 96 0 190 96 1 96 0 137 250 137 248 15 5 49 219 235 199 107 219 \
10 139 4 37 96 1 96 0 131 224 15 1 195 235 182 49 210 184 231 0 0 0 15 \
5' '|./binout > binout.bin
```

Reproducing a valid ELF executable presumably requires a few dozen more numbers, hopefully not hundreds.

So once you have that working, you can patch in a couple more features and fix up some jump offsets.

Arcadian plastics

Kragen Javier Sitaker, 2019-11-19 (3 minutes)

The thought that we
must eliminate single-use disposable goods
must eliminate plastics
proceeds not from environmentalism but from Arcadianism
humans for a hundred thousand generations had to cling to dead things
good linen, stone houses, stone tools, bone needles, bronze, steel, brass, gold
cling to a scrap of cloth like a grandmother, for it too cares for you through the winter
this Arcadian longing for those lost generations is anti-life
life is not tasteful
life is not restrained
life is not frugal
life is not conservative
life is not lasting
those are not virtues for life
those are virtues for human capital accumulation

life is exuberant
life is a wild, ever-changing fire upon the surface of the earth
life is algae blooming in a red tide
life is ceaseless but never constant
life is the merciless
life is the struggle of a thousand salmon that leap frantically past the bears
before laying five thousand eggs, destroying their viscera with steroids
life is a sequoia seed awaiting its awakening by fire
to sprout in the ashes
life is eager dandelions growing brightly in the cracks of the sidewalk
life is desperate air plants drilling for moisture in the rain forest bark
life is a thousand-year-old ginkgo slowly consumed by a fungus in its heartwood
protecting its delicious nuts with the stench of ten thousand corpses
life is unstable, exciting, impermanent, and full of death
life is refulgent purple jacarandá flowers covering you in brilliant yellow pollen
life is a peaceful marsh where a crocodile is resting just under the water

when a mushroom is fabricated overnight in the forest
more intricate than the carvings of any sculptor
more beautiful than the brushstrokes of any painter
it is made of a single-use disposable biopolymer
and is gone inside a week

trees regret not shedding leaves made of single-use disposable biopolymer
wolves ferociously devour single-use rabbits made of biopolymers and leave disposable droppings

humans had to cling to dead scraps of cloth and care for them like

newborn babies
 could not change raiment with the seasons as the snow hare or the goldfinch do
 because a spool of yarn was a day's work
    a century ago a tarnished mirror was a sign of wealth
 today they lie discarded in the gutters
    those who know the secrets of life and the nature of matter
 can use its own materials for their products
 they are no longer limited to heavy, fragile clay, rusting iron, and dead wood
 but can use the diaphanous resins we call plastics
 to carry water or adorn their children
 they can evaporate aluminum onto glass that floated on tin
 their children can race carbon-fiber bicycles
    a cellophane wrapper, a sterile catheter, a condom
 betoken the liberation of the humans from the toil of a hundred thousand generations
 and pitiless disease that killed one out of every five children before adulthood

Interval raymarching

Kragen Javier Sitaker, 2019-11-02 (updated 2019-11-10) (6 minutes)

In talking with banyaszvonat, the following idea arose: I think it's possible to speed up raymarching with signed distance fields enormously using affine arithmetic and possibly even interval arithmetic.

Raymarching with signed distance fields

Raymarching with signed distance fields is a currently popular computer graphics technique (in particular Inigo Quilez has achieved visually amazing results, and perhaps as a result, the technique is widely used throughout the demoscene) and is also the basis of Christopher Olah's ImplicitCAD solid-modeling system. The "signed distance field" or "SDF" of an object is a function from points in 3-D space to the Euclidean distance to the nearest point on the object's surface, except that it's positive outside the object and negative inside. Since it's the distance from a point to the *nearest* point on the object, it's a *lower bound* on the distance from that point to *any* point on the object.

Constructing such a function is a very convenient and expressive way to model a wide variety of geometry.

Raymarching successively approximates the intersection between a ray and the object by advancing a point along the ray toward the object. The SDF enables us to use a variant of raymarching called "sphere tracing" in which the distance to advance is given by by the SDF at that point. This is guaranteed not to overshoot the intersection, since the SDF gives a lower bound to the distance to that intersection (as to any other point on the object), but if the intersection point is not the nearest point on the object — which it almost never is --- the point will only move closer to the surface, not reach it. If the intersection is in a smooth part of the surface, each new point will be closer to the surface by a factor of $1/\sin(\theta)$, where θ is the angle the ray makes with the surface normal.

This is known as "linear convergence" and results in iteration counts in the dozens to hundreds per ray in typical scenes.

Note that the above algorithm has no trouble with the case where the SDF is actually an *overestimate* of the true surface distance, but may fail if the SDF is an underestimate. Conservative-estimate SDFs are extremely useful for a variety of purposes.

Interval and affine arithmetic along the ray

It occurred to me that interval and affine arithmetic could perhaps speed up the process immensely.

The reason we can't just leap down the ray an arbitrarily long distance and see if we're inside the object is that, if it's not thick enough, we might leap right through it and out the other side, eventually hitting some other part of the object or just the sky. But if we use interval arithmetic to evaluate the SDF over an interval of the ray, rather than at a point, we can check to see whether that interval includes zero — that is, whether it is possible for the ray to intersect

the surface anywhere inside this interval. This allows us to test points on the other side of the surface without the risk of missing intersections, which should allow us to reliably linearly interpolate to find the zero of the SDF, effectively using the method of secants with its φ degree of convergence rather than the linear degree of convergence given by sphere tracing.

(Jorge Eliecer Florez Diaz wrote his dissertation, which I still haven't managed to finish reading, on using interval arithmetic to handle this case correctly for raytracing of implicit functions. I'm sure what's above is in there.)

By using affine arithmetic or reduced affine arithmetic instead of simple interval arithmetic, we get an affine form which gives the SDF value over the chosen interval of the ray as a linear function of the position along the ray plus an error bound. This allows us to find all possible zeroes of the SDF reliably and probably much more quickly than with just interval arithmetic, because the subinterval or subintervals in which the SDF *might* have a zero will often be very small compared to the original interval.

Interval and affine arithmetic on screen coordinates

Using interval values for the distance along the ray, as described above, can be combined with using interval values for the position and angle of the ray as well (a so-called "view frustum"), permitting in many cases the computation of an affine expression for the color of a part of the screen. See Reduced affine arithmetic raytracer (p. 2007) for more on this.

Gradients and surface normals

Since surface normals are needed as input to lighting calculations, we need some way to calculate them from the SDF; they are the gradient of the SDF at the surface. This is normally approximated by sampling the SDF in octahedra or tetrahedra near the intersection point, choosing the epsilon size comparable to the projected pixel size to attenuate aliasing of surface bumps with pixel sampling. But I think affine arithmetic inherently calculates an approximation of the gradient, which may be adequately precise for these purposes. Moreover, unlike automatic differentiation, the coefficients in the affine form potentially pertain to an entire interval, not just a point.

Related work that I probably should have read by now

In addition to Florez Diaz's dissertation, https://www.shadertoy.com/view/lssSWH is relevant, and maybe "Interval Arithmetic and Recursive Subdivision for Implicit Functions and Constructive Solid Geometry", Duff 1992.

Archival transparencies

Kragen Javier Sitaker, 2014-06-05 (updated 2014-06-29) (7 minutes)

I've written before a bit about "transparency holograms" and how they might be useful as an archival medium for text. Here I want to do some calculations on that.

Let's suppose we're printing out on both sides of a 4-mil (102µm) Mylar transparency foil, using the simple grille pattern where all but one pixel is blacked out in each N×N square; I'll take N to be 7 in this case, and assume 600dpi, so the grille has a hole spacing of 7"/600 = 296µm, or 85.7 dpi. The other side of the foil has the pixels of 49 different 85.7 dpi pages interleaved. (For the moment I'll assume this is for a viewing distance of infinity.)

If we use a 6-pixel-tall font for text, which works out to 5.04 points at 85.7 dpi, each of the 49 pages has space for 157 rather long lines of text, about 208 characters each if we assume an average of 3.5 pixels. (I don't remember if this is the right average from bible-columns.png.) That's about 1.6 megabytes of text on the transparency, and it should all be visible to the naked eye, hopefully.

Do the viewing angles work out? The angle between two pages needs to not be impracticably small, and the angle for the most extreme left, right, top, or bottom page needs to not be impracticably large. Mylar's index of refraction is about 1.6, so those 101.6 microns are, optically speaking, closer to 63.5 microns. But our 600dpi page has 42.3µm pixel spacing, which means that we have to go 25° to the left, right, up, or down to see the next pixel in that direction: 20 cm to the side at a viewing distance of 50 cm. The refraction linearizes this somewhat, so the next page is closer to being 20 cm further to the side than to being 25° further; about 60cm to the side gets you to the third page. So we can do 7×7 without extremely distorted viewing angles—barely! At the extreme corners of viewing angle, the page is foreshortened by 36% in both X and Y dimensions.

So at 600dpi on heavy-duty transparency film, it's barely doable; at 1200dpi it's eminently doable, with more like 6 megabytes of text per page; at 300dpi you would need thicker transparency film.

14-mil (356µm) and 7-mil (178µm) Mylar sheets are sold as art supplies for making stencils, pre-frosted on one or both sides, even. This would work even with a 300dpi printer, but necessarily with a wider grille spacing. "Matte Dura-Lar" is one brand name for double-frosted Mylar. "Drafting film" is another way this kind of thing is sold. I suspect that clear film will work better, though. Grafix, the manufacturer of Dura-Lar, claims that neither inkjet nor laser will print on Dura-Lar, but other people claim success with inkjet, while claiming that the laser-printer heat curls up Mylar.

A related idea: shrink film, like Shrinky-Dinks, might enhance the resolution of a printer at the same time as thickening the film; it shrinks 2:1 when heated, which should quadruple its thickness, initially 254µm. But I don't know if it's available in transparent, and it's made of polystyrene, which is apparently not archival-safe if exposed to ultraviolet or, maybe, oxygen. However, it seems that polystyrene's better-knn problem is that it's so stable that it can last a long time after being discarded, resisting biodegradation and

photodegradation for up to centuries. (Obviously you can't put shrink film through a laser printer.)

Mechanically, though, polystyrene is far, far more fragile than PET. PET stick-on films are used to make windows smash-resistant and even mildly bullet-resistant.

At the other end of the spectrum, polycarbonate ("bulletproof glass") can be recovered from CDs, and is, ounce for ounce, less fragile than almost anything, although it has a weakness for ammonia and other alkalis. Melting CDs also causes them to shrink, just like polystyrene shrink film; but they're optically clear. It's also an archival-stable plastic.

A test

I snarfed rosettaproject_zul_gen-1.pdf (SHA1 296b27e22a720a8d3c10fa971d262f798b27906d) from https://archive.org/details/rosettaproject_zul_gen-1 and converted it first to PS with pdf2ps, then to 100dpi PNGs. GhostScript by default just does point sampling rather than antialiasing, which is shitty and loses parts of letters entirely when rendering bitmaps at low resolution, so I antialiased by brute force with ImageMagick:

```
time gs -dNOPAUSE -r300 \
    -sOutputFile=rosettaproject_zul_gen-1-large-p%d.png \
    -sDEVICE=pnggray -dBATCH rosettaproject_zul_gen-1.ps
time for x in rosettaproject_zul_gen-1-large-p*; do
    mogrify -scale 827x1169! -threshold 90% "$x"
done
```

827×1169 is from `units A4paper` telling me A4 is 210mm by 297mm, and that those work out to be 827 and 1169 pixels respectively at 100dpi. The `!` is to indicate that the images are to be stretched and squeezed as necessary to make them fit, because by default ImageMagick preserves aspect ratios and doesn't fit the box. The `-threshold` option is to convert the image to bilevel, while dilating the letterforms somewhat to keep any lines from getting lost.

Anyway, then I use the `interleave.py` I just wrote using PIL; unfortunately this is only 5 pages, so to get to 3×3, I had to duplicate some.

```
time ./interleave.py \
    rosettaproject_zul_gen-1-large-p1.png\
    rosettaproject_zul_gen-1-large-p2.png\
    rosettaproject_zul_gen-1-large-p3.png\
    \
    rosettaproject_zul_gen-1-large-p4.png\
    rosettaproject_zul_gen-1-large-p5.png\
    rosettaproject_zul_gen-1-large-p5.png\
    \
    rosettaproject_zul_gen-1-large-p5.png\
    rosettaproject_zul_gen-1-large-p5.png\
    rosettaproject_zul_gen-1-large-p5.png
mv interleave-output.png bible-zulu-interleaved.png
```

`interleave.py` took like 3½ minutes to do this, and the result looks

okay.

(Now I guess I need to turn that into a PDF so I can print it, plus printing the grille.)

My theory on the numbers on this prototype is that, even if the number of pages changes, the size of the composite pixels shouldn't; there should still be about 86 of them per inch in each direction. This image has 100 of them per inch in each direction, and only 9 pages; this should be less challenging in the dimensions of legibility, viewing angle delta, brightness, and maximum viewing angle.

A thing that surprised me about this, but shouldn't have, is that some of the text is readable without the grille. In particular, since page 5 is repeated 5 times, it's quite readable despite the other four page images interfering.

A second test

I downloaded Murray R. Spiegel's "Mathematical Handbook of Formulas and Tables" from https://archive.org/details/MathematicalHandbookOfFormulasAndTables (SHA1 efc83d86ae251e4ef7bf6ec852caeb95708ba98d) and extracted pp. 27, 28, 30, 31, 37, 38, 39, 40, and 43 with Evince's "print; range; pages" to a PDF file. Then I processed this into PNGs:

```
time gs -dNOPAUSE -r300 -sOutputFile=spiegel-select-p%d.png \
    -sDEVICE=pnggray -dBATCH ~/Documents/spiegel-select.pdf
time for x in spiegel-select-p*; do
    mogrify -scale 827x1169! -threshold 70% "$x"
done
```

The 90% threshold came out shitty because this book contains gray halftoning with super important black text in it, but a 50% threshold washes out the text badly. 70% was better than either 66% or 75%, although it still has some problems.

```
time ./interleave.py spiegel-select-p*
mv interleave-output.png spiegel-interleaved.png
```

It seems to have worked pretty well.

Topics

How small can we make a comfortable subset of JS?

Kragen Javier Sitaker, 2018-11-27 (updated 2018-12-02) (3 minutes)

I just hacked together some crappy JS. I thought it would be good to write down a grammar for the subset of JS I happened to use, as a sort of benchmark of how big a grammar for a usable JSish language needs to be. Here I'm using lowercase for tokens.

```
Stmt ::= Expr semicolon | Decl | Function | Block | Controlflow
Controlflow ::= If | For | Forin | Forof | continue semicolon | Ret | Throw
Ret ::= return semicolon | return Expr semicolon
Throw ::= throw Expr
Expr ::= Assexpr
Assexpr ::= Orexpr eq Assexpr | Orexpr
Orexpr ::= Orexpr or Andexpr | Andexpr
Andexpr ::= Andexpr and Cmpexpr | Cmpexpr
Cmpexpr ::= Cmpexpr Cmpop Addexpr | Addexpr
Cmpop ::= eqeqeq | eqeq | leq | geq | lt | gt | noteqeq | noteq | in
Addexpr ::= Addexpr (plus | minus) Mulexpr | Mulexpr
Mulexpr ::= Mulexpr (times | divide | modulo) Incexpr | Incexpr
Incexpr ::= not Incexpr | Atom | Atom plusplus | Atom minusminus

Atom ::= Literal | name | Listdisplay | Methodcall | Property | leftparen Expr ri
ghtparen
Literal ::= string | null | true | false | regexp
Listdisplay ::= leftbracket Exprlist rightbracket
Exprlist ::= Expr comma Exprlist | Expr
Methodcall ::= Property leftparen Exprlist rightparen
Property ::= Atom period name | Atom leftbracket Expr rightbracket
Decl ::= (let | const) Decls
Decls ::= name eq Expr | name | name eq Expr comma Decls | name comma Decls
Function ::= function name leftparen (Params | ε) rightparen
Params ::= name | name comma Params
Block ::= leftcurly Stmts rightcurly
Stmts ::= Stmt Stmts | ε
If ::= if leftparen Expr rightparen Stmt (else Stmt | ε)
For ::= for leftparen Forinit semicolon Fortest semicolon Forinc rightparen Stmt
Forinit ::= Decl | Expr | ε
Fortest ::= Expr | ε
Forinc ::= Expr | ε
Forin ::= for leftparen (let | ε) name in Expr rightparen Stmt
Forof ::= for leftparen (let | ε) name of Expr rightparen Stmt
```

Noticeably missing are function expressions, object displays, try-catch statements, `break`, `new`, arrow functions, unary prefix operations + and - (same precedence as `!`), … spread operations, bitwise operators, and semicolon insertion. That's because I happened not to use them in the code in question.

The tokens are something like the following:

```
semicolon ::= ';'
```

```
continue ::= 'continue'
return ::= 'return'
throw ::= 'throw'
eq ::= '='
or ::= '||'
and ::= '&&'
eqeqeq ::= '==='
eqeq ::= '=='
leq ::= '<='
geq ::= '>='
lt ::= '<'
gt ::= '>'
noteqeq ::= '!=='
noteq ::= '!='
in ::= 'in'
plus ::= '+'
minus ::= '-'
times ::= '*'
divide ::= '/'
modulo ::= '%'
not ::= '!'
plusplus ::= '++'
minusminus ::= '--'
leftparen ::= '('
rightparen ::= ')'
string ::= '"' ([^"\\] | '\\' char)* '"' | "'" ([^'\\] | '\\' char)* "'"
null ::= 'null'
true ::= 'true'
false ::= 'false'
regexp ::= '/' ([^/\\] | '\\' char)* '/'
leftbracket ::= '['
rightbracket ::= ']'
comma ::= ','
period ::= '.'
let ::= 'let'
const ::= 'const'
name ::= [A-Za-z_\u0080-\u10ffff] [A-Za-z0-9\u0080-\u10ffff]*
function ::= 'function'
leftcurly ::= '{'
rightcurly ::= '}'
if ::= 'if'
else ::= 'else'
for ::= 'for'
of ::= 'of'
```

This omits whitespace, comments, and the complications of automatic semicolon insertion.

The tricky part for PEG implementation would be the left-recursion in Orexpr, Andexpr, Cmpexpr, Addexpr, and Mulexpr; the comma ambiguity (once you add the comma operator) probably requires distinguishing Exprs from Commalessexprs, and the if-else ambiguity is handled reasonably by PEGs.

Current hardware trends tend toward raytracing

Kragen Javier Sitaker, 2016-10-07 (4 minutes)

From at least the 1970s until the present day, semiconductor RAM has been the dominant form of memory measured in number of memory accesses, and the number of bytes of memory on an interactive computer has roughly equaled the number of instructions per second it could execute, from about a hundred thousand around 1980, to about a million a few years later, to about ten million in the early 1990s, to about a hundred million in the late 1990s, to about a billion in the early 2000s, to about ten billion today.

But in theory time-space tradeoffs are possible, and indeed we have been achieving reasonable performance on these machines by storing a lot of precomputed results in their memory.

But current microcontrollers have dramatically more computational power than they have onboard memory, and adding off-chip memory dramatically increases power usage. It's entirely typical to find a CPU capable of 50 or 100 million 32-bit integer instructions per second, but limited to 16 or 32 kilobytes of SRAM, a ratio of about 2000 instructions per byte.

The extreme on this axis, in a sense, is GreenArrays; each of the 144 cores on a GreenArrays chip executes about a billion 18-bit integer instructions per second, but only has 64 18-bit words of memory, which would be 144 bytes. That's about 7 million instructions per byte. I say "in a sense" because, with that little memory, it's really kind of in between being an FPGA and being a regular computer.

If nowadays CPU cycles are cheap compared to memory, how should we adapt our software to that? Maybe we can do more stuff with convolutional and recurrent neural networks, but how about regular things like graphical user interfaces?

You could imagine raytracing your GUI. Raytracers use almost no memory for intermediate rendering results, although they do usually build up a scene graph. I just ran a quick raytracer I'd written to benchmark, generating 1920×1080 pixels, and got these results:

```
==22338== Cachegrind, a cache and branch-prediction profiler
==22338== Copyright (C) 2002-2011, and GNU GPL'd, by Nicholas Nethercote et al.
==22338== Using Valgrind-3.7.0 and LibVEX; rerun with -h for copyright info
==22338== Command: ./raytracer 1920 1080
==22338==
--22338-- warning: L3 cache found, using its data for the LL simulation.
==22338==
==22338== I   refs:      1,348,631,580
==22338== I1  misses:            1,263
==22338== LLi misses:            1,230
==22338== I1  miss rate:          0.00%
==22338== LLi miss rate:          0.00%
==22338==
==22338== D   refs:        459,287,791  (331,081,906 rd   + 128,205,885 wr)
```

```
==22338== D1  misses:          21,360  (     19,098 rd   +       2,262 wr)
==22338== LLd misses:           2,292  (      1,719 rd   +         573 wr)
==22338== D1  miss rate:          0.0% (        0.0%     +         0.0%  )
==22338== LLd miss rate:          0.0% (        0.0%     +         0.0%  )
==22338==
==22338== LL refs:             22,623  (     20,361 rd   +       2,262 wr)
==22338== LL misses:            3,522  (      2,949 rd   +         573 wr)
==22338== LL miss rate:           0.0% (        0.0%     +         0.0%  )
```

So that took 1.348 billion instructions, about 650 instructions per output pixel. It missed in its level-1 data cache (which is 128 KiB) 21,360 times; its cache lines are 64 bytes, so that totals about 1.37 megabytes of data I/O, about 10% of which was output.

Suppose this 650 instructions per pixel is typical (although I was raytracing a very simple scene, you could imagine getting close to this performance on general scenes using all kinds of clever hacks). Then you could paint a 320×240 screen in 50 million instructions; with ten or twenty small processors you could raytrace a small-screen UI.

However, 2560×1440 tablets are becoming common now! These would require 2.4 billion instructions per frame at that rate.

So, maybe not for a while yet. The trends seem clear.

Topics

Sample reversal

Kragen Javier Sitaker, 2018-12-18 (updated 2019-01-17) (5 minutes)

One problem that can happen with sampled sounds is a discontinuity at the end of the sample. If the sample is long enough, this sounds like a click, but a short sample (e.g. a single oscillation of a waveform) can turn it into a sawtooth buzz, one that can overwhelm the rest of the signal.

One tool available in old MOD trackers was time-reversal of the sample, so instead of playing the wavetable from beginning to end repeatedly, it would play boustrophedonically, first from beginning to end, then backwards from end to beginning, and then repeat. This approach eliminates the discontinuity. It also cuts the size of your wavetable in half.

Audacity has a "zero-crossing finding" tool on the Z key which adjusts your selection boundaries to the nearest positive-going zero crossing. This also helps with the same problem.

The boustrophedon approach has an interesting effect on the signal, though. Since the resulting waveform is reflection-symmetric, it can only contain cosine waves; the phase of all the signal components is forced to zero, or rather all imaginary components are canceled, because the time-reversed part of the signal has conjugated phase. (All harmonics of the period of the doubled-length wavetable are possible, though.) So the extent to which a partial makes it through this procedure is dependent on its phase — if it happens to have perfectly real phase, it's untouched, but if it happens to have perfectly imaginary phase, it's entirely canceled. This means that filtering a signal with an allpass filter before this procedure can radically change the frequency content on the output, even though the signal going in may sound identical.

I propose a probably known extension to the procedure: rather than repeat(wavetable[1:] || reverse(wavetable)[1:]), use repeat(wavetable[1:] || reverse(wavetable)[1:] || 2·wavetable[0] - (wavetable[1:] || reverse(wavetable)[1:])), reversing the sample both in time and in sign, eliminating the discontinuity in the derivative at the beginning of the wavetable (though not its end) and extending the generated waveform to four times the length of the wavetable. This allows the generated waveform to contain all of its period's harmonics with any phase, rather than just real phases, and it cuts in half again the number of samples needed to represent a waveform of a given fundamental frequency.

For example, a 440-Hz A note at a sampling rate of 16kHz (a common rate in MODs) would require a wavetable of 36.3636 samples for a full oscillation; a 36-sample version of this wave would be out of tune by 1%, which sounds inconsequential but is 17 cents, easily audible. So you'd probably use three oscillations, 109 samples, which gives you 440.37 Hz, only off by 1.4 cents. If you try to use this approach with ¾ of an oscillation, it will work, but you're constrained to 27 or 28 samples, corresponding to 108 or 112 samples in the full three-period time, which would be 36 or 37⅓ samples per oscillation.

I was thinking that you could choose to duplicate the initial/final

sample of a segment, or not, to correct this detuning, but I think that probably a better way to inexpensively tune up or down by fractions of a semitone is to occasionally duplicate or omit samples at points where the sample value and, especially, derivative are zero or nearly so. I don't know how this will sound, but maybe if it works well enough, you could represent an arbitrary 440Hz harmonic sound with a 12-sample 16ksps wavetable. This is very appealing not just because it takes 24 bytes but because optimizing over a 12-dimensional space, whether in the frequency domain or the time domain, whether by hand or using an algorithm, seems much more tractable than optimizing over a 109-dimensional space.

For images, you can use this kind of approach to make a smoothly tiling texture out of any image by reflecting it at the border. A kaleidoscope works this way; the tiling need not be square but it does need to have only vertices of even degree, which probably limits you to variants of square and triangular tilings.

You can also use this approach to make smoothly stretching display window frames from a single example: by inserting reflected sections into the middle of stretched dimensions as necessary, you can make the window whatever size you want, down to the minimum of the original drawing. You won't introduce discontinuities in colors, but you may introduce discontinuities in line angles; if you can choose preferred direction-reversal points where the lines are all either perpendicular or parallel to the edge, you can keep that to a minimum, but you may not be able to eliminate it entirely.

Notes on higher-order programming on the JVM

Kragen Javier Sitaker, 2016-09-06 (6 minutes)

How do I dynamically generate bytecode?

Aside from understanding the JVM bytecode (for which `javap -c` and chapter 6 of the JVM spec are helpful), there's the question of how to get from a plan for code to generate to actually being able to run the code on the JVM, as described in chapter 5 of the JVM spec.

At the most basic level, you write a custom ClassLoader, which is five or six lines of code, and invoke `.loadClass(name)` on it. But then you still have to generate the bytecode that will define your class.

(There's an existing overview of bytecode-generation and -manipulation libraries for Java at java-source.net.)

That's what ObjectWeb ASM does; it's a library for JVM assembly programming, and it comes with a disassembler, which produces Java source code that invokes the ObjectWeb ASM APIs. It's used by CGLib, Hibernate, Clojure, Jython, JRuby, and so on. It may be actively maintained (it supports Java 8) but change is mostly limited to bugfixes at this point. It has a reputation for being simpler to use than BCEL, because it's more narrowly focused on generating, transforming, and analyzing byte arrays representing JVM-bytecode classes. Generating a hello-world class with it is 14 lines of code in the documentation, and generating a simple method as a sequence of bytecode ops is another six.

Javassist is an actively maintained 16-year-old free-software library for Java bytecode manipulation, with what seems to be a better-thought-out and more convenient interface, although it's hard to find reasonable documentation (Javadoc doesn't count!). It's integrated with its own Java compiler, so you can even specify bytecode to insert in the form of Java source code! (However, its Java compiler supports a subset of the full language.) It's part of the JBoss project now, and apparently uses ObjectWeb ASM.

Soot is an actively maintained framework for analyzing and optimizing Java bytecode, supporting different intermediate representations (each of which has a textual syntax). It also supports Android bytecode (which I assume means Dalvik), which makes it unique among the libraries I've looked at. It's mostly oriented toward program analysis (e.g. interprocedural dataflow analysis) rather than dynamic code generation, but you can also use it for dynamic code generation; the hello-world Soot dynamic class requires 28 lines of code to generate. Despite being actively maintained, it doesn't yet support Java 8.

BCEL, previously known as JavaClass, is a library for generating and transforming JVM bytecode,. It comes with, among other things, a Java disassembler to Jasmin syntax. It's at a very similar level to ObjectWeb ASM, but it looks somewhat more cumbersome to use, although there are some very cool facilities in it; its most basic example, called HelloWorldBuilder, is over 100 lines, although that includes things like try-catch blocks. BCEL seems to have been

abandoned in 2006.

SERP is another actively maintained library for, mostly, bytecode modification, apparently with a stateful DOM-like API. It's almost completely undocumented.

How do I profile?

The crudest tool is a thread stack dump, which you can get by typing control-backslash or by using `jstack` (included with the JVM) with the appropriate PID. This will show you the stack of each thread in your JVM process, from which you can see what it's currently taking too long to do.

There's also a profiler that comes with the JVM called HPROF; you invoke it for CPU-sampling profiling with `java -agentlib:hprof=cpu=samples YourProgram` or with entry-and-exit instrumentation, which slows the program down by an order of magnitude but gets accurate call counts, with `-agentlib:hprof=cpu=times`.

Profiler4j, open-source, abandoned in 2006, "in beta stage", based on bytecode instrumentation.

Some old profilers use the JVMPI interface, which has been phased out to be replaced with JVMTI in current Java.

The Netbeans folks wrote a profiler which is now this separate thing called VisualVM, which has now expanded far beyond just profiling. VisualVM is free software but apparently hasn't been ported along with OpenJDK, although there seems to be no licensing reason not to; maybe you can compile it from source, and it supports OpenJDK.

JIP is a profiler that hooks the classloader and uses ObjectWeb ASM to instrument bytecode as it's loaded. It's supposedly much lower overhead than hprof. But it's been abandoned since like 2008.

TPTP was a profiler integrated into Eclipse, built on JVMTI. It was abandoned in 2011.

Jvmtop monitors all the JVMs on a machine, like top, and includes a high-overhead sampling-based CPU console profiler. Jvmtop as a whole was abandoned in 2013.

GCViewer is a currently maintained viewer of GC statistics, using the GC profiling functionality built into the JVM, to help you understand GC behavior with pretty graphs and extensive statistics. Jörg Wüthrich took over maintenance from tagtraum industries in 2008.

Can a simple nonlinear VCO enable super cheap oscilloscopes?

Kragen Javier Sitaker, 2017-05-04 (updated 2017-05-10) (5 minutes)

I want to build an oscilloscope out of recycled e-waste. This is problematic because parts like analog oscilloscope CRTs and 60Msps ADCs are not common in e-waste, and parts like TV CRTs and 2Msps ADCs are not adequate substitutes. A 100kHz "oscilloscope" is a joke. 20MHz is the minimum standard, and for an analog scope, that's just the 3dB cutoff frequency; it can still detect signals of higher frequencies, just attenuated and maybe phase-shifted.

Once I have a digitized signal, basically the hard part is over. Everything after that is a simple matter of programming. Digitizing the signal fast enough is the hard part.

To be concrete, I want to be able to sample a signal to the following specifications:

- at a rate of at least 60 million samples per second;
- at a resolution of at least 8 bits per sample;
- for at least 2048 data points;
- for at least two data channels.

(Ideally I could do this many times per second, but I don't think that's going to be a meaningful constraint.)

So I've been exploring a variety of different possibilities, and I think I might finally have a design approach that will work.

To digitize a channel, you first use it to control eight separate nonlinear VCOs with one-octave ranges and center frequencies distributed around 350MHz. At their lowest frequencies, they will be around 250MHz; at their highest, around 500MHz. The linearity of their voltage- frequency response matters almost not at all for this application; deviations from linearity of a factor of 2 or more can be tolerated. This should make it possible to use very simple, primitive designs for the VCOs; something like the 5¢ MMBT6428 npn RF transistor, with its 700MHz transition frequency, ought to be adequate for each VCO.

The spread in frequencies among the VCOs prevents them from locking to one another through unintentional cross-coupling. This probably means they'll need to be spread apart by more than 15MHz (thus 120MHz between the highest and the lowest), which I will disregard in what follows, hoping it's unimportant.

So now you have eight channels carrying waveforms, each of which is in the 250MHz to 500MHz range, and which collectively have between 4 and 8 billion transitions per second. This means that during a 17-nanosecond sample period (at 60Msps), they have between 65 and 133 transitions, depending on the input voltage and on how the phase of each oscillator happens to line up with the sample period. I think you should expect rms noise of .82 counts per sample period from the random phase thing, compared to rms noise of .29 counts for just quantizing at all (a factor of $\sqrt{8}$ smaller), which means ENOB is $\lg(66*.29/.82) \approx 4.5$, which is inadequate, even before some of those bits are spent on tolerating nonlinearity.

(I think the above calculation is still wrong. See https://en.wikipedia.org/wiki/Effective_number_of_bits.)

Then you need to count these pulses. If each channel is connected through a MOSFET to a capacitor and a 500MHz ripple counter, we can freeze the count by turning off the MOSFET and letting the ripple finish, and then we can latch it by reading out the ripple count data in parallel. You just need the capacitor's RC time constant with the MOSFET to be well under 1ns, and its discharge time while driving the ripple counter to be long enough to give us time to read the count (say, 1µs).

A 500MHz ripple counter has a first bit that transitions at 500MHz, a second bit that transitions at 250MHz, a third bit at 125MHz, a fourth bit at 62½MHz, and then we're down to ranges where any old ripple counter will do. But the first four bits of the counter might need to be built with special care.

This requires us to transfer eight 8-bit transition counts (64 bits) from the ripple counters to FIFOs every 17-nanosecond sample period, probably not over a shared 8-bit bus, in order to keep the bus clocks down at 60MHz instead of 480MHz. The FIFOs need to hold 2048 data points (128 kibibits in total, 16 kibibytes), but don't need to be dual-ported. Then we can read them at our leisure when we're not acquiring data. For example, if we trigger a data collection 60 times a second, we have 17 milliseconds to read the data out of the FIFOs, about a microsecond per data transaction or 125 nanoseconds per data transaction on a given FIFO.

It's probably necessary to measure the temperatures of the VCOs in order to compensate for thermal effects on their voltage-frequency relationship.

Using larger ripple counters is probably a good idea because it means you can get higher precision at lower sampling rates.

A language whose memory model is a bunch of temporally-indexed logs

Kragen Javier Sitaker, 2019-05-12 (updated 2018-05-21) (20 minutes)

The Mill CPU uses a randomly-readable queue, called the "belt", instead of stacks or registers; the last *n* instruction outputs (I think *n* = 16?) are addressable as inputs. This makes the instruction set encoding denser, due to the lack of need for output register fields in the instructions. It also makes superscalar scheduling simpler, because inter-instruction dependencies are simpler to detect.

Normal RAM is made of registers; imperative programming languages expose this in the language semantics, indeed centering it. A register is a function from time to values, computed from a sequence of writes at different times; at any time *t* its value is the value written by the last write at time before *t*. What if, instead of a RAM made of registers, we had a RAM made of belts, each storing the entire sequence of writes to that location? Indeed, what if it were made of infinite belts?

Similar language features

I was debugging some Octave† code today. In Octave, an assignment statement like `x = y + z` generates a line of output by default saying something like `x = 5.4405`. To suppress this, you have to append a semicolon, which is only legal on assignment statements. So if you write a piece of Octave code without any semicolons and then run it, it outputs a history of all the values assumed by variables during its execution, interleaved by time, a trace which is very valuable when debugging. If only one variable is thus semicolonless, the trace shows the history of its values. By examining the overall behavior of the trace, you can often understand things about your program's behavior that are difficult to see from its state at a single point in time.

Of course you can do something analogous in almost any programming language with `print` statements, and this "printf debugging" or "logging" is a common tactic, superior to stepping in a debugger under many circumstances; my friend Charity is doing a very influential startup right now called honeycomb.io based on elaborations of printf debugging. But in Octave, logging every new value assumed by every variable is a default. You have to turn it off explicitly. (Unfortunately, you do that by editing the code.)

Another thing I've wanted to do frequently with Octave when writing numerical algorithms that compute a series of x_i values is to change the code between returning a vector x of all the values or just returning the last value x_n. Typically one direction of this transformation amounts to replacing `x =` with `x(end+1) =`, and `x` otherwise with `x(end)`.

The DDD debugger frontend to the GDB debugger also has facilities to capture values of specified variables every time a given breakpoint is hit; then you can plot or list the logged values.

Bret Victor has done a couple of experimental programming environment sketches which log each new value produced and annotate your source code with them, placing time on the horizontal axis — one aimed at defining and exploring recurrence relations, another intended to make imperative looping more understandable to new programmers.

Python and ES6 have a "generator" feature in which you can define lazily-computed sequences of values by writing an imperative function to `yield` them one by one; for example:

```
def lc_words(fileobj):
    for line in fileobj:
        for word in line.split():
            yield word.lower()

def pairs(seq):
    last = next(seq)
    for item in seq:
        yield last, item
        last = item
```

† Octave is a free-software clone of MATLAB.

A language with nondestructive assignment statements

What if assignment statements like `x = 3` still changed the value of `x`, but left its previous values accessible, say, as `x@1`, `x@2`, and so on? Then you could inspect all the previous values when you were trying to debug a program. Moreover, you wouldn't have to do anything special to enable my iterative-calculation Octave functions to return their whole list of values — though if the number of iterations wasn't known ahead of time, they'd have to return the length of the list, too.

Many DSP algorithms would become slightly simpler to write, since you could just write `x` when you wanted the latest value of x, and `x@1`, `x@2`, etc., when you wanted x_{i-1}, x_{i-2}, etc.

The downside is that refactoring would become somewhat trickier; `x = f(y); x = f(x)` would no longer be equivalent to `x = f(f(y))`, `x = 0; if (g(n)) x = n` would no longer be equivalent to `x = g(n) ? n : 0`, and functions would expose the entire value history of their return value, not just its final value, even if only the final value was intended to be used.

As described in Usability of scientific calculators (p. 2379), writing down numerical state machines in such a notation is very convenient.

It might be worthwhile to provide an `#x` operation to tell you the total number of values that have been written to x so far. This would allow you to note `#x`, call some function that appends things to x, and then subtract from the new `#x` when its execution finishes to see how many values it produced. I think this is probably pretty bug-prone, though, since it tempts you to write code that assumes that nothing has ever written to x previously, and puts you in danger of writing code that will break if `#x` has some unexpected value. Maybe if `#x` starts at 1'000'000 or something, that would ameliorate this problem. (Alternatively, you could set `#x` to 0 in the language model for local

variables `x`.)

In the framework of *Essentials of Programming Languages*, the *expressed values* of the language, those that expressions can evaluate to, would still be atomic values like numbers and characters, but its *denoted values* would be integer-indexed limitless logs of such atomic values.

There's no way for a subroutine in such a language to reduce its memory consumption; all previously produced values are available for inspection. So it probably needs to be short-lived.

Could we get by without any other kind of indexed memory addressing?

If the memory in our language's virtual machine consists not of registers but of limitless logs of past values, any single variable can then contain an entire array, and indeed a limitless number of arrays one after the other.

For the first ten or twenty years, say from 1945 to sometime between 1955 and 1965 in different lineages, the memory addresses to access (typically "registers of the store", at the time) were hardcoded into the instruction. This made it hard to write loops like this one:

```
int total = 0;
for (int i = 0; i < n; i++) total += x[i];
```

That's because the different items of `x[i]` are stored at different memory addresses, and the same addition instruction has to access all of them. So you had to modify the instruction. Typically you would add the index to it, since the source address field was typically stored in the least significant bits of the instruction, though this could obviously cause surprising effects if the arithmetic generated carries out of that field.

The solution to this problem was the "index register", and later also "base registers" and "pointer registers", which are just CPU registers whose values enter into the computation of the effective address. This allows you to compile code like the above without generating self-modifying code — you just store `i` in an index register, or maybe even `&x[0]` if the index register is wide enough. (C goes further and declares array indexing to be merely a matter of pointer arithmetic.)

Could we replace array and structure indexing entirely with this kind of indexing into the past? Maybe our instruction set could disallow indexing space and only allow indexing time.

It turns out that you can, and it doesn't really cost you performance except in the case of random indexed writes, for which it costs you a logarithmic slowdown. Programs are arguably slightly clearer than the same programs written using index registers, but not as clear as programs written using indexing and field access in modern programming languages.

Arrays

Well, if the memory consists not of registers but of infinite logs of past values, a single variable `x` can then contain the entire array:

```
int total = 0;
```

```
for (int i = 0; i < n; i++) total += x@i;
```

This has the potential disadvantage that, as in core LISP, reading happens in the opposite order from writing. For this case it doesn't matter, but when it does, you can write `x@(n-i)`, for Octave-style 1-based indexing, or `x@(n-i+1)` for C-style 0-based indexing.

If `n` is a constant, you can access item *i* of the *j*th previous value of *x* with `x@(n*j - i + 1)`.

On the other hand, if the past values of `n` are the lengths of past arrays stored in `x`, then we can index the *j*th of them with *O(j)* work; the length of the previous `x` array is `n@1`, and its latest value is `x@n`. The one before that ends at `x@(n+n-1)` and is of length `n@2`, the one before that is `x@(n+n@1+n@2)` and is of length `n@3`, and so on.

If we want random access to the past `x` arrays, we can store the prefix sum of their lengths instead of just the lengths themselves. If the prefix sums are stored in `s`, then the length of the latest `x` array is `s-s@1`, the previous one is `s@1-s@2`, and the one before that is `s@2-s@3` (and its last element is `x@(s-s@2)`).

This storage scheme sort of prevents you from appending elements incrementally to the latest `x` array, which is maybe undesirable; in that case you can store its length in a variable `n` that you can increment, and only store the cumulative sum of the *completed* array lengths in `s`. So then you have `n+s-s@(j-1)` elements after the end of the *j* th-from-last array, for $j > 0$.

If no typing discipline prevents it, you could get by with writing the lengths and their cumulative sums and whatnot to the same variable as the array values themselves, but that gets awkward to program.

These schemes generalize with little difficulty to multidimensional arrays; if you want to regard the *n* last items of *x* as a two-dimensional $w \times h$ array, such as a grayscale image, you can index item (i, j) as, for example, `x@(w*i + j)`.

Statically-typed immutable heap records

Consider structures less regular than arrays, though — binary search trees, for example. You might have a single type of tree node with a key field and nullable left and right pointers. You can store this as parallel arrays `K`, `L`, and `R`, and a count `n`. (Parallel arrays really suck if you're deleting objects, but fortunately that's something we don't have to worry about here.) `L` and `R` can be integer indices. You can't mutate anything, but you can add new nodes, which is enough to allow you to create a new updated root for a new tree state.

Here's a binary tree search using this representation:

```
next = root
while next != 0:
    node = next
    if needle == K@(n - node): break
    next = (needle < K@(n - node)) ? L@(n - node) : R@(n - node)
```

Generally, though, when we have a bunch of records floating around in the heap with links to each other, we have multiple different types of records (classes of windows, productions of syntax, etc.), so we want dynamic typing. Dynamic typing is a bit hairier.

Let's call the structure formed by `K`, `L`, `R`, and `n` a "table", and `K`, `L`, and `R` its "columns". For a sum type, we need one table per variant type, plus a sum-type table with a tag column (telling which table the real value is in) and a pointer column (giving its index in that table), or with one pointer column per variant type. Optionally, if there's some data in common among all variants, you can move that data into an extra column in the sum-type table, which gives you more or less the conventional RDBMS approach to inheritance subtyping if you continue it a bit further.

(Syntactic sugar for this "table" construct might be necessary to make this approach actually usable.)

Random writing to arrays

We've talked about reading from random indexes into arrays. But what about algorithms that want not to *read* at random indexes but to *write* at them? For example, suppose we want to draw a diagonal Bresenham line on the `x@(w*i + j)` grayscale image mentioned just above. There's no direct way to do this; we can only write to the end of `x`.

You could, though, stick all your lines and other graphical primitives in a buffer and use the scanline rendering rasterization algorithm to compute the scan lines of the image in order. This is potentially more difficult for hairier primitives like splines and IFS fractals.

However, we can totally construct a sparse matrix in COO format — a table with columns `row`, `column`, and `value`. You can append onto these things in whatever order you like. Converting a COO sparse matrix to a dense matrix is conventionally done in linear time with random writes, but you can also do it by sorting the items and then traversing the sorted list. This adds a logarithmic slowdown, but perhaps with a well-tuned sort, that would be tolerable.

(Technically radix sorts are linear-time in input size because your number of distinct sort keys can't approach infinity without their length also approaching infinity, but in the approximation where we have less than, say, 2^{64} different sort keys, their execution time is more nearly linearithmic, like comparison-based algorithms.)

Implementations in hardware or software

Programs written in this bizarre fashion have the pleasant feature that their memory writes are in some sense sequential, which — aside from whatever debugging benefits it may or may not provide — works well with WORM media (which are not very important at the moment, but may be in the future) and block-erased NAND Flash.

However, it's not really plausible that future computers will be without at least a few kilobytes of traditional register-style RAM, writing to which will be much cheaper than writing to WORM or Flash. So pushing the sequentiality of writing down to the atomic program operation level may not make sense. Also, if you want to keep the writes actually sequential in real life, you can't use a separate memory for each variable; you need some system that dynamically apportions blocks of data written to the sequential medium among the variables that are actually being written to, and adds enough indexing that you can index far into those variables' past quickly,

without using up too much space.

Binary instructions (whether executed by software or in hardware) accessing a memory made of belts could use a smaller number of bits to select a belt in RAM than normal instructions use to select a byte or word in it.

If you're implementing this model in software on today's hardware, with its supercharged multilevel SRAM caches and gigabytes of SDRAM, you probably should store the current value of each variable in a fixed memory location, allocating a page or so of buffer to log its previous values into; you may be able to take advantage of page faults, Electric-Fence-style, for overflow detection, and thus avoid the overhead of bounds-checking instructions on every write (at the expense of TLB pollution).

Garbage collection

Generally, as I said, garbage collection is impossible, but there may be cases where some memory can be reclaimed.

First, of course, if variables are local to a subroutine, they can be freed when the subroutine returns.

The following presumes that there's no Fortran-style array aliasing going on when we pass parameters to subroutines; otherwise, the problem becomes quite a bit hairier.

Some variables may never be indexed at all; if their previous values are saved at all, it's only for debugging purposes. Some variables may only be indexed by constants, for example, in DSP code, so their previous values can be saved in a small circular buffer.

Bounds on variable index expressions are more difficult. It may be deducible that a variable i is always in the range [0, n), or is never negative; this would allow us to deduce that `x@(n-i)` can never index further back than n. But for this to allow us to discard values of x older than n, we need to also be able to show that n cannot increase, or at least cannot increase any faster than x is extended.

Instead of rigorously proving such bounds correct, you could try using relatively conservative allocation sizes for different variables, and restarting the program from a checkpoint if it suffers a bounds violation, indicating that it was trying to access values that it had already forgotten. For code that generates the forgotten values in linear time — that is to say, at an asymptotically constant speed, rather than one that increases without bound — doing this with a multiplicative increase in the space for the bounds-violated variable is "only a constant factor" slowdown. But it's a constant factor that's a multiple of the number of such variables, if you just increase the size of the one. (Generating values at a speed that increases without bound is of course impossible; you can at most generate one value per instruction.)

Alternatively, spilling memory to disk could permit your program to generate a terabyte or more of past values before any must be discarded.

You could imagine some class of programs might be easier to automatically parallelize or strength-reduce in this memory model, since in a way what it supports natively are simple recurrence relations like those discussed in Notations for defining dynamical systems (p. 2872). The idea is that you write your program as an initial state and a reduction function that updates the initial state, either according to

an input datum or on its own; then the compiler turns some or all of the program into elementwise operations and parallel prefix-sums using some subset of the program it's proven associative so that the parallel prefix-sum algorithm applies. Thus the different reductions aren't really running sequentially.

Topics

Flux deposition for 3-D printing in glass and metals

Kragen Javier Sitaker, 2016-07-03 (15 minutes)

Suppose you do a powder-bed 3-D printing process where the binder you deposit is a flux that lowers the melting and sintering temperatures of the powder filler, then bake the block at a temperature high enough to sinter or melt the binder-modified part of the structure. This might make 3D printing in new, unusual, or very inexpensive materials feasible.

The baseline I'm coming from here is that a spool of fucking PLA on Amazon goes for fucking US$23/kg. And, yeah, PLA is light and dimensionally stable and doesn't require your hotend to get super hot (180° is enough), but it's also pretty weak (50 MPa), and it sure takes a long time to come out of that teeny little hole.

Soda-lime glass

There are many possible binder-filler systems that could be used, but the one that seems most promising to me at the moment would use quartz sand as the filler and a mixture of sodium and calcium carbonates as the binder, forming soda-lime glass. Soda-lime glass has a glass transition temperature of about 570°, and so sintering should be possible a bit below that, while unfluxed quartz melts at 1670°. With 1100° of headroom, it should be very easy to keep the kiln temperature in the range required to sinter or melt only the fluxed part, not the unused filler. Indeed, it might be possible to pit-fire the piece, which typically reaches heats between 1000° and 1200°.

The usual mixture for soda-lime glass is about 73% silica, 13% sodium oxide, 10% calcium oxide, and 4% other impurities. Sodium and calcium carbonates, which are themselves fairly safe to handle, decompose to form these caustic oxides at 851° and 840°, respectively, though I suspect the presence of quartz will lower the required temperature. Sodium bicarbonate (aka sodium hydrogen carbonate), which is even safer to handle, decomposes to sodium carbonate starting at 50°, releasing water and CO_2. All of these ingredients are safe enough that they are used in cooking.

If calcium is omitted, the resulting "waterglass" material is water-soluble at high temperatures; this may not be a concern, depending on the application. The potential advantage of this method would be that sodium carbonate and bicarbonate are water-soluble, up to about 5% or 10% in warm water. However, that isn't enough to properly flux the quartz, so it will have to be applied in solid form.

You could have a robot with a valved funnel carefully dribbling the appropriate amount of mixed carbonates onto each layer of silica sand, or you could have an entire row of such nozzles.

Soda-lime glass doesn't start to flow freely until about 1000°, so as long as the temperature doesn't get that high, the fluxed part of the print won't soak into the rest of the unused filler too badly.

Lead glass might be an alternative: rather than calcium, you use lead(II) oxide (or, with air, galena or just plain lead), and rather than sodium oxide, you use potassium oxide, or in practice, potassium

carbonate. Lead glass, however, is less viscous than soda-lime glass, which is undesirable in this case, and doesn't have a lower softening point (still around 600°).

Feldspar?

The only mineral more common (and thus, I hope, cheaper) than quartz is feldspar, or rather, the feldspars, which melt at a wide variety of temperatures, from 600° to 1200°. I'm not sure what, if anything, to flux them with, other than quartz itself. I guess calcium-rich plagioclase can be fluxed with sodium-rich plagioclase.

Sodium and potassium feldspars are traditionally used as fluxes in pottery to vitrify silica and boron trioxide, so in a sense this is just a slightly different angle on the soda-lime glass from the previous section.

Alumina ceramic

Alumina (aluminum oxide, also known as ruby or sapphire) is the hardest mineral commonly used in ceramics, because the harder diamond and carborundum (silicon carbide) are tricky to deal with, cubic boron nitride is expensive (I think?), and tungsten carbide is about as hard as alumina, but more expensive.

Alumina doesn't melt until the truly unreasonably hot 2072°, which was a great difficulty in the development of the Hall-Héroult process that converted aluminum from a precious metal into a cheaper substitute for steel. The trick that made it feasible was fluxing the alumina in cryolite, Na_3AlF_6, so that the mix melts at only 1000°.

So you could imagine fluxing an alumina powder bed with just enough cryolite to get the grains to sinter together into a glass at around 1000°. You can probably do this with an arbitrarily small amount of cryolite; it melts at 1012°, and I believe it will wet the alumina grains immediately and begin to dissolve them, recrystallizing or vitrifying upon cooling. So the question is merely how much cryolite is needed to wet the alumina grains enough to form a solid mass.

I don't know how hard or strong the resulting cryolite-cemented alumina aggregate will be.

Lead-tin solder and type metal

Lead melts at 327°; tin melts at 232°; but 63% lead and 37% tin melts at 183°. So you could flux lead filings with tin filings, and then heat the piece to anywhere between 183° (or even a bit less) and 327°. Lead costs about $2.20/kg; tin costs about $22/kg. So the mixture costs about US$10/kg, which is not outrageous, but not cheap either. (You could probably reduce the price further by reducing tin content, at the cost of a higher and less crisp melting point.)

However, lead is very dense (11.3g/cc), so a kilogram of this metal is not very much, and the tin-lead alloy is very soft; you can nick it with your fingernails. Tin itself, at 7.4g/cc, is considerably less dense.

Another problem with tin-lead solder is that it shrinks when it solidifies, resulting in a rough surface. Type metal, Gutenberg's great invention, is a variant with a significant quantity of antimony (US$6.60/kg, melts at 630°), which prevents this shrinkage and

improves hardness further. The eutectic alloy is supposedly 84% lead, 12% antimony, and 4% tin, which works out to US$3.50/kg; it melts around 241°. (The antimony-lead eutectic alloy melts at 252°.)

Type metal has a Brinell hardness of around 20, which is four times that of lead, but one sixth that of soft steel. This suggests that its tensile strength might be .36 * 9.8 * 20 = 70 MPa, a little better than PLA.

Another possible alternative is pewter, which is tin fluxed with about 1% copper (US$4.40/kg) and 5% antimony. This is considerably harder than tin because of the alloying elements, and I believe immune to tin pest, but it's even more expensive.

Brass and bronze

Bronze (copper, which melts at 1084°, alloyed with about 12% tin; bronze melts at about 950°) and brass (copper alloyed with around 40% zinc, US$2.20/kg; zinc melts at 420°, brass a bit past 900°) are other possible alloys that could be shaped by this method. Sprinkling 12% pricey tin filings into a copper bed to lower its melting point by 134° seems ideal.

Using one metal as a binder for other metals, as in brazing

Brass is commonly used as a binder for other metals in brazing; you could, for example, use a powder bed of iron filings and deposit brass filings onto it before baking. You could easily get most of the strength and cost of the final piece from the iron filings.

The inexpensive metals — those less expensive than copper — are aluminum (US$2.20/kg), arsenic (US$2.20/kg), iron (US$0.88/kg), manganese (US$0.80/kg), silicon (US$2.40/kg), and zinc (US$2.20/kg); and we should include carbon, since iron is commonly alloyed with carbon (super cheap, depending on purity; flake graphite costs US$1.50/kg) to make steel or cast iron.

Among these, zinc in particular (even without making brass by being mixed with copper) seems like it would be a good choice as a binder for an iron or steel filler, or possibly even for aluminum. Zinc and aluminum form a variety of useful alloys, and apparently there's a technique called "diffusion soldering" similar to this. I'm not sure what would be needed to remove the aluminum-oxide layer from the surface of aluminum powder that has been exposed to air, though, and both zinc powder and aluminum powder are a bit of a fire hazard.

Cast iron

Cast iron melts around 1150° to 1200°, while pure iron melts at 1538°. Steels have intermediate melting points; mild carbon steel is the most common family, and ASTM A36 is a typical mild carbon steel; it has up to 0.29% carbon and 0.28% silicon, and according to the iron-carbon phase diagram, its melting point should still be above 1500°. Cast irons typically contain 1–3% silicon and 2–4% carbon, although the eutectic point is at 4.3%. At 3.5% carbon, the melting point is reduced to 1200°.

So, you could take a bed of ASTM A36 filings and selectively flux them with 3.25% carbon and 1% silicon, then heat them up to almost

1200°, or maybe a bit more, but not past 1500°. The part you've selectively fluxed should sinter, and then you should be able to bake it more thoroughly to make a more homogeneous cast-iron part; deformation from the printed shape should be almost zero due to the silicon content forcing carbon to remain in graphite form.

It might be a better idea to use a much smaller amount of carbon and/or silicon, so that when the powder is heated, only a small part of each filing around each carbon grain is melted, rather than the entire filing; this way, the printed part will not liquefy completely, and the finished part will be high-carbon steel rather than cast iron.

Tungsten carbide

Tungsten carbide, one of the most important industrial ceramics, can be made by reacting metallic tungsten with carbon at 1400° to 2000°; it melts around 2800°, while tungsten melts at 3422° and graphite sublimes at 3600°. So you could "flux" a graphite powder bed (US$1.50/kg) with powdered tungsten (US$200 per "short ton unit", which is 7.19 kg of tungsten, thus US$28/kg) and heat it up to 2000° or a bit less.

Alternatively, you could "flux" the graphite with tungsten trioxide , which melts at 1473°, and heat it only to 900° to react it with the graphite and immediately produce the tungsten carbide.

All of this might need to happen under pressure, I'm not sure.

Alpaca: raising the melting point instead of lowering it

Here in Argentina, the common alternative to stainless steel or silver used in silverware and whatnot is an alloy, invented by Qing China, called "alpaca", from the 19th-century brand name of a German company; worldwide this is typically 60% copper, 20% nickel (US$22/kg, melts at 1455°), and 20% zinc, working out to US$7.50/kg. It looks like silver, it's bactericidal like silver, and it's strong and easy to electroplate with, for example, silver.

The CRC Handbook of Mechanical Engineering gives the melting point of the ASTM B122 formulation of alpaca in its quaint folk units of measurement as 2030°F and its modulus of elasticity as 18 Mpsi, which are 1110° and 124 GPa in SI.

Alpaca probably cannot be 3D-printed in the way discussed above, because it melts at a higher temperature than copper, zinc, or alloys thereof. If you were to try selectively depositing copper and zinc into a bed of powdered nickel, you would have the problem that the product formed would be much larger than the powder it was deposited into.

However, perhaps you could deposit powdered nickel into a bed of powdered 75%-copper brass, and then heat it up to about 1000° or 1100°. If the nickel has sufficiently diffused into the brass, the brass will melt and run away, leaving a solid alpaca object coated and perhaps permeated with liquid brass, as long as the nickel doesn't diffuse too far and become too dilute to prevent melting. This approach would eliminate the extra processing steps that commonly attend powder-bed 3-D printers: the careful brushing of the powder from the recesses of the solid part and extra processing steps to eliminate porosity from the solid part.

This process may depend sensitively on grain sizes and morphologies and on the temperature profile of the process. It's necessary for the nickel to have diffused enough into the alpaca part to solidify it, and for its grains to have sintered together enough to hold together, before the unmodified brass becomes liquid; but if the nickel diffuses too far, you will lose surface detail, as some brass outside the desired part acquires enough nickel to keep it from melting, while some of the alpaca inside the desired part loses enough nickel to allow it to melt.

Using the alpaca approach for steel printing

This approach should also work for printing carbon steel: by increasing the carbon content of the unwanted part of the metal to the eutectic 4.3%, it should become a low-viscosity liquid cast iron at a sharp eutectic melting point of 1148°, permeating the pores of the sintered higher-melting steel and contributing carbon to it.

Adding so much carbon is not quite as trivial as it sounds, because the iron weighs 7.8 g/cc, while carbon black weighs only about 2 g/cc, and graphite about 2.2 g/cc. So 4.3% carbon by weight is about 15% carbon by volume, which is significant. I think it should still fit into the interstices of the iron filing bed if the carbon particles are sufficiently smaller.

(And yes, this is an even bigger problem for alpaca.)

How to make Dercuano work on hand computers?

Kragen Javier Sitaker, 2019-05-18 (updated 2019-12-30) (56 minutes)

Foreseeably, most personal computers now are hand computers, commonly called "cell phones" or "mobile phones", for archaic reasons (with a few exceptions called by names like "e-readers"). Less foreseeably, they mostly run user interfaces that limit the user's power over them considerably; in particular, although they generally have WWW browsers and most of them can download files and save them locally, they cannot extract a .tar.gz file full of HTML and browse it.

This poses a problem for Dercuano, because right now I am publishing it as a .tar.gz file full of HTML. But its objective is to remain readable even if my server or domain name fails, as they inevitably will someday. It's really important (to me, anyway) that people be able to continue reading Dercuano in that case. There are a variety of possible alternative formats that could work well on hand computers.

The problem: gratuitous handicaps and tiny screens

Hand computers have an additional problem, aside from being gratuitously crippled in a way that requires compatibility hacks: **their screens are tiny**. For example, until I broke the screen, I was using a discount hand computer with a 45×63 mm screen; a more modern one I looked at last night has a 64×115 mm screen. Also, the screens used to be low resolution: the PalmPilot was 160×160 (monochrome!), and the original iPhone was 320×480. (At 163 pixels per inch, that was 50×74 mm, bigger than the one I broke.) Modern cellphones have much higher-resolution screens, and e-readers generally have much larger screens, though with fewer pixels.

Making text readable at all on such small screen sizes requires serious compromises in typographic design. For example, the typography I'm using at the moment (see Dercuano stylesheet notes (p. 374)) is "22px", with max-width of 45em and line-height of 1.5 (em), and 1 em of padding around the body; on my 158 dpi laptop screen, that's a font size of 3.5 mm or 10 (PostScript) points, with 5.3 mm from one baseline to the next. I use a ragged right margin extra vertical whitespace between paragraphs, as is normal on the WWW, and a somewhat smaller font size for <pre> blocks.

At this font size, on my 45×63 mm screen in portrait mode (my observations on the subway and bus suggest that people strongly prefer using their hand computers in portrait mode, only switching to landscape mode to watch landscape-mode videos, play landscape-mode video games, or occasionally read PDF files whose lines are too long), the 7 mm of padding on the left and right would leave room for almost 13 ems of text, about four or five words' worth. Using the greedy paragraph-filling algorithm web standards short-sightedly require (at least in the case where there are floats, according to pcwalton), and especially without hyphenation, this

would frequently have lines with only one or two words on them. Less than 12 of these tiny lines would fit on the screen, one of which will frequently be consumed by a paragraph break, so you might have 40 words of actual text on the screen.

Worse, Chromium's Blink HTML engine, like the WebKit and KHTML engines it derives from, doesn't support hyphenation at all; Firefox's Gecko engine is the only significant WWW browser engine that does, and on hand computers, almost nobody uses Firefox.

Once you add any extra block indentation, like that in a blockquote or indented list, the situation quickly deteriorates to one or two words per line.

Reducing the text size to a less-comfortable size is a necessary compromise to avoid such uncomfortably short line lengths. (Generally, when I read things on it, I also used portrait mode.) Also, though, using less padding around the text is very helpful (in this example, using 0.5em instead of 1em padding would increase the text column width from 13em to 14em). The line length will still necessarily be shorter, which reduces the need for leading between lines to avoid disorientation when moving from one line to the next.

It's possible to do far worse than my default style on hand computers, though. The worst reading experiences on hand computers are when you have very long lines in PDFs or ASCII text files with hard line breaks, such that even in landscape mode, you can't fit an entire line on the screen at a readable font size. This requires you to scroll left and right on every single line to read the text.

Somewhat less annoying are academic papers which preserve the traditional book layout of two columns of text per page, rather than the single-column layout that has become popular recently, since about 1850. The columns are generally narrow enough to be readable on the tiny hand computer screen, which is a great blessing, but once you reach the end of one, you have to spend several seconds panning diagonally across the page to find the top of the next one — and, half the time, that's the wrong thing to do, because the next column is on the next page.

(I lied, though. The worst reading experiences on hand computers are file formats you don't have an app for.)

Some kind of adaptation to widely varying screen sizes is necessary, since hand computers in common use range from the kind of tiny 45×63 screen I mentioned up to Amazon Swindles with 600×800 screens at 167 dpi grayscale, which works out to 91×122 mm, almost 4× as big, and 51% bigger than the 64×115 mm "cellphone" I mentioned above. (For comparison, a page of a paperback book is 105×175 mm and about 600 dpi, but without grayscale.)

Possible formats

DHTML with offline reading via cache-manifest or service workers

The first thing that occurred to me was that I could just add a cache-manifest to the HTML generated for Dercuano so that when a browser loads one page, it loads them all into the appcache, and (at least if you bookmark the thing) the whole thing remains accessible even if you're offline or the server goes down.

This has the advantage that anything that works in the current HTML tarball incarnation of Dercuano would keep working the same way. In fact, more things would work — the difficulties with full-text indexing I mentioned in Dercuano search (p. 1532) wouldn't exist.

This is the lowest-effort approach, but it wouldn't work very well. Although the cache-manifest mechanism is widely supported, including on pretty much all hand computers, it's considered obsolescent (the documentation for it has been removed from the current version of the WHATWG standard), to be replaced with the new and shiny service-workers mechanism. Since Firefox 60 and Chrome 69, it's also unavailable if you aren't using HTTPS. It enjoys invisible resource limits — the amount a browser is willing to cache is not exposed to the user, but typically it's 5MB or 10MB, and if the download fails because not enough space is available, no error message is given; it just fails when you're offline or the server is down.

There's a sort of polyfill to support the cache-manifest API on top of ServiceWorker, but ServiceWorker also requires HTTPS.

The bigger problem, though, is that both service workers and the appcache are totally dependent on, and vulnerable to, the origin server. This violates my intent with Dercuano in three ways:

• If my server is down, one person with a copy of Dercuano would not be able to give it to another person, except by giving them their entire browser state. This means that once my server is gone, copies of Dercuano would gradually diminish one by one until they are all gone, rather than being shared with new people who want them.
• If malicious actors gain access to my server or my domain, they could use that access to delete all the copies of Dercuano, if it were using service workers or appcache. Malicious actors have gained access to the vast majority of domains that were on the web 20 years ago, usually to put generic linkspam pages on formerly high-PageRank domains, so it's a good bet that this will happen sooner or later to canonical.org.
• If a patent examiner reads some idea in their copy of Dercuano, and Dercuano uses service workers or appcache, they can't tell if that idea was inserted into their copy of Dercuano the last time they connected to the internet, or ten years earlier. This means that ideas in Dercuano would not be able to serve as prior art to invalidate patent claims, as "rapid genetic evolution of regular expressions" did.

MobiPocket .mobi format

A more reasonable alternative approach, for which I am indebted to cajg, is to convert Dercuano into some kind of ebook format. Ebook formats in general solve the three problems I mentioned above.

The popular Amazon Swindle hand computer uses a variant of this format. I don't know much about it, but it's not fully documented in public. Its text is formatted with (X)HTML and CSS. Mobipocket themselves did a bunch of work on hyphenation, but their work is no longer available (except on the Swindle), and other .mobi readers may not have such good hyphenation support.

Support for .mobi files is not available on most e-readers (except the Swindle), and on cellphones it is available but not installed by default. You can install, for example, Okular or FBReader to be able

to read them.

.mobi doesn't seem to have very good graphics support — in particular, nothing like SVG or EPS, *but* it does support embedded JS which could, in theory, implement that kind of thing, maybe. It supports embedded GIFs and JPEGs, but with a size limit of 63 KiB.

I'm not sure if one part of a .mobi file can contain a hyperlink to another arbitrary part of it, although it does of course support tables of contents. This is important for Dercuano.

.ePub format, the modern replacement for .mobi

EPUB, as it's sometimes written, continued to evolve after .mobi forked from it around 2005, and the current version *does* support SVG images. It's fully documented, not suffering from the reverse-engineering problem .mobi does. Otherwise (in terms of supported features, preservability, file size, and so on) it seems to be pretty similar.

One giant HTML file

At first I didn't think of this as an option, since my experience with hand computers is that they typically can't read HTML offline reliably.

Recent versions of (Chrome on) Android are capable of saving HTML pages for offline reading, including the CSS and JS and whatnot, so combining the entire contents of Dercuano into a single fifteen-megabyte, six-thousand-page HTML file might be a possible alternative. This would probably require fiddling with the CSS and JS a bit to get it to scale and not clash, but perhaps more importantly, I think Blink may choke on such large HTML documents; it's designed for HTML files two or three orders of magnitude smaller. Even Dillo might balk.

It appears Chrome is saving a multipart/related MIME document with a filename ending in ".mhtml", which is a totally reasonable way to do this, and provides a reasonably readable file adhering to well-known standards, in a single file. It does, however, have a couple of significant drawbacks:

• Basically any useful access to it requires reading the whole thing, though that's really probably the least of your troubles if 90% of it is a 15-megabyte HTML document.
• If you open the file in Chrome from a file manager, Chrome renders it as plain text. It's only when you load it from the "downloads" app that Chrome opens it as expected.

I'm not clear on how easy it is to transfer these from one hand computer to another, which, as I was saying earlier, is a sine qua non. I was hoping it would be a matter of just copying the .mhtml file across, but it doesn't seem to be.

However, the one-giant-HTML-file approach might be useful as a first step in other workflows, like creating PDFs or ePubs.

PDF

That brings us to PDF, which is usually in last place in anyone's list of candidate document formats, due to decades of painful experiences; PDF doesn't support text reflow†, so using it for hand computers whose screens vary by a factor of about 4 would seem, at best, perverse. However, for better or worse, PDF is supported by almost

all hand computers (Android, iOS, and Swindle all ship with PDF support out of the box), and it always looks the same, within the limits of the screen or printer, while maintaining a file size similar to that of gzipped HTML. It supports hyperlinks, including hyperlinks within the document, and it supports vector graphics, including transparency (though not, as far as I know, SVG-like convolution filters). PDF is designed for random access, so a few thousand pages in a document is not a problem on modern computers, including hand computers.

PDF also has the advantage that there are a lot of people out there who take seriously the problems of archiving PDFs and making them searchable. The ISO has a PDF standard and also a standard for a "PDF/A" subset designed for archival. (Well, several non-backwards-compatible versions of the standard, actually, which likely defeats the purpose, but possibly they'll pull their heads out of their asses at some point.)

The worst problems with reading PDF on hand computers, as I said above, result from formatting with long lines. Wide margins are a secondary offense, since in many readers they mean you have to zoom to a readable size every time you switch pages, and when panning on touchscreens, you're always at risk of panning a little bit diagonally and losing the last few letters of the column you're trying to read.

Typically, though, PDF viewers only let you pan diagonally when you're zoomed in in two dimensions. If you have the entire page width visible, you can only pan vertically, and if you're looking at the entire page, you can't pan at all.

† Recent versions of acroread do claim PDF reflow support, but I haven't tried it.

.chm

Microsoft distributes help files in CHM format, which, like ePub, is an archive (in ".cab" "cabinet" format, IIRC) full of HTML files. This used to be popular as a way to distribute technical books, and maybe it still is, but support on hand computers is limited. Play Store app reviews suggest that nowadays it's found a niche for distributing medical reference books to doctors.

My proposed solution: PDF with pages of 24 ems × 60 ems with ½ em of margin all around

Maybe PDF's vices can be turned into virtues.

Consider a page that measures 24 ems by 60 ems, with 1.2-em line spacing and ½ em of margin, so eight to twelve words per line, much like a paperback book, but with much taller pages: 49 lines. On my tiny 45×63 mm hand computer, these numbers give a barely bearable 5.3-point font in portrait mode and a tolerable 7.4-point font in landscape mode, when the page is zoomed to fit the width of the display rather than its height. On the larger 64×115 one I mentioned earlier, these numbers are a tolerable 7.6-point font in portrait mode and an eminently readable 13.6-point font in landscape mode. Indeed, even fitting the height of the page to the display gives a bearable 5.4-point font on that machine.

These four possibilities — landscape zoom-to-width, landscape

zoom-to-height, portrait zoom-to-width, and portrait zoom-to-height — provide four roughly evenly spaced magnification levels covering a linear zoom range of about three to four times, or an areal zoom of about 12 to 20 times. None of them suffer the janky diagonal panning problems that plague PDF reading on hand computers, since none of them require zooming in so far that diagonal zooming is possible. The number of words per line is suboptimal but readable.

Some screen real estate to the left and right of the page is left unused. On a 91×122 mm Swindle, zooming to fit the whole 60-em-tall page in portrait mode gives you a 5.8-point font, but only the middle 49 mm of the display is used. Many PDF readers (I don't remember about the Swindle's) offer an option to view pairs of facing pages next to each other, rather than single pages; doing this on a Swindle-sized screen would give you a 5.4-point font, which is still bearable, and two pages of text at a time.

If we think of an em as nominally representing 12 PostScript points, the 24×60 em page size is 102 mm (4 inches in archaic units) by 254 mm (10 inches in archaic units). So this column size actually closely approximates the size of a column in a traditional two-column folio page, or a two-column A4 or US letter-sized page.

Given how precious hand-computer screen real estate is, we'd probably want to use indentation, rather than extra vertical space, to demarcate paragraphs, in the way that has been standard for several centuries. The addition of PDF's unavoidable page breaks with ragged right margins adds an additional rationale for this: if a sentence starts at the beginning of a line at the top of a page, how can we tell if it starts a new paragraph or not? It will have extra whitespace above it simply because of the page break.

A hypothetical PDF reader that supported zooming to fit the page height, with more than two pages next to each other, would allow reading any number of such columns with horizontal scrolling.

To some extent, small font sizes can be compensated by holding the computer closer to your face, wearing reading glasses, and squinting, but a more absolute limit — without resorting to temporal antialiasing, anyway — is the actual number of pixels. I've done a 3½×6 pixel font that is marginally readable, and I think you can do better than that with antialiasing and especially subpixel rendering, but usually a minimum for reasonable letterforms is 5×8 pixels, and standard VGA fonts were 8×16. But at these line widths, that's not going to be a problem. If we divide the original iPhone's 320-pixel width by 24 ems, we get a line height of 13 pixels, so an average glyph of around 6×13 pixels. And modern hand computers have considerably more pixels than that.

Given that all these point sizes are a little on the small side, and the actual paperback book I was looking at has lines of only about 20 ems wide and is eminently readable, you'd think I could get by with a font size about 10% or 20% larger than what's implied above (and thus 21% or 44% less areally dense). 45 mm / 21 em would be 2.1 mm per em, which is a 6-point font; in landscape mode, the same tiny screen would have 63 mm / 21 em = 8.5 points, which is easily readable. But the other force pushing for smaller fonts and wider lines is the occasional <pre> block, which needs to be able to accommodate 80 columns, nominally 40 ems. That's a text size of 0.6 em for the <pre>.

Using an even larger font size for the normal body text would cause an even larger disharmony between the two text sizes.

Hyperlinks in PDF

PDF supports tables of contents and hyperlinks, but at least the default PDF viewer on Android 7.0 (which is the Google Drive PDF viewer) doesn't seem to have any way to see them. It has a fairly effective scrollbar, though, so page numbers may be a reasonable replacement — but they need to count monotonically from 1 at the beginning, since the page numbers displayed in the Android viewer do that; even though PDF supports page numbers that do things like "i, ii, iii, iv, 1, 2", they are not displayed.

ZUI in PDF for navigating illustrations?

Illustrations (see Dercuano drawings (p. 64)) are a really hard problem in HTML-based formats for small screens: your lines are already too short to flow text around large pictures, and small pictures are unreadable unless they contain only a little bit of information, like sparklines. But if we assume that the reader is using a hand computer with pinch-to-zoom, and our image format is vector, perhaps we can rely on zooming to provide more information about illustrations on demand, and even some degree of hierarchical navigation.

Hyperlink navigation within the illustration is probably not supported, though, and the maximum zoom is probably quite limited; the popular AndroidPdfViewer open-source component defaults to 3× as its default maximum zoom, but the Android 7.0 default PDF viewer defaults to 10×. It also permits zooming *out* until several pages are on the screen, though, sadly, stacked vertically.

Hyphenation and equations in PDF

The major advantage of PDF over the HTML-based formats is that things will look exactly as I formatted them. This means that I don't have to rely on hyphenation support on the reader's computer; I can use a decent hyphenation algorithm, and if necessary I can tweak the text to deal with rotten formatting (although, honestly, I'm trying to import a couple of million words of unfinished notes into this thing; I can't stop to futz with per-paragraph formatting on more than a tiny part of it).

Also, an enormous advantage accrues to math formatting (see Dercuano formula display (p. 495)). In theory, EPUB supports some part of MathML, but MathML rendering is generally kind of shitty (where it's not done through MathJax), and writing MathML is worse. With PDF, I can render equations at build time using T_EX, subsetting Computer Modern fonts as necessary to include just the glyphs I'm using, and get well-formatted formulas.

Further progress

2019-12-28

I've hacked together a janky PDF by parsing the Dercuano output HTML as XML, and now most of the content of Dercuano is readable in this format.

Page sizes and typewriter font woes

Initially I tried the "24 ems × 60 ems with ½ em of margin"

configuration described above, but I found it to be uncomfortably narrow. For regular running text it was reasonably okay, and for low-resolution cellphones that probably means "ideal", but for 80-column-wide <pre> blocks, it was terrible --- that's 0.3 ems per character, and Courier really wants more like 0.63 ems per character, which would be over 50 ems, making non-<pre> text of the same size uncomfortably wide and also requiring a high-resolution screen for readability without constant diagonal scrolling.

(I haven't actually implemented <pre> proper yet.)

Another pressure is that 24 ems is too narrow for a large number of URLs. At some point I guess I'll have to implement some kind of line continuation for long strings like that, but having less broken lines like that will always be better.

However, to some extent text dimensions are fungible. Making text taller makes it more legible, as does making it wider. The much harder constraint on <pre> text is its width; scrolling more because it is taller than would be ideal is far preferable. So, a reasonable alternative is to use a compressed font. I found Bogusław Jackowski and Janusz M. Nowacki's font Latin Modern Mono Light Condensed, which comes in regular and oblique versions (but no bold), which is derived originally from Knuth's Computer Modern Teletype, which is in the public domain; but Latin Modern has much broader coverage of some 760 Unicode characters than cmtt does.

lmtlc, as this font is called in the TeX Live distribution, demands only about 0.36 ems of horizontal space per character, and is still quite readable, although visibly compressed. I had to use FontForge to convert it from the OTF on CTAN because Reportlab said, "TTF file "lmmonoltcond10-oblique.otf": postscript outlines are not supported."

So I've widened the page width to some 29 ems (and extended it vertically to 66 ems, purely for reasons of silly nostalgic printer traditions --- US letter paper is, in medieval units, 11 inches long, and a standard 12-point line height thus gives you 66 lines). This reduces the page count from some 4700 to 3700. Even 3700 seems large for a book of only 1.3 million words or less, but 500 of those pages are the topic listings at the end.

As I said before, a key consideration is for the PDF version of Dercuano to be readable on hand computers without diagonal scrolling or reflowing, because reflowing a PDF is pretty hard. This has two aspects: pixel readability and absolute size.

As for pixel readability, reviewing dimensions from above, the PalmPilot was 160x160, and the iPhone 1 was 320x480. At 24 ems wide in landscape mode, 480 pixels is 20 pixels per em, like a 10x20 xterm font; this is quite comfortable. 160 pixels across 24 ems is only 6.7 pixels per em, which is at the very edge of readability. So, by going to 29 ems, I'm sacrificing PalmPilot readability, which would be 5.5 PalmPilot pixels per em, but 16.6 original-iPhone pixels per em --- still quite readable in landscape mode.

In addition to avoiding pixelation to prevent unreadability in an absolute sense, I'd also like to keep the letters reasonably large in millimeters to avoid sacrificing readability-without-a-magnifying-glass. The original iPhone was 50x74 mm; 50 mm across 29 ems is 1.72 pixels per em, which is 4.9 printer's points. That's a pretty small font! That's why I was trying to

make do with 24 ems. But in landscape mode on an iPhone-1-sized device that would be a 7.2-point font, suboptimal but not outside the realm of readability. On the discount hand computer I was using earlier this year, the screen was 45x63 mm. 29 ems across 63 mm makes it a 6.1-point font: painful to read, but, again, not infeasible.

If that hadn't worked, maybe /usr/share/texlive/texmf-dist/fonts/opentype/public/cm-unicode/comuntt.otf would have been another possibility, maybe with some kind of coordinate transformation.

Remaining major bugs

I have a number of showstopper bugs left in the PDF generation; among them:

• The vertical positioning is wrong, so PDF links are displaced vertically relative to their target text, and I have to leave a bunch of extra bottom margin to minimize the number of pages that get truncated.
• I haven't implemented `<pre>` yet.
• The 3% or so of notes that aren't well-formed XML are getting totally mangled, with mojibake and total loss of formatting. For many of these, getting the formatting totally right would require implementing tables and SVG, which may not be in the cards this weekend, but surely I can do better than this.
• I haven't implemented font cascade fallbacks yet for missing characters.
• The ET Book license needs to be included.
• `<li><p>foo</p></li>` puts the paragraph on a separate line from the `<li>` bullet.

There are also a lot of other bugs that aren't showstoppers but might be easy to fix:

• Headers aren't red.
• Headers aren't underlined.
• Line spacing is too tight.
• Blockquotes aren't visibly distinct at all.
• `<script>` and `<style>` contents are treated as text.
• I don't have page numbers on links yet.
• An extra space gets added after the ends of every HTML element.
• Notes aren't in any order in the PDF file.
• I think it's splitting on no-break spaces as well as normal spaces, so they aren't no-break.
• The link to lua-%23-operator may be broken.

And other bugs that are serious but maybe aren't in either category:

• There are no per-note tables of contents.
• There are no superscripts or subscripts.
• `<ol>` isn't bulleted.
• The PDF is huge, like 12 megs.

Font cascade fallback fonts

As a fallback for monospaced text, /usr/share/fonts/truetype/droid/DroidSansMono.ttf might work, although it's going to be much wider than lmtlc and only covers 874

codepoints (though some of those are things I use that aren't in lmtlc!). /usr/share/fonts/truetype/ttf-liberation/LiberationMono-Regular.tto of covers only 663. /usr/share/fonts/truetype/ubuntu-font-family/UbuntuMono-R.ttf has 1225, comparable to the 1259 in /usr/share/fonts/truetype/msttcorefonts/cour.ttf. /usr/share/fonts/truetype/dejavu/DejaVuSansMono.ttf has 3197, and /usr/share/fonts/truetype/freefont/FreeMono.ttf has 4126. Moreover, FreeMono has 3511 codepoints that lmtlc doesn't, and DejaVu Sans Mono has 2645, of which 515 are also not in FreeMono.

So, for monospace coverage, if you had to choose a single fallback font with no worries about licensing, it would be FreeMono, expanding lmtlc's 760 codepoints to 4271, but if you could choose a second one, DejaVu Sans Mono would expand that to 4786.

For serif body text, ET Book (a copy of Bembo) covers only 233 codepoints. The corresponding brand-name fallback fonts would be /usr/share/fonts/truetype/freefont/FreeSerif.ttf with 6450 codepoints and /usr/share/fonts/truetype/dejavu/DejaVuSerif.ttf (my browser's standard fallback) with 3331 codepoints. From the size, it is clear that neither of these covers Chinese; the built-in PDF font that seems to work best for Chinese (in Reportlab, the PDF-generation library I'm using) is `reportlab.pdfbase.cidfonts.UnicodeCIDFont('STSong-Light')`, which is sadly a gothic monoline (I would say "sans-serif" but of course what's missing isn't really serifs) font. Also, I've figured out how to tell which codepoints a TrueType font covers using Reportlab: `reportlab.pdfbase.ttfonts.TTFontFile( '/usr/share/fonts/truetype/ubuntu-font-family/UbuntuMono-R.ttf').charToGlyph` is a dict. I don't know how to do this for STSong-Light, so I don't know how to fall back from it.

Freefont is a GNU project, although it seems to have largely gone idle in 2012. The licensing is GPLv3+, which is somewhat aggressive as fonts go, and it's not clear that there's a legal way to embed it, or a subset of it, into a PDF file and then convey that PDF file to others.

Oh, actually there's a special exception for document embedding in its README, which Debian left out of /usr/share/doc/fonts-freefont-ttf/copyright:

> Free UCS scalable fonts is free software; you can redistribute it and/or modify it under the terms of the GNU General Public License as published by the Free Software Foundation; either version 3 of the License, or (at your option) any later version.
>
> The fonts are distributed in the hope that they will be useful, but WITHOUT ANY WARRANTY; without even the implied warranty of MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE. See the GNU General Public License for more details.
>
> You should have received a copy of the GNU General Public License along with this program; if not, write to the Free Software Foundation, Inc., 51 Franklin Street, Fifth Floor, Boston, MA 02110-1301, USA.
>
> As a special exception, if you create a document which uses this font, and embed this font or unaltered portions of this font into the document, this font does not by itself cause the resulting document to be covered by the GNU General Public License. This exception does not however invalidate any other reasons why the document might be covered by the GNU General Public License. If you modify this font, you may extend this exception to your version of the font, but you are not obligated to do so. If you do not wish to do so, delete this exception statement from your version.

DejaVu is an extended version of Bitstream Vera, which was distributed under a BSD-like license that requires changing the name of extended versions; the DejaVu changes are in the public domain. They are far from complete Unicode coverage, lacking even some Greek and Cyrillic and most Arabic, as well as all the Indic scripts. Still, I think it might cover most of the characters I actually use.

DejaVu Serif isn't very harmonious with ET Book; it's a slab-serif font with little emphasis and a tall x-height --- roughly as far as it could be from ET Book while still being technically a serif font. It does have ℤ and ² and ³ and ^{64} and μ and × and ∞ and ÷ and Ω and ≈ and ⇒ ∃ ε ∈ $_{01}$ †, though many of them copy and paste wrong. Combining arrow above $\vec{v}$ is missing (renders as an empty box), but maybe I'm outputting it wrong. And it's missing ℓ. But those are the only things I've seen missing so far.

The elusive 'ℓ' is found in FreeMono, Liberation Mono, (Microsoft's) Courier New, and Droid Sans Mono, and likely their non-monospaced equivalents as well. Liberation is a Red Hat font set licensed under the GPLv2 with a document-embedding exception plus some other weird anti-Tivoization exception.

Liberation Serif covers ≈, †, ∞, ←↓↑→, ² and ³, and Greek, but not $^{-6}$ or ɑ or $_2$ or ^{48} or ℤ. It's somewhat more harmonious with ET Book.

Freefont's FreeSerif is considerably more harmonious with ET Book than the others, and it does contain ℓ.

Misparsed data

I've been trying to use ElementTidy to read in the things ElementTree can't handle directly, about 30 of the 997 notes in Dercuano, but this has been failing completely. One reason is that the tag names it gives me are bullshit like '{http://www.w3.org/1999/xhtml}html'. Another is that it seems to be parsing things as some incorrect encoding.

elementtidy is apparently dead having just been removed from Debian a few months ago, so it may not have been the best choice...

This seems to work to solve the mojibake problem:

```
>>> b = TidyHTMLTreeBuilder.TidyHTMLTreeBuilder(encoding='utf-8')
>>> b.feed(open('dercuano-20191226/notes/nova-rdos.html').read())
>>> t = b.close()
```

Although honestly, looking at the source, I think this does the same thing without TidyHTMLTreeBuilder:

```
import _elementtidy
t = ET.XML(_elementtidy.fixup(open(
       'dercuano-20191226/notes/nova-rdos.html').read(), 'utf8')[0])
```

...although that's not without ElementTidy, just without its Python. It still has the namespace problem, though.

But the fixup() function there seems to just give us the stdout and stderr we would get from invoking HTML Tidy. Which, as it turns out, has options `-ashtml` and `-utf8` that would probably do the right thing here without saddling us with an `xmlns`. I wonder if Python tidylib has a way to get that?

This looks promising:

```
>>> xs = tidylib.tidy_document(
        open('dercuano-20191226/notes/nova-rdos.html').read(),
        {'input-encoding': 'utf8',
         'output-encoding': 'utf8',
         'output-html': True})
>>> print xs[0][:1024].decode('utf-8')
```

That *almost* works:

```
>>> t = ET.XML(xs[0])
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "<string>", line 124, in XML
cElementTree.ParseError: undefined entity: line 16, column 43
```

It's complaining about ` `.

Well, can I use ElementTidy (or for that matter tidylib) in XML mode, but just strip off the namespace tags?

```
>>> t = ET.fromstring(_elementtidy.fixup(
    open('dercuano-20191226/notes/nova-rdos.html').read(), 'utf8')[0])
>>> def deprefix(tree):
...  for kid in tree:
...   deprefix(kid)
...  tree.tag = re.compile('{.*}').sub('', tree.tag)
...
>>> deprefix(t)
```

That seems to have worked! And tweaking the tidylib recipe above (no output-html, yes numeric-entities) allowed me to excise the ElementTidy dependency. So that's one out of six showstopper bugs fixed.

`<pre>`

As MDN says about CSS "white-space: pre":

> Sequences of white space are preserved. Lines are only broken at newline characters in the source and at `<br>` elements.

Right now I have a "font stack" which is separate from the element stack and also a "current link" which is restored from the element stack. But now I'd need to have a "white-space" stack so that I restore white-space to its `normal` value at the proper place.

I think a better alternative is to use the element stack to restore elements of the current style, which can include link destination, font-family, font-size, and white-space. Then I can just pass the current style to `render_text`.

`white-space: pre` is simple to implement:

```
#words = re.split('[ \n\r\t]+', text)
words = re.split('\n', text)

    if True or t[0].getX() + width > max_x:
        newline(c, t, font)

    t[0].textOut(word)# + ' ')
```

Okay, I have that working. Four showstopper bugs left: newlines after bullets, the ET Book license, vertical positioning, and font cascade fallbacks.

In the process, though, the PDF seems to have grown by about 700K and become slower to display in some PDF viewers. I suspect resetting the font on every word may be causing this, so I'm going to try adding another level of indirection so I can make an apples-to-apples test.

Indeed, without redundant font setting, it takes 4m37s of user time and produces a 12.4 MB PDF, while with redundant font setting, it takes 5m45s and produces a 12.9 MB PDF. So the extra complexity to avoid redundant font setting is worthwhile.

2019-12-29

Well, so, I revisited the code that emits textobjects, and I made it emit a new textobject for every line, which can be positioned with some appropriate Y-offset, and now I have the links actually over the text they're supposed to be (except when a link splits across pages, which is still a bug) although at the cost of an extra megabyte. This also enables me to eliminate the fudge-factor margin at page bottoms, which cuts the book down to 3718 pages.

So, that's one more showstopper bug down, and so now it's down to three remaining showstopper bugs: the missing ET Book license, the newlines following bullets, and tofu. I think FreeSerif and FreeMono are reasonable fallback fonts, but I have to figure out how to do the fallbacking in practice.

Font cascades

So, I've added FreeFont FreeSerif as a fallback font and added a bunch of logic for font fallback. I probably should add some kind of regexp-based fast path for when all the characters in a word are in ET Book, because it's noticeably slower, but it does seem to cover nearly all the characters I use. FreeSerif-Italic seems to be missing a bunch of subscript letters I use, though, unless I'm screwing something up.

It takes about 9 minutes instead of about 5 minutes to generate the PDF now.

It turns out that subscript index letters like ₖ or $_k$ (bold: $\mathbf{_k}$, bold italic: $\boldsymbol{_k}$) are not in (this version of) FreeFont, but they *are* in DejaVuSerif and DejaVuSerif-Italic. They're used in Isotropic nonlinear texture effects for letterforms from a scale-space representation (p. 1609) and Observable transaction possibilities (p. 2086). So I'm going to go ahead and add the relevant DejaVu fonts, including for typewriter text (ₖ, $_k$, $\boldsymbol{_k}$, $\mathbf{_k}$), to the font cascade.

That seems to solve the problem. So maybe I can declare the Dercuano PDF pipeline tofu-free, at the cost of dozens of megabytes of fonts added to the source repository.

So, the remaining showstopper problems are the ET Book license and newlines following bullets. Then I can work on some problems that are annoying but less critical, like subscripts and superscripts, page numbers, blockquote formatting, ligatures, per-note tables of contents, extra spaces, extra newlines in <pre>, header colors, and header padding.

(Although, as it turns out, I spent some time adding caches to the font cascade code to see if I could make it a little less slow. This cut the PDF build time from 9.5 minutes to 8 minutes.)

Newlines following bullets

This happens with the construct `<li><p>fulano</p></li>`. Entering the `<li>` causes one newline (followed by a bullet), and entering the `<p>` causes another. The correct solution is to make the `<p>` a box vertically nested inside the `<li>` box without any extra padding, so that, unless there's something above it to push it down, their tops are at the same position. But the janky PDF generation script doesn't have a box model; it just has newlines. How could we avoid generating a newline?

Well, the problem is specifically when a block element is the first thing inside another block element. So maybe I can just have a boolean about whether we're at the top of a block.

Okay, I was able to hack that in, and as a bonus I can use it to eliminate paragraph indents when paragraphs are the first thing inside a block element. That avoids list items having an indent on the first line next to the bullet. It will probably also help with blockquotes. Gah, blockquotes.

That just leaves the ET Book license as a showstopper.

2019-12-30

No, wait, another one just popped up: in between the two 6's in "mooTzNujJpx 66\n" in the middle of powerful-primitives.html, the font switches to italic, which it doesn't in the browser, and stays that way for the rest of the note. The culprit seems to be `mOoTzNujJpx 6<I=EInw>6\n`. I tweaked this to use `` in the Markdown, which hopefully will make the problem go away, but even if it interpreted that as an `<i>` tag, it should have at some point found an end to it --- maybe Tidy worked too hard here...

Oh also I implemented **bold** as `typewriter` due to what looks like a copy-and-paste error. Fixed!

I've fixed another couple of problems mentioned earlier in a drive-by fashion: `<script>` and `<style>` contents and no-break spaces.

So, the biggest remaining problems with the PDF, in more or less priority order (a sort of mix of estimated effort with estimated benefit):

- The link to the ET Book license is broken.
- Headers don't have enough padding above them.
- Links are not indicated in any printable way, so they're invisible in, for example, MuPDF. Also, they don't have page numbers, even when they are internal links, so PDF viewers without link support (such as printers and Google Drive's PDF viewer, the default on Android) can't use them.
- Overlong lines are cut off rather than wrapped.
- Individual notes have no tables of contents.
- `<sub>` and `<sup>` are not implemented.
- Character-level markup like `<em>` produces spurious spaces.
- Character-level markup inside `<pre>` produces spurious newlines.
- The notes are not in any particular order, but they should be in the roughly chronological order they are in the table of contents.
- URL-encoded links are broken.
- I haven't imported file `ceramics-notes`.
- The PDF is humongous, 13.5 megabytes.
- Tables aren't implemented.

• Ordered lists <ol> are bulleted rather than numbered.
• Headers aren't red or underlined.
• Line spacing is too tight.
• Blockquotes aren't visibly distinct at all.
• Text isn't hyphenated, justified, or ligated (even things like "fi" and "fl".)
• SVG isn't implemented.
• Sometimes there are spurious blank lines between paragraphs and list items.
• Superscript 0 and 456789 are larger than superscript 123.
• Fallback characters in <pre> have the wrong width.

This is a lot to fix in the next 22 hours and I'm definitely not going to finish all of it, but I ought to be able to make a significant dent.

Okay, adding the ET Book license was a little harder than expected, but done.

I sort of have the padding thing working. It's not working for the "Topics" section at the end because that's the first thing in a and my check for paragraphs in list items means that they don't get a newline. I guess I could make that specific to list items.

Now I have the page numbers thing sort of working, although as with LaTeX, page number references will only work the *second* time you generate a document, which in some sense doubles the generation time from 8 minutes to 16. This is sort of alarming given that I have 20.5 hours left, which is 82 times 16 minutes. I can only do 82 more full rebuilds at that pace. This code will only ever be run 82 more times, ever.

How about overlong lines? I could use a regular "\" to indicate the wrapping of the line, although I think an outdented "–" would be nice. But then I need to chop the overlong word up into lines somehow. If I were just positioning it at an (x, y), I feel like I could easily enough position it a full column width to the left, but the textobject seems to be taking care of positioning for me, unfortunately. So maybe a better option is to binary search on word widths.

Damn it, I just scalded my hand with this teakettle. Not sure being awake at 4 AM is such a good idea. But I still have almost 20 hours left.

All right, I have overlong lines chopped and marked with little circles, sort of like flowchart connector circles. And it's almost sunrise, and damn is it hot, despite the air conditioner going full blast.

Adding tables of contents with ElementTree shouldn't be rocket science, but those tables of contents will be sort of lame without bookmarks to jump to. So I'd need to add a bookmark for each header, which I might as well try to add to the document's outline as well; actually with some PDF viewers that would be a sufficient navigational interface.

However, the 1300 or so outline items are already a bit of a problem for many PDF viewers; I'm not sure how well they'll handle another order of magnitude. I may put this off for a few hours and work on other problems.

Superscript and subscript are supposedly implemented by reportlab.pdfgen.textobject.setRise. That can be made to work... although line breaking between a base and the exponent is possible and pretty undesirable. Also it seems like the line spacing below

increases for a superscript and decreases for a subscript, which is pretty bogus; this very note has some trouble with that with the word "TEX". This is maybe enough of an implementation for the moment --- now it's a formatting problem instead of a semantic problem --- but it sucks pretty bad.

Sunrise is well underway, though the streetlights have not yet gone out.

The character-level markup problem is because the way words get separated in the document is that every word gets a space appended to it, regardless of whether what followed it was a space, the element end, or an element beginning. Originally I was using `words = text.split()` but now that I'm using `re.split` this problem should actually be easy to fix:

```
>>> re.split(r'[ \t]+', 'a b')
['a', 'b']
>>> re.split(r'[ \t]+', 'a b ')
['a', 'b', '']
>>> re.split(r'[ \t]+', ' a b ')
['', 'a', 'b', '']
```

So, I only want to append a space if the word is not the last word in the string.

This small change yields an enormous improvement in formatting. I was whispering, "Holy fuck, holy fuck, holy fuck," as I looked at the results. Exponents are better (in, *e.g.*, Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138)); formulas with italic letters are better (for example, Robust local search in vector spaces using adaptive step sizes, and thoughts on extending quasi-Newton methods (p. 1138)'s presentation of the law of cosines); inline typewriter text is better (in, *e.g.*, Eur-Scheme: a simplified Ur-Scheme (p. 876), though it still has major problems with `<pre>`); italic words in paragraphs are better; links are better.

A similar but somewhat larger change fixed the `<pre>` problem in Eur-Scheme: a simplified Ur-Scheme (p. 876), although now I am getting to the point where I am surprised when some code works, which is probably a danger sign that I'm introducing bugs. It's now light enough outside that the streetlights have gone out, though there is still no direct sunlight. Maybe I should sleep for a while if I can manage it; I have almost 18 hours left in the day.

I also just tweaked the link boxes to go 0.1 ems to the right as well as 0.1 ems to the left of the link text, and tried URL-decoding URLs to fix the problems with links to Improving Lua #L with incremental prefix sum in the ∧ monoid (p. 2008) and $1 recognizer diagrams (p. 1264), which seems to have worked.

So, now that I've solved the above eight problems, that leaves the following problems:

- Individual notes have no tables of contents.
- The notes are not in any particular order, but they should be in the roughly chronological order they are in the table of contents.
- Blockquotes aren't visibly distinct at all.
- Superscript and subscript screw up the line spacing. One of the

worst examples is on the second page of Some thoughts on SDF raymarching (p. 312), which is totally unreadable. The beginning of Why you can't run a diesel engine on water and diesel fuel with electrolysis (p. 345) also has a somewhat less egregious example.
• I haven't imported file `ceramics-notes`.
• The PDF is humongous, 16 megabytes.
• Tables aren't implemented.
• Ordered lists `<ol>` are bulleted rather than numbered.
• Headers aren't red or underlined.
• Line spacing is too tight.
• Text isn't hyphenated, justified, or ligated (even things like "fi" and "fl".)
• SVG isn't implemented. (It's only used in Dercuano drawings (p. 64) and A mechano-optical vector display for animation archival (p. 3047), so translating the seven or so diagrams manually into PDF paths and operations might be a reasonable option.)
• Sometimes there are spurious blank lines between paragraphs and list items.
• Unicode superscript 0 and 456789 are larger than superscript 123.
• Fallback characters in `<pre>` have the wrong width.
• Superscripts and subscripts don't nest; see Dercuano stylesheet notes (p. 374) in the first example of superscripts to see an egregious error.

I'm pretty pleased with how the result looks now, actually, although there are still clearly places where it does the wrong thing.

After sleeping

I slept 6 hours and now have 10 hours left.

I tried an optimization that turned out to slow things down by 10%, that of handling word spaces separately from the words. I hacked in a reasonable approximation of English spacing, in the sense of larger spaces after sentences: colons, periods, exclamation marks, and question marks get a double-sized space after them, except when it's a period at the end of an abbreviation. (In particular, an extra space is added after ordinals in sequences like "1. Ready. 2. Set. 3. Go!")

This is a small change, but I think it improves nearly every paragraph, even though there are still much worse problems than the use of French equal sentence spacing throughout the book.

It would probably work better to use the indication of double spaces (or newlines) after periods in the original Markdown, since I'm pretty consistent about doing that, but, bleh.

So, what next? I think I should see if any of the next three items turn out to be relatively yielding: individual-note tables of contents, ordering of notes, and blockquote formatting.

I was thinking as I went to sleep that hanging indents (as are conventional for bulleted lists) should be relatively easy to handle: add a property to the style that has a string to place before each new line, and set it to a few spaces. This is a crude approximation of proper indentation for bulleted lists, but it might be adequate, and in particular for blockquotes. This does not exist as a CSS stylesheet property, except in the sense that `margin-left`, or `padding-left` can be used to indent the contents of a block with whitespace, and `text-indent` can be used to give the first line of each paragraph an extra indent.

An absolute minimum thing to do for blockquote formatting is to reduce the font size, and that's easy, so I'll do that.

Hmm, not quite so easy, because I haven't implemented font inheritance for block elements, so paragraphs inside a blockquote don't inherit the font. So I implemented font inheritance for block elements.

Also I added `<ol>` and `<ul>` back as block elements, causing them to have space at the top, so that the quoted lists in Flexures (p. 2211) don't collide with the headers right above them.

Oh! I think I know how to fix the subscript/superscript problem. I just need to do the opposite setRise before setRise(0), because the implementation of setRise in Reportlab adds an increment to `self._y`:

```
def setRise(self, rise):
    "Move text baseline up or down to allow superscrip/subscripts"
    self._rise = rise
    self._y = self._y - rise    # + ?  _textLineMatrix?
    self._code.append('%s Ts' % fp_str(rise))
```

So, when we restore the rise back to zero, we need to also restore `_y`. So if we previously did setRise(6) we should do setRise(-6) before setRise(0). Well, that will work for the simple case of 0; what if the rise was previously 2? We don't want setRise(2) to result in an additional 2 points of displacement for `_y`. So we should do setRise(-8) before setRise(2). So, I got that fixed, although sometimes the fix does the wrong thing when it restores the rise on a different line.

Hmm, "P_{out}" looks like shit maybe because of inconsistent font fallbacks; it's the same problem as the superscript digits.

Okay, so with those fixes, I have 6 hours left.

Changing the basis to a more expressive one with better affordances

Kragen Javier Sitaker, 2016-09-29 (5 minutes)

Tile graphics hardware with sprites, like that on the NES, was designed to make scrolling color video-game graphics achievable in 1983 at a reasonable cost. But it also makes certain kinds of visual effects fairly easy to achieve, like wallpapering an area with a repeating pattern or scrolling or globally changing the appearance of a certain kind of tile. Other effects, like changing the on-screen size of anything, are harder.

Sprites themselves are an affordance for making moving objects on a static background; without hardware sprites, given mutable tiles, you could always just use four tile types per sprite, compositing the sprite in the appropriate place in each tile type each frame. I saw MS-DOS text-mode programs that did this for the mouse pointer.

Given enough tile definitions to have a separate definition for each tile on the screen, and enough colors that you can

Nowadays our affordances run more to gradients and alpha-blending, although to some extent that's only because our program output doesn't go through a video codec, which has different affordances.

Polynomials

There's a variety of ways you can express the space of polynomial functions.

You can express a degree-N polynomial as N+1 coefficients, which is convenient for many calculations but doesn't make it particularly easy to achieve any given effect.

Given some k, you can express it as N+1 coefficients of a polynomial in (x-k). If k happens to be one of the zeroes of the polynomial, you only need N coefficients, since the constant term is zero.

Extending this idea to its limit, you can express it as a scale factor and a set of zeroes: $3(x-1)(x+2)(x+5)$ has a scale factor of 3 and zeroes at 1, -2, and -5; its representation as zeroes is thus [3, 1, -2, -5]. It works out to $3x^3 + 18x^2 + 9x - 30$, so its representation as coefficients is [3, 18, 9, -30], although sometimes people prefer to write that in the other order. (Transforming from zeroes to coefficients is easy; going the other way can be hairy.)

You can express it with its values at some given abscissas and then use Lagrange interpolation. For a given set of abscissas, such as the nonnegative integers, you have a constant set of Lagrange basis polynomials; the polynomial is a weighted sum of its values at these points, which is to say that the transformations between this Lagrange form and the form as coefficients are linear. But the Lagrange form allows you to express the polynomial function in terms of its value at some given points, which is often more convenient.

That of course leaves open the question of the set of abscissas to

choose. Sometimes it's more expressive to be able to choose which abscissas to use, but this is somewhat dangerous with Lagrange interpolation, just as with splines of orders greater than 3; a bad choice of nodes can easily lead to unwanted oscillations (the Runge phenomenon). If you're approximating some existing smooth curve, using the Chebyshev nodes minimizes this.

The Chebyshev polynomials form another orthogonal basis into which you can linearly transform a polynomial.

For a given step size and starting point, you can express the polynomial in terms of the initial state of the method of divided differences for tabulating values of the polynomial. These values are a linear transform of the coefficients and thus also of the Lagrange form; you can easily derive them by calculating some values of the polynomial and writing a difference table. They are called the "Newton form" of the polynomial. The Newton form is in some sense not very expressive, in that the numbers in it don't correspond very directly to any interesting feature of the polynomial itself. However, it's very convenient for calculation.

Order-n polynomials on the real numbers (or even the rationals, or any dense set) are entirely determined by their value and first n derivatives at any arbitrary point; this is the basis of the Taylor-series approximation of a function, which is the analytic equivalent of the Newton form. A polynomial function is equal to its Taylor series as soon as the Taylor series' order equals or exceeds that of the original polynomial. So the derivatives at some given point are yet another representation of the polynomial, another one which is linearly related to the coefficients.

It isn't necessary for all the derivatives to be at the same point; it's adequate to specify N+1 values or derivatives as long as no two of them are the same.

State machines

You can specify state machines as regular expressions...

Dumb vocoder

Kragen Javier Sitaker, 2017-05-10 (2 minutes)

Watching TinselKoala's (TKLabs's) transmission-line model demonstration, which uses an analog delay line made of inductors and capacitors to set up a standing wave that varies by frequency, with LEDs connected to show where the antinodes were, it occurred to me that perhaps you could use this approach for analog detection of voice frequency spectrum.

He's using the interference patterns of the reflection in the unterminated analog delay line to get different patterns of lights on the LEDs. This is purely a linear phenomenon, so the pattern of standing voltages that will show up for signals at different frequencies is the sum of the voltages for the individual signals.

I think that you can get signals to bounce back and forth in the transmission line many times by using a large resistor on the input. Only harmonic frequencies will produce recognizable patterns of nodes and antinodes, I think? I don't know how well this will work to separate harmonic frequencies from inharmonic ones.

Anyway, can you use these standing-wave shapes to detect a set of frequency buckets spread across several octaves? I think so. And you don't need, necessarily, a compact analog delay line made of capacitors and inductors. You may be able to use AM modulation to upconvert a waveform from audio frequencies up to frequencies high enough that you can fit them into a short piece of coax, although perhaps they won't be resonant frequencies.

Iterative string formatting

Kragen Javier Sitaker, 2013-05-17 (9 minutes)

Every language seems to have string formatting as some kind of DSL. C has its `%3.4g` nonsense. JS, Perl, and Python programmers often use the same thing. C++ has iostream format manipulators `cout << setw(3) << setprecision(4) << x`. BASIC had `PRINT USING`. Fortran had FORMAT. Common Lisp has its own insanely powerful FORMAT, taking strings like "~3,4g", which means something almost, but not quite, completely unlike `%3.4g`. Even Excel has its own numeric formatting language; if you want your lakhs and crores properly displayed, apparently you can say "Format Cells → Custom" and then `[>9999999]##\,##\,##\,##0.00;[>99999]##\,##\,##0.00;##,##0.00;[<-9999999](##\,##\,##\,##0.00);[<-99999](##\,##\,##0.00);##,##0.00`

Forth's embedded domain-specific language for "pictured numeric output"

Forth "pictured numeric output" is, like C++'s approach, an embedded DSL, but much more direct in its functioning; the typical example is something like

```
: .pesos <# # #  [char] . hold  #s  [char] $ hold #>  type ;
```

which has the format string actually backwards, because that's the order in which you do decimal conversion, and is also using double-precision fixed-point math because that's the way you do things in Forth.

Because it's an embedded DSL, you can use the standard methods of abstraction. For example, if you want more flexible currency display, you can factor out parts of your format string into subroutines or variables:

```
defer currency
: pesos [char] $ hold ;
: pounds C" £" dup 1+ C@ swap 2 + C@ hold hold ; ( assuming UTF-8 )

variable decimal-point

: .$ <# # # decimal-point @ hold #s currency #> type ;

: argentina  [char] , decimal-point !  ['] pesos is currency ;
: usa        [char] . decimal-point !  ['] pesos is currency ;
: england    [char] . decimal-point !  ['] pounds is currency ;

8.4300 7.8300 d+ d2/ d>s constant dolar-blue \ www.dolarblue.net 2013-03-31
1.5195 d>s constant £                        \ in dollars; xe.com 2013-03-31
: /$ 10000 swap m*/ drop s>d ;
: convert 2dup ." AR"    argentina                .$
          2dup ."  = US" usa     dolar-blue /$    .$
          2dup ."  = "   england dolar-blue /$ £ /$ .$
          2drop ;
```

```
cr 1500.00 convert   \ my rent in Buenos Aires
```

You could even put a complex iterative state machine into your format string; in this case we take advantage of Forth's compile-time metaprogramming to factor out a duplicative control structure:

```
char , constant thousands-separator
: ?#  postpone #
    postpone 2dup  postpone d0=
    postpone if  postpone exit  postpone then ;  immediate
: #,s  begin  ?# ?# ?#  thousands-separator hold  again ;
: #             s  ?# ?# ?#  thousands-separator hold
  begin ?# ?#  thousands-separator hold  again ; ( for e.g. 1,00,00,00,000 )
: .,  <# #,s #> type ;   : .              <# #             s #> type ;
```

Forth's particular implementation of this concept is quite limited, though; you have to build the output string backwards, the buffer area is quite limited in size, and it's eager.

The more usual approach of external DSLs

But, when it's a non-embedded DSL, the DSL only goes so far. I seem to end up writing a lot of string formatting code that looks more or less like this:

```
    def __repr__(self):
        return 'Note(%r, %r, %r, %r)' % (self.instrument,
                                         self.start_time,
                                         self.pitch,
                                         self.volume)

    def __repr__(self):
        return '[[ %r %r %r ]]' % (self.left, self.op, self.right)
```

This is, in all likelihood, grossly inefficient. Erlang's approach, which I used in Ur-Scheme, is called "IO lists", and it's similar to "ropes": represent strings with arbitrary unbalanced binary trees, waiting until I/O time to walk the trees in O(N) time. This gives you O(1) concatenation, which makes string concatenation efficient, but it doesn't really solve the DSL problem.

(The description makes it sound complicated but the implementation is about 23 lines of code in Ur-Scheme, and it could have been shorter with a little more cleverness.)

Here's a use of IO lists in Erlang:

```
join([])          -> "";
join([W])         -> W;
join([W1, W2])    -> [W1, " and ", W2];
join([W1, W2, W3]) -> [W1, ", ", W2, ", and ", W3];
join([W1|Ws])     -> [W1, ", ", join(Ws)].
```

When invoked with `io:format("~s; ~s; ~s; ~s; ~s.~n", [commalist:join([]), commalist:join(["Apple", "Banana", "Carrot"]), commalist:join(["One", "Two"]), commalist:join(["Lonely"]), commalist:join("abcdefg")])`., this produces, "; Apple, Banana, and Carrot; One and Two; Lonely; a, b, c, d, e, f, and g."

Smalltalk's approach: output to a string (and capture it if necessary)

Smalltalk has an interesting approach; in general, instead of concatenating strings (which is APLish , in Smalltalk) you sequentially write them to a stream, and if you need them in a string, you can use `WriteStream on: String new` for that string, and there's even a `String#streamContents:limitedTo:` method for this. Here's the code that gets run from `Date today asString` in Squeak 3.9, eventually yielding '31 March 2013', with some added commentary in case you're not familiar with Smalltalk syntax:

```
asString
    "Answer a string that represents the receiver."

    "^, read 'answer', means 'return' and was once displayed as ↑."
    ^ self printString

printString
    "Answer a String whose characters are a description of the receiver.
    If you want to print without a character limit, use fullPrintString."

    ^ self printStringLimitedTo: 50000

printStringLimitedTo: limit
    "Answer a String whose characters are a description of the receiver.
    If you want to print without a character limit, use fullPrintString."
    "The following declares a local variable limitedString."
    | limitedString |
    "_ is assignment and was traditionally displayed as ←.
    Nowadays it is usually written := instead.
    [:s | self printOn: s] is JS's function(s){return self.printOn(s)}.
    So the following in JS would be
    var limitedString = String.streamContentsLimitedTo(function(s) {
        return self.printOn(s);
    }, limit);
    "

    limitedString _ String streamContents: [:s | self printOn: s] limitedTo: limi
ot.
    limitedString size < limit ifTrue: [^ limitedString].
    ^ limitedString , '...etc...'

printOn: aStream
    self printOn: aStream format: #(1 2 3 $  3 1 )  "$  is space, #() array"

printOn: aStream format: formatArray
    "Print a description of the receiver on aStream using the format
    denoted the argument, formatArray:
        #(item item item sep monthfmt yearfmt twoDigits)
        items: 1=day 2=month 3=year will appear in the order given,
        separated by sep which is eaither an ascii code or character.
        monthFmt: 1=09 2=Sep 3=September
        yearFmt: 1=1996 2=96
        digits: (missing or)1=9 2=09.
```

```
    See the examples in printOn: and mmddyy"
    | gregorian twoDigits element monthFormat |
    "The #dayMonthYearDo: method strikes me as bizarre in this context:"
    gregorian _ self dayMonthYearDo: [ :d :m :y | {d. m. y} ].
    twoDigits _ formatArray size > 6 and: [(formatArray at: 7) > 1].
    1 to: 3 do:
        [ :i |
            element := formatArray at: i.
            element = 1
                ifTrue: [twoDigits
                        ifTrue: [aStream
                                nextPutAll: (gregorian first asString
                                        padded: #left
                                        to: 2
                                        with: $0)]
                        ifFalse: [gregorian first printOn: aStream]].
            element = 2
                ifTrue: [monthFormat := formatArray at: 5.
                    monthFormat = 1
                        ifTrue: [twoDigits
                                ifTrue: [aStream
                                        nextPutAll: (gregorian middle asString
                                                padded: #left
                                                to: 2
                                                with: $0)]
                                ifFalse: [gregorian middle printOn: aStream]].
                    monthFormat = 2
                        ifTrue: [aStream

                                nextPutAll: ((Month nameOfMonth: gregorian middleo
o)

                                        copyFrom: 1
                                        to: 3)].
                    monthFormat = 3
                        ifTrue: [aStream

                                nextPutAll: (Month nameOfMonth: gregorian middle)o
o]].
            element = 3
                ifTrue: [(formatArray at: 6)
                            = 1
                        ifTrue: [gregorian last printOn: aStream]
                        ifFalse: [aStream
                                nextPutAll: ((gregorian last \\ 100) asString
                                        padded: #left
                                        to: 2
                                        with: $0)]].
            i < 3
                ifTrue: [(formatArray at: 4)
                            ~= 0

                        ifTrue: [aStream nextPut: (formatArray at: 4) asCharactero
o]]]
```

And down inside of String:

```
padded: leftOrRight to: length with: char
    leftOrRight = #left ifTrue:
        [^ (String new: (length - self size max: 0) withAll: char) , self].
    leftOrRight = #right ifTrue:
        [^ self , (String new: (length - self size max: 0) withAll: char)].
```

And the `Number#asString` method that's being used to do the actual conversions ends up writing to a string stream, then reversing it:

```
printStringBase: base
    | stream integer next |
    self = 0 ifTrue: [^'0'].
    self negative ifTrue: [^'-', (self negated printStringBase: base)].
    stream _ WriteStream on: String new.
    integer _ self normalize.
    [integer > 0] whileTrue: [
        next _ integer quo: base.
        stream nextPut: (Character digitValue: integer - (next * base)).
        integer _ next].
    ^stream contents reversed
```

This demonstrates that Smalltalk code is not uniform in simply using `nextPutAll:`. Indeed, since Smalltalk has garbage collection, code that uses string concatenation is simpler than code that repeatedly writes to an output stream; it's just less efficient.

The streamContents:limitedTo: method mentioned earlier takes advantage of XXX

```
streamContents: blockWithArg limitedTo: sizeLimit
    | stream |
    stream _ LimitedWriteStream on: (self new: (100 min: sizeLimit)).
    stream setLimit: sizeLimit limitBlock: [^ stream contents].
    blockWithArg value: stream.
    ^ stream contents
```

The "limitBlock" here can be invoked from deep inside of whatever code runs from `blockWithArg`, leaping over many stack frames to discard half-completed execution and return the so-far-accumulated data. (I assume it executes `ensure:` blocks on the way?)

Coroutines for string formatting

Instead of a buffer or a stack, use a channel, and run the string-formatting code as a coroutine. That way you get the benefits of an embedded DSL, along with laziness, laziness which in this context will very often reduce memory usage rather than increasing it; and you can avoid generating intermediate copies of parts of the string you're generating.

This requires efficient coroutine support in your language, and likely a certain amount of buffering: probably at least a machine word, if not a whole cache line. Otherwise you need a coroutine context switch on every byte transferred, which will slow some applications significantly.

Notes on reading eForth

Kragen Javier Sitaker, 2007 to 2009 (9 minutes)

These notes are on stuff I got out of EFORTH.ZIP, 61213 bytes, which I downloaded from http://www.baymoon.com/~bimu/forth/ linking to http://www.baymoon.com/~bimu/forth/eforth/EFORTH.ZIP. Beware! This software is not under an explicit free-software license, and the web page says, "Permission is granted for non-commercial use, provided this notice is included."

Bill Muench's eForth may be the closest thing I've seen to a minimal FORTH kernel. The assembly-language kernel of 8086 eForth ITC16i 971014.1, an indirect-threaded FORTH system, implements only these 36 words:

```
EXIT ( -- ) ( R: a -- ) ( 6.1.1380 )( 0x33 ) \ ITC
EXECUTE ( xt -- ) ( 6.1.1370 )( 0x1D ) \ ITC
_LIT ( -- n ) ( 0x10 )
_ELSE ( -- ) ( 0x13 )
_IF ( f -- ) ( 0x14 )
C! ( c a -- ) ( 6.1.0850 )( 0x75 )
C@ ( a -- c ) ( 6.1.0870 )( 0x71 )
! ( n a -- ) ( 6.1.0010 )( 0x72 )
@ ( a -- n ) ( 6.1.0650 )( 0x6D )
RP@ ( -- a )
RP! ( a -- )
>R ( n -- ) ( R: -- n ) ( 6.1.0580 )( 0x30 )
R@ ( -- n ) ( R: n -- n ) ( 6.1.2070 )( 0x32 )
R> ( -- n ) ( R: n -- ) ( 6.1.2060 )( 0x31 )
SP@ ( -- a )
SP! ( a -- )
DROP ( n -- ) ( 6.1.1260 )( 0x46 )
SWAP ( n1 n2 -- n2 n1 ) ( 6.1.2260 )( 0x49 )
DUP ( n -- n n ) ( 6.1.1290 )( 0x47 )
OVER ( n1 n2 -- n1 n2 n1 ) ( 6.1.1990 )( 0x48 )
CHAR- ( a -- a )
CHAR+ ( a -- a ) ( 6.1.0897 )( 0x62 )
CHARS ( n -- n ) ( 6.1.0898 )( 0x66 )
CELL- ( a -- a )
CELL+ ( a -- a ) ( 6.1.0880 )( 0x65 )
CELLS ( n -- n ) ( 6.1.0890 )( 0x69 )
0< ( n -- f ) ( 6.1.0250 )( 0x36 )
AND ( n n -- n ) ( 6.1.0720 )( 0x23 )
OR ( n n -- n ) ( 6.1.1980 )( 0x24 )
XOR ( n n -- n ) ( 6.1.2490 )( 0x25 )
UM+ ( u u -- u cy )
REDIRECT ( asciiz -- f )
!IO ( u -- ) ( initialize I/O device )
?RX ( -- c -1 | 0 )
TX! ( c -- )
BYE ( -- ) ( 15.6.2.0830 )
```

And these "procs" --- not FORTH words but machine-code

routines:

```
PROC RESET ( cold start entry )
PROC LIST1          ( entry for : words ) \ ITC
PROC VCOLD             ( cold start entry )
```

Those 39 primitives are the basis for implementing everything else. Here are some brief notes on them. It took me a while to understand how "next," works in eForth; it's defined in EMETA.X86 and inserts a single JMP instruction to the "NEXT1" label. I'm also not quite sure about the conditionals. So my instruction counts may not be quite right.

- EXIT (--) (R: a --) (6.1.1380)(0x33) \ ITC
  This pops the return-stack pointer to return from a colon definition.
  5 instructions.
- EXECUTE (xt --) (6.1.1370)(0x1D) \ ITC
  This calls a word that's on the stack.
  2 instructions.
- _LIT (-- n) (0x10)
  Pushes the next cell in the colon definition.
  3 instructions.
- _ELSE (--) (0x13)
  Unconditional branch in a colon definition.
  3 instructions.
- _IF (f --) (0x14)
  Conditional branch in a colon definition.
  7 instructions.
- C! (c a --) (6.1.0850)(0x75)
  Store a byte.
  4 instructions.
- C@ (a -- c) (6.1.0870)(0x71)
  Fetch a byte.
  5 instructions.
- ! (n a --) (6.1.0010)(0x72)
  Store a cell.
  3 instructions.
- @ (a -- n) (6.1.0650)(0x6D)
  Fetch a cell.
  3 instructions.
- RP@ (-- a)
  Push the return stack pointer.
  2 instructions.
- RP! (a --)
  Set the return stack pointer (e.g. to throw an exception or switch threads)
  2 instructions.
- >R (n --) (R: -- n) (6.1.0580)(0x30)
  Push something on the return stack.
  3 instructions.
- R@ (-- n) (R: n -- n) (6.1.2070)(0x32)
  Copy something off the return stack. (Not in the minimal set.)
  2 instructions.

• R> (-- n) (R: n --) (6.1.2060)(0x31)
Pop something off the return stack.
3 instructions.
• SP@ (-- a)
Get the stack pointer (e.g. for .S).
3 instructions.
• SP! (a --)
Set the stack pointer (e.g. to throw an exception or switch threads.)

2 instructions.
• DROP (n --) (6.1.1260)(0x46)
2 instructions.
• SWAP (n1 n2 -- n2 n1) (6.1.2260)(0x49)
5 instructions.
• DUP (n -- n n) (6.1.1290)(0x47)
4 instructions.
• OVER (n1 n2 -- n1 n2 n1) (6.1.1990)(0x48)
Not in the minimal set.
6 instructions.
• CHAR- (a -- a)
Subtract 1. Not in the minimal set.
4 instructions.
• CHAR+ (a -- a) (6.1.0897)(0x62)
Add 1. Not in the minimal set.
4 instructions.
• CHARS (n -- n) (6.1.0898)(0x66)
No-op. Not in the minimal set.
1 instruction.
• CELL- (a -- a)
Subtract 2 (the size of a 16-bit cell). Not in the minimal set.
4 instructions.
• CELL+ (a -- a) (6.1.0880)(0x65)
Add the size of a cell (2). Not in the minimal set.
4 instructions.
• CELLS (n -- n) (6.1.0890)(0x69)
Multiply a number by the size of a cell (2). Not in the minimal set.
4 instructions.
• 0< (n -- f) (6.1.0250)(0x36)
See if a number is less than 0.
4 instructions.
• AND (n n -- n) (6.1.0720)(0x23)
Bitwise.
5 instructions.
• OR (n n -- n) (6.1.1980)(0x24)
5 instructions.
• XOR (n n -- n) (6.1.2490)(0x25)
5 instructions.
• UM+ (u u -- u cy)
Unsigned add, pushing a carry flag.
8 instructions.

The code words up to this point are the fundamental internal operations of the virtual machine. They total 117 instructions. The next few code words are OS interface primitives:

• REDIRECT (asciiz -- f)
Open a file as stdin using INT 21h calls; returns “f” success or failure.
15 instructions.
• !IO (u --) (initialize I/O device)
No-op, for compatibility with some other eForth systems I don’t know about.
2 instructions.
• ?RX (-- c -1 | 0)
Read a key if ready using INT 21h, otherwise return 0.
16 instructions.
• TX! (c --)
Emit a character using INT 21h.
4 instructions.
• BYE (--) (15.6.2.0830)
Exit program with INT 20h.
1 instruction.
Those MS-DOS interface primitives are 38 more instructions.

• PROC RESET (cold start entry)
Placed at the beginning of the program, to jump to VCOLD, wherever it might be.
2 instructions.
• PROC LIST1 (entry for : words) \ ITC
Pushes the instruction pointer onto the return stack and sets a new one.
5 instructions.
• PROC VCOLD (cold start entry)
Sets up registers and starts the interpreter.
14 instructions.
So there are 21 more instructions; the whole thing is 117 + 38 + 21 = 176 machine-code instructions, if I counted it correctly. EFORTH.COM is 7936 bytes, of which the last 157 are “junk DNA,” all lower-case ‘b’, presumably so it would end on a 256-byte boundary; the part of EFORTH.COM up to the the end of the definition of TX! is 762 bytes, including the dictionary structure and copyright notice, and I think that encompasses basically the above machine-code words. (BYE and VCOLD are at the end, so they’re not included in the 762.)
Some things not included in the machine-language subset (that maybe should be): multiplication and division; subtraction; negation; PICK; string I/O; bit shifts; memory block copying.
The rest of eForth is about 700 lines of FORTH, defining 191 more subroutines:
NOOP _VAR _CON HEX DECIMAL ROT NIP 2DROP 2DUP ?DUP + D+ INVERT NEGATE DNEGATE S>D ABS DABS - PICK 0= = U< MAX MIN WITHIN LSHIFT UM* * RSHIFT UM/MOD SM/REM FM/MOD /MOD MOD / +! COUNT BOUNDS /STRING ALIGNED 2! 2@ MOVE FILL -TRAILING >ADR >BODY _USR 'S _PASS _WAKE PAUSE STOP GET RELEASE SLEEP AWAKE ACTIVATE BUILD DIGIT? >NUMBER NUMBER? HERE PAD <# DIGIT HOLD # #S #> SIGN CATCH THROW ABORT ?KEY KEY NUF? EMIT SPACE EMITS SPACES TYPE CR _" _S" _." _ABORT"

S.R D.R U.R .R D. U. . ? PACK DEPTH ?STACK ACCEPT SAME? _DELIMIT _PARSE NAME> WID? SFIND _[[SOURCE PARSE-WORD EVALUATE ASCIIZ STDIN FROM QUIT ALIGN ALLOT S, C, , COMPILE, LITERAL CHAR [CHAR] ' ['] PARSE .((\ SLITERAL ,C" S" ." ABORT" _]] GET-CURRENT SET-CURRENT DEFINITIONS ?UNIQUE HEAD, IMMEDIATE COMPILE-ONLY REVEAL RECURSE POSTPONE CODE next, :NONAME : ; _DOES> DOES> CREATE VARIABLE CONSTANT USER HAT WORDLIST ORDER@ GET-ORDER SET-ORDER _MARKER MARKER BEGIN THEN RESOLVE MARK IF AHEAD ELSE WHILE UNTIL AGAIN REPEAT .S !CSP ?CSP >CHAR _TYPE _DUMP DUMP .ID WIDWORDS WORDS NAMED? SSEE SEE COLD

Which is pretty much just a normal FORTH a bit on the minimal side, with just a few extras (multitasking, a decompiler), minus blocks (FORTH's low-budget "virtual memory") and an assembler.

(There are also some variables, which I haven't counted.)

The resulting MS-DOS executable, as I mentioned, is 7936 bytes.

The "metacompiler" is in a separate source file and is not included in those 7936 bytes; and Muench did not include the source to his assembler, just an executable, called B.EXE, which is relatively large.

So we have an "inner core" of 176 instructions in 39 routines, about 700–800 bytes including debug info; an "outer core" of another 191 FORTH routines, about 7000 more bytes (about 1000 of which is just their names); and presumably your program on top of that.

(It actually uses only the 22 instructions MOV, JMP, SUB, ADD, ADC, LODSW, POP, PUSH, AND, OR, JZ, JNZ, JB, XOR, SHL, CWD, XOR, INT, DEC, CLI, STI, and CLD, although there are a variety of operand types in use with some of those; so writing a minimal assembler to support it would be pretty straightforward.)

Looks like this isn't the original eForth though...

Introduction to closures

Kragen Javier Sitaker, 2019-12-07 (5 minutes)

Many programmers who haven't delved deeply into functional programming are puzzled about what closures are and why they would care. And this confusion sometimes gets worse when they find explanations that explain how closures are implemented, namely by storing some extra values along with a pointer to some function code and supplying those values to the function when it is invoked. But that doesn't get to the heart of the matter, which is:

Closures are the language feature that allow you to create new functions at runtime.

Here's an example. You can express the function (+) that adds two numbers in just about any programming language. In old-style JS you would write `function foo(a, b) { return a + b; }`, for example. And similarly you can express the function (3+) that adds three to things: `function foo(b) { return 3 + b; }`. But (3+) is obviously just one example of a large class of functions like (4+), (5+), (-3 +), and so on; it would clearly be nice to be able to generate instances of this class of functions automatically instead of copying and pasting code and editing the constant in it.

Closures are the language feature that make this possible; in JS, for example, you can write `function adder(a) { function foo(b) { return a + b; } return foo; }` and you have a function which, at runtime, creates arbitrary new instances of this adder class. This clearly requires the binding of `a` to, say, 3 or 4 or 5 or -3, to stick around somewhere, rather than being discarded when `adder` exits, which you will note is not at all explicit in the original code. Forth doesn't have closures but gets a similar ability in a different, more explicit way, "at compile-time", that is, when you're building the dictionary; you say `: adder create , does> @ + ;` which allows you to say things like `3 adder 3+`.

You might think that closures only allow the creation of a limited class of copy-and-paste functions at run-time, but in fact they allow you to create *any computable function* at run-time. In fact, you only need *one function that creates closures* to do this; Moses Schönfinkel showed in the 1920s† that it was possible with two curried functions, conventionally called S and K:

```
function S(x) {
    function S2(y) {
        function S3(z) { return x(z)(y(z)); }
        return S3;
    }
    return S2;
}

function K(x) {
    function K2(y) { return x; }
    return K2;
}
```

Or, in modern JS:

```
const S = x => y => z => x(z)(y(z)), K = x => y => x
```

And, in 2001, Chris Barker demonstrated that you can do it with just one, which can be written as `function ι(f) { return f(S)(K); }`. The reductions from things like ordinary arithmetic, to the λ-calculus, to S and K, to Barker's ι combinator, are an interesting kind of mind-bending, the kind that makes you wonder why it took you so long to understand them once you finally do understand them.

Pascal supports closures in a limited form that keeps them from surviving the function that instantiated them, while some other programming languages like Smalltalk-80 and GCC C have that restriction but don't enforce it, so your program will probably just crash if you violate it. Modern Smalltalk has full-fledged unlimited-extent garbage-collected closures like JS and Scheme, as do most modern languages: modern C++, Perl since Perl 5, Ruby since forever, Kotlin, Java since Java 8 (?), and so on. Smalltalk is particularly interesting in this regard because it uses closures instead of conditionals and loops, using an extremely lightweight syntax and some cheats in the compiler to make this practical. Some Scheme implementations actually use closures to implement not only conditionals and loops but even local variable declarations and statement sequencing; Olin Shivers wrote a widely-cited dissertation on how to make *that* insanity practical after struggling with the problem for years.

That might be more information about closures than you wanted, but hopefully it's enough to orient you and let you figure out what you want to know more about.

Footnote

† Actually, Schönfinkel invented the SKI-combinator system in the 1920s, but Curry's further work on it and Church's invention of the λ-calculus had to wait for the 1930s, and it wasn't until the 1940s that the concept of "computable functions" was really clear, thanks to the work of Curry, Gödel, Church, and Turing in the 1930s; at which point it became clear what Schönfinkel had really proved. At least that's my understanding of the history, but I've never read Schönfinkel's paper.

Is a phase vocoder or a bunch of PLLs a more efficient way to listen to all FM radio stations at once?

Kragen Javier Sitaker, 2018-06-17 (updated 2019-07-29) (7 minutes)

Could you listen to every FM radio station at once on your PC?

Standard FM radio runs from 87.5 MHz to 108 MHz with channels typically every 800 kHz or so in a given geographical area, although in theory they can be spaced as close as 200 kHz apart. That's 20.5 MHz divided into 103 200 kHz channels, of which typically about 25 are used. If an SDR is to pick up all of that 20.5 MHz at once, it needs to sample at 41 Msps or, preferably, substantially more, like 60 Msps, which is probably feasible with some work — I mean 640×480 video at 60 fps is 18 Msps per color channel, 55 Msps in total. (Direct downconversion sampling may be feasible with some filtering. Sampling at baseband would require 215 Msps.)

A couple of different algorithms occurred to me to do this: one using a bank of phase-locked loops ("PLLs") and one using a phase vocoder. Both seem likely to be feasible on a desktop PC, but the phase-vocoder approach should scale to a larger number of channels more efficiently.

Analyzing channels with PLLs

But then there's the issue of how to analyze the channels. You can of course run a PLL on each channel — say, 25 or 30 PLLs in all. Officially FM mono has 15 kHz of audio bandwidth, but unlike in AM, in FM there isn't a simple relationship between audio bandwidth and radio bandwidth — a 1 Hz audio signal could be encoded by swinging the frequency of the FM carrier back and forth over a "frequency deviation" of 1 MHz. The frequency deviation actually used is ±75 kHz. You need at least 15 kHz of audio out of each of those channels, so you need frequency information out of each of the PLLs at at least like 30 ksps. To decode FM stereo, you need to decode oscillations of the carrier frequency at up to 53 kHz, and thus your PLL needs to give you a frequency readout at 106 ksps or more.

The frequency reported by the PLL is always in some sense an average over some time period, and that's what these numbers mean. If it's "30 ksps" then the frequency needs to be able to slew from −75 kHz to +75 kHz in 33 μs, a slew rate of 4.5 GHz/s, and the frequency can't be an average over much more than those 33 μs. If it's "106 ksps" then it's 16 GHz/s and 9.5 μs. At 60 Msps, that's averaging the oscillation over 2000 samples for mono and 600 samples for stereo, which seems eminently feasible.

This approach requires about 15 operations per sample per PLL, which works out to some 400 operations per sample, 24 billion operations per second. It's possible to implement this without any multiplies at all.

Analyzing channels with a phase vocoder

An alternative to using PLLs might be to use a phase vocoder. This

amounts to taking an STFT of the signal often enough to reliably unwrap the phase — at least three times per cycle of the beat frequency, say — with enough frequency resolution to have only one sinusoid at most in each frequency bin.

As before, we need to divide the spectrum into frequency bins small enough that at most one station is in each, but the FFT bins are evenly spaced from 0 up to Nyquist, with one bin for every two samples in the window. We can't choose the bin center frequencies freely the way we could with the PLL approach.

If we use about 400 kHz spacing, then we need at least 52 frequency bins, so at least 104 samples in the STFT window, say 128, which gives us 64 frequency bins, ranging over 30 MHz if we're at 60 Msps; this gives us 468'750 Hz per bin. But the windows can overlap by as much as you want.

A somewhat tricky issue is that, in a phase vocoder, the rate at which you need to inspect the phase of each bin is not determined by how fast it is changing *frequency* (as in the PLL case), but by how fast it is changing *phase*. In a bin of 468-kHz width, the putative partial in the bin can only vary by ±234 kHz from the bin center frequency. This means we need about 600'000 STFT windows per second, which thus only overlap by 28 samples.

I think that, roughly speaking, this involves $(7 = \lg 128) \cdot 2 \cdot 5.1$ multiplies per sample, which works out to 71, which means we need 4.3 billion multiplications per second at 60 Msps. This sounds feasible but very challenging. For a CPU, anyway; it should be easy for a GPU.

(Intel and NASoftware reported in 2011 that a 256-point call to the VSIPL function `vsip_ccfftip_f`, which is probably not the fastest FFT function for this since its input is complex, takes 440ns using AVX on one core of a Core i7-2710QE when running at 2GHz, so it should in fact be feasible on a modern CPU, if not on my laptop. In the same slide deck, they also report results on a Core i7-2715QE (?) as 23273 megaflops, which I guess means each FFT is 10240 operations, or 40 operations per sample, which is a lot more than the 16 multiplies I was guessing.)

That sounds almost an order of magnitude better than the PLL approach, but it requires multiplies. So it might turn out that the approaches actually have similar efficiency in practice.

You might think to reduce computational load by using a smaller number of STFTs per second. But if you are using fewer STFTs of the same size per second, without increasing the size of the STFTs, you lose the ability to track frequencies near the edges of the bins; their phases vary too fast to be unwrapped, and they alias into frequencies closer to the center. To avoid this, you must increase the size of the STFTs exactly proportional to the reduction in the number of windows you shingle each second with. This almost exactly cancels out the original reduction in computational load, *except* that now you can decode more channels, *and* the logarithmic factor of the FFT complexity increases. So, for example, if you do 1024-sample STFTs instead of 128-sample STFTs, you can decode 512 radio channels instead of 64, at the cost of about 25% more computation.

This consideration suggests that, for a small number of channels, the PLL approach should be more efficient, and for a large number of channels, the FFT-based phase vocoder should be more efficient.

They just happen to be about equal at about the number of channels that exist in FM radio.

Ideas to ship in 2014

Kragen Javier Sitaker, 2014-04-24 (updated 2019-05-05) (35 minutes)

These are some 50 ideas I have that I think are important for me to pursue and in some form "ship", either by explaining and thinking about them ("shipping" an essay), researching them ("shipping" a review), or experimenting with them ("shipping" experimental results and, in some cases, software). The question is, which ones are the *most* important to pursue.

I can't possibly do all of them, or even a large minority of them, so I'm making this list for two reasons: first, to help me prioritize them (feedback welcome!), and second, to get enough information out there that someone else can maybe tackle the ones that I'm not going to do.

Here I'm using "AOWTBITF" as an abbreviation for "Amount of work to bring it to fruition" and "SNSTWBU" for "Smallest next step that would be useful".

The natural relationship between violence and religion

Summary: an essay about how boundaries between religious groups inevitably produce violence as long as both groups believe in self-defense.

Benefit: if I'm wrong, maybe someone will tell me; otherwise, maybe people will understand violence and religion better, better enabling them to organize society to minimize violence.

AOWTBITF: 8 hours. **SNSTWBU**: write an outline, ½ hour.

The effectiveness of Leviathan in reducing violence

Summary: an essay exploring whether Hobbes' proposed justification for the existence of states is empirically justified by what our current state of anthropological, epidemiological, zoological, and archaeological knowledge, which has advanced substantially since 1651.

Benefit: if I'm wrong, maybe someone will tell me; otherwise, people might understand violence better, better enabling them to organize society to minimize violence.

AOWTBITF: 32 hours. **SNSTWBU**: dig up a copy of Pinker's angel book, 4 hours.

The path toward a world not organized around violence

Summary: an essay exploring whether there's an alternative to Leviathan.

Benefit: if I'm wrong, maybe someone will tell me. Otherwise, maybe people will better understand violence and its role in society and have a clear plan for making the world less violent; and my own point of view on violence will be publicly declared.

AOWTBITF: 16 hours. **SNSTWBU**: write an outline, 1 hour.

De-heroizing mass killers

Summary: an essay exhorting people not to honor the military. Related to http://lists.canonical.org/pipermail/kragen-tol/2010-June/000916.html.

Benefit: if I'm wrong, maybe someone will tell me. Otherwise, if the argument is effective, it weakens the credibility of those with the strongest inclination to argue against pacifism and nonviolence.

AOWTBITF: 16 hours. **SNSTWBU**: write an outline, 1 hour.

The equivalence between violence and censorship or dishonesty

Summary: an essay arguing that advocacy of free speech necessarily entails advocacy of nonviolence. Gandhi talked about this, as did the Redonditos de Ricota. Related to http://lists.canonical.org/pipermail/kragen-tol/2008-February/000880.html, which discusses how censorship causes violence.

Benefit: if I'm wrong, maybe someone will tell me. Otherwise, people might understand the seriousness of censorship and dishonesty and be less willing to endorse them as a result, although presumably some people will go the other way and conclude that permitting free speech amounts to collective suicide.

AOWTBITF: 8 hours. **SNSTWBU**: write an outline, ½ hour.

The prospects for material abundance, the path to an abundance-based economy

Summary: an essay about the future of society: we're living in an age where many things that were once scarce have become so abundant that anyone could have as much as they want, and it seems likely that more and more things will be abundant in this way. How do we take advantage of this? Mentioned in http://lists.canonical.org/pipermail/kragen-tol/2010-June/000916.html.

Benefit: if I'm wrong, maybe someone will tell me. Otherwise, maybe I'll come up with an idea or two that's worth implementing and improves our chances of surviving as a civilization.

AOWTBITF: 8 hours. **SNSTWBU**: write an outline, ½ hour.

The obsolescence of the Marxist classes for understanding modern society

Summary: an essay, or perhaps book, proposing more accurate replacements for Marx's concepts of "bourgeoisie" and "proletariat", which made some sense in the 19th and 20th century, however oversimplified they may have been, but today are more misleading than useful; social dynamics have changed fundamentally, and even in the 20th century, the predictions Marx made based on his theory could hardly have been more incorrect.

Benefit: I'll understand both society and Marxism much better by writing the essay. Surely other people will tell me I'm wrong, which might improve my understanding further if they have something more substantive to say than just "false consciousness!". Ultimately, I'll provide a framework for understanding 21st-century society that

supplants the Marxist framework commonly used by Marxists and capitalists today, but writing this essay is just the first step in that process. (Fuck, that sounds arrogant, doesn't it? I hope the high aims I'm setting for myself don't backfire on me as they did for Aaron.)

AOWTBITF: 512 hours. **SNSTWBU**: finish carefully reading Capital, 128 hours.

Why people do things

Summary: a series of essays analyzing human motivations in different cross-cutting ways: a division between personality, situation, and free will; a division between instinct, culture, and self-interest; a division between loyalties to the group, beliefs in ideals, and egoism; and a division between habit, improvisation, and planning. The essays will integrate the best current understanding from experimental psychology with a poorly-understood version of Buddhism, while remaining accessible through parables and analogies.

Benefit: I'll understand human motivation better, including, in particular, my own, which might help improve my ability to act consciously, but also that of others, which will improve my ability to cooperate with other people. Hopefully other people will tell me where I'm wrong and improve my understanding further. Maybe by reading the essays, other people will understand these issues better too.

AOWTBITF: 64 hours. **SNSTWBU**: translate the first draft of the first essay into English, revising it, and post it, 8 hours.

How to be right

Summary: an essay on techniques I have found useful in abandoning beliefs that are at odds with reality and adopting new ones that are more accurate, and explaining why I think this is a desirable thing to do; in short, a bite-sized introduction to philosophy.

Benefit: anyone will be able to point to this essay whenever someone accuses them of having a strong desire to be right, as if that were a bad thing, perhaps citing some one-liners from it. Maybe someone will point out that some of these techniques aren't as useful as I think they are, or that I've left out others, which could substantially improve my ability to be right in the future if I learn from them.

AOWTBITF: 16 hours. **SNSTWBU**: brief outline, 1 hour.

In favor of the ontological legitimacy of ghosts and moods

Summary: an essay arguing that, although the modern mindset scoffs at entities such as "ghosts", "demons", and "God", these concepts seem to be pragmatically at least as useful as metaphors for grappling with our incomprehensible universe as other concepts that the modern mindset accepts without question, and they ontologically seem to have the same kind of objective existence as such everyday entities such as "laws", "dollars", "theorems", "moods", "nations", "rights", "corporations", and "birthday parties".

Benefit: I don't know, probably people will think I'm nuts, but hopefully it will keep me from getting too attached to my own

conception of the universe. Maybe it'll change some other people's minds and keep them from being too sure of themselves, too.

AOWTBITF: 8 hours. **SNSTWBU**: brief outline, ½ hour.

States as a kind of corporation and corporations as a kind of state

Summary: an essay describing the parallels between states and other corporations, both historically and at present, and arguing that it doesn't make much sense pragmatically to relate to the two institutions on different terms; also, exploring the possible near-future evolution of these and related institutions. The concept is mentioned in passing in http://lists.canonical.org/pipermail/kragen-tol/2007-October/000870o2.html.

Benefit: maybe someone will point out important differences between the institutions that I've overlooked. Or, if I'm correct, maybe other people will sharpen their understanding of these institutions, which will benefit them and society.

AOWTBITF: 8 hours. **SNSTWBU**: brief outline, ½ hours.

FIR kernel factorization

Summary: find out if FIR filtering in the time domain can be done with less computation by factoring a FIR kernel, approximately or exactly, into a convolution of two or more sparser FIR kernels, or FIR kernels with more heavily quantized coefficients; then publish the results, a comparison with the efficiency of convolution in the frequency domain, and software for reproducing them.

Benefit: if the technique works more efficiently than known IIR and DFT-based techniques for a significant set of applications, which is unlikely, people will be able to do some kinds of linear filtering of signals with substantial improvements in efficiency, which will have applications in medicine, communications, remote sensing, music, and data compression, particularly in cases with very low hardware budgets or very high performance requirements.

AOWTBITF: 32 hours. **SNSTWBU**: implement some particularly easy filters in the time domain and compare the computational efficiency to frequency-domain convolution, 4 hours.

LZ77 modified with carefully chosen contexts

Summary: LZ77 wastes most of its sliding window on substrings that are unlikely to appear again. Tampering with the sliding-window contents in a deterministic fashion that the decoder can reproduce, which doesn't seem to have been tried before, could produce substantially better compression. Try this out and publish the results and resulting software.

Benefit: if it works, it could produce a novel variant of LZ77 with compression comparable to LZMA, but perhaps faster; this would improve the efficiency of everything that stores data on a disk or transmits it over a wire, if it's sufficiently adoptable that people adopt it. Unfortunately, for the same reason, it's pretty unlikely to work; there are a *lot* of smart people panning for gold in this river.

AOWTBITF: 32 hours. **SNSTWBU**: ask A. if someone's tried the idea already, 1 hour.

The magic kazoo

Summary: toy pianos are popular because they're easy to use and kids love making music, but they're still a little hard to use, and they're not very portable. An electronic synthesizer whose pitch and rhythm was instead controlled by the human voice would be much easier to use, and could be downloaded as an Android or iOS app or manufactured as a separate electronic device the size of a stick of gum.

Benefit: lots of new people could make music with synthesizers. It would be a hell of a lot of fun, and it would provide a much more comprehensible answer to "What have you been up to lately?" than, say, "exploring the ontological legitimacy of ghosts and moods".

AOWTBITF: 128 hours. **SNSTWBU**: write a software vocoder, 8 hours.

Mechanical computation with lookup tables

Summary: make a general-purpose mechanical computer using some version of the heightfield lookup table mechanism described in http://lists.canonical.org/pipermail/kragen-tol/2010-June/000919.html. Modern manufacturing techniques, while not necessary, should make this much easier than before.

Benefit: I would be the first person to construct a fully-programmable mechanical computer. Nobody has ever done it. Seven generations later, the dream of Babbage, patron saint of irascible eccentrics everywhere, would finally become reality. Zuse's Z1 and the Analytical Engine are the closest anyone has ever come, and the Z1 not only failed to work reliably, but it lacked control flow; while the Analytical Engine has not yet been built, because the cost of Babbage's inefficiently- designed mechanisms is astronomical. The dramatic reduction in parts count provided by heightfield LUT mechanism makes general-purpose mechanical computation feasible for the first time in history, if it works. It would change people's conception of the achievable and demonstrate conclusively that the missing factor that delayed automatic computation for over a century until the 1940s was not in manufacturing technology or in materials science, but merely in our motivation and our logical understanding of the nature of computation.

AOWTBITF: 1024 hours. **SNSTWBU**: construct a mechanical 4-bit multiplier, 64 hours.

Bicicleta

Summary: construct an interactive IDE for Bicicleta, my ς-calculus-based purely-applicative programming language, that other people can practically use.

Benefit: many of the benefits sought by projects like Bret Victor's "learnable programming" and Jonathan Edwards's Subtext are much more achievable in the ς-calculus than in languages based on the λ-calculus or ALGOL; the resulting programming environment will provide unprecedented power to expert programmers while also

being unprecedentedly accessible to novice programmers, replacing Excel for many purposes. Consequently, if the platform is developed to the point where people use it, there will be many more programmers, and they will program many more things; and platforms like Android that allow their users to program will gain an advantage over platforms like iOS that do not; additionally, people adopting Bicicleta instead of Excel will substantially weaken Microsoft's market power.

AOWTBITF: 512 hours. **SNSTWBU**: get a DHTML-based interpreter running, however slowly, with live display of results, 16 hours.

Telecommunication using clouds (of water vapor, in the sky)

Summary: reflect lasers off clouds in the sky for long-distance communication; probe the available bandwidth.

Benefits: This seems like the most practical way to establish long-distance high-speed data links without onerous licensing restrictions, extremely low bandwidth, or need for massive amounts of fixed capital that introduce single points of failure. It may be possible to reach ranges of up to 1000 km at megabits per second. If it works, it reduces the investment needed for intermittent high-speed round-the-world communication to some 20 ground relay stations.

AOWTBITF: 4096 hours. **SNSTWBU**: get laser communication working in my living room with laser pointers reflected off my living room wall, 16 hours. Maybe start by getting L's oscilloscope back from D.

Automatically-controlled low-temperature hot-water tanks

Summary: build a slightly more sophisticated microcontroller-based solar hot-water system using simple insulated-back plastic flat-plate solar collectors with two-sun or three-sun illumination from flat aluminum reflectors and multiple valve-controlled superinsulated hot-water tanks.

Benefits: dramatically cheaper and safer domestic hot water. Most of the expense of domestic hot-water systems in general, and solar hot-water systems in particular, is a result of the inefficiently high temperatures at which the water is maintained, the even higher temperatures reached by flames and electric heating elements, the high hydrostatic pressure within the tank, and the primitive control systems still in common use in hot-water heaters. A microcontroller-based system can maintain water temperatures in a safe range that can be contained with inexpensive bacteriostatic materials rather than expensive materials such as stainless steel. A transition to systems like the one described here would eliminate a significant percentage of world marketed energy consumption, while providing on-demand hot water --- one of the greatest luxuries I have ever experienced --- to a much greater fraction of the population. In http://lists.canonical.org/pipermail/kragen-tol/2007-December/000080875.html I talked about climate control a bit, but mostly in the

context of cooling things down.

AOWTBITF: 256 hours. **SNSTWBU**: get that solenoid-driven valve I salvaged from the discarded washing machine running off the relay I salvaged from the discarded microwave oven, 8 hours.

Ghettobotics

Summary: write a manual for bootstrapping a self-sustaining electronics lab from the municipal waste stream. **Benefits**: ending the perception that electronic gadgetry is something that only the rich and the Chinese can make. Improving my electronics skills to the point where I can solve problems of substantial commercial interest.

AOWTBITF: 2048 hours. **SNSTWBU**: write a working Tinkerer's Tricorder program for Arduino. No, wait, buy another Arduino: 4 hours.

Automatic dependency-driven recomputation

Summary: build a prototype of a rearchitecture of the personal computer platform around the caching of computational results, as described in http://lists.canonical.org/pipermail/kragen-tol/2012-July/000963.html. Related work includes Meteor and http://facebook.github.io/react/, with comments in https://news.ycombinator.com/item?id=5789055. **Benefits**: substantially simpler and more efficient personal computing, which means both that it can run longer on batteries and that it's more practical to experiment with alternative ways of doing things.

AOWTBITF: 16384 hours. **SNSTWBU**: build a chat app on Meteor, 8 hours.

Improvements on PWM

Summary: make improved approaches to PWM practical. PWM, or "pulse width modulation" is a popular method of providing varying output power from a circuit without increasing the circuit's power dissipation enormously; its use for controlling motors, LEDs, and incandescent lights is extremely widespread, and it can also be used to provide a "virtual analog output" from a digital output, most notoriously in Arduino. But it has serious drawbacks: heavy harmonic distortion in the output signal, plus time-domain artifacts that often have quite visible effects, can damage equipment and degrade quality of operation in other ways, such as undesired stroboscopic illumination. Four sometimes-better methods that often go unused because of a lack of good examples and libraries (aside from Don Lancaster's Magic Sinewaves) are dithered PWM, PDM (pulse density modulation), rational-approximation PWM, and PWM for less-significant bits combined with a different approach, such as an R-2R DAC, for more-significant bits. **Benefits**: nobody else will blow out tweeters like I did, and taillights and fading power LEDs will stop doing that annoying flickery thing.

AOWTBITF: 64 hours. **SNSTWBU**: try rational-approximation PWM for audio output on the Arduino and write up my results, 8 hours.

Free software is like owning your own home

Summary: essay advocating a new metaphor for advocating free software. Richard Stallman's standard similes liken using proprietary software is like being enslaved, collaborating with enemy occupiers, or breaking promises. These are not accurate reflections of the modern computing environment, where using proprietary software generally does not require agreeing to NDAs and is substantially less disheartening than living in captivity performing forced labor. Consequently, many people reject Stallman's ethical vision as out-of-touch, and unfortunately, the free-software movement as a whole. A better metaphor is that free software is a home you own yourself, or lease long-term rather than renting on an at-will basis from a landlord: it provides you with better security, greater privacy, and greater individual autonomy, at the cost of being responsible for the maintenance of the thing, whether DIY or outsourced. **Benefits**: a new and more comprehensive vision of the importance of freedom of software that, I hope, provides a more nuanced understanding of the serious issues at stack, and which will resonate better with the current public.

AOWTBITF: 16 hours. **SNSTWBU**: write an outline, 1 hour.

The cheap-junk laser display and camera

Summary: Draw pictures on the wall, in the dark at least, with a laser pointer and some speakers; and use the same low-cost apparatus, plus a photodiode to capture the time-domain reflectance signal, to capture reflectance-range images. Described in some detail, except for the camera part, in http://lists.canonical.org/pipermail/kragen-tol/2010-July/000922.html. **Benefit**: high-resolution big-screen displays for US$10 for everybody else. Awesome show-and-tell device for my living room and get-togethers.

AOWTBITF: 256 hours. **SNSTWBU**: hook up a spinning mirror to a motor, bounce a laser pointer off it, and modulate the laser to make a *one-dimensional* pattern and measure its response time, 32 hours.

The user interface as a real-time program

Summary: essay and proof-of-concept software that uses hard-real-time software techniques to ensure that a layer of the user interface remains *always* responsive, regardless of machine load. **Benefits**: you can immediately fix even badly overloaded servers, using personal computers becomes much more pleasant, and even machines with little RAM and CPU become highly usable, allowing much longer battery life, Kindle-style, for general-purpose applications.

AOWTBITF: 256 hours. **SNSTWBU**: some kind of real-time GUI for a Linux running under a real-time hypervisor (e.g. L4Linux, RTLinux), 64 hours.

A language for real-time programming

Summary: Develop a language that permits the verification and automatic satisfaction of maximum-time and maximum-space

properties for real-time embedded software. Some discussion of requirements at http://lists.canonical.org/pipermail/kragen-tol/2012-January/000943o o.html. **Benefits**: C is still the lingua franca for real-time and embedded programming, but it falls far short of what can be achieved, leaving a lot of work to the programmer that could be done by the computer. This language would do that work for you, allowing an improvement in the productivity of real-time programming comparable to the productivity improvement provided by very-high-level languages like Python or Matlab for software that is primarily computational rather than reactive in nature; this would dramatically extend what amateurs can do with systems like Arduino, where amateurs can easily do simple things but rapidly hit a glass ceiling when going further requires them to understand issues like stack-heap collisions, nondeterministic interrupt response times, shared-state concurrency, and scheduling.

AOWTBITF: 2048 hours. **SNSTWBU**: a minimal compiler that can provide time and space guarantees for a tiny concurrent Actors language, with compilation to Arduino, 32 hours.

Natural language is a digital phenomenon

Summary: an essay describing the difference between analog and digital representations of information (for computation and communication), and explaining the obvious (to me) and surprising (to many people) conclusion that natural language (what we use for verbal communication) is a digital representation of information, not an analog one; and explaining the importance of this fact in human history up to the 20th century.

As the Wikipedia entry for "Digital" says, "Although digital signals are generally associated with the binary electronic digital systems used in modern electronics and computing, digital systems are actually ancient, and need not be binary or electronic. [For example,] Written text in books (due to the limited character set and the use of discrete symbols - the alphabet in most cases)".

Benefits: hopefully people will finally understand this and stop pissing me off by talking about "analog books", as if there is such a thing. More seriously, hopefully people will understand the distinction between "digital" and "computerized", which will improve their ability to predict and deal with 21st-century technology.

AOWTBITF: 8 hours. **SNSTWBU**: an outline, ½ hour.

aaronsw (as Vincent)

Summary: write my long-overdue eulogy for Aaron Swartz, quoting Don McLean's song "Vincent", which is painfully apt. **Benefits**: I will pay some of my karmic debt to my strange friend and painfully missed mentor, and maybe I can stop crying about his suicide. I mean, shit. It's been almost five months and I can't write even this without tears in my eyes.

AOWTBITF: 4 hours. **SNSTWBU**: a first draft, 1 hour.

Phyle sousveillance

Summary: an essay exploring 21st-century approaches to personal

safety and crime, taking as given that nation-states are becoming less effective and more corrupt, and may hollow out dramatically (to inflict one of John Robb's neologisms on you), while the available alternative approaches are exploding. (The term "phyle" is from Stephenson's *The Diamond Age*, but while I think "phyle" is a useful concept, I don't share Stephenson's enthusiasm for violence. I think "sousveillance" is a neologism due to Steve Mann, but Howard Rheingold has also popularized it.)

Benefits: maybe some of the approaches I propose will be practical to implement, and discussion will show some of them to be socially beneficial, and maybe other people will point out that some of them are not workable. Then we can see about trying some of them out.

AOWTBITF: 8 hours. **SNSTWBU**: an outline, 1 hour.

Queer numbers

Summary: some years ago (XXX include link), I proposed a way to produce stable identifiers for individual paragraphs of a changing document, which I called "queer numbers". There is now plenty of data easily available to evaluate the effectiveness of my proposed algorithm. I should do the experiment and publish the results.

Benefits: if it doesn't work, it won't waste anybody's time any more. If it does work, future hypertext systems can incorporate queer numbers to enable robust fine-grained hyperlinks and transclusion.

AOWTBITF: 16 hours. **SNSTWBU**: politely crawl the history of a single Wikipedia article and try the algorithm out on it, 4 hours.

File similarity

Summary: some years ago, I proposed some general algorithms for efficiently finding files with textually similar contents. Current thoughts at http://lists.canonical.org/pipermail/kragen-tol/2010-December/000o0931.html. **Benefit**: substantial improvements in data compression, spam filtering, genomics, virus detection, intrusion detection, and queer numbers, if it works.

AOWTBITF: 64 hours. **SNSTWBU**: try the simplest possible implementation and see if I can get it to work, 4 to 16 hours.

Set-valued bloom filters

Summary: compare the generalization of bloom filters I developed in 2006 or 2007 (XXX include link) to signed-hash full-text indices (XXX is that the right term?), comparing their performance rigorously enough to publish the result as a peer-reviewed paper. **Benefit**: other people would be more likely to be able to find out if this data structure is useful for their purposes, and it might produce marginal improvements in the performance of full-text search engines. Also, I'd have another academic publication.

AOWTBITF: 128 hours. **SNSTWBU**: contact a researcher in the area to see if they'd be interested in helping to guide me through the publication process, 4 hours.

The post-HTTP web

Summary: in 2006, I wrote "What's Wrong With HTTP" (XXX include link) but I never published the promised follow-up essay

describing how to solve the problems. There are now lots of systems in the field demonstrating pieces of the solution. I should rewrite the essay and publish it at last.

AOWTBITF: 16 hours. **SNSTWBU**: find the draft I wrote in 2006, 2 hours.

The colectivos app

Summary: I want the Guia "T", the standard guide to Buenos Aires's bus system, in a free-software Android app. Except that it can be much, much better, because people can contribute. **Benefits**: I'll be able to travel around the Capital more easily. So will other people using free-software Android phones. There will be a wealth of free bus traffic data if the app becomes popular.

AOWTBITF: 128 hours. **SNSTWBU**: get an Android phone.

A free-software predictive input method for Android

Summary: I want something as good as SwiftKey, but free software. Initial thoughts at http://lists.canonical.org/pipermail/kragen-tol/2012-July/000961.html; more details at http://lists.canonical.org/pipermail/kragen-tol/2012-July/000965.html. **Benefits**: free-software Android on common (non-QWERTY) devices would become practical for writing. I'd have a really kick-ass program to show off for job interviews.

AOWTBITF: 256 hours. **SNSTWBU**: get an Android phone.

"Pick activism tactics as if they might work"

Summary: essay advocating care in the choice of activism tactics, in particular condemning the widespread current practice among Democrats in the US of calling for boycotts against people or groups for advocating unpopular political positions, but more broadly, discussing common unintended consequences of poorly-thought-out political advocacy. **Benefits**: my aunt Jessie has already blocked me on Facebook for advocating this position, and I can expect to offend many more people, but explaining the idea in a way that isn't personally directed at a particular other person should have a better persuasion-to-offending ratio. My earlier clumsy advocacy of this position on kragen-tol (XXX include link) provoked some thoughtful discussion. Perhaps someone will even persuade me I'm wrong.

AOWTBITF: 8 hours. **SNSTWBU**: outline, 1 hour.

Binate

Summary: implement Binate, the database query language based on binary relations. XXX include link. **Benefits**: Binate is designed to support live feedback on queries as you're constructing them, which will make fans of Bret Victor happy, and perhaps can woo away some users from Excel; it lets you write common queries in five or six words that would take five or ten lines of SQL; and it is dramatically better at abstraction than SQL is, so you can avoid

writing the same thing over and over again, the way you must in SQL.

AOWTBITF: 128 hours. **SNSTWBU**: a Binate interpreter that lets you interactively query MySQL databases from a browser with Comet, 16 hours.

Suffix-array construction

Summary: write a full-text search engine using one of the linear-time suffix-array construction algorithms discovered in the last decade. **Benefits**: practical full-text substring and regexp search on the desktop.

AOWTBITF: 64 hours. **SNSTWBU**: an in-memory implementation of one of them, 8 hours.

FeML

Summary: implement the FeML minimalist programming language (XXX include link). **Benefits**: the safety of ML, the flexibility of Python, the speed of C, if it works.

AOWTBITF: 256 hours. **SNSTWBU**: a FeML interpreter in OCaml, 16 hours.

Matchscheme

Summary: a Scheme that gets OO and conditionals from built-in pattern-matching, in email with Darius Bacon. **Benefit**: an interesting bottom layer for a language stack.

AOWTBITF: 32 hours. **SNSTWBU**: find the old email thread, 4 hours.

Constrained image approximation using automated image quality assessment and AI

Summary: use a model of the human visual system to guide general AI algorithms in constructing images. Initial thoughts at http://lists.canonical.org/pipermail/kragen-tol/2012-April/000949.html. **Benefit**: a huge range of visual-artistic possibilities (fake pencil portraits, ASCII art, mosaic designs, stencil designs, texture synthesis to match hand-drawn line art, shadow painting), and dramatically better image compression.

AOWTBITF: 1024 hours. **SNSTWBU**: read Taylor's thesis thoroughly, 32 hours.

Polar flutterwumpers

Summary: build a machine that moves physical objects to precise positions relative to each other using only circular motions, thus avoiding the need for precise slides, low-backlash gearboxes, lubrication, and other mechanical pitfalls of linear motion. Initial math at http://lists.canonical.org/pipermail/kragen-tol/2012-April/000956.html. **Benefit**: printers, including 3-D printers, with much simpler hardware, if it works.

AOWTBITF: 512 hours. **SNSTWBU**: a 3-D simulation in JS on a web page, 8 hours.

Backtracking HTML templating

Summary: a new way to write low-logic HTML templates that actually simplifies the task of HTML generation beyond what we had in 1994 with server-side includes. Description at http://lists.canonical.org/pipermail/kragen-tol/2012-April/000951.html. **Benefit**: slightly easier templating, especially of HTML, for extra-difficult cases. Something cool to talk about in job interviews.

AOWTBITF: 32 hours. **SNSTWBU**: a minimal, demoable implementation, 8 hours.

Parser generator with code reuse

Summary: a parser generator that comes with a large host-language-independent library of syntactic features that you can mix and match to describe the language you want to parse, which is impossible with commonly-used parsing algorithms like LR and LL. Some notes at http://lists.canonical.org/pipermail/kragen-tol/2012-April/000953.html. **Benefit**: developing new language syntaxes and parsers would be really easy, due to the parser generator already having most of them in its library, as would developing new interpreters and compilers (in new languages) for existing languages that have existing parsers using this system. World fame. Unless nobody uses it.

AOWTBITF: 4096 hours. **SNSTWBU**: extend peg-bootstrap or one of Darius's libraries to produce reasonably efficient parsers, and abstract out the semantic actions, 32 hours.

Radix-sorting rational numbers

Summary: write up my algorithm for representing rational numbers so they can be radix-sorted, described at http://lists.canonical.org/pipermail/kragen-tol/2011-October/000942.html, such that it could be published in a peer-reviewed venue. **Benefit**: a potential academic publication of little importance.

AOWTBITF: 64 hours. **SNSTWBU**: write an implementation and characterize its behavior, 8 hours.

Very-low-bandwidth speech-formant codec

Summary: encode sampled speech in real time by estimating formant center frequencies and widths and transmitting those, entropy-coded to reduce bandwidth below 1kbps, perhaps as low as 500bps. Speculated on in http://lists.canonical.org/pipermail/kragen-tol/2010-March/000911.html. **Benefit**: if it works, which is unlikely, I could push real-time speech transmission into 500-bit-per-second channels, an unprecedented feat. However, this is basically only useful if you have a low-latency communications channel between 500 and 1000 bits per second; there are already codecs that work at 1000 bits per second. It would be pretty awesome to be able to say I was the guy that achieved this.

AOWTBITF: 1024 hours. **SNSTWBU**: learn enough about DSP to write working code to find the centers of formants (and plot and play them), 32 hours.

Fix one of the JS Markdown libraries

Summary: there are two widely-used libraries in JS for rendering Markdown to HTML. Both are buggy, and neither of them supports inline HTML. Fixing one of them to handle safe HTML tags is a must. **Benefit**: every Markdown-using JS site in the world would be able to handle safe HTML tags. I'd become famous, and in any future job interview, I have a good chance of telling them their site is already running code I wrote.

AOWTBITF: 32 hours. **SNSTWBU**: write a simple test case and make it fail, 2 hours.

Update yamemex

It needs to be fixed to work with current versions of its dependencies, it needs to publish and sync, and it needs a Firefox version. **Benefit**: my bookmarks from the last several years will be shared, people will be able to see what I'm doing, and I'll have all the bookmarks; and maybe other people will start using it too.

AOWTBITF: 32 hours. **SNSTWBU**: update dependencies, 8 hours.

Topics

Query evaluation with interval-annotated trees over sequences

Kragen Javier Sitaker, 2019-08-30 (updated 2019-09-03)
(30 minutes)

Consider queries of the following forms:

```
select * from foo where bar between 80 and 101;
select * from foo order by bar limit 10;
select * from foo order by abs(bar - 13) desc limit 10;
select * from foo where bar between 80 and 101 and baz between 2 and 3;
select * from foo order by (bar-10)*(bar-10) + (baz-2)*(baz-2) desc limit 6;
```

Conventional SQL indices permit answering the first three of these with good efficiency, but not the others; conventional SQL query optimizers do not produce a reasonable query plan for the third given an index on foo.bar, although it is in theory feasible. Usually queries like these are answered with K-d trees or, in the last case in case of high dimensionality, ball trees, but these structures occupy significant space, and constructing and updating them is time-consuming.

Such queries are unfortunately common in applications like geographical maps, as described for example in Fast geographical maps on Android (p. 455).

An alternative that is somewhat more flexible is to construct a tree of substrings over an existing file of records, annotated with intervals describing the data in each substring.

The interval-annotated-tree data structure

(There is a standard data structure called an "interval tree" which is not the same thing, thus the awkward name.)

The underlying data to be queried is a sequence or "file" of records, which have some attributes. The tree is a sort of index for some of these attributes; each node of the tree pertains to some contiguous substring of the overall record sequence, and is annotated with the minimum and maximum value for each indexed attribute that occurs within the subsequence. The substrings all begin and end on record boundaries. Leaf nodes contain pointers into the sequence of records, indicating the start and end of the substring to which they pertain; internal nodes, instead, pertain to the union of their child nodes, which are disjoint and consecutive. The root node of the tree pertains to the entire sequence.

Different branching factors may be appropriate in different situations; if memory is random access, the structure is in theory fastest with a branching factor of 2, but with a memory hierarchy, a larger branching factor is probably better.

If there is some kind of reasonable locality within the existing sequence, this structure can perform as well as a K-d tree, at a much

lower space cost (since its leaves contain merely pointers into the sequence of records). If there is not, it should perform about as well as brute force.

Interval query

To find all the records within a given multidimensional interval — a criterion of the form attr0 between min0 and max0 and attr1 between min1 and max1 and attr2 between min2 and max2... — we do a tree search from the root, pruning a node from the search when the interval annotation on that node can show that none of the records in its substring of the sequence can match the query. In the case where the query is on a single attribute and the records are sorted by that attribute, this will take O(lg N) time. So, too, if the records are sorted in the order of a traversal of a K-d tree, and the query is on a subset of the attributes indexed by that K-d tree, even if the branching factor is not the same.

In some cases it may make sense to also halt the traversal when it can be determined that *all* the records within a substring match the query interval, for example if only a count of the matching records is required.

Altering a record in the sequence requires updating as many as all of its ancestor nodes. Appending a record to the end requires creating or updating as many as all of its ancestor nodes, and, as with a B-tree, potentially deepening the tree and adding a new ancestor node when the root node overflows.

This generalizes, of course, to the case where leaf nodes contain intervals rather than point-values of attributes, but I think a standard interval tree (with its sorted lists of intervals crossing each node's partition) will perform better in that case, perhaps much better.

A simple example

Suppose we have a branching factor of 8, a leaf size of 32 records, a total of 16,777,216 records of 64 bytes each, two perfectly-uniformly-distributed 32-bit attributes indexed, and the data arranged according to the traversal of a 2-D K-d tree on those two attributes. The data amounts to one gibibyte. There are 524,288 leaf nodes and 599,187 tree nodes in total distributed across 8 tree levels, including a root node with only two children. The pointers in the tree nodes can be all entirely implicit as long as we don't have to insert and delete in the middle of the sequence, even if we mutate or append records to the end of the sequence, so each tree node can be stored in 16 bytes (4 bytes for the minimum X, 4 bytes for the minimum Y, etc.)

So the tree occupies only 9,586,992 bytes, under 0.9% of the data size. It can be built in time linear in the data size — in a single sequential input pass outputting tree nodes to 8 sequential buffers, or in 8 sequential passes reading from a single sequential input stream and writing to a single sequential output stream.

A tree traversal for a two-dimensional interval that includes only a single record will prune all nodes but one at each recursion level, so it will visit the root node, its two children, and 8 nodes at each of the other six levels, for a total of 51 tree nodes, then the 32 records belonging to the leaf. If we consider 4096-byte memory pages, the top four levels can be in a single memory page, and then each of the

other four tree levels will require reading a single page; the 32 records of the leaf node will also be in a single page. This puts the total read cost of the query at six pages.

Suppose the query is instead for an interval similarly tightly bounded in one attribute but open in the other. This interval will only prune 6 of the 8 children of any given internal node, so it will visit, say, the root node, its two children, and then at the other six levels, 4, 8, 16, 32, 64, and 128 nodes, respectively, and then 256 leafnodes, which will be in 256 separate pages. The top four levels are again in a single page, while we can suppose that all the other nodes are in different pages, so we have 1 + 16 + 32 + 64 + 128 + 256 pages: 497 in total, a total of just over 2 megabytes out of the 1.075 gigabytes of data. Still, to answer this query from 8-ms spinning rust, you would need almost four seconds.

Actually, though, that's overly pessimistic: the groups of 8 nodes we are examining at each level are siblings, and so they are presumably contiguous. So in fact it's 1 + 2 + 4 + 8 + 16 + 256 pages. Adding another level that includes the actual values of the attributes for the records would cut that final 256, and thus the query time by a factor of 8, but bloat the index from 0.9% to 25% of the size of the original data.

At the other extreme, suppose we do the traversal with an interval that includes all the nodes. This is simply a tree traversal that never prunes, so it just has to traverse an extra 0.9% amount of index data as it sequentially examines the gigabyte of records.

As explained above, updating or appending a record just involves updating or creating up to its 8 ancestor nodes; however, if the update results in the record being out of order, it may degrade the index's query performance thereafter. 8 levels of tree is sufficient up to four gigabytes, at which point the tree deepens and it becomes 9.

A tiny sketch of building such an index with numpy

I hacked this out quickly just in order to get some kind of performance measurement; it could obviously be cleaned up. I kept the data size super small because I was plotting things and, although numpy can deal with tens of millions of items with no problem, matplotlib falls over. Obviously in real life you would need some provision for non-power-of-two sizes, and probably appending records as well, and you wouldn't want a special-case array for the leafnode annotations.

```
x = rand(2**17)
x.sort()

leafnodes = x.reshape((len(x)//32, 32))
lmin = leafnodes.min(axis=1)                    # leafnode min/max
lmax = leafnodes.max(axis=1)

imin, imax = zeros(lmin.shape), zeros(lmax.shape)
size = len(lmin) // 2

imin[:size] = lmin.reshape((size, 2)).min(axis=1)
imax[:size] = lmax.reshape((size, 2)).max(axis=1)
```

```
pos = size

while size > 1:
    size //= 2
    imin[pos:pos+size] = imin[pos-2*size:pos].reshape(size, 2).min(axis=1)
    imax[pos:pos+size] = imax[pos-2*size:pos].reshape(size, 2).max(axis=1)
    pos += size
```

Building the index this way on my laptop takes about 3–5 milliseconds. Taking precautions to limit the load on matplotlib, increasing `x` to 2^{24} items (128 mebibytes) slows it to 227 ms one time, 194 ms another time, 182 ms a third time. Increasing it to 2^{26} items, I accidentally crashed my laptop trying to re-evaluate the IPython cell (thus resulting in two half-gibibyte arrays in memory at once); sorting it took 10.8 seconds; but building the index tree only took 892 ms.

Ordering and reindexing flexibility

The interesting thing here is how the indexing data structure is valid entirely independent of the record ordering. For some record orderings, it reduces to brute force, but it doesn't give incorrect results, and the extra cost is mild.

The above case is precisely equivalent to the K-d tree whose traversal order we suppose the records are encountered in, with some of its internal nodes purely implicit. But with some mild degradation, amounting I think to a small constant factor, the same index data structure would accelerate such queries on data that is ordered according to a K-d tree whose node boundaries were not perfectly aligned with the node boundaries of the index tree.

If the tree traversal is done in a Hilbert-curve order, so that adjacent nodes in the serialization are also adjacent in the K-d space, you gain about a factor of 2 in the case of such misalignments. I'm not sure if this is at every tree level or as a constant factor of about 2 overall.

Other traversal orders may provide better performance for some data distributions; for example, an approximate TSP solution might be better at keeping the intervals smaller, and thus permit better pruning. Some applications might even be able to get away with doing the simplest thing — leaving the records purely in insertion order --- because the insertion order already had enough locality in the relevant attributes to make queries adequately efficient. For example, in a zooming user interface, most queries for drawable objects are restricted to a particular (x, y, size) interval, and generally when you create new objects, you create them in a small area in a small range of sizes.

If the records are instead sorted in a lexicographic order by some sequence of attributes, such as (x, y), then the performance characteristics are equivalent to a normal sorted SQL index: criteria `x=x0` or `X=x0 and Y=y0` are evaluated in logarithmic time, while a bare criterion `Y=y0` is nearly as slow as sequential search. Again, this happens without changing the definition of the index tree, just rebuilding it for the new sort order.

Suppose you instead append some new random records to the end of the record sequence. As discussed above, this means that most queries will have to traverse not only their normal path but also much of the path down to these new update records, in case one of them contains a relevant record; the standard index update takes care of this automatically. But until you have a whole leafnode full of extra records, the number of extra nodes each query needs to visit is just a single linear path — 8 nodes in the above example. Each additional leafnode normally adds just a single additional node, for a total of 9 nodes in the above example, or occasionally 10 or even more rarely 11.

This is recognizable as the standard database approach of having an "update file" that every query must examine sequentially in addition to its usual index traversal, but it is in some sense simpler — the index structure handles it automatically. In a sense this is just an extension of the earlier-described property, that the same index structure is valid for different sorting orders — in this case, we have different sorting orders within the same file, one part of the file sorted in a useful way, while another part is unsorted and requires a sequential search.

We can extend this to a whole "LSM-tree" or "log-structured merge tree" approach like the one used by LevelDB or Lucene: if you have 8,388,608 sorted records, followed by 4,194,304 separately sorted records, followed by 2,097,152 sorted records, then most queries will do no pruning in the first few levels of the tree search, then doing a search within each segment in the usual efficient fashion. At any time if we we atomically replace any substring of the file with a reordered version of itself, as well as the relevant index nodes, the system remains valid, but potentially handles queries more efficiently.

It's often advantageous to handle record updates as well as insertions through such an update file, because it avoids spreading the updates all over the file and frustrating early pruning during query evaluation. To strictly maintain the validity of the index in such a case, you need to somehow null out the outdated versions of the records, replacing them with some kind of N/A or NaN or broken-heart value, one which participates in the min and max computations by just being left out. This might require also maintaining explicit rather than implicit record counts in tree nodes. Upon nulling out a record in this way, you can either update its ancestor nodes in the index — preserving the index's precise nature — or you can leave the index untouched, so that the index is only a conservative approximation of the actual data.

The flip side of this ordering-indexing orthogonality is that you can rebuild the index with different parameters — a different leaf-node size, branching factor, or indexed set of attributes, for example — without sorting the records again.

Conservative approximation of queries

To answer a query such as

```
select * from foo where (x-10)*(x-10) + (y-2)*(y-2) < 100;
```

we begin by constructing a conservative approximation

```
where x between 0 and 20 and y between -8 and 12;
```

which can potentially be answered efficiently by this index structure. An alternative conservative approximation with better precision would be

```
where x between 0 and 20 and y between -6 and 10
or x between 2 and 18 and y between -8 and 12;
```

or

```
where x between 0 and 2 and y between -6 and 10
or x between 2 and 18 and y between -8 and 12
or x between 18 and 20 and y between -6 and 10;
```

Records returned by the conservative approximation must then be tested against the precise criterion.

Alternatively, instead of testing the multidimensional interval covered by each index node against such a multidimensional interval, you might be able to do better by testing it against the original precise criterion, using interval or affine arithmetic.

Evaluating nearest-K queries

Consider again my introductory example

```
select * from foo order by abs(bar - 13) desc limit 10;
```

The standard way of evaluating such a query, lacking a functional index on abs(bar - 13) — which won't work for abs(bar - 2), for example — is to compute a sort or partial sort over all the records, which involves examining all the records' bar attribute at least once.

You could imagine doing this query with a series of queries like the following:

```
select abs(bar - 13) as k, * from foo where k < 1 order by k desc limit 10;
select abs(bar - 13) as k, * from foo where k < 2 order by k desc limit 10;
select abs(bar - 13) as k, * from foo where k < 4 order by k desc limit 10;
select abs(bar - 13) as k, * from foo where k < 8 order by k desc limit 10;
```

and stop once you got enough records from one of the queries. Each of these queries can be efficiently evaluated by the index structure described above, repeating the same tree traversal as the previous query, but pruning perhaps fewer nodes.

A more efficient approach is to do the traversal once, storing all the pruned nodes in a priority queue according to *by how much* they were excluded. This allows you to revisit enough of them to ensure that you have found all the points within the radius at which you found the Nth-best point you've found so far (N=10 above). That point

won't necessarily be in one of the nodes whose intervals are nearest to the query point, either in upper bound or lower bound.

Evaluating minimum, maximum, and top-N queries

Consider these queries:

```
select min(x) from foo;
select min(x) from foo where y = 41;
select min(x) from foo where y between 38 and 42;
select * from foo where y between 38 and 42 order by x desc limit 5;
```

If you have an interval-annotated tree built for attribute `x`, and you're updating it precisely rather than conservatively, the first query can be answered instantly — it's stored in the root node of the tree. The second and third queries are not instant, but if there are contiguous ranges of records all matching the selection criterion, it is unnecessary to examine each record individually; you can use the min(x) annotation from their tree nodes instead.

The fourth query is somewhat more interesting, because once we have done enough traversal to define the set of records matching the selection criterion (as a smaller set of tree nodes covering disjoint parts of the file), we would like to return them starting from the largest *x*. Well, we can look at the max(x) annotations to figure out beneath which node in the set the largest x (say 112) is to be found, then recursively trace down through the tree from that node to find some record with x = 112. *Then we remove it from the set*, by removing the tree node we had found it from, adding that node's children, if any, and then recursively repeating that process for the child node by which we found the record; this leaves us in a position to repeat the process four more times. By maintaining the nodes in a priority queue ordered by max(x), we can do this update quite efficiently.

Column-oriented index storage

Above I said that for an index covering two 32-bit attributes, each node will occupy 16 bytes, and in my analyses of locality I assumed they were contiguous in memory. But in the case where a query only needs to examine one of the attributes, it would be better to store the trees for the two attributes separately — the query will need to transfer half as many cache lines from RAM, and perhaps an extra level near the root of the tree will fit into the first page.

Pointer files

In cases where the records are sorted in an inconvenient order, you can do the usual database-index thing of making a sorted file of pointers to the records, perhaps augmented with the sort keys, and build the index tree on that. In the case where you use a simple lexicographical sort, this is just a normal database index, but you also have the possibility of using a different order.

Some explorations of a generalization of

the index structure, and a surprising connection with mathematical morphology

The tree search pruning merely depends on being able to efficiently compute the bounds of the search key in certain substrings of the file; you could imagine using some other structure to accelerate that computation, rather than just a tree for a given set of substrings.

An alternative structure is the preprocessing for the Urbach-Wilkinson erosion algorithm described in Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm (p. 216): given some string of pixels, you can compute summary strings of maxima of all substrings of 2, 4, 8, 16, 32, etc., pixels, starting at all the possible offsets. Then the maximum of an arbitrary-length substring can be computed in constant time by finding two potentially-overlapping substrings, typically within the same level of summary, whose union is the you want to find the maximum of.

More briefly, say $S_{0,j}$ is pixel j of the string of pixels, and define

$$S_{i,j} = S_{i-1,\,j} \vee S_{i-1,\,j+2^{i-1}}$$

whenever all of the subscripts are within bounds, and $x \vee y$ gives the maximum of x and y. This gives us the N-ary maxima $\vee_j$ of all the size-2^i substrings

$$\vee_{j \in [m,\, m+2^i)} S_{0,\,j} = S_{i,\,m}$$

and from that we can compute the maximum of an arbitrary range of pixels as

$$\vee_{j \in [m,\, n]} S_{0,\,j} = S_{a,\,j} \vee S_{a,\,j+n-m-2^a}$$

where a is chosen such that $n - m + 1 \in [2^a, 2^{a+1})$ to prevent a gap from occurring between the two size-2^a substrings.

If we precompute all the S_i, of which there are a logarithmic number, we can do this in constant time.

Of course all of the above goes *mutatis mutandis* for minima rather than maxima.

An interesting property of this structure is that, without any further metadata, we need only logarithmic time to trace any range maximum thus computed back to one of the pixels where it originated; for example, $S_{4,\,3}$ is either equal to $S_{3,\,3}$ or it's equal to $S_{3,\,11}$, and $S_{3,\,11}$ is either equal to $S_{2,\,11}$ or to $S_{2,\,15}$. By following the trail this way, we can figure out where in the range to find the maximum pixel value. In particular, this allows us to find the runner-up value in logarithmic time: if it turns out that the maximum value came from pixel 12, we can split the range into two halves that exclude pixel 12 and calculate their maxima, one of which is the runner-up.

This is suggestively similar to the query algorithms described above, and as it turns out, we can view the interval-annotated-tree structure we started with as a sort of decimated version of this layer-cake structure, where we only keep $S_{i,\,j}$ if j is divisible by 2^{i+k}, where 2^k gives the number of records in a leaf node, and perhaps if i is divisible by some number — above I used 3. This makes for a much smaller index, but it also makes even the simplest queries take logarithmic time rather than constant time, and it adds a constant factor to logarithmic-time queries. Intermediate points on this time-space tradeoff spectrum may be worth considering. For

example, you could have nodes further up the tree overlap somewhat, without storing every possible offset.

Annotations using lattices and semilattices other than total orderings

The above data structures generalize to general lattices and semilattices. As an example closer to normal databases, you could consider indexing some attribute with small Bloom filters, using bitwise OR between the Bloom filters rather than min or max. Suppose you use 256 bits (16 bytes) and a single hash function:

Records indexed	Expected fullness	False positive probability
1	0.4%	0.4%
32	12%	12%
128	39%	39%
256	63%	63%

So you could skip over about a third of your 256-record chunks after just checking a bit in their Bloom filters, and almost 90% of your 32-record chunks (although there's a conditional probability there that I'm not calculating — if you're looking at a 32-record leafnode at all, it might be because it's, say, one of eight children of a 256-record that had the right bit set, and at least one of those eight children needs to have that bit, and so on average almost two of them will.)

This suggests that aggregating Bloom filters in this way is only useful over a couple of orders of magnitude, and also that you should use a low branching factor like 2 in this case.

I think this gets worse rather than better with more hash functions: false positive probability goes down for single records and small groups, and up for large groups. Consider the case with three hash functions:

Records indexed	Expected fullness	False positive probability
1	1.2%	0.0002%
32	31%	3.1%
128	78%	47%
256	95%	86%

The problem is that Bloom filters are most efficient when they're about half full, but trying to calculate the parent bitvector from the child bitvectors means that they have to be the same size. You could consider giving that up — maybe you use three hash functions, and for 16-record leafnodes, you use 64-bit (8-byte) bitvectors, giving you a 14.9% false-positive probability; while for their 32-record parents, you use 128-bit (16-byte) bitvectors with 14.8% false positives; and for their 64-record parents, 256 bits (32 bytes) and 14.7%; and their 128-record parents, 512 bits and 14.7%; and so on. But then if you delete a record or update it in place, you either have to let the Bloom filters decay a bit, or you have to rehash all 128 of them. At some point you have to stop expanding the filters or deleting a single key ultimately requires rehashing the whole file.

Bloom filters can do some operations that go beyond simple membership testing. For example, if two Bloom filters are built compatibly, you can efficiently compute not only their union (as above) but also the Bloom filter of their intersection. This is potentially useful for joins somehow.

There are also cases where you have honest-to-goodness bitvectors

stored in a database, perhaps in a SAT solver or a database of combinational-logic circuits, and it might be useful to query not only for a particular bit pattern but for things that have supersets or subsets of it set.

Affine-arithmetic nodes

Suppose that instead of annotating each node with just the (min, max) values of each indexed attribute, you annotate it with a coefficient which gives a *predicted* attribute value when multiplied by its offset within that node, and a (min, max) value pair for the *difference* between the predicted value and the real value. If the coefficient is 0, then the (min, max) values are the same as before, but if there's some correlation between the attribute value and the record position (at least locally), this may allow much tighter bounds, and in particular much faster range narrowing — interpolation search on steroids.

(You might want some kind of extended-precision data type to handle the necessary arithmetic on string keys.)

This is quite close to a totally trippy paper from Google Research on training neural nets as database index nodes, whose authors and title I forget.

Phase change unplugged oven

Kragen Javier Sitaker, 2019-12-15 (0 minutes)

If you want a solar oven, or an electric oven powered by photovoltaic panels, to work at night, you need an energy store. The best approach is probably a phase-change heat reservoir, perhaps with a phase-change temperature somewhere around 200° or 250°. Heat can be moved in and out of the heat reservoir with fan-forced convection.

Index set inference or domain inference for programming with indexed families

Kragen Javier Sitaker, 2007 to 2009 (updated 2019-05-05)
(27 minutes)

If you infer parametric types for variables used to index arrays (and then for functions that have them as arguments, and functions that call them, and so on), I think you can substantially simplify code that deals with arrays by defining new arrays in terms of pointwise transforms of old ones, and additionally reduce the distinction between functions and arrays. If this information is available reflectively at run-time, you can get some additional power.

Although the idea looks like it might be a bit clumsier than I was thinking at first, I still think it may have some merit.

(Further development of the idea is in A principled rethinking of array languages like APL (p. 1995), from 2015 to 2018.)

Major Problems

I think this needs static domain (i.e. dependent type) inference to work at all (see in the "Efficiency" section) but maybe it's an interesting idea anyway.

I sort of took for granted that you would want C-style curried arrays, where if you have a two-dimensional array a[i][j] you can meaningfully say a[i] and get an array b[j]. But this seems to have led to some extra complexity in the definition of asymmetric-union, in the kinds of domain inference that can plausibly be done in different situations, and even in the notation to define a two-dimensional matrix "narrowed" from some underlying function.

Backus's Matrix Multiply Program

So I've been reading John Backus's 1977 Turing Award lecture paper. (See Why John Backus Was on the Wrong Track (p. 2722) for more commentary.) In it, among other things, he gives this definition in his FP language for matrix multiplication:

```
Def MM = (alpha alpha IP) o (alpha distl) o distr o [1, trans o 2]
```

where (less rigorously than in the paper)

```
: represents function application
< > enclose data vectors
(alpha fn):<z[1], z[2], ...z[n]> = <fn:z[1], fn:z[2], ...z[n]>
(f1 o f2):z = f1:(f2:z)
1:<z[1], z[2], ...z[n]> = z[1]
2:<z[1], z[2], ...z[n]> = z[2]
distr:<<z[1], z[2], ...z[n]>, y> = <<z[1], y>, <z[2], y>, ...<z[n], y>>
distl:<y, <z[1], z[2], ...z[n]>> = <<y, z[1]>, <y, z[2]>, ...<y, z[n]>>
trans:<<z[1][1], z[1][2], ...z[1][n]>,
       <z[2][1], z[2][2], ...z[2][n]>, ...
```

```
      <z[m][1], z[m][2], ...z[m][n]>> =
                                  <<z[1][1], z[2][1], ... z[m][1]>,
                                   <z[1][2], z[2][2], ... z[m][2]>, ...
                                   <z[1][n], z[2][n], ... z[m][n]>>
x is multiplication
[fn1, fn2, ...fnx]:z = <fn1:z, fn2:z, ... fnx:z>
```

IP is his previously given program for the dot product of two vectors (contained in a vector of two items), which reads as follows:

```
Def IP = (/+) o (alpha x) o trans
```

where /fn: = fn:...>>

If you put it all together and squeeze, you get

```
Def MM = (a a((/+)o(a x)otrans))o(a distl)o distr o[1,trans o 2]
```

A Simpler Matrix Multiply Program

So I couldn't help but think, leaving aside all Backus's points about algebraic manipulations of programs and how his unreadable point-free style is so cool — let's go to the other extreme! Wouldn't it be easier if you could instead write this?

```
MM[m][n][i][j] = sum(k) { m[k][j] * n[i][k] }
```

Or, if you use space for procedure application, and curry in the usual Haskell/OCaml way:

```
MM m n i j = sum(k) { m k j * n i k }
```

Or in a Lispy syntax, but still assuming that same kind of currying, so that ((((MM m) n) i) j) is the same as (MM m n i j):

```
(define (MM m n i j) (sum k (* (m k j) (n i k))))
```

Unifying Arrays With Functions

I've thought for some time that it would be interesting to have a programming language where arrays and dictionaries are treated as kinds of functions — they have the distinction that their domains are finite, but that is the case for many functions.

"sum" in the program above is intended to range its dummy variable across all possible valid indices. Evaluating it for some particular i, j pair requires it to interrogate m for its domain — and, more interestingly, (n i) for that i. (What it should do in the case where the two domains are different, I'm not sure; probably it should signal an error by default.)

Given that n has some associated thunk that yields its domain for

such purposes, it's clear to see that the compiler could construct a similar domain thunk for the result of (MM m n), which would merely call n's domain thunk; and for, say, (MM m n 2), given that this reduces to (lambda (j) (sum k (* m k j) (n 2 k))), it can infer that j can range over the domain of (m k j) for some k. (Again, it's not clear what to do in the case that the domains are different for different values of k; if the domain of (MM m n 2) is never requested, the issue doesn't arise, but if it is, it might be a good idea to signal an error by default rather than taking their intersection.)

Domain Inference as Type Inference

This "domain inference" is really just a kind of type inference, so it ought to be possible to do it at compile time. Maybe we could statically infer that MM has a type something like

```
('a:'b -> 'c:'d -> 't) -> ('e:'f -> 'a:'b -> 't)
    -> 'e:'f -> 'c:'d -> 't
```

(I'm assuming here that multiplication has the type 't -> 't -> 't, i.e. it can only multiply two things of the same type. There are other alternatives, but I think that for static inference to work, the compiler at least has to know whether or not multiplication is going to yield something a function that has a domain of its own, and if so, what that range is going to be.)

Doing it statically is a little more trouble than doing it dynamically because you end up with complicated relationships between implicitly-universally-quantified variables, like the above, instead of just some numbers.

Some kinds of control constructs can allow this domain inference to flow through them as well:

```
(define (zeroextend vec zero i)
  (cond ((= i (- (domainbegin vec) 1)) zero)
        ((= i (domainend vec)) zero)
        (t (vec i))))
```

This is a function which, given a function such as a one-dimensional vector, and a zero value to extend it with, makes it into a one-dimensional vector with a domain of indices greater by 1 in each direction. I'm using made-up functions "domainbegin" and "domainend" to return the minimum and maximum+1 values of the domain, which presumably therefore must consist of a single contiguous sequence of integers. This is a useful abstraction to have when, say, implementing numerical simulations with fixed border conditions.

It seems like making the above conditional transparent to domain inference would be pretty hard; you could do partial evaluation and get, say:

```
(lambda (zero i)
  (cond ((= i -1) zero)
        ((= i 4) zero)
```

```
      (t (vec i))))
```

at which point you could deduce that the domain of i was the union of -1:0 (i.e. {-1}), 4:5 ({4}), and 0:4 (the domain of vec), which union comes out to -1:5. Is there an easier way, say, one that could be done at compile time? Even one that required restructuring "zeroextend"? I don't think macros per se particularly help here. Maybe you could say:

```
(define (zeroextend vec zero i)
  (cond ((valid? (vec i)) (vec i))
        ((valid? (vec (+ i 1))) zero)
        ((valid? (vec (- i 1))) zero)
        ; otherwise error:
        (t (vec i))))
```

Termination

I'm not claiming that you can infer which inputs will lead to an infinite loop. That "Total Functional Programming" approach is not something I'm considering here, although it does kind of look interesting.

Narrowing

To make such a system useful, the programmer needs to be able to artificially impose boundaries on functions with much larger underlying domains. For example, you could define the identity matrix in the abstract as follows:

```
(define (identity i j) (if (= i j) 1 0))
```

But, if the matrix multiply routine from earlier is going to insist that its arguments be conformable, you need to be able to wrap it in something to restrict its domain, like this:

```
(narrow (domainbegin m) (domainend m) identity)
```

or even

```
(narrow (domainbegin m) (domainend m)
        (lambda (i) (narrow (domainbegin (m i)) (domainend (m i))
                            (identity i))))
```

or even (in cases where you already have a function handy with the desired range)

```
(narrow m (lambda i (narrow (m i) (identity i))))
```

Inference Rules for Primitives

So if we want to infer the domain for some parameter, and it's being used somewhere deep inside of a context that has some known domain, we can often solve it. Here is a non-exhaustive list for cases of contiguous integer ranges; p is the parameter whose domain we want to infer, and k is a constant.

```
(+ p k) as n:m => p as n-k:m-k
(+ k p) as n:m => p as n-k:m-k
(- p k) as n:m => p as n+k:m+k
(- k p) as n:m => p as k-m+1:k-n+1

(* p k) as n:m => p as n/k:m/k      for k positive  (how do we adjust this when k
o/n is noninteger?)
(* p k) as n:m => p as m/k+1:n/k+1  for k negative  (who cares about the 0 case?)
/, >>, << can be treated as cases of *, I think, although / raises
funny issues about approximate results (which way are they
rounded?)
(& p bitmask) as n:m => p can be any int if the bitmask ensures that
                        the result is in n:m; complicated otherwise
(& bitmask p) likewise
(remainder p k) likewise
(min p k) as n:m => p as n:inf if k < m; complicated otherwise
(max p k) as n:m => p as -inf:m if k >= n; complicated otherwise
(abs p) as n:m => p as -m+1:m if n <= 0 and m > 0; complicated otherwise
```

My hypothesis here is that these rules don't have to successfully analyze every possible program; it just has to be possible to write programs that they can analyze that do what you want, at least most of the time.

Difficulties in Domain Inference

A parameter that is used exactly once in one of the following ways poses no difficulties for domain inference:

- to index a concrete array
- to pass to a primitive function with a fixed domain
- to pass to some other user-defined function as a parameter with a known domain

Parameters that are passed to certain primitive functions may have more restricted domains inferred for them; for example, the domain of (lambda (i) (m (+ i 1)) is the same size as the domain of m, but offset by 1; and (lambda (i) (m (/ i 2))) is twice the size of the domain of m. (And depending on what kind of division that is and whether m's range consists only of integers, it might have twice as many elements.)

Parameters that are not used at all therefore could have any value, which is a problem, in a way. Parameters that are used more than once require deciding what to do in the case of overlapping, but not equal, domains. (Maybe there should be a default, and maybe the default should be to intersect the domains rather than to raise an error.)

This is reminiscent of the restrictions placed by Girard's "linear

logic" and Henry Baker's "Linear Lisp", in which each variable must be used exactly once in a particular path of execution. In this case, some paths of execution (those that depend on the value of the variable itself) may not count, but that's perhaps a detail.

Perhaps the solution, then, is to require or allow explicit duplication of parameters that are used for things with more than one domain, specifying how to resolve differences between the two. For example, you could define a "deltas" function as follows:

```
(define (deltas vec i)
  (- (vec (+ i 1)) (vec (intersecting i))))
```

to specify that the domain inferred for the second "i" is to be intersected with the other inferred domain, rather than raising an error. (I'm not sure that this shouldn't be the default.)

Domain Inference In Conditionals

So if we have (if cond result alt), what do we do?

If the cond tests a parameter we're trying to infer information about, we may be able to infer something about the values that parameter can take in the branch taken. If we have (if (< i 2) (foo i) (bar i)), then we know that in the i<2 case, we're interested in foo's domain, and in the i>=2 case, we're interested in bar's domain. So if foo's domain is 0:10 and bar's is -10:5, the correct domain to infer is 0:5:

- first we construct -inf:2 and 2:inf domains;
- we intersect -inf:2 with 0:10 and get 0:2;
- we intersect 2:inf with 0:5 and get 2:5;
- we union 0:2 and 2:5 and get 0:5.

(This gets tougher if we have ((if (< i 2) foo bar) i).)

Suppose the conditional doesn't test the parameter of interest, though. Now the domain is harder to figure out. Should we intersect the domains computed for the two branches, as if they both got executed (a conservative approximation to the domain)? Should we complain if the domains computed are different (when in doubt, refuse the temptation to guess)? Or should we take the union of those domains (a liberal approximation)?

Asymmetric Union

I recently wrote this C function:

```
// returns an approximation of 256 * sqrt(sqr)
int inline interp_sqrt(int sqr) {
  if (sqr < max_sqrtx256) return sqrtx256[sqr] >> 4;
  int high = sqr >> 8; // we hope high < max_sqrtx256-1
  int below = sqrtx256[high];
  int above = sqrtx256[high+1];
  int spread = above - below;
  int correction = ((sqr & 0xff) * spread) >> 8;
  return correction + below;
}
```

The table sqrtx256[ii] contains (int)(0.5 + 256 * 16 * sqrt(ii)) for values of ii up to max_sqrtx256; that's the rounded value of 256 * sqrt(ii * 256), or sqrt(ii << 8) << 8. For largish values of sqr, it linearly interpolates sqrt(sqr) between two adjacent values from that table, but I found that was too inaccurate for small values of sqr, so I used the table directly for them. (sqrt(ii * 256) is 16 * sqrt(ii).)

(This is all integer math because floating-point is absurdly slow on my CPU.)

So to look at it another way, I constructed two approximations of sqrt:

```
(define (approx1 sqr) (>> (sqrtx256 sqr) 4))
(define (approx2 sqr)
  (let* ((high (>> sqr 8))
         (below (sqrtx256 high))
         (above (sqrtx256 (+ (intersecting high) 1)))
         (spread (- above below))
         (correction (>> (* (& (intersecting sqr) 0xff) spread) 8)))
    (+ correction below)))
```

Now, if sqrtx256 has a known domain, it should be straightforward to infer the domains for approx1 and approx2, given appropriate rules for (>> x constant) and (+ x constant). (In my case, it happened that approx1's domain was a subset of approx2's.) So it would be nice to construct a combined function that used approx1 for arguments within its range, and approx2 when they were outside of approx1's range but within approx2's — a sort of asymmetric union —

```
(define interp_sqrt (asymmetric-union approx1 approx2
                                      (lambda (x) (* (sqrt x) 256))))
```

You can define asymmetric-union, for two functions and a single argument, as follows, in terms of the valid? predicate from the earlier "zeroextend" function:

```
(define (asymmetric-union x y i) (if (valid? (x i)) (x i) (y i)))
```

I'm not sure to what extent you can write an asymmetric-union that works for an arbitrary number of arguments.

Space-Time Tradeoffs as Annotation

In general it's desirable when you can have the actual code to solve a problem in one place, while the optimizations that make it possible to execute the code with adequate speed are somewhere else. SQL databases are probably the most-widely-known example of this; indices make it possible to execute queries at a reasonable speed, but most SQL statements are guaranteed to return the same results regardless of what indices exist, at least if they ever finish. (The ability to replace a table with a view, and then possibly materialize that view, is a more extreme example of the same thing.)

Any kind of separation of interface and implementation gives you this ability to some extent, in the sense that the code that calls the interface will only run fast if the implementation (which is somewhere else) is adequately efficient. But it is often the case that our implementations mix together their essential semantics with efficiency-driven choices of representation and so on, which makes it difficult to determine whether the code is actually correct.

Another common way to separate the optimizations from the semantics is to put the optimizations in the compiler, or even in the CPU. While this is very economically efficient — it allows all programs compiled by the compiler or run on the CPU to get the benefit — it has a certain incentive problem, namely that the guy who thinks his code runs too slowly usually isn't in a position to modify the compiler or the CPU to speed it up.

So recently I was computing, in Numerical Python, a bunch of animation frames of expanding haloes for a game-like program I was writing. (I say "game-like" because it doesn't have a score or a goal; it's a simple sound sample sequencer.) The NumPy code that renders a frame looks more or less like this, although I'm leaving out the stuff that computes the RGBA palette (indexed by 'take' in the last line), interacts with SDL, and handles varying object lifetimes.

```
# inputs are size, max_age, fuzz, age
shape = (size*2, size*2)
cx = cy = size                  # x and y at center
xs, ys = Numeric.indices(shape) # x and y coords of each pixel
(dx, dy) = (xs - cx, ys - cy)   # distances from center for each pixel
rsq = dx*dx + dy*dy        # squared distance from center

max_level = size**2/2 * (1 - (1 - age*2)**2)
density = Numeric.clip(Numeric.absolute(rsq - max_level),
                       0, fuzz**2).astype(Numeric.Int)
colors = Numeric.take(palette, density)
```

Originally I was computing each frame like this on the fly, but I was taking a hit on my frame rate. So I made an object that stored up everything except age, max_level, density, colors, and palette, which involved quite a bit of change to the above code. That worked OK but was still slow, so I precomputed 48 frames the first time any of them was requested, which took a second or two, and then just fetched the precomputed frames from then on.

That was fine, but then I used a larger halo somewhere else and the pause when it was computed was rather dramatic. So I changed the strategy again to compute, then store, each frame as it was asked for; this improved the situation to a slightly perceptible slowdown the first few times the larger halo was used (since only a few of the frames would be requested each time), but introduced a couple of visible levels of indirection into the code. Now the NumericHaloMovie object has a `__getitem__` that renders frames on KeyError, and there's a get_halo_movie function that stores references to the existing NumericHaloMovies and creates new ones when needed. This extra code complicates the task of someone who wants to see where the images are coming from.

In a system where the contents of arrays, the contents of dictionaries, and the return values of functions are defined the same way and accessed the same way, the decision about whether and how a particular function is memoized would not need to be part of that function's actual code. You could simply say somewhere:

```
(declare-concrete rsq density colors)
```

to tell the system to eagerly materialize those functions as concrete arrays. And possibly

```
(memoize frames)
```

to tell the system to materialize items of frames when they are needed, but then remember them. (Maybe. It will require some cleverness to actually make that possible.)

(Of course, now that I write this, I think maybe I should have just written a DictionaryMemoizer and ArrayMemoizer in Python, which, in a way, is just the approach of merely separating interface from implementation. Oh well. Maybe I will.)

My Halo Animation Expressed This Way

Compare to Python code earlier.

```
(define (sq x) (* x x))
(define (colors palette size max_age fuzz age x y)
  (let* ((rsq (let ((dx (- x size)) (dy (- y size)))
                (+ (sq dx) (sq dy))))
         (max_level (* (/ (sq size) 2) (- 1 (sq (- 1 (* age 2))))))
         (density
          (int (clip 0 (sq fuzz) (abs (- rsq max_level))))))
    (palette density)))
(define (discrete-colors palette size max_age fuzz age)
  (narrow-to-int-range 0 (* 2 size)
    (lambda (x)
      (narrow-to-int-range 0 (* 2 size)
                           (colors palette size max_age fuzz age x)))))
; already defined in Numeric, but here it is:
(define (clip min max val)
  (cond ((< val min) min) ((> val max) max) (t val)))
```

The Python code is clearer, I think. Infix syntax helps for numerical things! Also, the two-layer-deep narrow-to-int-range thing is a mess.

However, this looks a lot like what I would write in C, and consequently isn't all that novel; none of the variables (other than discrete-colors) have what you'd think of as a matrix value.

I tried writing a version in which the variables x and y were passed explicitly to each thing that needed them, making it clear that, say, rsq and density varied by pixel, while max_level and palette didn't. So they were arrays, in a sense. But it was far more wordy than this version.

Windows and Sprites

Asymmetric union is exactly what you need for drawing windows on the screen: consider the window to be a function from coordinates to pixel values that is only defined at some pixels. If your system additionally supports domains that are more complicated than simple contiguous ranges of integers, you get the ability to composite sprites and shaped windows.

Efficiency

Of course if you're checking (dynamically or statically) that the parameters you're passing to a function are inside a domain where that function won't violate any array bounds, you can leave off checking for that inside the function. This subsumes a lot of the kind of type checking needed for safety and dynamic dispatch as well.

So suppose you use the dynamic strategy I suggested with the matrix multiply program I had at the beginning:

```
(define (MM m n i j) (sum k (* (m i k) (n k j))))
```

When you are evaluating, say, (MM m n 3 4), you check upon entry to MM that 3 is within the relevant domain, given m and n. Then, in the inner loop, you don't need to do much bounds checking:

- you know 3 is within the domain of m, because that's where the range of (MM m n) came from;
- you know k is within the domains of (m 3) and n, because that's where its values came from.

However, you still need to verify that (n k j) is valid, each time through the loop, because in the dynamic approach, you don't know if each of the (n k) is a different length. I think that this is a serious problem because it means you can't actually find out what the domain of (MM m n 3) is at all.

If you are calling MM from inside some larger loop, you may be able to push the bounds-checking of i and j out even further, using the same approach. For example, if for some reason you were to write

```
(sum i (sum j (MM m n i j)))
```

then, each time through the inner loop, you would know that i and j were within the bounds of (MM m n) because that's where the sum operators are getting them, so you wouldn't need to do any bounds-checking inside at all.

Other Related Stuff

Neel Krishnaswami said, in a thread on Fortress, "Look at Hongwei Xi's work on Dependent ML http://www.cs.bu.edu/~hwxi/DML/DML.html. Checking matrix sizes was the first thing I thought of when I read his work." So far, I haven't.

From

http://www.haskell.org//pipermail/haskell/2004-August/014397.html

Our example is `bsearch', taken from the famous paper "Eliminating Array Bound Checking Through Dependent Types" by Hongwei Xi and Frank Pfenning (PLDI'98). Hongwei Xi's code was written in SML extended with a restricted form of dependent types. Here is the original code of the example (taken from Figure 3 of that paper, see also http://www-2.cs.cmu.edu/~hwxi/DML/examples/)

```
] datatype 'a answer = NONE | SOME of int * 'a
]
] assert sub <| {n:nat, i:nat | i < n } 'a array(n) * int(i) -> 'a
] assert length  <| {n:nat} 'a array(n) -> int(n)
]
] fun('a){size:nat}
] bsearch cmp (key, arr) =
] let
]     fun look(lo, hi) =
]         if hi >= lo then
]             let
]                 val m = (hi + lo) div 2
]                 val x = sub(arr, m)
]             in
]                 case cmp(key, x) of
]                     LESS => look(lo, m-1)
]                   | EQUAL => (SOME(m, x))
]                   | GREATER => look(m+1, hi)
]             end
]         else NONE
]     where look <|
]     {l:nat, h:int | 0 <= l <= size /\ 0 <= h+1 <= size } int(l) * int(h)
]             -> 'a answer
] in
]     look (0, length arr - 1)
] end
] where bsearch <| ('a * 'a -> order) -> 'a * 'a array(size) -> 'a answer
```

The text after `<|' are dependent type annotations. They *must* be specified by the programmer -- even for internal functions such as `look'.

Enumerating binary trees and their elements

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

Raphael Finkel's book says, "Enumerating binary trees (see Chapter 2) is quite difficult in most languages, but quite easy in CLU." Of course I am not enthusiastic about the idea that CLU has any merits not shared by my own favorite languages, and so I am curious how hard it would be in, say, Python or Scheme.

So, I thought, enumerating the binary trees of a particular size should be fairly straightforward in Python:

```
# With a generator.
def enum_bin_tree(n):
    if n == 0:
        yield None
    for leftsize in range(n):
        for left_tree in enum_bin_tree(leftsize):
            for right_tree in enum_bin_tree(n - leftsize - 1):
                yield left_tree, right_tree

# With a multi-for list comprehension.
def enum_bin_tree_eager(n):
    if n == 0: return [None]
    return [(left_tree, right_tree)
            for leftsize in range(n)
            for left_tree in enum_bin_tree_eager(leftsize)
            for right_tree in enum_bin_tree_eager(n - leftsize - 1)]

# With a simple nested loop.

def enum_bin_tree_simple(n):
    if n == 0: return [None]
    rv = []
    for leftsize in range(n):
        for left_tree in enum_bin_tree_simple(leftsize):
            for right_tree in enum_bin_tree_simple(n - leftsize - 1):
                rv.append((left_tree, right_tree))
    return rv
```

Or in Scheme:

```
(define (enum-bin-tree n)
  (if (= n 0) '(())
      (mapappend (lambda (left-size)
                   (mapappend (lambda (left-tree)
                                (map (lambda (right-tree)
                                       (list left-tree right-tree))
                                     (enum-bin-tree (- (- n left-size) 1))))
                              (enum-bin-tree left-size)))
                 (iota n))))
```

```
(define (iota n) (iotaplus (- n 1) '()))
(define (iotaplus n rest)
  (if (< n 0) rest (iotaplus (- n 1) (cons n rest))))
(define (mapappend fn lst)
  (if (null? lst) '()
      (append (fn (car lst)) (mapappend fn (cdr lst)))))
```

Then I looked at Finkel's pseudo-CLU version; it is 24 lines, compared to 14 for the Scheme version and 6–8 for the Python versions. However, it happens to be very similar to the first (7-line) Python version above; the only differences in the algorithm are the position of the -1 and its use of side effects in place of constructing new tree nodes.

A variant of the approach above can be used to enumerate the sentences of a given length in at least some context-free languages; the tricky part is making sure that the recursion terminates. I think it will work for grammars with no epsilon-productions and no cycles in which a nonterminal can expand to itself A -> A. I'm not quite sure if it can be expanded to include those languages; I'm pretty sure allowing the cycles don't add any power (you can rewrite the grammar to an equivalent grammar without them) but I'm not sure about the epsilon-productions.

Enumerating binary search tree keys

Another example Finkel's book gives, which is perhaps more to the point, is comparing two binary trees to see if their nodes have the same value in inorder traversal. This is very similar to the samefringe problem, in that the recursive formulation of inorder traversal is very straightforward:

```
def inorder_traverse(fn, bintree):
    if type(bintree) is type(()):
        left, middle, right = bintree
        inorder_traverse(fn, left)
        fn(middle)
        inorder_traverse(fn, right)
```

A nonrecursive procedural formulation, on the other hand, is considerably more opaque.

```
def inorder_traverse_nr(fn, bintree):
    stack = [("node", bintree)]
    while stack:
        action, arg = stack.pop()
        if action == "node":
            if type(arg) is type(()):
                left, middle, right = arg
                stack.push(("node", right))
                stack.push(("visit", middle))
                stack.push(("node", left))
        else:                           # action == "visit"
            fn(arg)
```

And if you want to be able to get those items on demand, for example so that you can compare them with the items being

produced from another such traversal, you end up structuring it into some objects:

```
class Inorder_Iterator:
    def __init__(self, bintree): self.stack = [Node(bintree)]
    def next(self):
        if self.stack: return self.stack.pop().next(self)
        raise StopIteration
    def push(self, other): self.stack.push(other)
    def __iter__(self): return self
class Node:
    def __init__(self, bintree): self.node = bintree
    def next(self, stack):
        if type(self.node) is type(()):
            left, middle, right = self.node
            stack.push(Node(right))
            stack.push(Visit(middle))
            stack.push(Node(left))
        return stack.next()
class Visit:
    def __init__(self, val): self.val = val
    def next(self, stack): return self.val
```

By contrast, Python generators let you write this:

```
def inorder_traverse(bintree):
    if type(bintree) is type(()):
        left, middle, right = bintree
        for item in inorder_traverse(left): yield item
        yield middle
        for item in inorder_traverse(right): yield item
```

That's 6 lines of code instead of the 19 of the explicit object version. Both are noticeably shorter, however, than the 25-line pseudo-Simula version with coroutines that Finkel presents (in chapter 2, subsection 2, p.33, figure 2.8).

Opacity holograms

Kragen Javier Sitaker, 2016-08-16 (8 minutes)

We present an algorithm and example images demonstrating a new form of full-color "holography" printable on a standard laser printer that supports full parallax, rather than just one-dimensional parallax, like lenticular 3D and unlike traditional full-color holograms and Beaty's "scratch holograms". Like Beaty's design, these "opacity holograms" do not take advantage of the wave nature of light, but like interference holograms, measures of their quality degrade only proportional to the square root of the number of encoded frames, rather than linearly as with lenticular 3D.

Consider an image obscured by a grille, of the kind used for cryptography in the past. The grille is an opaque sheet with holes in it. When laid atop a ciphertext, a viewer sees portions of the ciphertext where the holes are, and the color of the grille elsewhere, which we will take to be black.

Naor and Shamir (1994) demonstrated how to use the grille approach to optically perform a one-time pad encryption of a bilevel image. The present author extended this algorithm to grayscale images, without loss of security, in a non-peer-reviewed publication in 2007.

The present work demonstrates an extension in a different direction: discarding security entirely as an objective, it uses N random grilles, or equivalently N spatial shifts of the same random grille, to optically decode approximations of N unrelated plaintext images from a single encoded image, with the addition of Gaussian noise with a standard deviation of $O(\sqrt{N})$ added, resulting in an $O(1)$ loss of intensity and contrast, and an $O(\sqrt{N})$ loss of effective resolution. XXX If the grille is physically mounted parallel to and a short distance away from the encoded image — for example, by printing them on opposite sides of transparency film or float glass — these spatial shifts can be achieved merely by viewing the assemblage from slightly different angles.

From here on, we will speak of N grilles, one for each input image, and we will speak of the image as grayscale, with possible values ranging from -1.0 black to +1.0 white; but everything generalizes to the cases of RGB images and N spatial shifts of a random grille. For the time being, we will take the grille's distribution to be 25% open holes, a number we will call L, and 75% opaque black.

The encoded image is a pixelwise sum of N different encoded subimages, each generated from a single plaintext image. A given pixel in the encoded image from among those visible through a hole in a particular grille consists of the corresponding pixel of the input image, plus Gaussian noise from the other subimages. If the noise has a uniform distribution with a mean at 0 across the entire image, then it will merely decrease the effective resolution of the image.

How can we get the sum of the other subimages to have a spatially uniform zero-centered Gaussian distribution? Consider each pixel in each subimage as a random variable, which with some probability shows through a hole in that subimage's grille and therefore must be equal to the original image's pixel, and otherwise can be chosen to have any value. By the Law of Large Numbers, the sum of the corresponding pixels in each subimage will tend to be Gaussian with a

variance that is the sum of the variances of the pixels in each subimage. So we are faced with the task of ensuring that this sum of N-1 subimages has mean 0 at each pixel and has a spatially uniform variance, even though with some significant probability the values of the pixels in particular subimages are fully determined by the corresponding input image pixel.

So, a given pixel in a given subimage might have some plaintext value, such as -.21, with probability L = 0.25, and be a free choice otherwise, while some other pixel in that same subimage might have a different plaintext value, such as .99, with probability 0.25, and be a free choice otherwise. The problem is making the free choice such that the mean of both distributions is zero and the variance is equal.

Getting the mean to be zero is easy: the naïve approach would be to always pick, for example, .07 for the first pixel and -.33 for the second one, when the choice is available. But an encoded subimage generated using this naïve algorithm will have widely varying variances, and worse, they will tend to vary in a spatially coherent way — where the plaintext image is close to medium gray, it will add almost no noise to the other subimages, while where it is close to black or white, it will add a great deal of noise. This will result in crosstalk visible in the decoded images.

The simplest way of fixing this defect of the naïve algorithm is simply to compute the variance for each pixel, and add an additional N+1th subimage purely of random noise with a compensating amount of variance for each pixel. (You could use a Gaussian distribution, or you could try to construct a distribution that will bring the distribution of the sum as close as possible to Gaussian.) Another possible way is to use more complicated distributions in each of the subimages, perhaps shaped to be as close to perfectly Gaussian as possible, so that the Law of Large Numbers kicks in immediately. I don't know how much the higher moments of the noise distribution will be visible, though. And I don't know how much this choice matters.

The final result image will, in general, have pixels outside the [-1.0, 1.0] range, and so will require some amount of clipping. We can scale and translate its range somewhat (diminishing contrast) to reduce the damage from clipping. Translating values is more harmful near -1.0, where it reduces contrast, than near +1.0, where it merely reduces brightness. Probably the most pragmatic approach is to do a linear scaling such that, say, the 1st and 95th percentile values are mapped to -1.0 and 1.0. XXX calculate how much damage this does and how it changes with the number of images.

However, a bilevel output device like a laser printer cannot reproduce continuous grayscale; it can only produce black pixels and white pixels. We would like the probability of a pixel being white to be proportional to its ideal whiteness, which we could do by XXX the usual dithering approaches, no? But it would be nice if we could avoid adding still more noise, by like just thresholding at 0 or something, but that would probably result in undesirably nonlinear performance.

The grille's load factor L (25% in the above) is independent of the number of images, but it affects the effective resolution and the noise levels. Higher load factors L will result in proportionally more noise (i.e. noise with a proportionally higher standard deviation), but also

proportionally more resolution. But the noise also affects the effective resolution: twice the noise requires four times the resolution to compensate. It would seem, then, that the lower the load factor, the better, which of course is absurd, because it implies that the optimum is L=0, a fully opaque grid. This is because the noise isn't actually proportional to L; it's proportional to L/(1-L), which, hmm, that doesn't fix the absurd conclusion, so maybe that's not it. XXX

Thinking further about L. To maximize effective resolution, we want to maximize $L/\sqrt{(L/(1-L))}$.

Topics

Fermat primes

Kragen Javier Sitaker, 2019-07-07 (4 minutes)

Fermat conjectured that all Fermat numbers, numbers of the form $2^n + 1$ where $n = 2^i$ for some $i \in \mathbb{N}$, were prime. In fact, as far as we know, only the first five ($i \in [0, 4]$) are prime, namely 3, 5, 17, 257, and 65537; Euler showed in 1732 that when $i = 5$ the number you get, 4'294'967'297, is composite. Fermat's original conjecture was in 1650, so it's sort of puzzling that it took 82 years to disprove it.

In fact, you can disprove it using Fermat's Little Theorem, that $a^n \equiv a \pmod{n}$ if n is prime. Nonprime numbers n that pass this primality test for every a are called "Carmichael numbers" or "Fermat pseudoprimes", and they do exist, but 4'294'967'297 happens not to be one of them. So, for example, when $n = 4'294'967'297$, $3^n \% n = 497'143'886$, which is not 3. (It does pass the test with $a = 2$.) This is usually a very much easier way to show that a large number is composite than by finding its factors.

You could reasonably argue that Fermat didn't have a gigaflops netbook in his lap when he made his conjecture, and so he could hardly be expected to go around raising numbers to such powers, but actually the calculation is something you could do with pen and paper in a day or two, particularly if you had a table of squares to speed you up. You proceed by successive squaring, dropping out a 4'294'967'297 when necessary; each number here is the square mod n of the previous one:

$3^{1} \% 4294967297 = 3$
$3^{2} \% 4294967297 = 9$
$3^{4} \% 4294967297 = 81$
$3^{8} \% 4294967297 = 6561$
$3^{16} \% 4294967297 = 43046721$
$3^{32} \% 4294967297 = 3793201458$
$3^{64} \% 4294967297 = 1461798105$
$3^{128} \% 4294967297 = 852385491$
$3^{256} \% 4294967297 = 547249794$
$3^{512} \% 4294967297 = 1194573931$
$3^{1024} \% 4294967297 = 2171923848$
$3^{2048} \% 4294967297 = 3995994998$
$3^{4096} \% 4294967297 = 2840704206$
$3^{8192} \% 4294967297 = 1980848889$
$3^{16384} \% 4294967297 = 2331116839$
$3^{32768} \% 4294967297 = 2121054614$
$3^{65536} \% 4294967297 = 2259349256$
$3^{131072} \% 4294967297 = 1861782498$
$3^{262144} \% 4294967297 = 1513400831$
$3^{524288} \% 4294967297 = 2897320357$
$3^{1048576} \% 4294967297 = 367100590$
$3^{2097152} \% 4294967297 = 2192730157$
$3^{4194304} \% 4294967297 = 2050943431$
$3^{8388608} \% 4294967297 = 2206192234$
$3^{16777216} \% 4294967297 = 2861695674$
$3^{33554432} \% 4294967297 = 2995335231$
$3^{67108864} \% 4294967297 = 3422723814$

$3^{13421772^8} \% 4294967297 = 3416557920$
$3^{26843545^6} \% 4294967297 = 3938027619$
$3^{53687091^{12}} \% 4294967297 = 2357699199$
$3^{10737418^{24}} \% 4294967297 = 1676826986$
$3^{21474836^{48}} \% 4294967297 = 10324303$
$3^{42949672^{96}} \% 4294967297 = 3029026160$

This final result at the end would have needed to be 1; if you multiply it by 3 mod 4'294'967'297, you get the number I gave earlier, 497'143'886, which is manifestly not 3.

Squaring a ten-digit number like 3'422'723'814 by hand is a significant amount of work, though you can reduce it substantially by looking up the first and last digits in a table of squares. But of course poor old Fermat couldn't just run off the 60-page table of the first ten thousand squares with a one-line command:

```
perl -le 'print "$_^2 = ", $_*$_ for (1..10000)' | pr -3 | lpr
```

He might have had such a table available — people were printing books with mathematical tables of this size around this time — but I'm uncertain as to whether he did. If he did, it probably contained many errors. Wikipedia suggests no such table was available until Antoine Voisin published a table of 1000 squares in 1817, although multiplication algorithms using them have been known since ancient Babylonia.

And he didn't even have Karatsuba multiplication (see Karatsuba (p. 2090)) to help him along.

Interactive calculator 0

Kragen Javier Sitaker, 2015-09-17 (2 minutes)

I want a calculator that lets me do instant calculation with low precision and then do the same calculation to higher precision, and that is instantly responsive.

I want to be able to mix values that are functions of time with simple scalars.

One aspect of this is using interval arithmetic or some similar kind of approximation to ensure that the rendering is responsive and doesn't block user input.

Another aspect is that I want to see a time-series dangling from each non-scalar-valued operator and variable in my expression, although maybe not all of equal prominence; maybe mouseovers to focus on the active ones. And in some cases, I'd like to see it updating in real time as I'm editing the expression, like if it's a sound signal I'm generating.

I want the time axis to be vertical, rather than the usual horizontal, because the expression is traditionally represented horizontally, and trying to run the time axis horizontally too would mean that you can't see much of any variable.

Another is that the RPN aspect of rpn-edit works really well: each keystroke has an immediate effect, and there are no unbalanced-parentheses errors. So I want to stick with that. If I'm playing music, I probably want the leftmost top-level value to be the one that's played by default, rather than the ones I'm building up to the right.

Another thing, though, is that I want to be able to move back and forth between continuous and discrete time-series without changing the formula, and I want to be able to apply the same function to different input time-series. This requires some kind of functional abstraction, at least giving names to things.

For trading analysis, I need more powerful time-series manipulation than what I've implemented so far. I need to be able to control, and in particular subset, time. I need to be able to conform time-series acquired with different (and irregular) time bases. I need operations on selections like "extend ten minutes into the future". I need to be able to apply smoothing filters.

Caustic simulation

Kragen Javier Sitaker, 2018-09-10 (updated 2018-11-04) (2 minutes)

I'd like to do simulation and optimization of optical caustics. The basic phenomenon is that caustics can have a very high dynamic range and project a reasonable distance, and in particular can produce divergence-limited-brightness lines in the projected image.

Fundamentally the simplest idea is that if you take a single pencil of a collimated beam impinging on a nearly-flat mirrorlike reflector surface and look at the pattern it makes on a target — whether an interface between optical media or a metallic surface — the point where the pencil lands on the target is a continuous function of its position on the reflector, and can be computed using Heron's law of reflection. However, the pencil may be deformed to be convergent, divergent, or both, by the curvature of the reflector at that point. If it is converged to a point or a line, then there is a singularity of infinite brightness in the caustic.

The derivative of the point to which the pencil is directed with respect to the point where it's reflected may go through zero at these points, in X, Y, or both. The product of the two derivatives gives, in some sense, the size of the spot.

Probably the most sensible thing to do is actually to compute a bunch of reflected rays from different points, then calculate some kind of spline joining them. The area of each square of the spline grid provides a local brightness, but the grid may fold back on itself through the aforementioned lines of singularity. This is close to the approach taken by Evan Wallace in WebGL-Water.

(Of course the bright lines are limited in brightness both by the divergence of the incident light and diffraction over the focusing zone.)

Data archival on gold leaf or Mylar with DVD-writer lasers or sparks

Kragen Javier Sitaker, 2018-04-27 (5 minutes)

I was doing some calculations yesterday about blowing holes in things with lasers from DVD writers. My estimate is that you can blow a micron-diameter hole in just about anything with those 400-milliwatt red lasers if you get them properly focused, in about a microsecond.

That would store a few gigabits in a fairly permanent way into a 3.5" square of material, in a few gigamicroseconds, so a few kiloseconds. This is the first long-term archival technology that I think is feasible to do on a shoestring; a DVD-writer is a lot cheaper than a focused-ion-beam etching machine. One of the most appealing media to use for this purpose would actually be old floppy discs, because the Mylar medium is extremely chemically stable, and the oxide coating is nice and optically absorbent, but glass or aluminum seems like it would work fine.

An even simpler alternative that would work with metal foils or even metal surfaces: blow holes in them using sparks from a graphite point (of a radius on the order of a micron, about as sharp as a new scalpel, a bit sharper than the sharpness of a razor blade) driven by a capacitor. However, most metals are not very stable in Earth's atmosphere.

Gold leaf as a medium

Gold is an exception; it's stable in Earth's atmosphere. I can buy 100 sheets of 140mm square gold leaf for AR$350 (US$20), which works out to about 2 million square millimeters, or 100 000 square millimeters per US$.

The data density we're talking about here is about a megabit per square millimeter, so 2 million square millimeters is about 250 gigabytes. Hard disks are a bit cheaper at this point, by a factor of maybe 4, but they weigh more and won't last as long.

Gold and spark properties

Gold boils at 2970°, occupies 19.30 g/cc, and consumes 12.55 kJ/mol of latent heat of melting and 342 kJ/mol latent heat of vaporization; its molar heat capacity is some 25.42 J/mol/K. At the 650-nm wavelength of red lasers, it's about 98% reflective, which makes red lasers kind of a shitty way to boil it, but an arc in air deposits about 90% of its energy at the negative electrode (the one that's releasing electrons and being bombarded with positive ions). Gold leaf can be as thin as about 100 nanometers thick or a bit more, but 200 to 400 nanometers and thicker is also sold. Its molar mass is 197.0 g/mol.

Gold leaf calculations

The per-mole quantities above work out to 63.7 kJ/kg latent heat

of melting, 1.74 MJ/kg latent heat of vaporization, and 129 J/kg/K of specific heat. So boiling gold from something like room temperature should take, roughly, 383 kJ/kg of heating plus the latent heats, or 2.19 MJ/kg, or 2.19 J/mg. A cubic micron of gold weighs 19.3 picograms, so boiling it requires about 42.3 nJ. But our gold leaf is a fraction of a micron thick, perhaps 200 nanometers, so you only need a fifth of that; if you get the polarity right and the pulse quick enough, you need maybe 10 nJ per spark to blow holes in a sheet of gold foil, or about 500 nJ per laser pulse, which would be 1¼ microseconds of 400 mW — I hope that's fast enough to keep the heat from conducting away.

The 250 gigabytes on 100 pages of 140-mm gold leaf would occupy, hypothetically, some 20 microns of thickness, if you laid them atop one another, for a volumetric density of about 10 exabits per cubic meter or 10 gigabits per cubic millimeter. But you can't do that because they would cold-weld together and then you wouldn't be able to separate them in order to read a particular page.

Gold is kind of a worst-case material in some ways — you lose a factor of 25 or 50 compared to any substance that is reasonably emissive in the relevant wavelength range, and it has very high thermal conductivity.

Nearly any other material will be a factor of 2 or more less dense, boil at a factor of 2 lower temperature, and have a factor of 10 or higher emissivity, have similar or lower heat of vaporization, and have worse thermal conductivity, so will be easier to blow holes in. Even aluminum has a third lower thermal conductivity of gold, though it has higher heat of vaporization.

Bench trash power supply

Kragen Javier Sitaker, 2018-04-27 (9 minutes)

So I was thinking that an AVR-driven lab power supply from trash (except for the microcontroller) would be a good idea. You need a lab power supply for a lot of electronics tinkering.

Lots of discarded electronics have power supplies in them. They usually have a few problems we would need to fix for them to be decent lab power supplies:

• They're noisy switching power supplies, not quiet linear ones.
• Their output voltage is fixed, not adjustable.
• They don't have output current limiting, so it's easy to blow them up by shorting them out.
• They have no readout to tell you what the actual current (and voltage) is.
• A lot of them are only 5 volts.

Problem #1 is really tough to solve, so I think I'll ignore it. I think I can solve the others pretty reasonably, though, with a generic microcontroller and a relatively simple circuit plugged into the output of some generic salvaged power supply, like an ATX power supply, say.

The basic idea is that you drive a buck-boost converter (a diode, an inductor, a capacitor, and a MOSFET) using a microcontroller's digital output. To its output you hook, in series, an inductor, a sense resistor, and the load, with a capacitor and megohm resistor across the load; then you add some diode protection. You hook each end of the sense resistor to a separate high-impedance voltage divider to scale down the voltage to a range adequate to the microcontroller's analog inputs. Calibration trimpots form part of these voltage dividers.

Two additional potentiometers are attached to other analog inputs of the microcontroller for use as user input, and an old Nokia serial LCD is attached to five digital I/O pins of the microcontroller.

Actually, I think maybe the inductor and capacitor on the load end aren't necessary. The AVR can respond to changes in load in about 50 µs. I was thinking that the inductor would keep the short-circuit current from rising too quickly for the Arduino to respond, but in fact the buck-boost converter can't respond instantly either — if its output impedance suddenly approaches zero, it won't dump an unlimited amount of energy into it because it doesn't contain an unlimited amount of energy in the first place! It isn't until the next cycle that it has the opportunity to charge up, but of course the microcontroller then has the opportunity to *not* charge it up.

ATX power supplies have ±12V lines, but they are very limited in power. The 5V lines are where the real power is at, typically hundreds of watts of it. A pretty minimal bench power supply should be able to produce up to 30 volts and at least an amp or so, say 1.5 amps, which works out to 45 watts. (You can run four to eight of these off a single ATX power supply.)

Consider first the simple inverting topology, even though that isn't the right thing for a bench power supply.

If we're running the buck-boost converter at 31.25 kHz (the highest

frequency an Arduino running an AVR at 16MHz supports with its native PWM with full 8-bit resolution) then each cycle is 32 microseconds and involves converting up to 1.44 millijoules from the input voltage of 5 V up to the output voltage of 30 V.

At this case, the duty cycle is 17%: the inductor (on the 5V side of the freewheel diode) is getting its current ramped up with 5V for 83% of the time, then getting its current ramped down with 30V for the other 17% of the time when the transistor is turned off. During that time it dumps 83% of its 1.44 millijoules into the capacitor and 17% of it into the load, I guess, which means that the capacitor actually needs to be able to hold several times those 1.44 millijoules in order to keep ripple reasonable.

In particular, say our output ripple is 3%, one volt. That means that the difference between the capacitor energy at, say, 29V, and 30V, is that 1.44 millijoules. $C(30^2-29^2)V^2/2 = 1.44\text{mJ}$, so $C = 2\cdot1440\mu\text{F}/(30^2-29^2) = 49\ \mu\text{F}$. This means that the total energy in the capacitor is $CE^2/2 = 22$ mJ. If you were to short it out with a ¼Ω short circuit (about the internal resistance of a D cell), you would briefly get 120 A and 3.6 kW — but with a time constant of 12 microseconds.

Suppose we use a 10Ω sense resistor to measure the current, though. Now at 1.5 A, we drop 15 V across the resistor, and at 30 V, it's impossible to draw more than 3 A, no matter how we short the output. This, however, requires that the capacitor charge up to 45 V, in order to get 30 V to such a hefty load. So we could draw as much as 4.5 A actually, and a rather alarming 45 W on the sense resistor very briefly, coming down to 15 W after the control circuit kicks in. Gonna need a hefty heatsink on that sucker.

So now the duty cycle is 11%: 5 V to spin up the inductor for 89% of the time, then 45 V as it charges up the capacitor the other 11% of the time. And instead of 1.44 millijoules, because of the extra power in the sense resistor pushing us up to 60 W, it's 1.92 millijoules, so our capacitor goes up to 65 μF, and the total stored energy is 29 mJ. And if you short out the output, the time constant is 290 milliseconds.

This is sort of alarming because it means you can't get a reasonable slew rate on the output voltage, whether in response to changing load or in response to user input. I think the solution is a combination of a higher switching rate and a somewhat smaller sense resistor, basically in order to keep the energy stored in the capacitor down.

(No, wait, all of the above is wrong. The time constant was 650 microseconds.)

It's useful to have some kind of scale for how much energy we're talking about here. 2.3 kJ is enough to boil a gram of water, a cubic centimeter. 2.3 J is enough to boil a milligram of water, a cubic millimeter. 2.3 mJ is eough to boil a microgram of water, a cube 100 microns in diameter. This would still be enough to vaporize the bond wire of a chip if it could somehow be released there, but the bond wire will never be more than 0.1Ω, so even with a sense resistor of 1Ω we can ensure that the majority of the short-circuit energy is dissipated in the sense resistor and not the bond wire. So tens of millijoules should be fine, but not more.

Let's suppose we can manage a higher PWM frequency — say, 125 kHz, maybe by using 6-bit resolution, since we're only shooting for 3% ripple anyway. And a 4.7Ω sense resistor, so at 1.5 amps we only

dissipate 10.6 watts in its 7 V, for a total of 55.5 W, which means 0.4 millijoules per cycle, and 15 microfarads is enough to keep the ripple acceptable, and our time constant when shorted is 70 µs. Our duty cycle then is 5V/37V = 13.5%.

You might also want some kind of minimum load there, in parallel with the real load, to keep the time constant reasonable when you're trying to adjust the voltage under open-circuit conditions. 50 ohms or something.

Okay, enough about the capacitor and sense resistor. What about the inductor? It needs to spin up to some current Imax at 5 volts in 6.9 microseconds, then spin back down at 37 volts in 1.1 microseconds, delivering 0.4 millijoules. 0.4 millijoules in 1.1 microseconds at 37 volts is an average of 9.8 amps, so the max should be 19.6 amps. Let's say 20 amps. That means the inductor needs to be 1.7 microhenries.

Such inductors exist; Digi-Key lists a 12.8 × 12.8 × 7 mm item that costs US$1.20.

What happens if the inductor is some other size? Like, will it work better if the inductance is bigger or if it's smaller?

Copper plating furniture

Kragen Javier Sitaker, 2017-07-19 (updated 2017-09-01) (4 minutes)

Copper plating is an effective technique for preventing microbial contamination of surfaces; it can also prevent corrosion and contact dermatitis from other metals. US pennies are zinc electroplated with 20 microns of copper; this is sufficient to prevent them from wearing visibly even over the course of decades. The Royal Mint claims that their 25-micron coating is sufficient to give circulating currency a life of 25 to 30 years.

Materials cost

How much would it cost to buy enough copper to copper-plate furniture, plates, doorknobs, silverware, walls, etc.? Let's suppose that 10 microns is adequate, since we can replate when it wears through after a few years, so each m^2 of surface is 10 $\mu(m^3)$ = 10 $m\ell$. Copper's density is 8.96g/$m\ell$, so that's 0.0896kg/m^2. At the moment, the price of NYMEX HG contracts — in some sense the wholesale price of copper — is US$2.26 to US$2.30 per pound. That works out to about US$5 per kg, which works out to a copper cost of about US$0.45/$m^2$ for this 10-micron plating.

So copper-plating your entire house is going to be dominated by the cost of the plating process, not of the copper itself. The copper itself is a quite affordable cost.

Dumpster-diving

In fact, you might be able to dumpster-dive enough copper to copper-plate every surface in your house. An AWG20 copper wire, suitable for carrying 5 amps, is 0.812 mm in diameter, according to Induction kiln (p. 2352); a meter-long power cord cut off a small discarded appliance might contain two of them, contains just over one cubic centimeter of copper, which is to say 8.96 g — enough to copper-plate a thousand square centimeters, which is quite a bit of silverware and door handles.

Around here, larger chunks of copper and copper alloys are rapidly dumpster-dived by *cartoneros*, who even break the yokes off discarded CRTs to recover the copper, typically within an hour or two. So finding free copper by the kilogram is not common; nevertheless, I've picked up a discarded microwave oven or two.

Electroplating chemistry

As reported in Immersion plating of copper on iron with blue vitriol (p. 1099), it's feasible to electroplate copper using vinegar and salt, though professional metal finishers are not enthusiastic about "hardware-store chemistry". A nickel flash (also platable with vinegar and salt) is recommended to get an adherent copper coating on steel, while for chromium-based stainless steel, people on #electronics have told me that copper will adhere directly, while *nickel*-plating it requires a *copper* flash. I haven't tried it yet, but I bought some Argentine 1941 50-centavo pieces made of pure nickel.

Energy cost

The 2001 edition of the ASM Specialty Handbook *Copper and Copper Alloys* says, on p.133, Figure 4, in the "Copper and Copper Alloy Coatings" chapter, that it is practical to achieve copper deposit thickness of 3 to 3.5 μm per minute with 8–10 amperes per square decimeter with periodic current reversal, at I think 6 volts; as its source it cites "*Electroplating Engineering Handbook*, Reinhold, 1971, p. 748, 750". This would provide the desired 10μm thickness in about three minutes at a cost of, say, 9 A/dm² · 100 dm²/m² · 3 minutes · 6 V = 972 kJ/m² ≈ 1MJ/m². That's about US$0.027/m² for the energy at a retail cost of US$0.10/kWh, which is measurable, but more than an order of magnitude lower than the cost of the copper itself.

Waterfryer

Kragen Javier Sitaker, 2019-04-20 (1 minute)

An "airfryer" is a sort of convection oven that rapidly achieves frying-like results by blowing hot air over the food at very high speed, browning the surface. It occurred to me that you could, similarly, use high-speed pumped water circulation to rapidly heat food to boiling, or with some pressure, a bit higher than boiling. You can't brown the surface but you can cook the food.

This may be less of a difference from regular cooking (than an airfryer) because the bubbles rising in a boiling pot already produce substantial water circulation, far more than the air convection in a conventional oven; also, the water's thermal conductivity and specific heat are much higher and close to the food's, so perhaps in a boiling pot heat is already being transferred to the food so rapidly that most of the thermal resistance is in the food, not the heat transfer medium.

Topics

Wang tile font

Kragen Javier Sitaker, 2018-08-16 (5 minutes)

Old computer display systems used a "character generator" to drive the raster display (see Gradient pixels (p. 2202) for more detail), giving rise to the traditional "terminal screen" look and feel, with its single shitty typewriter font, blaring primary colors, block cursors, and readability-slaughtering background-color transitions on character-cell boundaries. The major advantage of this system is that it saves a lot of memory; in Gradient pixels (p. 2202), I gave the example of a color 80×25 terminal with 8×16 pixels per character, which requires somewhere between 2000 bytes and 8096 bytes for a 1-bit-deep font, and perhaps 20 kilobytes or so for a font with antialiasing or color. But a framebuffer for the 256000 pixels would require probably 128–768 kilobytes.

An interesting alternative that occurred to me today is to drive the pixel generator from a complete set of Wang tiles. The pixel generator still uses a rectangular array of data directly corresponding to physical screen positions, but the "font" is potentially larger, because the pixels on the screen are a function not only of the glyph index at the underlying location, but also of some pixel generator state. Specifically, you have, say, two bits of "bottom-edge-color state" from the corresponding cell in the previous line (that is, the cell above this one), and, say, two bits of "left-edge-color state" from the corresponding cell in the previous column (that is, the cell to the left). And the font entry indexed by these four bits and the bits of the glyph index contains not only pixels but also the new bottom-edge-color state and left-edge-color state.

In the simplest case, where the rectangular array has no bits per character position, the screen contents are entirely determined by the font; at each position, the four bits of edge state uniquely determine the pixels to display at that position, from the 16 available glyphs in the font, and also determine the new edge state. With a single bit of color per edge, and thus only 4 glyphs, this is sufficient in itself to generate some simple fractals and count in binary, but nothing more interesting, but with two bits of edge state, all kinds of interesting programs are possible. (There are $16^{16} = 2^{64}$ possible programs that can be encoded in the font edge state bits.)

When the rectangular array actually has some data in it, we can think of the bits in it as specifying which of the valid alternative tiles, as constrained by the environment, is to occupy the space; this, in turn, affects the environment of the cells below and to the right.

To take a slightly more interesting case, you might use 5 bits per character position to encode which letter is to appear there, with four variants of the space character — one to set the right-edge state to any of four alternatives, which we could gloss as FIGURES, TITLECASE, UPPERCASE, and LOWERCASE. The TITLECASE glyphs might be identical to the UPPERCASE glyphs in appearance, but the right edge of a TITLECASE glyph leaves the left-edge state set to LOWERCASE, while the right edge of an UPPERCASE glyph remains in UPPERCASE. This is a somewhat suboptimal way to handle case-shifting, since it means that each

case-shift leaves a blank space on the screen — undesirable if you're talking about Mohamed ElBaradei, or example — but it shows that there are some interesting possibilities.

Accommodating descenders from previous lines, or using special word-initial forms of letters, are other possible uses at the character-cell level.

But what if instead we use Wang tiles at a slightly finer granularity than per character cell? After all, if we try to have 256 possible tiles for any given environment, we need 4096 tiles if we have two bits of color on each edge, which implies an uncomfortably large "font ROM". What if each tile only covers *part* of a letter? Maybe "ɑ", "d", and "q" could share a common code for the common part of the letter, while "d" and perhaps "l" could share a common ascender glyph. Perhaps we could even have a smaller font ROM rather than a larger one.

For circuit schematics, we could use edge colors to note whether a wire is or is not present at each edge of a tile, eliminating some duplication. However, without backtracking, the potential promise for this to propagate changes across your whole schematic without further work is limited — they can only propagate down and to the right.

Deep freeze

Kragen Javier Sitaker, 2017-08-22 (updated 2019-01-22) (7 minutes)

A person needs about 2000 kcal of food energy per day, which, according to conventional nutritional thinking, should ideally be broken down as about 40% carbohydrate, 30% protein, and 30% fat: 800 kcal of carbohydrate (weighing 160 g), 600 kcal of protein (weighing 120 g), and 600 kcal of fat (weighing 67 g), for a total weight of 350 g of macronutrients.

But foods do not consist entirely of macronutrients, even in storage. To take an example food, soybeans are normally required to have ≤11% moisture content for food use; 172 g of cooked soybeans contains (according to one source which cites USDA SR-21) 17 g carbohydrate, 15 g fat, 29 g protein, and 1.6 g of micronutrients, totaling 63 g, but 10 g of the carbohydrate is indigestible fiber, about 16% of the total macronutrient mass. So only about 75% of dry soybeans is made of digestible macronutrients, a number which I will take as typical for other dried foods.

This means you need about 470 g of stored dried foods per day to get to 2000 kcal. This is an amount that is reasonably tractable to store; 64 years' worth is just 11 tonnes. (If we take soybeans as a typical bulk food, they cost about US$10 per bushel, which is 60 pounds; 11 tonnes is 404 bushels or US$4040, US$370 per tonne.) But without further work, stored foods will deteriorate in nutritional value during 64 years, and may even rancidify, producing free radicals and other poisons.

The only way to prevent this nutritional deterioration is to keep the food cold in a freezer, which generally requires three components: insulation, refrigeration, and passive thermal storage (either thermal mass or phase-change materials).

In habitable regions of Earth, the ambient temperature is too high for long-term food storage, so insulation is needed to prevent heat exchange between the food and the environment. You can measure the thermal resistance around a thing in K/W, kelvins per watt — generally the heat flow is proportional to the temperature difference. This thermal resistance is proportional to the thickness of the insulation, inversely proportional to the surface area through which the heat is flowing, and proportional to the insulance of the material. Insulances range from 1000 W/m/K for diamond down to 20 mW/m/K for silica aerogel. Water's insulance is 580 mW/m/K, though it rises to 2200 mW/m/K when frozen, and commonly-used low-temperature insulating materials range from straw at 90 mW/m/K to styrofoam at 33 mW/m/K. (Refractory insulators are trickier; firebrick is normally around 500 mW/m/K). Minerals are less insulating; quartz is 3 W/m/K, sandstone is 1.7, graphite is a metal-like outlier at 168, copper is 400. Water-saturated dirt is about 2–4 W/m/K, while dry sand is about 150–250 mW/m/K, an order of magnitude better.

Because the heat leakage is proportional to the surface area, larger freezers are more efficient — they have less surface area per unit volume, so they lose less heat per unit of food stored, if we hold constant the insulation thickness and material. A cubic-meter sphere

has about 4.8 m² of surface area; a thousand-cubic-meter sphere has 480 m² of surface area, only 0.48 m² per m³. So it will warm up ten times more slowly, and it will need only a hundred times as much refrigeration — one-tenth as much per unit of food stored.

Refrigeration is needed both to initially cool the food down and to compensate for heat lost through the insulation. In the steady state, the refrigeration needed is proportional to the temperature difference (to ambient) and inversely proportional to the thermal resistance (to ambient).

Passive thermal storage is needed to keep the food cold when the refrigeration is turned off, either because the thermostat has turned it off or because energy is not available to power the refrigeration. (A solar-powered refrigeration system might only work on sunny days, for example, and a grid-tied system won't work during blackouts.) As with refrigeration, the passive thermal storage needed is inversely proportional to the thermal resistance of the insulation. The food itself has a certain thermal mass, typically about 2kJ/kg/K, and it can be supplemented with a phase-change material such as water ice, which has an enthalpy of fusion of some 79 kJ/kg. XXX XXX I think this is wrong and the correct figure is 333 kJ/kg. Adding phase-change materials increases the volume that must be insulated, which increases the surface area, requiring a greater depth of insulation over a larger area. Consequently, there is a tradeoff between resiliency to power outages and energy efficiency.

Water-saturated dirt is not a very good insulator, with insulances of around 3 W/m/K, about 30 times worse than straw and 90 times worse than styrofoam. But you can get 30 meters of water-saturated dirt insulation just by drilling a 30-meter well, while the equivalent meter of straw insulation requires you to buy and then move around cubic meters of straw. Better still, dry sand is only a factor of 3 worse than straw, so it's easy to get an enormous thermal resistance in dry areas. Straw is by far the cheapest decent insulation material; it costs at a minimum about US$25 per tonne just to replace its fertilization value and bale it; in places the cost can be two or three times that, depending on competing demand for livestock feed.

If you were to try to build a mound of dry sand aboveground in order to get dry-sand thermal insulances in an otherwise swampy area, you'd need the sand to cost less than about US$10 per tonne to make it cheaper than straw. Construction sand for concrete costs about US$20–40 per tonne delivered here in Buenos Aires, but if you can instead just move earth around locally (producing a pit and a mound), you could conceivably improve on that. However, excavation costs are typically close to that same US$20–40 per tonne using construction-scale hydraulic earthmoving equipment.

So probably straw insulation is the

What can you build out of 256-byte ROMs?

Kragen Javier Sitaker, 2018-12-02 (1 minute)

Suppose we have, as a fundamental unit, a simple finite state machine: an asynchronous ROM with some address inputs fed from its own registered output and other address inputs coming from elsewhere. To be concrete, consider the case where the ROM contains 256 8-bit words, 4 address lines attached to its own registered output, and 4 address lines coming in from elsewhere. The ROM contains 2048 bits; if it is in fact programmable (for example by way of a serial bitstream) it amounts to a programmable lookup table; it can plainly run quite fast. What can we do with such a machine?

It's straightforward to use it to hold 4 bits, or one decimal digit, of an up/down counter; you can also use it as a 3-bit accumulator slice, adding its input to its contents on each clock cycle, with carry in and carry out.

However, upon further thought, I think this is probably not a useful design; it necessarily contains upward of 4000 transistors, enough for an entire 8-bit CPU. The 256×8 configuration memory is surely better off as 128 16×1 memories, as in a normal FPGA.

Augmenting a slow precise ADC with a sloppy fast high-pass filtered parallel ADC

Kragen Javier Sitaker, 2017-03-20 (2 minutes)

A 16MHz AVR like the one in an Arduino can read an 8-bit port fairly frequently, in theory every 4 cycles or so (4MHz), though I think in a real program you'd be lucky to get every 15 cycles (1MHz). It occurred to me that you could maybe do a quasi-equivalent of an R-2R DAC to get some kind of sample at that frequency: by running different voltage dividers from a voltage source across the different pins, the digital level thresholding can maybe give you some approximate idea of how high a signal is: a 3-bit idea of it, to be exact.

This sounds kind of useless, but I was thinking you could use it in combination with the ADC, which on the ATMega328 runs at up to 76.9 ksps or up to 15 ksps at maximum resolution. Each conversion takes 13 ADC clock cycles, where the ADC clock runs at between 1/128 and 1/2 the system clock, thus 125kHz to 8MHz at a 16MHz system clock speed; this gives us 9.6 ksps to 615 ksps, although I'm guessing that running the ADC clock at over 1MHz won't produce useful results.

I was thinking that you could run the normal ADC at its 15 ksps speed, thus providing an absolute 10-bit measurement of the input voltage, but then sample a high-pass-filtered version of the input voltage at about 1MHz and only three bits per sample. This would give you about 64 3-bit relative samples for each 10-bit absolute sample, gathering information about frequency components up to 500kHz. If there is significant overlap in the frequency responses of the two parts of the system, you can use the slow, absolute, high-precision ADC to calibrate the fast, relative, low-precision ADC.

You probably want to buffer the input voltage on its way into the high-pass filter and voltage dividers in some way — at least an emitter follower or source follower, maybe a whole op-amp buffer or something.

This seems like it might be capable of converting an ATMega328 into a 500kHz-bandwidth "oscilloscope", which is like 2½% of a real oscilloscope.

Hash gossip exchange

Kragen Javier Sitaker, 2015-11-19 (4 minutes)

I saw an article on HN the other day with a title like "the opposite of a Bloom filter", making the observation that if you make a hash table where you resolve collisions by simply discarding one of the colliding keys, then you get a probabilistic-set data structure that may have false negatives but never false positives, which is in some sense the reverse of a Bloom filter. It's very similar in a sense to a CPU memory cache (which also tracks the contents of memory as well as the data present there).

This comes at a fairly heavy space cost compared to typical Bloom filters, since you have to actually store the keys in order to ensure that you aren't getting false positives.

It occurred to me that you could use this approach to implement an efficient stateless gossip protocol for large datasets, but then it occurred to me that actually you can do better with Bloom filters.

Bloom filter approach

When you make contact with a new peer, generate a high-false-positive-probability Bloom filter of your current set of keys, using HMAC as the hash algorithm, keyed with a random nonce. Send the filter and the nonce to the peer. The false-positive probability can reasonably be as high as 90%, which should allow you to use a single hash function and much less than one bit per key.

When you receive a filter and a nonce, hash all your keys with the nonce and probe to see which are in the filter. If any are not in the filter, send them in your reply.

This sends a randomly selected 10% of the missing data to the peer. This should be sufficient to provide efficient information distribution if encounters are frequent but happen at intervals relatively large compared to the communication latency. In particular, it should be possible to keep the filters several orders of magnitude smaller than the dataset being synchronized, and each node will almost always receive each data item only once, even if it's simultaneously syncing with multiple peers.

With a fixed false-positive probability, the filter will grow linearly with the dataset. This problem can be avoided by increasing the false-positive probability over time, but of course that makes the network gradually slower as information accretes. Suppose that, instead, we partition the dataset into epochs of, say, one day each, in such a way that each node can determine independently which epoch a particular key belongs to, and we compute and transmit a separate filter for each epoch. Then we can choose a different convergence rate for each epoch: perhaps I want today's epoch to have a 90% false positive rate, but yesterday's 95%, 97% for the day before, and so on. In this way it is possible to continue very slow convergence even for very old epochs.

(Rathe than choosing different filter sizes, you could merge different numbers of epochs into each filter, producing different load factors; this is probably actually a better idea. So you might have one filter for the current minute, one filter for the previous three minutes,

one filter for the previous nine minutes, and so on.)

In addition to being more efficient, this approach is somewhat more privacy-protecting than the standard approach used by e.g. BitTorrent, in which you send a full list of all the keys (pieces, in the BitTorrent case) you have. That list of keys is almost certainly enough to identify you uniquely for a period of time. By contrast, it should be somewhat more difficult to identify the sender of such a filter: infeasible if you have no idea what keys might have been hashed into it, but even if you have some candidate keys, each one only gives you a small, probabilistic amount of information.

Analogies between spring–mass–dashpot systems, electrical systems, and fluidic systems

Kragen Javier Sitaker, 2016-10-30 (4 minutes)

The direct stiffness method of the finite element method turns a system of springs into a system of linear equations, imposes boundary conditions by removing some of the variables to make the system nonsingular, and then solves the system.

If we restrict our attention to systems of Hookean springs in one dimension connected at nodes, we have essentially two relationships:

• The net force from the springs on any node, except for those held fixed by boundary conditions, is zero.
• The force through a spring is its rigidity times the difference in displacement between its endpoints.

This immediately suggests comparison to electric circuits. For example:

• The net current from the resistors into any node is zero, except for those connected to current sources.
• The current through a resistor is its conductance times the difference in voltage between its endpoints.

And the resulting series, parallel, and bridge laws are the same for springs and for resistors.

This suggests extending the analogy {force = current, rigidity = conductance, displacement = voltage, springs = resistors} to other components. In this analogy, a dashpot, whose force is its "dashpoticity" times the rate of change in the displacement between its endpoints, or equivalently the difference in velocity between its endpoints, is analogous to a capacitor, whose current is its capacitance times the rate of change in voltage between its endpoints. This extends the analogy to the following:

Mechanical	Electrical		
force	current	F = kd	I = GV
stiffness/rigidity	conductance	k = F/d	G = I/V
spring	resistor		
displacement	voltage	d = F/k	V = I/G
dashpot	capacitor	F = x dd/dt	I = C dV/dt
dashpot-stiffness	capacitance		C = Q/V = ∫I dt/V

For reasons of conservation of energy, an inductor has no passive mechanical equivalent in this analogy; it would need to have a displacement proportional to the rate of change of force.

But that's not the only possible analogy, since other linear circuit elements (inductors and capacitors) combine in series and parallel in

the same way. For example, making capacitors instead of resistors analogous to springs:

• The net charge at any node is zero, except for those connected to current sources.
• The charge across a capacitor is its capacitance times the difference in voltage between its endpoints.

That is:

Mechanical	Electrical		
spring	capacitor	???	???
compliance? stiffness?	capacitance? elastance?		
velocity			
force			

In this analogy (force = charge, displacement = voltage, rigidity = capacitance) if we differentiate with respect to time, we find that velocity is rate of change of voltage and FUCK I HAVE NO FUCKING CLUE. It seems like inductors should be masses, what? Since they're 180° away from springs? On a mass, the derivative of velocity is force divided by mass. On an inductor, the derivative of current is voltage divided by inductance. So does that mean {velocity = current, force = voltage, inductance = mass}?

Presumably you can make the analogy equally valid in exactly the opposite direction, with springs representing inductors, masses representing capacitors, and dashpots representing resistors. In this analogy, I think charge represents displacement, velocity represents current, and force represents voltage: the rate of change of displacement of a mass is its velocity, and the rate of change of velocity of a mass is the force divided by the mass, thus {force = voltage, velocity = current, capacitance = mass}. This is exactly contradictory to what I came up with in the previous paragraph, so clearly I am smoking crack.

This analogy has:

force	voltage				
velocity	current	v = dd/dt	I = dQ/dt		
displacement	charge				
spring	inductor				
dashpot	resistor				
mass	capacitor				
stiffness	inductance?	k = F/(dv/dt)	L = V/(dI/dt)	!?!?!?	

Fuck, I have no idea.

Constructing error-correcting codes using Hadamard transforms

Kragen Javier Sitaker, 2013-05-17 (updated 2013-05-20) (22 minutes)

(I think this was published previously on kragen-tol.)

Last night, I encoded some messages in ASCII by hand, including error-correction coding: like the printer dots Seth Schoen decoded, matrices of 8 columns of 8 bits each, with an extra column and row for parity. (I used even parity, but odd would have been a better choice.) Matrix parity lets you correct single-bit errors: a single-bit error will show up as a parity error in both the row parity and the column parity. And it's simple enough and spatial enough that you can both detect and correct errors by hand.

This got me to thinking about what kind of more powerful error-correction coding might be feasible to perform by hand, and I think I came up with one, which at first glance appears to be related to the Hadamard transform, but in the end seems to be something simpler.

Existing Hadamard-code work is quite different

For many years, Hadamard matrices have been used for error-correction coding by the simple expedient of using a row of the matrix for each codeword; since the rows are perfectly uncorrelated, they have a large Hamming distance, and the Fast Hadamard Transform of the received (possibly corrupted) codeword gives you the Hamming distance from all the N codewords in 2 N lg N additions and subtractions. (This is now apparently obsoleted by better codes.)

A problem with this for human use is that it's not just some checksum symbols you glom onto your data; it makes your data totally unrecognizable.

I want to discuss a different application of Hadamard matrices for error-correction codes. As far as I can tell, this is not related to "Hadamard-Craigen error correcting codes" (Craigen 2002), and in the unlikely event that these codes become popular, I hope that nobody decides to call them "Hadamard-Kragen codes".

The Hadamard transform and its relevance briefly explained

The Hadamard transform of a vector is a "holographic representation" of the vector in the sense that the vector can be recovered from it (by repeating the Hadamard transform and dividing by the determinant) and that every value in the Hadamard transform is affected by every element in the original vector. This means that any local change in the original vector results in a global change in the Hadamard-transformed vector --- in the case of the Hadamard transform, *every* element changes.

(For simplicity, I'm going to consider only dimension-`2**n` Hadamard matrices produced by the Sylvester method here, although

others exist.)

The Hadamard transform is particularly interesting among such holographic representations because the Fast Hadamard Transform enables computing the HT very efficiently.

The fast Hadamard transform of a vector or characters, illustrated

So suppose you have a vector of characters, say, 'Hadamard'. You compute the Fast Hadamard Transform of this vector:

```
def hadamard(vec):
    if len(vec) == 1: return vec
    pairs = zip(hadamard(vec[:len(vec)/2]),
                hadamard(vec[len(vec)/2:]))
    return ([lv + rv for lv, rv in pairs] +
            [lv - rv for lv, rv in pairs])

>>> hadamard(map(ord, 'Hadamard'))
[786, 4, -36, -30, -54, -48, -20, -26]
```

Note that a local change in the input produces a linear global change in the output:

```
>>> hadamard(map(ord, 'Hadamarc'))
[785, 5, -35, -31, -53, -49, -21, -25]
>>> hadamard(map(ord, 'Hacamarc'))
[784, 4, -34, -30, -54, -50, -20, -24]
```

And you can reconstruct the original input vector from the Hadamard-transformed version:

```
>>> ''.join(chr(c/8) for c in hadamard(hadamard(map(ord, 'Hadamard'))))
'Hadamard'
```

And, naturally, local errors in the Hadamard-transformed version result in linear global errors in the result:

```
>>> ''.join(chr(c/8) for c in hadamard([786,4,-36,-30,-54,-48,-20,-26]))
'Hadamard'
>>> ''.join(chr(c/8) for c in hadamard([778,4,-36,-38,-54,-48,-20,-26]))
'Fad_karb'
>>> ''.join(chr(c/8) for c in hadamard([700,4,-36,-38,-54,-48,-20,-26]))
'<WZUaWhX'
```

How to use this for a human-friendly error-correction code

So suppose you want to be able to correct errors. You can pick some subset of the Hadamard transform to transmit along with your raw data. If there's a single-character error, it will show up in every transformed value you transmit, but with varying signs; each sign after the first gives you one bit of information about where the error is --- *exactly* one bit, I thought, since the rows of the Hadamard matrix are *perfectly* uncorrelated; so you should be able to localize the

error with lg N bits. (That turns out to be false, as demonstrated below; it matters a lot which rows you pick.) In fact, since the whole transform is linear, you should be able to just run the inverse transform on your error signal and get the location of the error.

Using the inverse transform on arbitrary outputs to localize errors works poorly

Let's try:

```
>>> orig = hadamard(map(ord, 'Hadamard'))[:3]
>>> computed = hadamard(map(ord, 'Hagamard'))[:3]
>>> [computed_i - orig_i for computed_i, orig_i in zip(computed, orig)]
[3, 3, -3]
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed, orig)] + [0] * 5)
[3, -3, 9, 3, 3, -3, 9, 3]
```

Not quite. We got a nice peak in the transformed error signal at the location of the actual error, it's true, but we got an equally big one elsewhere. It doesn't work with four values either:

```
>>> orig = hadamard(map(ord, 'Hadamard'))[:4]
>>> computed = hadamard(map(ord, 'Hagamard'))[:4]
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed, orig)] + [0] * 4)
[0, 0, 12, 0, 0, 0, 12, 0]
```

It does work with five:

```
>>> computed = hadamard(map(ord, 'Hagamard'))[:5]
>>> orig = hadamard(map(ord, 'Hadamard'))[:5]
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed, orig)] + [0] * 3)
[3, 3, 15, 3, -3, -3, 9, -3]
```

And of course the first value tells us the sign and magnitude of the actual error:

```
>>> computed[0] - orig[0]
3
```

What if we pick different values, like the ones from the end? We still need five of them to locate the error:

```
>>> orig = hadamard(map(ord, 'Hadamard'))[-3:]
>>> computed = hadamard(map(ord, 'Hagamard'))[-3:]
>>> computed
[-45, -23, -29]
>>> hadamard([0] * 5 + [computed_i - orig_i
                        for computed_i, orig_i
                        in zip(computed, orig)])
[-3, -3, 9, -3, 3, 3, -9, 3]
```

```
>>> orig = hadamard(map(ord, 'Hadamard'))[-4:]
>>> computed = hadamard(map(ord, 'Hagamard'))[-4:]
>>> hadamard([0] * 4 + [computed_i - orig_i
                        for computed_i, orig_i
                        in zip(computed, orig)])
[0, 0, 12, 0, 0, 0, -12, 0]
>>> orig = hadamard(map(ord, 'Hadamard'))[-5:]
>>> computed = hadamard(map(ord, 'Hagamard'))[-5:]
>>> hadamard([0] * 3 + [computed_i - orig_i
                        for computed_i, orig_i
                        in zip(computed, orig)])
[-3, 3, 15, -3, -3, 3, -9, -3]
```

How about a different error?

```
>>> computed = hadamard(map(ord, 'Hadamerd'))[-5:]
>>> hadamard([0] * 3 + [computed_i - orig_i
                        for computed_i, orig_i
                        in zip(computed, orig)])
[-4, -12, 4, -4, -4, 20, 4, -4]
```

How about an error in the transformed values? That produces a distinctly different pattern:

```
>>> computed = [0] + orig[1:]
>>> hadamard([0] * 3 + [computed_i - orig_i
                        for computed_i, orig_i
                        in zip(computed, orig)])
[30, -30, -30, 30, 30, -30, -30, 30]
```

It seems like it ought to be possible to correct multiple errors.

How about a longer text? Correcting one error in eight characters by appending five error-check symbols is not at all impressive. Can we correct an error in a 64-character text with 11 Hadamard results? (Not the way I've been doing it, but see later sections for successfully doing it with 7.)

```
>>> text='correct an error in a 64-character text with 11 Hadamard results'
>>> len(text)
64
>>> orig = hadamard(map(ord, text))[:11]
>>> errtext = text[:20] + 'x' + text[21:]
>>> errtext
'correct an error in x 64-character text with 11 Hadamard results'
>>> computed = hadamard(map(ord, errtext))[:11]
>>> orig
[5806, -74, 100, -304, 68, -576, -166, -78, -170, 310, 212]
>>> computed
[5829, -51, 123, -281, 45, -599, -189, -101, -147, 333, 235]
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed, orig)] + [0] * 53)
[69, 23, 23, -23, 253, 23, 23, -23, -69, -23, -23, 23, 115, -23,
-23, 23, 69, 23, 23, -23, 253, 23, 23, -23, -69, -23, -23, 23,
115, -23, -23, 23, 69, 23, 23, -23, 253, 23, 23, -23, -69, -23,
```

```
-23, 23, 115, -23, -23, 23, 69, 23, 23, -23, 253, 23, 23, -23,
-69, -23, -23, 23, 115, -23, -23, 23]
```

No, it identifies four equally likely locations for the error. 13?

```
>>> orig = hadamard(map(ord, text))[:13]
>>> computed = hadamard(map(ord, errtext))[:13]
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed, orig)] + [0] * 51)
[69, -23, -23, -23, 299, 23, 23, 23, -69, 23, 23, 23, 69, -23,
-23, -23, 69, -23, -23, -23, 299, 23, 23, 23, -69, 23, 23, 23, 69,
-23, -23, -23, 69, -23, -23, -23, 299, 23, 23, 23, -69, 23, 23,
23, 69, -23, -23, -23, 69, -23, -23, -23, 299, 23, 23, 23, -69,
23, 23, 23, 69, -23, -23, -23]
```

No, mysteriously the new Hadamard results didn't give us any new information about the location of the error; we still have four equally likely locations. It's as if the relevant Hadamard rows are somehow correlated with the basis comprised of the rows we have already, though not any of those rows individually.

It turns out that better choices are available:

```
>>> orig_full = hadamard(map(ord, text))
>>> computed_full = hadamard(map(ord, errtext))
>>> orig = orig_full[:11] + [0] * 51 + orig_full[-2:]
>>> computed = computed_full[:11] + [0] * 51 + computed_full[-2:]
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed, orig)])
[115, 23, -23, -23, 207, 23, 69, -23, -115, -23, 23, 23, 161, -23,
-69, 23, 23, 23, 69, -23, 299, 23, -23, -23, -23, -23, -69, 23,
69, -23, 23, 23, 23, 23, 69, -23, 299, 23, -23, -23, -23, -23,
-69, 23, 69, -23, 23, 23, 115, 23, -23, -23, 207, 23, 69, -23,
-115, -23, 23, 23, 161, -23, -69, 23]
```

That reduces the choices to two. What if we choose by a different approach?

```
>>> orig = orig_full[::5]
>>> len(orig)
13
>>> computed = computed_full[::5]
>>> orig_expanded = [0] * 64
>>> orig_expanded[::5] = orig
>>> orig_expanded
[5806, 0, 0, 0, 0, -576, 0, 0, 0, 0, 212, 0, 0, 0, 0, 86, 0, 0, 0,
0, 438, 0, 0, 0, 0, -108, 0, 0, 0, 0, -220, 0, 0, 0, 0, 4, 0, 0,
0, 0, -358, 0, 0, 0, 0, 96, 0, 0, 0, 0, -102, 0, 0, 0, 0, 120, 0,
0, 0, 0, 406, 0, 0, 0]
>>> computed_expanded = [0] * 64
>>> computed_expanded[::5] = computed
>>> hadamard([computed_i - orig_i
              for computed_i, orig_i
              in zip(computed_expanded, orig_expanded)])
```

```
[69, 161, -23, 161, 23, -69, 23, 23, 23, -161, 23, 115, -23, -23,
69, -23, -23, 69, -23, -23, 299, 23, 23, 23, 23, 23, -69, 23, -23,
-23, -23, 69, -23, 161, -23, -115, 23, 23, -69, 23, 23, 115, 115,
115, 69, -23, 69, -115, -23, -23, 69, -23, 23, 23, 23, -69, -69,
23, -69, 115, -23, 69, 253, 69]
```

That has a max, 299, at the right spot, with "only" 13 Hadamard-transformed values to give us six bits of error-location information.

So, although this can be made to work, it doesn't perform as well as I had hoped, and I didn't really understand why. I did find out how to stop it; see later sections.

Using the assumption that there's just one error doesn't help

But that approach is, in essence, attempting to find an estimate of an *arbitrary* difference between the two vectors. But we're assuming that the difference here comes from a transmission error corrupting a single letter.

What if we just use the signs of the differences, and try to figure out which single input position could have caused that pattern of signs? That doesn't work either with poor choices of rows:

```
sgn = lambda x: 1 if x > 0 else 0 if x == 0 else -1
matrix = lambda n: [hadamard([i==j for i in range(n)]) for j in range(n)]
def find(prefix, items):
    for ii, item in enumerate(items):
        if item[:len(prefix)] == prefix: yield ii

for i in range(64):
     print i, list(find([sgn(computed_i - orig_i)
                         for computed_i, orig_i
                         in zip(computed_full[:i], orig_full[:i])],
                        matrix(64)))

0 [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17,
   18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33,
   34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49,
   50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63]
...
2 [0, 2, 4, 6, 8, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30, 32,
   34, 36, 38, 40, 42, 44, 46, 48, 50, 52, 54, 56, 58, 60, 62]
3 [0, 4, 8, 12, 16, 20, 24, 28, 32, 36, 40, 44, 48, 52, 56, 60]
4 [0, 4, 8, 12, 16, 20, 24, 28, 32, 36, 40, 44, 48, 52, 56, 60]
5 [4, 12, 20, 28, 36, 44, 52, 60]
...
9 [4, 20, 36, 52]
...
17 [20, 52]
...
33 [20]
...
```

Picking particularly helpful rows of the matrix *does* help

Somehow, almost all of the additional rows we get are adding no new information. Rows 0, 1, 2, 4, 8, 16, and 32 apparently added a bit each. (I say row 0 because we need the information about which direction the change perturbed the input in order to interpret the others.) What if we use just those rows?

```
select = lambda x: [x[i] for i in [0, 1, 2, 4, 8, 16, 32]]
>>> len(set(tuple(select(row)) for row in matrix(64)))
64
```

This looks promising! Compare to:

```
>>> len(set(tuple(row[:5]) for row in matrix(64)))
8
```

And it works, see?

```
>>> list(find([sgn(computed_i - orig_i)
               for computed_i, orig_i
               in zip(select(computed_full), select(orig_full))],
              [select(row) for row in matrix(64)]))
[20]
```

So there we have seven Hadamard values that successfully localized the error using only their signs. (If the change were negative, we'd've had to try `-sgn` as well as `sgn`; you could presumably avoid that by using the pattern of sign *changes* instead of signs). What if we use the reverse-transform approach with these values instead of the arbitrary ones we were using before?

```
def expand(vals):
    rv = [0] * 64
    for val, pos in zip(vals, [0, 1, 2, 4, 8, 16, 32]): rv[pos] = val
    return rv

hadamard(expand(computed_i - orig_i
                for computed_i, orig_i
                in zip(select(computed_full), select(orig_full))))

[69, 23, 23, -23, 115, 69, 69, 23, 23, -23, -23, -69, 69, 23, 23,
-23, 115, 69, 69, 23, 161, 115, 115, 69, 69, 23, 23, -23, 115, 69,
69, 23, 23, -23, -23, -69, 69, 23, 23, -23, -23, -69, -69, -115,
23, -23, -23, -69, 69, 23, 23, -23, 115, 69, 69, 23, 23, -23, -23,
-69, 69, 23, 23, -23]
```

And that does indeed have a clear peak of 161 at position 20, which is where the error is.

What if we have a different error? That seems to work too:

```
>>> errtext = text[:35] + '!' + text[36:]
>>> errtext
'correct an error in a 64-character !ext with 11 Hadamard results'
>>> computed_full = hadamard(map(ord, errtext))
```

```
>>> select(computed_full)
[5723, 9, 183, -15, -253, -55, 5]
>>> select(orig_full)
[5806, -74, 100, 68, -170, 28, -78]

...     hadamard(expand(computed_i - orig_i
...                     for computed_i, orig_i
...                     in zip(select(computed_full), select(orig_full))))

[-83, -249, -249, -415, 83, -83, -83, -249, 83, -83, -83, -249,
249, 83, 83, -83, 83, -83, -83, -249, 249, 83, 83, -83, 249, 83,
83, -83, 415, 249, 249, 83, -249, -415, -415, -581, -83, -249,
-249, -415, -83, -249, -249, -415, 83, -83, -83, -249, -83, -249,
-249, -415, 83, -83, -83, -249, 83, -83, -83, -249, 249, 83, 83,
-83]
```

And indeed there's a negative peak at position 35, where all seven differences of 83 ('t' - '!') line up with the same sign, producing -581. And using the approach of just looking at the signs? That works too, but since it's a negative change, we have to negate the signs:

```
>>> list(find([sgn(computed_i - orig_i)
...                    for computed_i, orig_i
...                    in zip(select(computed_full), select(orig_full))],
...                   [select(row) for row in matrix(64)]))
[]
>>> list(find([-sgn(computed_i - orig_i)
...                    for computed_i, orig_i
...                    in zip(select(computed_full), select(orig_full))],
...                   [select(row) for row in matrix(64)]))
[35]
```

This is very far from a proof that the method works, but it's suggestive. Here are the rows of `select(matrix(64))`:

```
[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1]

[1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1,
-1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1,
1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, 1,
-1, 1, -1, 1, -1, 1, -1]

[1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1,
-1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1,
-1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1, -1, 1, 1, -1,
1, -1, -1, 1, 1, -1, -1]

[1, 1, 1, 1, -1, -1, -1, -1, 1, 1, 1, 1, -1, -1, -1, -1, 1, 1, 1, 1,

-1, -1, 1, 1, 1, 1, -1, -1, -1, -1, 1, 1, 1, 1, -1, -1, -1, -1, 1, 1,
1, 1, 1, -1, -1, -1, -1]

[1, 1, 1, 1, 1, 1, 1, 1, -1, -1, -1, -1, -1, -1, -1, -1, 1, 1, 1,
```

```
1, 1, 1, 1, 1, -1, -1, -1, -1, -1, -1, -1, -1, 1, 1, 1, 1, 1, 1,
1, 1, -1, -1, -1, -1, -1, -1, -1, -1, 1, 1, 1, 1, 1, 1, 1, 1, -1,
-1, -1, -1, -1, -1, -1, -1]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, -1, -1, -1, -1,
-1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, 1, 1, 1, 1, 1, 1,
1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, -1, -1, -1, -1, -1, -1, -1, -1, -1,
-1, -1, -1, -1, -1, -1, -1]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
1, 1, 1, 1, 1, 1, 1, 1, 1, 1, -1, -1, -1, -1, -1, -1, -1, -1, -1,
-1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1, -1,
-1, -1, -1, -1, -1, -1, -1]
```

These appear to be precisely the most regular rows, the ones with sequencies 0, 63, 31, 15, 7, 3, and 1. You certainly don't need a Hadamard matrix to compute those! It's closely related to the matrix parity code I started with --- but instead of XOR, you're using addition, and instead of two dimensions, you're in 6, and instead of separately recording the totals modulo whatever of two 5-dimensional hyperplanes, you're recording only the difference between them.

So maybe this is already known under some other name!

Using finite fields instead of the integers?

I did all the above in the ring Z, the integers, which has the problem that you need a potentially unbounded number of bits to represent its members.

All of this also works over finite fields such as Z/7, the integers mod 7, as well as the integers themselves. In fact, it isn't even necessary to have a full field, which is why it's possible to do it in Z at all; you only need to be able to divide by the power of two that is your vector length. Unfortunately, this eliminates the most desirable group for computation, Z/256 or in general `Z/2**n`, since it will lose the upper bits of each character.

One option would be to use Z/257, the integers mod 257. Then you can represent the Hadamard transform results in a byte each, plus a usually-empty list of which transform results are equal to 256; or in 9 bits each.

Another somewhat more computationally expensive option, which might avoid that additional unnecessary message expansion, is to represent the entire message in some other finite field: start by interpreting it as a large number in base 256, then transform it into a sequence of digits in e.g. Z/7 or Z/257, then do the Hadamard computation in that field.

Using a field with fewer members makes the message longer, which improves the ratio lg N/N, which I strongly suspect is proportional to the number of Hadamard results you need to include to localize and correct a single error.

How do you find the peaks in the transformed error signal in Z/p, where big numbers can wrap around to be small ones again, and division can easily produce big numbers? I have no idea. But the sign-sequence-lookup approach should work, even though "sign" itself is not a well-defined concept in Z/p.

Constant time sets for pixel painting

Kragen Javier Sitaker, 2017-02-07 (2 minutes)

There's a data structure for representing sets of small integers, up to M integers less than N, using a count variable and two arrays, A of size M and B of size N. The membership test is

```
mem(i)  ⇐  B[i] < count  ∧  A[B[i]] == i
```

from which you can derive the constant-time item insertion, item deletion, start-unordered-iteration, iterate-next-item, and set-to-empty-set operations. Additionally the array contents do not need to be initialized, so creating a new such set is a constant-time operation (although not, I suspect, in standard C, since I think reading the uninitialized data in B[i] is undefined behavior).

You can also use this structure as a sparse array, either adding an additional array of data-values parallel to A or by making A an array of (small-int, data-value) tuples. And in particular I was thinking that this could be useful for scanline rendering of overlapping or self-intersecting polygons. The idea is that, to compute a scan line, you maintain a sparse array of pixel value changes (polygon boundaries), and the resulting scan line is the prefix sum of that sparse array.

This requires efficient sequential (rather than unordered) access to the items of the set, but this is readily provided by running a sorting step after you're done storing boundaries into the array, but before you start generating pixels. It's not quite constant-time per drawing operation, but it's pretty close.

(Asymptotically speaking, it would be better to iterate over the B array, since you need to visit every pixel anyway. In practice, this is probably silly.)

By using subpixel coordinates as the indices in B, you should be able to get decent antialiasing in the X dimension at little additional cost.

I don't know if you can extend this to painting translucent or gradient-filled polygons; that seems like it would require a nearest-neighbor kind of test to find out what color a given range currently was.

Topics

High-risk behavior in context

Kragen Javier Sitaker, 2007 to 2009 (5 minutes)

Most people in the US think riding in a car without a seatbelt is reckless, to the point that it should be prohibited by law — not to speak of activities like bicycling without a helmet, skydiving, skateboarding on busy streets, and so on.

The WHO's Burden of Disease Report from December 2004 gives death rates for various causes for various countries. Some selected data:

```
W149 III A Unintentional Injuries:      USA:  36.6; Argentina:  33.8
W150 III A 1 Road traffic accidents:    USA:  15.5; Argentina:  11.5
W157 III B 1 Self-inflicted injuries:   USA:  10.3; Argentina:  10.2
W060 II A Malignant neoplasms (cancer): USA: 191.9; Argentina: 157.6
W107 II G 3 Ischaemic heart disease:    USA: 176.8; Argentina:  90.3
```

These are death rates per 100 000 population for 2002. These numbers are affected somewhat by the age distribution of the countries; some of the causes of death are much more prevalent among the old than among the young, such as ischemic heart disease. So they will tend to be very low in countries where more of the population is young, either because people die young or because the birth rate has recently increased a lot (or infant mortality recently decreased a lot). Other causes of death, such as traffic accidents, affect various age groups more evenly, although there is still some variation.

I think the numbers might be more graspable as MTTFs, "mean time to failure", where "failure" in this case means "death". If you divide 100 000 person-years by the various causes of death, you get life expectancies from a fantasy world where everyone stays the age they currently are until they die, and are divided into groups only affected by a single cause of death:

```
W149 III A Unintentional Injuries:      USA: 2730; Argentina: 2960
W150 III A 1 Road traffic accidents:    USA: 6450; Argentina: 8700
W157 III B 1 Self-inflicted injuries:   USA: 9710; Argentina: 9800
W060 II A Malignant neoplasms (cancer): USA:  521; Argentina:  635
W107 II G 3 Ischaemic heart disease:    USA:  566; Argentina: 1110
```

These numbers are interesting for three reasons.

First, they give a sort of ceiling on the possible progress of medical science: we can probably defeat cancer through medical treatments, but eliminating suicide would require a kind of totalitarian mind control, and therefore is not ethically possible. But it seems plausible that we could raise average human life expectancy to several thousand years, merely by curing aging and other diseases.

Second, they provide a reasonable basis for comparing the two countries, risk-wise. Road traffic is slightly less dangerous in Argentina than in the US, despite the crazy driving; perhaps that's because people take public transit more, or because there's less traffic on the long-distance highways.

Third, they provide a basis for estimating the life-expectancy cost of various risky activities and the life-expectancy benefits of various

prophylactic measures, if we heuristically estimate their effects by adjusting known risks. If something doubles your risk of cancer, then your "cancer life expectancy" falls to about 300 years, modulo age-group differences — which means that it has something very roughly like a one in seven chance of killing you, but your *actual* remaining life expectancy of 40 years or so will only shrink by five years or so. (Less, really, since cancer risk is somewhat weighted toward your older years anyway.) On the other hand, if it multiplies your risk of cancer by 20 — as heavy smoking does for one particular kind of cancer — it shortens your life expectancy by quite a bit. And what about riding motorcycles?

Well, supposing that motorcycles are five times as deadly as cars (to their riders), they might reduce your "traffic life expectancy" from 6500 years to 1300 years. That risk *is* more or less evenly distributed over your lifespan, so if you have 50 years left, your risk of dying from the motorcycle would be about one chance in 26, and your life expectancy decreases by about a year.

I still wear a seatbelt, because I don't really get much benefit from not wearing one. But, as a result of calculations like these, I go ahead and bicycle to places even when I don't have a bike helmet handy.

Heat exchangers modeled on retia mirabilia might reach 4 TW/m³

Kragen Javier Sitaker, 2014-07-16 (updated 2019-08-21) (14 minutes)

I have this idea for a vastly more effective and efficient heat exchanger.

The basic issue is that heat exchangers have a tradeoff between thermal resistance and fluid resistance. Ideally you want to drive both of these parameters as far as possible toward zero, but thinner tubes or turbulence mean less thermal resistance and more fluid resistance, while thicker tubes or laminar flow mean less fluid resistance and more thermal resistance.

Consider recuperator-type heat exchangers, which use two separate fluids, typically in a countercurrent configuration.

I suspect you may be able to cut this Gordian knot using fractal geometry like that of the lungs. The idea is to perform almost all of the heat exchange along a very convoluted (wrinkly) fractal surface whose Euclidean dimension is 2 but whose Hausdorff-Besicovitch dimension is nearly 3. This surface is full of tiny capillaries, and it separates two volumes from each other, which we can denominate the "arterial" and "venous" volumes. These spaces are not themselves empty; each one contains two separate, non-communicating sets of branching passages which branch down to the capillaries. In one of these sets of passages, one fluid passes from the arterial space to the venous space; in the other, a potentially separate fluid passes from the venous space to the arterial space.

Each of these two spaces looks a lot like a cauliflower, with a branching tree structure (or rather two of them) of passages feeding a very rough surface.

The two sets of passages are separate and do not mix, but they intertwine progressively more intimately until, at the capillary boundary, they are separated only by very thin walls. Nearly all of the heat is transferred during the passage through the capillaries, and nearly all of the fluid resistance is also due to this passage through these thin capillaries; the passages in the arterial and venous spaces are so much wider than the capillaries that they offer relatively little resistance. But, because the surface through which the capillaries pass is so enormously convoluted, the total cross-sectional surface area of the capillaries is immense, allowing the fluids to pass with relatively little resistance.

You could imagine the convoluted membrane filling, say, 80% of a one-liter volume with a 50-µm thickness penetrated by many 10-µm-diameter capillaries some 10 µm apart. Roughly estimating, this gives you 16 m² of membrane pierced by 4 m² of capillary cross-sectional area dived among 40 billion capillaries, 2 m² for each of the two fluids. A flow rate of 500mℓ/s amounts to 250 microns/s through these capillaries; that is, the fluid spends about 200ms in the capillary, during which time it is in somewhat more intimate thermal contact with the other fluid 20µm away through the capillary wall than it is with its own predecessor or successor fluid 50µm away through the capillary.

(Branching to 20 billion capillaries involves some 34 levels of branching if they are binary.)

The cross-section through which the heat must travel by conduction is some twenty times (5× length, 4× four directions if the capillaries are in a checkerboard through the membrane) the cross-section of the capillaries themselves, so 40 m². Aluminum has a thermal conductivity of some 205 W/m/K; multiplying that by 40m²/10μm gives us 820 MW/K, which is a dramatically enormous number.

Some random online pipe pressure drop calculator tells me that, given .000000000025 l/s (25 pℓ/s, 250 microns/s * 10 microns * 10 microns), pipe diameter of 0.010 mm, pipe roughness of 0.001 mm, and pipe length of .000050 m, the flow should be laminar and the pressure drop should be 0.05 millibar if the fluid is water. That's 5 Pa or a column height of 0.5 mm of water. God only knows if it's using some approximation or other that isn't valid at these scales, but it's somewhat reassuring.

These two figures together suggest that you should be able to pump considerably larger amounts of heat and fluids through this heat exchanger. If we consider a 5 kelvin loss acceptable, then maybe we can deal with 4100 MW in our one-liter heat exchanger. Water can hold perhaps 100kcal/kg; that gives us 9800 kg/s, which is 9800 ℓ/s, which would be 4.9 m/s through the 2m² of capillaries, which amounts to 0.49 microliters per second per capillary. Entering this into the same calculator provides me with an answer of 999.83 millibar, or 10.2 meters of water column height, which is to say, one atmosphere.

If we take this seriously, it would seem that we can probably nanofabricate a 4-gigawatt water-based countercurrent heat exchanger with a 5-kelvin temperature drop, with only one atmosphere of pumping pressure, in a single liter. I find these numbers so outlandish that they are hard to take seriously, but I wonder how close we could really get.

(In some cases you might have a much lower heat capacity per unit volume, for example with air, and desire a much lower delta temperature, like 5 millikelvins. I think this is also achievable.)

Previous work

Apparently Lingai Luo wrote a book on this in 2013, "Heat and Mass Transfer Intensification and Shape Optimization"; they proposed doing this in 2001. In 2002, Yongping Chen and Ping Cheng wrote a paper, "Heat transfer and pressure drop in fractal tree-like microchannel nets", surveying the existing work and proposing a two-dimensional coolant duct structure for cooling semiconductor chips. They have 275 citations in Google Scholar, and since then there has been a lot of work in convection in porous and complex structures, including a 2004 book by Bejan, Lorente, and others. It contains this remarkable passage:

> Tree-shaped flows in balanced counterflow are a prevailing flow structure in subskin vascularized tissues (Weinbaum and Jiji, 1985; Bejan, 2001). The purpose of the intimate thermal contact between the streams in counterflow is to minimize the leakage of heat (an enthalpy current) along the counterflow, from the warm end to the cold end. The counterflow provides thermal insulation in the flow direction: this insulation effect has its origin in the minimization of thermal

resistance in the direction perpendicular to the streams (Bejan, 1979b, 1982). This special feature, and the fact that the streamwise leakage of heat vanishes as the thermal contact between streams becomes perfect, is the reason why the balanced counterflow is the best arrangement from the point of view of minimizing heat transfer irreversibilities.

Unfortunately, although he arranges his flows dendritically, Bejan's work does not seem to contemplate distributing the capillaries themselves over a fractal surface, although he alludes to lungs at some point.

He also describes our lungs:

The alveoli act as the primary gas exchange units of the lungs. It is estimated that an adult has approximately 600 million alveoli with a surface area for gas exchange of about 75 m^2, which are perfused by more than 2000 km of capillaries (see Section 6.2). ... In order to optimize its function (see Section 4.11), the airway tree exhibits 23 levels of bifurcations after the trachea (Weibel, 1963).

Note that this 75 m^2 in a few liters is comparable to the exchange area I described above for the heat exchanger.

That topology-optimization guy in Scandinavia has been using topology optimization to design heatsinks using CFD simulation of convection. Understandably, they come out dendritic.

Luo's book is about "process intensification", which she defined in 2001 as "enhancement of the density of flux transferred between two phases through an interface", which covers the heat-exchanger thing above as well as many other possibilities. Its chapter 4 is all about heat exchangers, and it says:

Microchannel heat exchangers usually have a surface area density above about 10,000 $m^2 \cdot m^{-3}$ (Shah 1991). One typical example in nature is the human lungs, as a very high performance ultra compact heat and mass transfer system which have a surface area density of about 17,500 $m^2 \cdot m^{-3}$.

The numbers I postulated above work out to about 80,000, so it isn't too far from what people were already achieving in 1991. A Karlsruhe project got 18000 MW/m^3 by these techniques, with a pressure drop of 4 bar (400 kPa), a 10-kelvin temperature jump, and a residence time of about 2ms, while my calculations above suggested you should be able to get 4 terawatts/m^3 (i.e. 4,000,000 MW/m^3), which suggests that my calculations are perhaps a bit optimistic but not entirely out of the ballpark. The Karlsruhe device, however, did not use a fractal geometry, and it used crossflow rather than counterflow.

Luo also points out that for microchannel heat exchangers you probably don't actually want to use a highly conductive material, because it conducts heat longitudinally in the wrong direction. You'd be better off with a highly insulating material, something silly like polyethylene! And this is far more important for the kinds of geometries I'm considering.

Luo does at some point start using fractal designs for her multi-scale distributors, but never for the capillary-bearing surface itself. She proposes a multi-scale branched tree structure, but don't give performance figures. She does cite da Silva et al. 2004 ("Constructal multi-scalar tree-shaped heat exchangers") and Zimparov et al. 2006 ("Constructal tree-shaped parallel flow heat exchangers"). The designs in Zimparov's and da Silva's papers are basically the same as the Chen and Cheng 2002 paper: essentially planar trees.

Luo's Chapter 7 shows the optimization of the distributor/collector

network from chapter 3 (which is basically the same as Chen and Cheng's) using cellular automata to improve flow, but never leaving two dimensions.

Sun, Huang, and Zhang did a paper in 2015 where they did a CFD analysis of the Chen and Cheng planar fractal heat exchanger.

Poltorak applied for a US patent in 2012 (publication 20120285660 A1, application US 13/106,640) which is more about branching heatsinks fractally to keep them from whistling. He's now formed a patent troll company to extort money with his patent, called Fractal Heatsinks Inc. But this is not really relevant.

As mentioned in Recuperator heat storage (p. 594), Galen discovered heat exchangers with this structure 1800 years ago dissecting animals, and in anatomy they are known as retia mirabilia. They are used both for heat transfer (for example, to prevent heat loss in the legs of sheep) and for mass transfer (for example, in all mammalian kidneys).

Other applications other than recuperator-type heat exchangers

Although heat exchangers themselves are very important — a perfect heat exchanger makes compressed-air energy storage 100% efficient, for example — there are other possible uses of this geometry.

Luo's book mentions a number of applications of "process intensification" beyond just heat exchangers, and Luo's and Bejan's books both go into some detail on mass transfer in lungs and kidneys. But in fact this kind of broccoli-like design can be used for a variety of other things as well:

- If you have just a single fluid, this kind of design provides a more efficient regenerator-type heat exchanger, although the advantage there over the traditional designs is smaller. You can use it with modern microencapsulated phase-change materials to get unprecedented regenerator performance.
- Catalytic chemical processes can, in some cases, benefit from mixing reagents uniformly and intimately as they pass over a catalyst. This design provides that possibility; the only missing piece is to run both fluids in a co-current direction and join their capillaries.
- Non-catalytic chemical processes, too. Consider feeding fuel (e.g. propane) and oxidizer (e.g. oxygen) through the two sets of passages at a controlled rate, mixing and heating evenly at the surface and producing a controlled hot blast of oxidation products on the other side.
- If some substance like water can diffuse through the walls between the capillaries, this design can work for mass transfer as well as heat transfer.
- If the substance you're transferring heat to is water, you can flash-boil it and get a steam explosion. A .22 LR pistol puts about 75 J of kinetic energy into its bullet in about 2 ms, a power of about 40 kW. The case on its cartridge is 15.6 mm long by 5.7 mm diameter, about 400 mm^3. That works out to about 94 GW/m^3 (94 MW/ℓ), so even the Karlsruhe heat exchanger mentioned above, at 18 GW/m^3, is only a factor of five below the power density of a handgun

cartridge, modulo the Carnot limit. This means you can totally make a steam-powered gun that's competitive in size and power to explosive-powered guns.

Needle binder injection printing

Kragen Javier Sitaker, 2019-08-05 (12 minutes)

Another atypical 3-D printing process I'd like to try out: injecting binder into a powder bed through an array of needles as they are withdrawn from the powder bed. Unlike normal powder-bed processes, this doesn't require depositing the powder layer by layer or smoothing each layer.

Basic single-needle process

You have a build chamber filled with loose powder. In the simplest form, there is a long hollow hypodermic needle sunk all the way through the build chamber. The needle is filled with a fluid binder, like those used in inkjet powder-bed 3-D printing processes. It is withdrawn gradually, during which time the flow of binder through them is alternately forced by pressure and stopped by a valve. This results in selectively depositing binder along the path of the needle, selectively solidifying the powder bed at the locations where binder is being extruded. When the needle is fully withdrawn, it is moved laterally and inserted in the new location, and then the process is repeated.

You need to inject enough binder to affect a radius in the powder bed equal to at least half the hole spacing. Assuming the powder-bed material is isotropic, this limits your resolution in the along-needle axis as well; for example, if the holes are 10 mm apart, you need to inject enough binder to spread 5 mm in all directions from the insertion point, which probably means you can't get much better than 10-mm resolution in the needle-withdrawal direction. You can probably control a small valve at 1 kHz or so (reed relays go up to 30 kHz, and inkjet print head pumps are controlled at some 5–20 kHz), so the limit on printing speed is then the needle withdrawal speed, unless you're withdrawing the needle at 10 m/s or more. This speed is probably limited by needle breakage.

Multi-needle variants

This can be done with many needles in parallel. Inserting sixteen parallel needles, moved as a single unit in a carriage, offers the possibility of printing sixteen times as fast as the single-needle process; additionally, if sixteen pixels in one dimension is adequate, the movement mechanics can support only two orthogonal axes rather than the three needed by the single-needle process.

More generally, if you have enough needles to cover an entire dimension of the build chamber, you can use only two orthogonal axes of movement. For example, with 2-mm needle spacing and 100 100-mm-long needles, you could print a 200 mm by 100 mm by 1000 mm print space with a single fast movement axis of a bit over 100 mm (probably moving the needles) and a single much slower 1000-mm movement axis (probably moving the powder bed).

If you have a larger number of needles, you can print with only a single axis of movement; for example, with 20-mm needle spacing and 144 needles of 120 mm each, you could print a 240 mm by 240 mm by 120 mm print volume in a single movement.

I suspect machines with large numbers of needles will tend to be unreliable, as the larger numbers of needles may experience clogging, breakage, and plastic flexion more often.

Layered hybrid

Ultimately the needle length will limit positioning precision, due to flexions from vibration and random powder-bed anisotropies or nonuniformities during insertion; reliability, due to needle breakage; and extrusion rate, if that isn't limited by valve speed, due to larger fluid friction in longer needles.

A more complex machine that combines some of the advantages of traditional powder-bed 3-D printers with the advantages of this design would deposit a thick layers rather than the usual thin layers, insert the needles only to the bottom of the new layer, and selectively bind that layer in 3-D. This permits the use of shorter needles at nearly the same printing speed. Some designs of machine may be able to use the needle carriage positioning to compact and level the powder bed.

Speed comparison

RepRap-descended FDM printers have a precision of about 100 μm and a deposition rate of about 20 mm/sec (times 500 μm times 300 μm, typically, although this depends on your print settings). If we approximate crudely, this amounts to a "voxel rate" of about 3000 voxels per second, but you only pay for the part of the build volume you're actually building things in.

This needle-binder-injection printing process can produce about 1000 voxels per second per needle, so with 16 needles, it should be about 16000 voxels per second. However, this includes the unused parts of the build volume. So that variant should be similar to RepRap-style printers in its productive capacity; the variants with more needles should be faster.

Inkjet-based powder-bed processes like those pioneered by Open3DP produce much higher voxel rates, on the order of 100k voxels per second.

Needle diameter and packing

Narrower needles are more flexible and, barring some kind of active control, will produce larger positioning errors. They are also more prone to breakage and produce more fluid friction. However, it's desirable for the powder-bed particles to be larger than the needle opening to limit clogging during insertion.

The space occupied by the needles after insertion probably needs to be occupied by void spaces between particles in the powder bed before insertion. This limits the needle diameter to a fraction of the hole spacing. This can be partly circumvented, in the designs that need more than a single insertion to complete a print, by spacing the needles on the carriage much further apart than the holes. For example, printing a 512×512 matrix of 1-mm-apart holes with 16 needles, the needles can be in a line in a 495-mm-long carriage spaced 33 mm apart rather than 1 mm apart, and can be moved laterally by 1 mm in between insertions rather than 16 mm, so that after printing a whole 513-mm-long slab of holes, each needle has made 32 adjacent

holes rather than 32 holes spaced 16 mm apart interspersed with the holes from the other needles.

(Variants: a hexagonal matrix is better than a square matrix, and staggering the needle insertion order somewhat, so that subsequent holes are not spatially adjacent, is probably better than making holes one next to the other.)

Needle design

To ameliorate the clogging tradeoff, perhaps the needle opening could be smaller than the bore through the center of the needle, unlike the usual practice with hypodermic needles. This would allow the needle to have the clog-avoidance capability of a very thin needle, but the stiffness and much of the fluid friction of a much thicker one.

A potential problem is that, once the needle is partly withdrawn, the empty bore behind it may channel binder being injected into what we hoped was higher up, allowing the binder to affect a much larger area than desired. It might be possible to ameliorate this somewhat by locating the binder injection ports on the side of the needle, some distance away from its tip, like the inflation needle for a basketball, rather than its end. Binder could still diffuse back into the channel from the powder bed, but the problem would be less serious.

Materials

Most of the material systems published by Open3DP should work, although the viscosity of the liquid binder may be a smaller consideration than it was for them. Not only might this reduce the need for alcohol, it opens up the potential of injecting more viscous binders such as sodium silicate.

Many of the candidate material systems described in 3-D printing by flux deposition (p. 466) and Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) are also applicable to this form of 3-D printing. Some of them will not work as described because there is no practical solvent to dissolve the binder in, but perhaps some of them can be made to work by depositing a soluble precursor (such as calcium sulfate instead of calcium hydroxide); by including all the reagents and a low-temperature organic binder such as carboxymethylcellulose in the powder bed, then injecting simply a solvent such as water, then removing unbound powder before firing; or by including all the reagents, and injecting a suitable solvent and/or catalyst to allow them to react.

However, as I've envisioned it here, this device can probably finish a print faster (in minutes), so faster-hardening binder systems may be worthwhile. And the needles have the possibility of injecting gases as well as liquids; two very interesting gases in this context are CO_2 and steam. CO_2 and heat applied with steam might be able to accelerate the hardening of slaked lime, which normally takes hours. And CO_2 injection is well-known as a way to harden sand that is stuck together with unhardened sodium silicate, acting within a few seconds. (Afterwards, you can wash off the unhardened sand and sodium silicate with water.) As I suggested in Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196), possible alternative sources of CO_2 include $CaCO_3$ and $NaHCO_3$.

Steam can deliver a great deal of heat very quickly to a fairly precisely located position, but of course it heats up the needle to 100°,

or more at greater-than-atmospheric presure. This means that the needle needs to be withdrawn quickly enough so that conduction from the needle surface is very small compared to the heat delivered by the condensing steam.

Particular cements that might be amenable to fast steam hardening include plaster of Paris, hygroscopic salts (such as NaCl, $CaCl_2$, sodium acetate, sodium silicate, or magnesium oxide), and organic gums and other organic binders (such as carboxymethylcellulose, gelatin, agar, guar gum, and gum arabic). Under pressure, steam condensation can reach high enough temperatures to melt many organic thermoplastics, but most of them are vulnerable to hydrolysis and must usually be dried before softening with heat.

Needle injection of nonpolar organic solvents like acetone, methyl ethyl ketone, ethyl acetate, or alcohol, either in liquid or vapor form, might be a reasonable way to cement a powder bed containing soluble organic plastics in powder form as a binder. It might also be an effective way to selectively deposit heat within the powder volume without subjecting fragile plastic molecules to aggressively-hydrolyzing water.

Either reactive gases like H_2S, Cl_2, or SO_2 or solvents might also be usable to provoke either hardening chemical reactions, or, in a reversal, the destruction of a previously solid binder and the selective conversion of remaining inert fillers into powder. This does, however, require that the solid material be sufficiently yielding and/or porous to get the needles into it in the first place. Selectively dissolving styrofoam with acetone, ethyl acetate, or gasoline is one example, though lacking in filler; EVA foam is another candidate material.

Topics

Material merits

Kragen Javier Sitaker, 2016-05-08 (6 minutes)

I was thinking about the relative costs of materials, and it occurred to me that there are three principal figures of merit on which you might consider using a material for mechanical engineering:

- Cost per tensile support: dollars per newton-meter before it breaks
- Cost per tensile stiffness: ???
- Cost per impact energy: dollars per joule

Of course, for non-mechanical and even manufacturing purposes, many other properties are relevant: transparency, color, smell, machinability, magnetic permeability, conductivity, dielectric constant, thermal conductivity, dielectric strength, melting point, electronegativity, heat capacity, chemical resistance, UV resistance, viscosity when molten, resistance to galling, lubricity, fatigue resistance, and so on. And even for mechanical purposes, ratios of weight or volume to tensile support, stiffness, and impact energy are of secondary importance; and there are other kinds of stiffness and strength other than tensile: shear and compressive, normally. Additionally, these fundamental properties give rise to emergent properties like Vickers hardness.

But mostly those three are the ones we care about.

Cost is an extensive quantity — twice as many grams of the same alloy costs twice as much — so, to take these ratios, we need to convert tensile strength, stiffness (Young's modulus), and impact resistance into extensive quantities too.

Cost per tensile support

Consider ASTM A36 structural steel, with a yield stress of 250 MPa. A square-millimeter fiber of it can thus support 250 N, about 25 kg weight. Suppose it costs US$0.60 per pound ($1.32/kg) and has a density of 7.8 g/cc; then it costs about 10.3 μ$ per cubic millimeter, which means that it costs 10.3 μ$ per millimeter to support 250 N.

Normalizing, this works out to about 41 μ$ per newton-meter. If you need to hang 1000 N one meter below a support, or 10kN 100 mm below, this steel will do it for you for 4.1¢.

This is just reinterpreting 250 MPa from 250 N / m² to 250 N m / m³, then dividing by the density to get 32 kN m / kg. Dividing the cost by that gets you to the 41 μ$ / (N m):

```
$ 0.60 / pound / (250 MPa / (7.8 g/cc))
```

Cost per tensile stiffness

The Young's modulus E has, like tensile strength, units of pressure; it's the stress that would stretch a cable to twice its natural length if it stayed Hookean over that range, which nothing does. A less fanciful, but more arbitrary, way of looking at it is that it's a million times the stress per microstrain.

If we consider the square-millimeter cable of A36 steel again, whose Young's modulus is about 200 GPa, it will elongate by a

microstrain under a force of 0.2 N. But we have a somewhat different situation. While the force needed to break the cable is independent of its length, that microstrain is a micron if it's a meter long, or ten microns if it's ten meters long. But if we make the cable ten times thicker instead of ten times longer, it becomes ten times stiffer rather than ten times less stiff.

How do we derive an extensive quantity from this, so that we can divide the cost per pound by it? I have no idea. I have to think about this.

Cost per impact energy

When our aforementioned square-millimeter cable of A36 steel is stretched, it stores energy in its elastic deformation. If deformed too much, beyond its tensile strength, it will deform plastically or break (sometimes the difference between these is important, but I'll gloss over it here). The ratio between its tensile strength (yield stress S in this case) and its Young's modulus is its elongation at break (or at yield), about 0.125%†, which is an intensive quantity; but in itself that doesn't tell us much.

† this differs by more than two orders of magnitude from the elongation at break in MatWeb, and ultimate tensile strength isn't that much higher than yield stress, so I'm probably wrong.

It turns out, though, that the energy it can store is also an intensive quantity — which ought not to be surprising in retrospect. If we integrate the force over the deformation distance up to the yield stress times the wire length, we get the energy that can be stored in the cable before breaking. This energy is proportional to the force, which is proportional to the cross-section of the cable and doesn't change with its length; it's also proportional to the distance, which is proportional to the length of the cable and doesn't change with its cross-section. The force $F = EAx/L$ is also proportional to the Young's modulus E: it's the cross-section A times the Young's modulus E times the distance x, divided by the length to get the strain. So we have $\int EAx/L\ dx$ from $x=0$ to $x=LS/E$, so the total energy is $\frac{1}{2}E\ A/L\ (LS/E)^2 = \frac{1}{2}ALS^2/E$. The AL part of this is just the volume of the wire, so $\frac{1}{2}S^2/E$ is the energy that can be stored per unit volume.

In the case of A36 steel, this gives us an impact energy (before plastic deformation) of about 156kJ/m³, or 20 J/kg, which works out to 6.6¢/J of elastic deformation at the US$0.60/pound price above:

```
$ 0.60 / pound / (1/(7.8 g/cc) * (250 MPa)^2/200GPa/2)
```

Use crit-bit trees as the fundamental string-set data structure

Kragen Javier Sitaker, 2013-05-17 (3 minutes)

DJB makes a good argument for using crit-bit trees as the fundamental string-set data structure: you get to use two words of memory per string, or three if you store the strings as pointers instead of inline in the nodes.

The trouble is, how do you generalize it? A hash table can store pointers to arbitrary objects as long as they support .hash() and .equals() methods. But crit-bit trees can apparently store only strings.

For a small set of strings, you could perhaps do even better. For up to 128 strings, say, you could use parallel arrays:

```
uchar left[128],  // left child pointer (as array index)
      right[128], // right child pointer
      nbits[128], // number of bits to skip from parent node bit offset
      start[128], // string #3 is contents[start[3]:start[3]+length[3]]
      length[128],
      contents[256];
```

These definitions support strings of up to 256 bytes total, with no shared prefix of 256 bits, 32 bytes, or more; the high bit being set in a pointer indicates a leaf node. Increasing `start` to 16 bits per entry allows your strings to be up to 255 bytes each, removing the aggregate limit.

An empty dict in CPython costs about 180 bytes. With a structure like

```
typedef struct { uchar left[N], right[N], nbits[N]; object *out[N]; } tinydict;
```

you have some 7 bytes per potential entry in your dict; that gives you Python's degree of overhead at N=25, so N=16 is probably a reasonable choice, using up 112 bytes per tinydict. (At which point you could save a little further space by using nibbles, but don't.)

An amusing thing about these parallel-array structures: like PHP's arrays, they have an implicit sequence to them, the sequence of array indices. You could imagine a routine that shuffles the order of treenodes around without changing the shape of the tree, thus providing an additional traversal order.

A larger `tinydict`:

```
typedef struct { u16 left[N2], right[N2], nbits[N2]; object *out[N2]; } smalldicto
o;
```

This can support up to 64Ki items.

What does the protocol for an `object` look like? Presumably you have a `.key()` method which returns a sequence of bytes — perhaps a lazy sequence, one or a few words at a time.

As an amusing exercise, perhaps many objects could be normally stored as strings, with a small cache (a few kilobytes) of objects built in a pointer-filled manner.

Burst computation

Kragen Javier Sitaker, 2017-03-20 (13 minutes)

Timesharing was originally intended to make computing power more accessible by allowing you to pay for your average usage rather than your peak usage, also promoting economies of scale through centralized computing facilities, in the same way you could publish classified ads in the newspaper from time to time without buying a web-fed offset press. In the day of the US$58 (in Argentina! retail!) 4-CPU-core 4-GPU-core 1200MHz Raspberry Pi 3, this might seem like an outdated concept. But there are still tasks that benefit from more computation than the Pi can provide.

(At some point in the 1970–1990 time frame, the economies of scale moved from the individual computers to the mass-production facilities for their integrated circuits, so the cheapest way to provide a lot of computing power is currently to buy a large number of some computing device that is produced in high volumes. Rather than amortizing the costs of building a powerful computer over many users, we amortize the cost of designing and making the masks for a powerful computer over many computers.)

Roy Longbottom benchmarked the Pi 3; he got 711 million Whetstone operations per second, in the neighborhood of 300 Whetstone megaflops (single precision), 2500 VAX MIPS, 180 Linpack double-precision megaflops, 486 Linpack single-precision megaflops with NEON, and 200 double-precision megaflops when memory-bandwidth limited (520 in 64-bit mode). Linux measures it at 38 BogoMIPS.

By comparison, the NVIDIA Pascal GP100 on a mezzanine P100 GPU Accelerator card, introduced in 2016, provides 5 double-precision teraflops, about the same as 25000 Raspberry Pi 3s. It isn't available in Argentina, but Amazon has it for about US$1500, which is about US$0.06 per Pi, showing that there still are *some* economies of scale in computation.

Moreover, I commonly run intensive computations where latency is important, but the duty cycle is low — my peak usage would ideally be much higher than my average usage. With the advent of per-minute Openstack vendors like Orange's Cloudwatt and per-request services like AWS Lambda, it seems like it might be quite feasible to spin up a temporary virtual supercomputer on demand.

Consider, hypothetically, that I am doing some interactive computations, like in IPython or whatever, and I would like to keep my interactive response time under a second; maybe I am doing 10 such computations in a minute, 10 such minutes in an hour, and 10 such hours in a day. And let's say that these computations are embarrassingly parallel, and each such computation involves about two minutes of calculation time on a GP100: 600 trillion floating-point operations.

It would in theory be possible to fulfill this wish by buying three million Raspberry Pi 3s for US$174 million, plus the networking and electrical equipment to harness them together. If we lower our aims to being able to complete 100 such computations per hour, we only need 83,000 Pis, costing only US$4.8 million.

A much more practical approach would be to buy NVIDIA GPUs and ATX PCs to plug them into, maybe two PCs per GPU; if this costs US$1750 per GPU, then we need two GPUs (US$3500) to provide the 36-second response provided by the five-million-dollar Pi cluster, or 72 GPUs (US$126,000) to provide the wished-for one-second response.

Cloudwatt charges €0.0102 per hour for its t1.cw.tiny-1 instances, comparable to DigitalOcean's smallest "droplet", and €0.0558 per hour for n1.cw.standard-1 instances, each with one virtual CPU; an "instance de type haute performance" n1.cw.highcpu-2 costs €0.0870 per hour and has two virtual CPUs. Supposedly these virtual CPUs are equivalent to one Xeon processor thread, but they don't seem to say what clock speed or generation of Xeon.

Suppose we're talking about the Xeon E5-2687W v3 Haswell-EP system Donald Kinghorn benchmarked at 788 gigaflops (Linpack, double precision) at 3.1 GHz in 2014. That's across two CPUs with 10 cores each. Then we should expect about 39 gigaflops per core, and maybe 20 gigaflops per core thread (assuming "hyperthreading" gives two threads per core). Then our 600 trillion floating-point operations work out to about 30000 vCPU seconds. This means that to get the computation results in a second, we need to spin up about 15000 n1.cw.highcpu-2 instances, then shut them down after they're idle for a minute, so we get billed for two minutes for each of them, 30000 minutes or 500 hours in all, €43.50.

Recall that this is €43.50 for one minute of computation (with a 17% duty cycle within that minute), and we're doing such minutes 100 times a day, so it works out to €4350 per day. This comes out to the US$126,000 (€117,000) cost of the 72-GPU cluster in only 27 days.

If we instead accept a 36-second response time, we only need about 420 n1.cpu.highcpu-2 instances, but we need them for ten hours a day, which works out to 420·10·€0.0870 = €365 per day, which works out to 320 days to add up to the cost of the cluster.

An instructive comparison would be the cost of a personal cluster of Xeons, since they might be a less efficient way to run your problem, and a more direct comparison to Cloudwatt's pricing.

I think a currently typical price for a 3.06GHz six-core Xeon X5675 CPU is currently US$215 including shipping. BOINC measured the E5-2687W mentioned above at 3.34 GFlops/core and the X5675 at 3.13 GFlops per core, and SETI@Home has a similar list , so the X5675 cores are probably more or less comparable to the ones Kinghorn was benchmarking. The X5675 is for an LGA-1366 socket, and a currently typical price for a motherboard like the SuperMicro X8DTN+ with two LGA-1366 sockets might be US$430, and it has on-board Ethernet. (I'm not 100% sure this motherboard will work for this processor, but a similar one should.) 4GiB of DDR3-1333 memory costs US$40 now, and 16GiB might be a reasonable amount to include in such a machine, so US$160.

So a Xeon machine with 12 Xeon cores on two CPUs with 16GiB of RAM might cost US$1020, not counting power supply, case, and labor. A cluster equivalent to 420 n1.cpu.highcpu-2 instances would have 210 cores and thus 18 machines, US$18,360 (comparable to the US$3500 GPU cluster); the 15000 instances would be 7500 cores and thus 625 machines, US$637,500 (comparable to the US$126,000

GPU cluster).

So, in effect, Cloudwatt lets you use a US$18k cluster for 10 hours a day for €365 a day (US$392/day), which pays for the cluster in 46 days, or a US$637,500 cluster for 100 or 200 minutes per day for €4350 a day (US$4650/day), which pays for the cluster in 137 days. The higher "efficiency" in the second case is because, in our scenario, the duty cycle is lower for the more powerful cluster — you only have instances spun up for 10 or 20 minutes out of each of the 10 hours you're using the thing.

Nevertheless, Cloudwatt's pricing is so high that they are only a good choice if you are experimenting with computation for a few days, even in an apples-to-apples comparison with CPU hardware bought outright. If you continue to do computation, you would be better off buying your own computer; the payback time is only one to four months, and the useful life of the computer is probably 18 months or more.

AWS Lambda charges per 100ms multiplied by RAM usage, specifically $0.00001667 per gigabyte-second, which I guess is 16.67 microdollars per gigabyte-second or 16.67 femtodollars per byte-second, plus $0.0000002 (0.2 microdollars) per request.

100ms is three orders of magnitude finer granularity than the per-minute billing of Cloudwatt, so you could imagine this would result in substantially improved costs.

Let's suppose you could farm out these one-second computations into 30000 AWS Lambda requests (maybe through four levels of request tree, each tree request farming out to 16 subrequests, or something) which each take one second and use 256MB of RAM during that time. That's 30000 seconds at 256MB, which works out to US$0.128 for the time for the computation, plus US$0.006 for the requests. At 10 computations per minute, 10 minutes per hour, 10 hours per day, that's US$128 per day. This is considerably better than Cloudwatt's US$4350 per day; it doesn't become more expensive than buying the US$126,000 72-GPU rig for almost 1000 days, which is probably longer than the depreciation time for the hardware, even in the current post-Moore era.

(There's the potential problem that even AWS Lambda functions in Java might suffer a serious performance penalty over native code.)

However, there's still a large efficient region in between Amazon's pricing and what it's economically feasible to provide. The 72-GPU rig in our scenario could support multiple users. If we expand it to a 144-GPU rig (US$252,000), then three users need to submit a computation during the same second for the response time to exceed the usual second.

It isn't obvious to me how to calculate the load statistics in closed form, but whipping up a quick numerical simulation, it seems like with repeated simulations with 10 users that all use the cluster during the same hour, typically about 30 of their 1000 requests (10 per user; 3%) will be submitted during a second which has two or more other requests. This lowers the cost per user to US$25,200. So you could probably charge each user US$50 per day (US$5 per hour) and still come out ahead, assuming answering only 97% of requests in under 1½ seconds (answering most requests in 500ms) is acceptable. Scaling up the cluster further should allow lower costs per user with lower numbers of slow requests.

Note that the cluster could produce other value streams as well; the 10,000 requests per day still leave it 88% idle, so it could run lower-priority batch computations at the same time.

At a smaller scale, you could imagine 32 users using US$58 Raspberry Pi 3s (US$1900 total) submitting 250-millisecond tasks to a shared dual-GP100 rackmount box (US$3500), which has the number-crunching power of 50000 Pis. At the same 100-task-per-hour pace, nearly all of the tasks will be completed in under 500ms, though the Pi would need four hours to complete one of them — in effect, at this low utilization, each of the 32 users are getting nearly the full benefit of a GP100 or two, for only US$170 each.

(The costs for the rackmount box may be a bit low. The US$430 motherboard I linked earlier has 18 memory slots and supports up to 144 GiB of RAM; for another US$720 you could give it 72GiB of RAM, which would work out to 2¼ GiB per user, which might be a bit low. The motherboard, a single US$215 CPU, and 72GiB of RAM work out to US$1365, bringing the total cost of the shared computer to US$4365, adding an extra US$42 per user, US$136 of shared computer per user and US$194 per user in total.)

This is one reason Google (and, presumably, Facebook) is so effective at beating competition: it has been standard practice for more than a decade that everyday engineers can fire off a 10,000-CPU computation and see results within a few minutes — though not, at the time, less than a second.

Micro pubsub

Kragen Javier Sitaker, 2017-06-15 (8 minutes)

HTTP has an "ETag" attribute, short for "entity tag", to identify the current state of a resource, which can be usefully used in four ways:

• In the response to a GET or HEAD request, to inform the client what the current ETag of the resource is, making the other three uses possible;
• In the If-None-Match header of a GET request, to request that the server not send (a representation of) the resource if it hasn't changed (validating the cache to ensure it hasn't gotten too out of date);
• In the If-Match header of a PUT request, to execute a kind of atomic compare-and-swap for safe lock-free concurrency, preventing the request from executing if the resource has changed since it was last fetched;
• In the If-Match header of a byte-range GET request to ensure that the underlying file hasn't changed in a way that would make previous byte-range requests invalid.

These three kinds of concurrency control, however, are limited by the request-response nature of the REST architectural style, which can only propagate invalidation notifications by polling; thus, it faces an unavoidable painful tradeoff between expected notification latency and polling load, as described in Khare's dissertation. Various approaches to this have been suggested, including Khare's proposed WATCH method for HTTP and the RFC 7641 Observe option for CoAP, which are very similar to one another, but in practice the most common solutions today are HTTP long polling and WebSockets, which are effectively ways to tunnel arbitrary application-layer protocols on top of HTTP.

There are a number of potential problems with the straightforward implementation of the Observer pattern in a distributed system, modified only by a timeout, as proposed by Khare's dissertation and RFC 7641:

• There is no flow control to the stream of update messages. If the client has a 10kbps connection, while the server has a 100Mbps connection, then under circumstances of constant updates, a 500-byte subscription can result in the client's network connection being overwhelmed by four orders of magnitude more traffic than it can handle, until the subscription expires.
• One of the great benefits of REST is its stateless-server constraint; by storing all session state on the client, it enables easy horizontal scalability of servers (including by serving the same resource from many physical servers), allows servers to operate reliably and correctly even with extremely limited resources, simplifies failure recovery, and permits extremely large client-to-server ratios. These event-notification proposals, however, obligate servers to maintain unbounded amounts of session state on behalf of clients.
• Thus, the subscription itself becomes a long-lived resource on the server; to support subscription inspection and cancellation, we begin

to desire defined protocols and content-types to manage the subscription, not to mention authentication and access control lists. This adds undesirable complexity not only to the server but also to the protocol suite.

• A typical factor we examine for network deployments nowadays is their DoS potential, as measured by their amplification factor — if an attacker forges a request from a victim, how much traffic can they direct to the victim? These proposals have potentially very large DoS potential.

I would like to suggest a minimal extension to HTTP and similar protocols which covers most publish-subscribe use cases and largely solves the above problems.

The solution

The client includes a new ETag-Change-To header which includes a webhook URL. The server is free to ignore this header or to add the webhook URL to a set of observers it maintains for the current ETag of the resource being requested. When the resource's state changes, it sends the URL of the resource in an HTTP request to each webhook in the observer set for the old ETag, then discards that observer set. This allows the client, if they are still interested, to immediately retrieve the new state of the resource (possibly resubscribing), while bounding the maximum possible traffic to one in-flight message at a time, and the maximum possible cost imposed on the server to sending a single such message.

By atomically adding the webhook to the set associated with the ETag associated with the representation that was actually retrieved, we ensure that no updates happen after the retrieval but before the subscription.

In contexts like CoAP, protocols other than HTTP might be more appropriate for delivering these cache invalidation notifications. For example, an additional CoAP Response message — as with the RFC 7641 Observe option, but lacking the payload — may be a perfectly adequate solution, since CoAP imposes no constraints on how far in the future that message can be sent; or a CoAP Request message analogous to the HTTP request to a webhook may be more appropriate.

This approach is not better under all possible circumstances. At times, as mentioned in Khare's dissertation, it's desirable to have many update messages in flight at the same time; a stock-price logging application might prefer to see all the intermediate market prices of a stock, even when they are milliseconds apart and it is separated from the data source by hundreds of milliseconds of latency. However, there is a very broad range of applications for which the drawbacks of such streaming data are greater than their advantages.

Furthermore, in many cases, the appropriate response to such a cache invalidation message is not to update the cache, but rather merely to purge the cache, possibly generating further cache invalidation messages.

Since the server is not required to store the ETag-Change-To webhook, the server may suffer a hardware failure, and in any case the invalidation message may be lost, the client must still poll the resource at intervals determined by its maximum tolerable staleness time.

As an alternative that doesn't depart from the strict request-reply

discipline, we could instead use a GET request with a new When-None-Match header, which delays the response to the request until the resource's ETag no longer matches the supplied ETag. That is, if the ETag is different, the server will respond immediately, as if with If-None-Match; but if the ETag is the same, the server will simply acknowledge that the request has been received, and perhaps send a response at some later time.

Derived resources

Mediators like Shodouka, Google Translate, CritLink, and the Jupyter Notebook Viewer host virtual resources derived from other resources whose URLs are passed as query parameters. These resources could, in principle, be cacheable — they only change when the underlying derivation code changes, or when the source resources do. (In practice, the Jupyter Notebook Viewer is rather annoyingly aggressively cached.)

If such resources wanted to participate in this kind of push cache invalidation, they would probably be best served by propagating cache invalidations downstream when they received them, rather than refetching upstream resources to repeat their mediating transformation, perhaps many times, in order to keep up-to-date a resource that will perhaps never again be used.

Achieving smooth curves in scanline image generation

Kragen Javier Sitaker, 2013-05-17 (1 minute)

I was thinking about chasing-the-beam-style raster-generation software in low memory, and how to achieve smooth curves.

Suppose you want to rasterize some kind of shape. You can approximate the border of the shape in a number of different ways: a polygon, a Bézier spline, etc. One particularly interesting way, to me, is as a tilewise polynomial.

Suppose you have divided your screen up into tiles of 256×256 pixels. The screen I'm looking at at the moment is 1024×600, so it would need four such tiles horizontally and three vertically, for a total of twelve. But coordinates within each tile are only 8 bits per coordinate, which means that you can do parallel computations over 16 tiles using SSE instructions.

Suppose you decide to represent the shape's border within a given tile as a polynomial, either for the horizontal axis in terms of the vertical or vice versa, along with limits. What degree of polynomial do you need?

Clearly if the shape border is of arbitrary complexity you need a degree-256 polynomial. But if you just want to hit three points in the tile, you only need a degree-2 polynomial. And if you need two points with specific derivatives — say, the top and bottom of the tile — you can do that with a degree-3 polynomial.

Optimizing the Visitor pattern on the DOM using Quaject-style dynamic code generation

Kragen Javier Sitaker, 2013-05-17 (updated 2013-05-20) (21 minutes)

(I think this was published previously on kragen-tol.)

Suppose you want to be able to execute the Visitor pattern as quickly as possible on some tree structure. You could compile your tree structure into executable code, each node a subroutine which invokes a method of the visitor object — traditionally each node type invokes a different method — and then passes the visitor object to each child node.

Using the "quaject" approach described in Henry Massalin's "Synthesis" thesis, and passing the pointer to the visitor object itself in %ebx, the code to invoke the appropriate method on the visitor might look like this:

```
    mov %ebx, %edx
    add $20, %edx
    call *%edx
    jc 1f
    ret
1:
```

Here we are checking the carry flag to see if the visitor object is requesting that we skip child nodes; if so, we return immediately.

The visitor "method" in this case is the code at offset 20 from the visitor base pointer; if its code is very short, it might be entirely inline at that point, but in many cases it will be longer, and only a call instruction will be present there. The called code will receive a pointer to the visitor itself in `%ebx`.

However, we probably want to pass some additional information to the visitor method; for example, if we're a variable node in a program AST, we might want to pass the name of the variable, or if we're an element node in a DOM, we might want to pass the tag name and attributes. So the entire call might look like this:

```
    mov $0xfe38d080, %eax
    mov %ebx, %edx
    add $20, %edx
    call *%edx
    jc 1f
    ret
1:
```

Following the call to the visitor method, we pass the visitor to the children. In the standard i386 GCC calling convention, `%ebx`, `%esi`, `%edi`, and `%ebp` are callee-saved registers, so if the visitor method follows this convention, we still have `%ebx` pointing to the visitor after it returns. So we can simply call our children one by one, implicitly passing them the visitor, then return:

```
    call 0xfe381000
    call 0xfe38d844
    call 0xfe391daa
    ret
```

For many applications, though, the visitor needs to take some action at the end of each node as well as the beginning. Perhaps it could inspect the child count at the beginning, maintaining its own stack of remaining child counts, and invoke the appropriate code when a child count reaches zero; but it's probably simpler to just notify it explicitly, by invoking another method on it before returning. This suggests putting the node pointer in a callee-saved register too, such as %ebp. With this additional modification, our example node looks like this:

```
  0:   55                   push   %ebp
  1:   bd 80 d0 38 fe       mov    $0xfe38d080,%ebp
  6:   89 da                mov    %ebx,%edx
  8:   83 c2 14             add    $0x14,%edx
  b:   ff d2                call   *%edx
  d:   73 0f                jae    0x1e
  f:   e8 fc 0f 38 fe       call   0xfe381010
 14:   e8 40 d8 38 fe       call   0xfe38d859
 19:   e8 a6 1d 39 fe       call   0xfe391dc4
 1e:   89 da                mov    %ebx,%edx
 20:   83 c2 1c             add    $0x1c,%edx
 23:   ff d2                call   *%edx
 25:   5d                   pop    %ebp
 26:   c3                   ret
```

(Note that this version has acquired an unfortunate limit of 127 bytes of child nodes, which is to say, 25 of them.)

That's 39 bytes for an executable representation of the data pointer 0xfe38d080 plus a variable-length list of child pointers that happens to contain three pointers; the most straightforward way to represent this

```
struct node {
  enum { document_node, element_node, text_node } nodetype;
  struct nodedata *data;
  int n_children;
  struct node *child[0];
};
```

would have needed 24 bytes, so making the data structure executable has cost us less than a factor of 2 in space.

(In the case where the children are sufficiently small, we can inline them, eliminating another 6 bytes (16%) of call and return.)

We can guarantee the visitor code a stronger calling convention than the usual; an executable tree built in the above fashion behaves in a very stereotyped way: of the caller-saved registers, it uses only %edx, plus %eax as an argument, so the visitor code is free to use %ecx as a private global variable, unless it calls some other code, in which case it must save it as usual. We can free up %edx too for the visitor's use as follows:

```
   0:   55                      push   %ebp
   1:   53                      push   %ebx
   2:   bd 80 d0 38 fe          mov    $0xfe38d080,%ebp
   7:   83 c3 14                add    $0x14,%ebx
   a:   ff d3                   call   *%ebx
   c:   73 0f                   jae    0x1d
   e:   e8 fc 0f 38 fe          call   0xfe38100f
  13:   e8 40 d8 38 fe          call   0xfe38d858
  18:   e8 a6 1d 39 fe          call   0xfe391dc3
  1d:   83 c3 08                add    $0x8,%ebx
  20:   ff d3                   call   *%ebx
  22:   5b                      pop    %ebx
  23:   5d                      pop    %ebp
  24:   c3                      ret
```

This has the side advantage of saving us two bytes (5%), but it also means the visitor method is invoked with a pointer to the visitor method rather than the visitor object; it is likely to need to subtract the method offset and add it back later. This seems like a fair tradeoff for giving it two private registers instead of one.

Additionally, the return value of the visitor method (that is, whatever it leaves in %eax) is either passed to the next visitor method called or is the return value of the entire node traversal.

For whatever it matters in today's world, this also means that the per-node overhead for tree traversal is 14 instructions, which seems pretty small. It may blow up your icache, though, and its single conditional jump might be mispredicted more often than the several in a more traditional implementation.

Consider this C implementation, listing generated as follows:

```
gcc -g -c -Wall -O4 -fomit-frame-pointer -Wa,-adhlns=nonquajectdom.lst nonquajectdom.c
```

```
   1                            .file   "nonquajectdom.c"
   2                            .text
   3                    .Ltext0:
   4                            .p2align 4,,15
   6                    _visit_node:
   7                    .LFB1:
   8                            .file 1 "nonquajectdom.c"
   1:nonquajectdom.c **** struct node {
   2:nonquajectdom.c ****   enum { document_node, element_node, text_node } nodetype;
   3:nonquajectdom.c ****   struct nodedata *data;
   4:nonquajectdom.c ****   int n_children;
   5:nonquajectdom.c ****   struct node *child[0];
   6:nonquajectdom.c **** };
   7:nonquajectdom.c ****
   8:nonquajectdom.c **** typedef int bool;

```

I separated the recursive function from the entry point so that by making it `static`, GCC could pick a more reasonable calling convention for it; which worked, but only up to a point.

Here our per-node overhead is 7 instructions of preamble, 2 instructions of dispatch (by chance, GCC happened to make dispatch fastest for this case), 3 instructions to call `element_callback` (using the three-byte `call` encoding optimized for function pointer tables), 2 instructions to conditionally skip the child nodes, 4 instructions of loop setup, 6 instructions per loop iteration (which we can count toward the child node's cost), 4 instructions to call `element_end_callback`, and 5 instructions of cleanup, for a total of (+ 7 2 3 2 4 6 4 5) = 33 instructions, of which four are conditional jumps, providing opportunities for branch misprediction. (However, the loop is simple enough that I imagine branch misprediction will be very rare.)

The listing of the C code points out that if the visitor is not a quaject, just a regular struct with function pointers, then we can eliminate two `add` instructions, which probably don't matter, and 4 of the 37 bytes, which probably do, and also build visitors in plain C instead of assembly, at the cost of an extra indirection. That is:

```
 0:   55                    push   %ebp
 1:   bd 80 d0 38 fe        mov    $0xfe38d080,%ebp
 6:   ff 53 04              call   *0x4(%ebx)
 9:   73 0f                 jae    0x1a
 b:   e8 fc 0f 38 fe        call   0xfe38100c
10:   e8 40 d8 38 fe        call   0xfe38d855
15:   e8 a6 1d 39 fe        call   0xfe391dc0
1a:   ff 53 08              call   *0x8(%ebx)
1d:   5d                    pop    %ebp
1e:   c3                    ret
```

Now our executable DOM node is 10 instructions and 31 bytes, only 7 bytes more than the 24 bytes the struct needs. Of those 7 bytes, 3 should properly be charged to the child nodes, so the overhead is more like 5 bytes and 8 instructions per node.

http://localhost:8000/wikipedia_en_all_nopic_01_2012/A/Dependoncy%20theory.html has 512 elements, 681 text nodes, and 17 other nodes. Traversing the whole thing should cost some (* 8 (+ 512 681 17)) = 9680 instructions, or about ten microseconds. The document text is 48962 bytes. The tree structure in this form should cost (* 21 (+ 512 681 17)) = 25410 bytes, plus the cost of the metadata (element names, string sizes and lengths, attributes). The entire document tree, then, nearly fits in the 32KiB L1 cache of my netbook, (although I think that's split, so only 16KiB is instructions), and very easily indeed in its 512KiB L2 cache.

The C code might be more efficient if its tree were binary.

Quadtree compression of terminal video RAM to do a megapixel windowing system in 6 KiB

Kragen Javier Sitaker, 2013-05-17 (9 minutes)

I wrote an Arduino program to generate musical scores with the following strategy: first, generate M 4-beat measures, each beat containing a note or not; then generate M 4-measure sequences from those measures; then generate M 4-sequence supersequences of 16 measures each; then generate M 4-supersequence hypersequences of 64 measures each; then use one or more of these 256-beat hypersequences as your score.

This worked reasonably well, fit the whole score into 128 bytes (I used one byte per sequence element and M=8, so each of the four levels was 8*4 = 32 bytes), and allowed me to encode the iteration state into a single byte. If I'd pressed harder, I could have used three bits per sequence element, for 4×8×4×3 = 48 bytes, except that I actually was using four bits per note.

It occurred to me that perhaps you could use this approach for other things, like general-purpose data compression or image compression, which I haven't tried yet, or building a pseudo-character-cell terminal with very low RAM requirements.

A typical character-cell terminal, like a VT100 or H-19, had about 25×80 character cells, each with about 5×8 pixels; and either one or two bytes of RAM per character cell, plus a ROM font containing something like 5×8×128 bits, say, 640 bytes. Each scanline could be built on the fly out of bits read out of the ROM, indexed by some simple arithmetic, so you only needed some 2000 bytes of RAM instead of the 80 000 (400×200) you'd need for a full screen image.

Suppose, instead, you used this quadtree scheme, but with a slightly unusual aspect ratio: 5×8-pixel characters, 16 lines, 128 columns, for 2048 characters on screen. Each character position would have a byte, as before, but instead of having a byte for each possible character position, you'd have M groups of four bytes for distinct 2×2 squares, where M was something less than 512. You'd need four levels of these, with each block at each level corresponding to respectively 4, 16, 64, and 256 character positions, plus 8 bytes at the top level for the 8 horizontal 16×16 chunks of the screen.

What would M be? You'd probably want it to be 256 or less in order to be able to fit the pointers to the next level into a byte; suppose it were 128. Then each level of the hierarchy would be 512 bytes (128 blocks of 4 bytes) and the total would be 2048+8 = 2056 bytes to hold the screen contents.

So far this sounds stupid, because you've "compressed" 2048 bytes into 2056 while losing the ability to have an arbitrary 2048 bytes on the screen! But there are some interesting possibilities here:

• You don't really need M=128 for the top. The top level of quadtree can only have a max of 8 of its nodes displayed at once. This approach means you could have M=8 and 32 for the top couple of

levels, cutting the memory usage almost in half, to (+ 8 (* 8 4) (* 32 4) 512 512) = 1192 bytes. You can use some of those bytes to give you "spare" blocks at the upper levels, to expand M further beyond 128 for the bottom level (so you can have, say, 1024 bytes of incompressible text at the bottom level).
• Scrolling horizontally by a multiple of 16 columns just involves changing the 8 data pointers at the top level, and possibly constructing a new "blank node" at each lower level.
• Scrolling by 8 lines, half a screenful, just involves modifying the 32 bytes that control the contents of the top-level quadtree nodes.
• You can use the saved RAM for a soft font, which gives you the ability to draw arbitrary graphics! As long as they're repetitive and compressible.
• If your terminal is programmable, you could use video RAM you're not using at the moment (because nothing points to it at the moment) for buffers and code.

It would probably make more sense to make your nodes horizontal instead of square. This means adjacent lines of text no longer interfere with each other's compressibility. Then you have:

• level T0, 256 nodes of four consecutive characters per node;
• level T1, 128 nodes of 16 consecutive characters per node;
• level T2, 32 nodes of 64 consecutive characters per node;
• level L1, eight nodes of two lines of 128 characters each;
• level L2, two nodes of eight lines;
• level L3, two bytes pointing to L2 nodes.

Total is (+ 2 (* 2 4) (* 8 4) (* 32 4) (* 128 4) (* 256 4)) = 1706 bytes, saving about 300 bytes over the traditional representation, at the cost of cutting the possible incompressible text on the screen in half.

Suppose that, instead of using the 5×8 characters that were common at the time, you took the quadtree approach all the way down to the pixels, using 8×16-pixel characters, just with a higher clock rate. Then you'd have, say, three more levels:

• Level P0: 4 8-pixel scanlines of a character, stacked vertically.
• Level P1: 16 scanlines of a character vertically, i.e. an entire cell.

A typical font ROM would likely be highly compressible with this approach, since lots of characters contain blank lines (not containing ascenders or descenders, say) and other repeated features. Suppose we have 96 ROM font characters, and each P0 node is used an average of twice. Then we have 96*8 bytes for the P0 nodes and 96*4 bytes for the P2 nodes. But that's assuming significant horizontal slices of characters are shared. That puts us at a total of 1152 bytes of ROM.

Anyway, what I was thinking was that if you had another 32 nodes in P2 that were in RAM (128 bytes), you could use that for a graphical character set, especially if you have another 128 bytes or so of P0 to play with.

But what about the latency of all these levels of indirection? We're talking about a total of eight indirections to get down to the pixels, now, right? Wouldn't that cut way down on your effective dot clock?

I think the answer is "no", because although there are lots of indirections, they're very *predictable* indirections, in lots of different

memories, so you can pipeline them. A four-byte FIFO at most levels would suffice: P0 needs only two 8-bit output registers, one of which is shifted to the electron gun, and a new output byte is latched into the "next byte" register; P1 similarly needs only a one-byte buffer, which feeds the next address to P0 for when it's ready; T0 fills up a four-byte FIFO going to P1 every 16 pixels of the scan line; T1 fills up a four-byte FIFO going to T0 every 64 pixels; T2 fills up a four-byte FIFO going to T1 every 256 pixels; L1 fills up a four-byte memory that T2 reads 32 times every 32 scanlines, or 32768 pixels; L2 fills up a four-byte FIFO going to L1 every eight lines, or 128 scanlines, or 131072 pixels; and L3 feeds L2 a byte every eight lines, or twice a screen. Each of the next-pointer reads can be loaded into a double-buffered register as soon as the previous value is used, so it's not in the latency critical path. P0, P1, and T0 each need to read a random byte every 8 dot clock cycles; T2 every 64; L1 every 65536; etc. So anything slightly over a single byte read per 2 dot clock cycles should be sufficient. Since we're talking about a (* 60 8 16 128 16) = 15 728 640 Hz dot clock, that would probably have involved separate hardware memories for some of these in the 1970s time period we're talking about, just to keep the RAM reads down to a manageable level, below 8 megabytes per second per channel.

However, I think this approach should make it possible to do a megabit windowing system on a terminal with on the order of 6kiB of RAM, rather than the usual 128kiB.

What about using this approach to generate random images?

Similarities between Golang and Rust

Kragen Javier Sitaker, 2017-01-11 (updated 2017-01-17) (7 minutes)

Golang and Rust have a lot of similarities, some stemming from their birth around the same time in groups of programmers with similar backgrounds and overlapping goals, and others due to direct borrowing.

Both use the C memory model of nested records and arrays with pointers, but add automatic memory management — a garbage collector in Golang's case, an innovative affine typing system in Rust's case (although Rust was born with a GC, it became garbage along the way and has been collected). This is a huge and underappreciated difference from mainstream garbage-collected languages like JS, Java, and Python, in which memory is just an object graph.

Both have interface inheritance but not implementation inheritance (and both use the keyword `struct` where C++ would use `class`). In both, an existing type can be retroactively caused to implement a newly invented interface (called a "trait" in Rust), but only in Rust does this permit you to add new methods to an existing type.

Both languages have untyped constants, where a number like `0` or `3.14` in the source code doesn't have a fully determined type — the precision of its type is determined by its context of use.

Both languages have limited type inference, eliminating nearly all type declarations for local variables but requiring nearly full type declarations for top-level module items. In both cases, the designers made the misguided choice to cede the `=` operator to mutation, while using a somewhat more verbose locution for the more common operation of declaring and initializing a variable. Rust's type system supports full parametric polymorphism, while Golang's type system, like C's, has some parametrically polymorphic types, but no mechanism to define new ones.

Both languages have very limited use of exceptions in the sense of nonlocal transfers of control (which both call "panics"), instead handling normal errors using return values somewhat richer than are practical in C and similar languages. In both languages, unused-value messages from the compiler prevent you from accidentally suppressing an error signaled by this mechanism. In both languages, the mechanism to explicitly ignore such an error is to assign it to a pseudovariable called `_`, a language feature I think both copied from ML.

In both languages, there is a dichotomy between "arrays" and "slices", which last are pointer-plus-length references to part of an array, while array sizes are statically known. Array indexing is checked at runtime in both languages.

Strings in both languages are sequences of implicitly UTF-8 bytes, rather than sequences of UTF-16 encoding units (as in Java and JS), of UCS-4 codepoints (as in Python), or bytes that each implicitly encode a character (as in C).

Both languages propose nonmainstream concurrency mechanisms in order to escape the disadvantages of pure event-loop languages like

ordinary JS and implicit-shared-everything languages like Java (and C or C++ with pthreads or Win32). Rust's novel type system statically prevents data races between threads; Golang has lightweight threads ("goroutines") and supports shared mutable state with the same concurrent-access bugs that Java does (and, at least originally, didn't even try to prevent segfaults from concurrent access to the same map), but provides special syntax for interthread communication over type-safe channels to minimize the use of shared mutable state.

Both languages add a simpler syntax for iterating over a range. In both languages, the range representation is half-open, including its left bound and excluding its right bound. Both of these are so universal nowadays that they hardly seem worth mentioning, but e.g. C, Java, and JS lack range syntax, and R, Matlab, and Fortran fail to use the half-open representation.

Both languages have acclaimed library package management systems (Cargo and `go get`) with integrated network access. Rust leans more heavily on its package manager in the sense that its standard library includes almost nothing — its `std::net` module, for example, implements no protocols higher-level than TCP, and it apparently offers no way to format a timestamp, parse a CSV file, or encrypt a string, although it does have things like binary heaps, hash tables, pathname handling, and some limited Unicode encoding. By contrast, Golang's standard library includes AES, ELF, DER, CRC, JPEG, suffix arrays, RFC-2822, SMTP, URLs, and JSON-RPC. In Rust these are available as external crates, except apparently there's no SMTP server; crates.io lists 7542 crates.

Both languages have syntactic support for user-defined external iterators, which sounds like a minor detail but turned out to be absolutely transformative to Python when Ka-Ping Yee introduced it.

The biggest difference seems to me that Rust focuses on static safety, even at the cost of programmer convenience, in a way that Golang does not. So, while in Golang it's common to define functions or data structures that pass around `interface{}` references — which can be converted to interfaces of the proper type with a run-time-checked type conversion — in Rust such practices are virtually nonexistent, instead using its parametric polymorphism facilities. In Golang all references are implicitly initialized to `nil` (as in Java, but much less problematically due to the difference in memory models), while in Rust null references are statically impossible, being supplanted by the `Option` type and pattern matching, which doesn't exist in Golang.

I'm tempted to make the analogy to the Pascal/C dichotomy of the 1970s: Rust, like Pascal, prioritizes static correctness and mathematical purity, while Golang, like C, prioritizes programmer convenience, practicality, and compatibility from one month to the next.

I think things might turn out differently this time around, though. First, probably no programming language will ever again be as dominant as C was during the 1980s; neither Rust nor Golang is likely to die within the next century. Second, static verification has become dramatically more effective over the last 40 years, which means that you can get a lot more safety with a lot less hassle. Third, we can afford a lot more CPU cycles and RAM for running compilers

nowadays, even if running the C++ preprocessor over hundreds of gigabytes of repetitively `#included` header files is not a particularly productive use of those CPU cycles. Fourth, cooperation with many other programmers is more important now than in the 1970s, and static safety helps a lot with that.

Fabric optimization

Kragen Javier Sitaker, 2019-10-28 (updated 2019-10-29) (17 minutes)

I was thinking about generating shapes via laser-cut geometry, and it occurred to me that laser-cut fabric can inexpensively form netting with quite flexible 3-D geometry, which can be applied to a variety of important applications.

Background: auxetic materials and conformal surface mapping

I just watched the presentations of "Beyond Developable" from SIGGRAPH 2016 and "Rapid Deployment of Curved Surfaces via Programmable Auxetics" from SIGGRAPH 2018, collectively by Mina Konaković-Luković, Julian Panetta, Keenan Crane, Mark Pauly, Sofien Bouaziz, Bailin Deng, and Daniel Piker. (I think this is mostly Mark Pauly's group at EPFL LGG.)

In the 2016 paper, they cut relatively rigid sheets of material into an auxetic triangular metamaterial pattern which can linearly stretch by up to a factor of 2, but more or less uniformly — that is, if a region of it is stretched by a factor of 1.3 along the x-axis, it's also stretched by about 1.3 along the y-axis, along the $x = y$ line, along the $x = -y$ line, and so on. The stretch can vary from one region of the material to another, but only gradually. These work out to mean that it expands *conformally*, which turns out to mean that it can be relatively easily hand-bent into computer-designed shapes or adapt to the form of the wearer's body.

In the 2018 paper, they extend this work in a couple of ways: cutting some of the material "pre-expanded", distorting the triangular mesh to vary the properties of the metamaterial, and sometimes replacing the cut sheet of material with a bunch of solid triangles linked together, with the sizes varied to limit the expansion. Then they force it to expand in different ways: by inflating it with a polyethylene bag or a balloon or by allowing it to hang freely from a frame.

Laser-cut netting from fabric

Although I haven't tried, converting fabric to netting by laser cutting should be straightforward: you just cut some holes in it. This is probably better to do with acrylic†, cotton, or silk fabric than nylon or polyester, although Engadget says it is also used with nylon and polyester. Cotton cut this way without further treatment will probably fray, but the other materials might form melted edges that impede fraying.

If you draw a Voronoi diagram of the hole centers, each vertex of the Voronoi diagram is in the middle of a piece of cloth which is connected along lines to adjacent vertices; these adjacent vertices are connected by cloth "bridges" under the Voronoi lines. If we expand the holes without allowing them to cross these lines, the bridges become thinner, but the overall surface retains the same Gaussian curvature as the original cloth, which had better be zero if we are going to be doing this on a garden-variety laser cutter.

If we want to allow a region of the netting to develop positive Gaussian curvature, the simplest thing we can do is to make the Voronoi lines of that region follow the bias rather than the threads of the fabric, assuming it's a woven or nonwoven fabric. (Actually, even simpler is to use a knit fabric, which is stretchy enough to curve any which way, but that gives up precisely the control I'm exploring here.)

However, we can do better than that. By making the fabric bridges squiggle, we can make them longer — potentially by orders of magnitude, serpentining almost arbitrarily far across the space from one node to another, filling in most the neighboring holes with their squiggling. The inside radii of these squiggles need to be large enough to prevent stress risers, also known as "rips", from starting; in some cases this will require discarding a teardrop shape from the inside of the curve, but in other cases the outside radius of a neighboring squiggle can fill the space, thus maximizing the use of cloth.

In this way, it should be possible to expand a 100-mm square of fabric (or even less) into a 1-m square (or more) of netting which assumes some complicated three-dimensional shape when fully inflated — either a fully determined form, if the graph of net nodes consists entirely of triangles (Bucky Fuller's "omnitriangulated"), or a more flexible form if some or all of the holes in the net have other shapes. By applying the process to heavy, strong fabrics such as twill, denim, seatbelt webbing, canvas, or burlap, it should be possible to quickly manufacture fairly complex, strong three-dimensional forms.

In some cases, particularly without omnitriangulation, squiggling is not necessary, because the nodes can be mapped into the plane of the original fabric in such a way as to put network-nearby nodes far apart. Consider, for example, a series of concentric rings of cloth linked together by quarter-turn spirals: if hung from the center of the cloth, the spirals untwist and become lines along a cone from its vertex, while the rings run around the cone. Some teardrops will still be needed at junctions to prevent stress risers.

Uniform amounts of squiggling over an area will not produce positive curvature when fully extended, but zero Gaussian curvature; in that case, a local reduction in squiggling will produce a region of *negative* Gaussian curvature, as demonstrated in the 2018 paper mentioned above.

† "Acrylic" fiber is polyacrylonitrile, which is not the same chemical as the poly(methyl methacrylate) "acrylic glass" (Lucite, Plexiglas, or Perspex) which is so popular as a laser-cutting medium. So it might not be as safe or convenient.

Geometry limitations

The shapes you can make from the fully extended omnitriangulated nets will necessarily be pretty convex; they can't have "pockets" in them, in the machining sense of a cavity eaten out of a surface, rather than the sartorial sense. Moreover, the net geometry, even if omnitriangulated, only controls the local curvature of the surface, not its global curvature. Once an omnitriangulated surface curves around to form a closed surface, the global curvature becomes fully determined, but until then it is potentially kind of floppy. For clothing this is usually considered advantageous, but not for some other possible applications.

Long protrusions are possible, but limited — they necessarily imply cloth density limited to their circumference-to-length ratio. That is, if they are twenty times longer than their circumference, they cannot have more than 5% cloth coverage.

Further alternative materials

Although ordinary textiles are probably the best material to use for this for many purposes, other possibilities exist. Nonwoven polyester (polar-fleece and *friselina*) can be dramatically cheaper and may be more computationally predictable, though not as strong or as stiff. Paper or Tyvek are cheaper still, and probably faster to cut. EVA foam ("foam rubber") is laser-cuttable and is widely used for shoes.

I haven't personally seen gel-spun UHMWPE fabric yet, whether woven or knit, but if you can get it woven, it might offer better strength and enormously better dimensional control than the other fabrics mentioned above. I've seen advertisements for pantyhose and bras (Katherine Homuth's SheerlyGenius, now Sheertex) and backpacks (Loctote) made from gel-spun UHMWPE fabric, knit in both cases.

Other sheet-cutting processes, such as high-powered laser cutting, waterjet cutting, and CNC torch cutting, could be used to cut sheet metal into similar netting-like structures, though its behavior under strain would be different; if you do manage to stretch it into shape, it will probably work-harden in the process, especially if you're using annealed copper or aluminum. Your dimensional precision is going to be shit.

Cloth made from carbon fiber, glass fiber, or basalt fiber would also provide higher strength and better dimensional control than more common fibers, but they might not be cuttable with a low-power laser.

Woven aluminum or steel window-screen material is another candidate for a higher-strength, higher-dimensional-precision material (though perhaps inferior to UHMWPE), and it could be cut very rapidly, possibly in several layers at a time, with plasma torches or high-powered lasers.

Coloring the net

The amount of fabric in an area has an upper bound determined by the degree of expansion that area experiences when going from the original flat fabric to the fully extended net, and a lower bound determined by the required strength of the netting. However, these will commonly be quite wide limits. This means that you can vary the net coverage in an area to moderate its color. In particular, white netting over a black background should be able to produce significant changes in luminance, though the maximum contrast will be limited as described.

Moreover, by using three or four layers of netting nested inside one another — red, green, blue, and possibly white — full-color images should be feasible, as long as moiré patterns and coregistration can be kept under adequate control.

Uses of shaped netting

Clothing and hammocks are the most immediately obvious uses. A

laser-cut woven or nonwoven netting layer can provide shape, while a fine knit layer underneath can prevent the netting from being uncomfortable or transparent when those are not desired. Netting shirts are already popular for hot days and for dance clubs.

Aeron-style chairs typically use knit netting for the seats and backs, providing much better ventilation than more traditional styles of chairs; laser-cut netting should be a reasonable alternative. Director's chairs and foldable camping chairs traditionally have canvas seats, but breathable fine netting would be an improvement.

Some other household items can be feasibly made in this way. My shoes hang in the closet in a cloth organizer that I think could be made from netting. A collapsible bucket for carrying water can consist of a hoop, some a plastic-bag liner, and netting to support the bag. Stuffed animals can be made of netting to give shape to fine knit cloth containing the stuffing. Houseplants can be potted in netting pockets suspended from railings. Backpacks, curtains, and clothes hampers can be made from netting.

Breathable shoe uppers can be made from EVA-foam "netting", and other uses might include objects like toolboxes that would benefit from being flexible and lightweight but cannot afford cloth netting's tendency to snag on anything sharp.

Inflatable sculptures, like those made by Ophélie Dorgans, can be easily inflated to multi-meter size, but historically it has been somewhat difficult to control their shape; most bouncy castles and advertising balloon critters are, geometrically speaking, kind of shitty. This approach offers an alternative: inflate a big shapeless plastic bag inside a shaping net. (This is demonstrated in the 2018 paper mentioned above.) As explained above, the shaping net can also provide color.

Such an inflatable sculpture could be inflated with methane, hydrogen, or helium and unleashed over a city, as with the 1970s UFO art prank Theo Jansen participated in and the earlier Los Angeles Meteor prank. (I can't remember if that last one is still anonymous or not.)

Blow molding of plastic bottles and vacuum molding of sheets of PET and other thermoplastics should be feasible using netting forms made in these ways, particularly if the fabric is cotton or nylon. As with clothing, a layer of fine knit fabric between the net and the hot plastic may be a useful mechanism for reducing netting marks on the surface.

With a reasonably flexible and gritproof liner — again, perhaps fine knit cotton — these netting forms could be suspended from frames and used as molds for poured-in plaster, concrete (which additionally demands alkali resistance, which cellulose and polyester have), lime cement, fluidized greensand, waterglass-bonded sand, or perhaps even slip (*barbotina*) for slipcasting.

Many of the above-mentioned castable materials are most interesting as refractory mold materials for metal casting, but of course in metal casting usually you want pocketing, which is, as I said above, impossible — assuming that the molding materials are on the convex side of the netting. An alternative might be to inflate the netting with a plastic bag, then pour plaster (or cement or whatever) around it to make the mold.

By painting, epoxy-impregnating, airplane-doping, sizing,

stuccoing, spraycreting, or applying *barbotina* to an inflated net, perhaps with knit-fabric layers on one side or the other, you should be able to make a thin composite material, reinforced by the fabric layer or layers to reduce its brittleness. Depending on the composition, this composite may be adequately sturdy even for some metal-casting processes.

In some cases, just filling the netting with sand may be sufficient; I suspect this may be one of the lowest-cost ways to get acoustic panels.

Cutting starched cloth board

The only laser-cutting machine I've used can cut 6-mm MDF at about 24 mm/s, but can cut thinner materials faster. Many interesting laser-cuttable fabrics are in the neighborhood of 200 µm thick, suggesting that the laser could cut them at a speed on the order of 1 m/s. However, particularly cutting complex shapes, the machine is mechanically capable only of a dramatically lower speed than that.

As I understand it, typical mass textile fabrication is done by cutting a thick stack of fabric to the pieces of the pattern with a bandsaw knife before sending the pieces out to be pieced together. Hundreds or thousands of layers of cloth are cut at once. (Mistakes here are ruinously expensive, ruining thousands of meters of cloth with a single bad cut.)

Typically the laser-cutting shop is not willing to cut multiple sheets of material at once, perhaps because they blow apart under the air blast, ruining the laser focus. But perhaps we could laminate several layers of cloth together with an adhesive to form a board similar to MDF, cut them, and later remove the adhesive.

One promising adhesive for this purpose is food starch: it is a polysaccharide like cellulose, so it doesn't stink when it burns, and it is commonly used for stiffening common fabrics, even polyester, which is a material notoriously resistant to being stuck to. As "wheat paste", it is also commonly used as an adhesive in bookbinding and papier-mâché. In fabrics that can withstand boiling — basically anything *but* polyester — removing it is also easy.

Papier-mâché practice demonstrates a risk of the cloth-board approach: drying time is necessary between layers in order to avoid trapping excessive moisture within the material. A warm air blast should be able to speed up this process.

This approach should make it possible to cut dozens of layers of cloth at once at MDF-like speeds, thus greatly reducing the cost of complex shapes, if you wanted more than one of them, anyway.

Alternative chemistries

Other candidate dissolvable adhesives for this purpose include sugar, PMMA, polystyrene, carrageenan, gelatin (or hide glue), calcium stearate, albumin, urea, and pectin. All of these could also be used as sizing to paint inflated netting to solidify it, as described earlier.

Salt is probably bad because it would produce HCl, chlorine, and sodium gases; waterglass is probably bad because it wouldn't cut with a low-power laser, and might swell up and block the cut instead; baking soda might work but might produce NaOH when cutting; nitrates are probably bad because they might offgas nitric acid and

nitrate the cellulose when fiercely heated; sulfates probably wouldn't cut (and might offgas acid sulfur oxides and produce toxic sodium sulfide); and soluble phosphates might have similar problems. (Ammonium phosphates in particular decompose to ammonia and molten anhydrous phosphoric acid upon fierce heating.) Some of these, especially waterglass and in-situ-formed phosphates of calcium or copper, might be suitable for painting onto an already-cut inflated netting form.

In other contexts, the possibility of selectively and precisely forming such gases on a surface or within a material with a laser-cutting machine might be very useful. Ben Krasnow on his Applied Science YouTube channel has reviewed a tactile-printing paper whose surface swells up when locally heated, for example.

Dercuano search

Kragen Javier Sitaker, 2019-05-16 (2 minutes)

I'd like to add full-text search to Dercuano; God knows I grep it often enough. Right now I have 4.5 megs of Markdown in 341 notes, producing a 2.0-megabyte gzipped tar file with static HTML files (plus tables of contents), and I'm planning to expand these numbers by a factor of about 2.5 by the time I'm done: less than 1200 notes amounting to 5 megabytes compressed, 11 megabytes plaintext. The index needed for full-text search with snippets is pretty much equivalent to the corpus of notes.

Grepping the 4.5 megabytes with grep takes 0.6 seconds on my laptop, but only 28 ms of that is user time; a second grep takes 42 ms of which 32 ms is user time. Generating a 200-megachar string in Firefox with `Array(100*1000*1000).join('a')` takes a few seconds and provokes a warning about slow scripts, but then `.indexOf('a,b')` in it takes 1.7 seconds, and `.indexOf('a,a,b')` in it takes 2.2 seconds, and `a,a,a,a,b` takes 2.8, which, interpolated down to 11 megacharacters, would be 150 ms; so even brute-force search, without even building an index, may be a reasonable implementation strategy.

The difficulty is that modern browsers generally don't allow file:// HTML to access other file:// URLs via XMLHttpRequest, although old versions of MSIE and the ActiveX XMLHttpRequest control did. So leaving the notes in static HTML makes full-text search impossible.

A possible solution would be to put the actual note text into .js files and load them with `<script src>`, rather than putting it into HTML. The various HTML documents could load their respective text from their respective .js files, while the search engine page could load all of them and maybe build an in-memory index.

To keep the search-engine page reasonable to load, the number of .js files should be limited. 64 might be a reasonable limit; this would be 4–7 notes per 70-kilobyte .js file at present, increasing to 17–20 notes and 170K each by the time it's done. This doesn't seem like a grossly unreasonable number for a page load from the local filesystem, and indeed it might end up being comparable to the amount of common JS liabilities they load.

Household thermal stores

Kragen Javier Sitaker, 2018-12-02 (updated 2018-08-19) (27 minutes)

Today is 2018-11-16. My house here in Buenos Aires has another power outage, an event which happens regularly during the summer months. They think power will be restored in some four hours, but this is uncertain. On one occasion a few years ago, I had a three-week power outage.

(Note: in fact, as I wrote this, the power came back and stayed on.)

The first thing I did was to check the refrigerator and put ice into it. So I was thinking about the sizes of the thermal stores that would be needed for the various temperature-control applications of electrical energy that I had been suddenly denied.

Refrigerators

In preparation for such events, I have some soft-drink bottles filled with water and frozen in the freezer, to absorb heat through their enthalpy of fusion, and more soft-drink bottles filled with water and chilled in the refrigerator, to provide thermal mass. When there's a power outage, I move ice bottles from the freezer into the fridge.

Unfortunately, my refrigerator is not a super-efficient model like the Sun Frost line; it's a rather normal refrigerator with a compressor, a magnetic-strip gasket, and a few centimeters of foam between the inside and outside walls. I've scoured it in vain for information about its energy-efficiency, except that it claims its nominal power is 230 watts, and it uses 180 watts to defrost the freezer and 15 watts for the light. Let's assume that 230 watts is the maximum power, but that it doesn't run the compressor and the defroster at the same time, so the compressor uses 215 watts. And, although I haven't measured this, the compressor needs to run somewhere around half the time. (This is normal. If your compressor needs to run 80% of the time or more to keep the fridge cold at normal ambient temperatures, you're in danger of going over the temperature setpoint and spoiling your food if it warms up a bit outside, say from 20° to 24°, and so compressors are sized to prevent this. But if your compressor only needs to run 20% of the time, you could have used a compressor half the size, and the fridge would be a lot cheaper.)

So let's say the compressor averages 110 watts at normal ambient temperatures, and let's suppose it has a coefficient of performance of 2, which is a normal kind of coefficient of performance for refrigeration systems. That means it draws off 200 watts of heat from the food within, on average, to compensate for the heat leakage through the walls and the seals and the losses when the door is opened and all the cold air falls out. (The bottles in the fridge also serve a bit to reduce the air losses.) And that means that those leakages are about 220 watts.

The enthalpy of fusion of ice is about 333 kJ/kg, so 220 W is about 660 mg/s of melting ice, which works out to 57 kg/day (19 MJ/day). I don't have 57 kg of ice in there. I have the following bottles:

| N | ℓ | total |

```
|---+-------+--------|
| 1 |  2.25 |   2.25 |
| 3 |  1.25 |   3.75 |
| 2 |   0.6 |    1.2 |
| 8 |   0.5 |     4. |
| 1 |  .375 |  0.375 |
|   | total | 11.575 |

```

So I have about 11.6 kg of ice in there, which works out to about 4.9 hours. Whew, that's not much! And I guess that's why old-fashioned iceboxes worked on a basis of daily door-to-door ice delivery.

Wrapping the refrigerator in a blanket might help the situation. But another possible solution would be a coolth reservoir where I actually could store 50 kg or more of ice, frozen when there's power and used for cooling when there's not. It could be relatively small, and indeed to keep the power costs acceptable it would need to be relatively small and relatively well insulated.

Dehydrators

At Burning Man, where you need to either burn or haul away any garbage you generate, down to the smallest fern leaf, we dehydrated our garbage by hanging it out in the dry wind in a net bag; this prevented it from rotting while we were there, improved its qualities as fire fuel, and reduced its weight enormously for the trip back. Though this is rarely done in the US, the same procedure is commonly used to dry clothes after washing them, though usually without the bag. And of course this is a common way to preserve sliced produce as well.

Putting air in contact with moist things causes the humidity in some surface layer of air to reach 100% (in the case of pure water) or whatever the equilibrium relative humidity of the solution is (when it has solutes such as salts). Water can diffuse across this layer into other air, or you can blow the surface layer away and replace it with new air, and in either case you remove water from the vicinity of the moist thing and increase the drying rate.

The amount of moisture required to reach 100% humidity rises exponentially with air temperature, doubling about every 10½°, so by raising the temperature of the air a few degrees, you can get very substantial increases in the drying rate. This is complicated by the fact that the evaporation itself cools down the air and the moist thing, and so your surface temperature is always a bit lower than the incoming air temperature; after a short while, the heat thus absorbed is necessarily replaced by the heat in the incoming air.

The principal difficulty with dehydrators is that they have to work relatively fast to be useful, and this requires the air to be both hot, which requires a lot of energy, and fast-moving, which requires a bit of energy but mostly careful airflow design. There's the additional difficulty that, if you're heating things up with fire or electricity, you need a thermostat, and ideally one that turns the heat off if it fails, rather than unexpectedly setting fire to things and melting things.

The enthalpy of vaporization of water is 2.26 MJ/kg, an enormous number, and it swamps the specific heat of air or vapor, so nearly all

of the energy that goes into the dehydator is used to evaporate water.

Here, I've been using my electric oven to dehydrate garbage. The oven has a thermostat that goes down to 50°, and also a fan and a shutoff timer. So far, the thermostat has been dependable, but I'm not sure that it's designed to fail safe; the shutoff timer fails when there's a power outage (as I said before, a frequent event), and in those cases the oven turns back on when power is restored. This is unacceptable and so I cannot depend on the shutoff timer.

(Ideally a dehydrator would be driven by a humidistat and would shut off when the desired humidity was reached.)

Depending on what you're dehydrating, different temperatures may be acceptable, and clothes dryers are designed with a relatively sensitive thermostat for precisely this reason — the high heat that most quickly dries cotton clothes would be disastrous for delicate synthetics. 35° is a fairly safe temperature for anything other than certain exotic materials you probably shouldn't be playing with anyway. Raw-foodists require their food not to be heated above 42° for somewhat debatable nutritional reasons. 75° is generally considered adequate for sterilizing food; although there are a few exotic thermophile microbes that can survive higher temperatures, they are not active at 37° (the temperature they are at after you eat them) and so they are generally not pathogenic. Some common plastics, especially PET — the polyester used for both cloth and Coke bottles — soften and change shape above 90°, and in my oven I've observed dried egg whites browning somewhere in the 70°–90° range. Water, of course, boils at 100°. Wood starts to brown around that temperature, too, though the autoignition temperature of paper is 233° according to Bradbury.

Using the psychrometic exponential rule of thumb, even at 35°, you evaporate water almost 3× as fast as at 20°, and at 75° you evaporate it 38× as fast. Furthermore, the same air heated to 75° has 38× lower relative humidity, so if the relative humidity is 70% outside, it's 2% in the dehydrator. This means not only that you can dry things faster, but also that you can dry things that wouldn't dry at all in room-temperature air, because they have enough salt or other hygroscopic substance in them that they're already in equilibrium.

Predicting the exact drying rate is very complicated, because it depends not only on the rather complicated diffusion and advection processes I mentioned above, but also on airflow patterns, specimen thickness, humidity diffusion rate through the specimen, salinity, and the presence of other hygroscopic substances. But usually, in my oven at its nominal uncalibrated 75°, my tens-of-millimeters-thick food garbage dries out satisfactorily in an hour or two.

How much energy does this require? 100 g of food garbage (orange peels, chicken bones, outer onion layers, food particles washed off dishes, and whatnot) might be a meal's worth, assuming you don't let food rot. Say that's 75% water, so 75 g of water. That's 170 kJ at 2.26 MJ/kg. Air's fairly low specific heat of 1.01 kJ/kg/K means that putting 170 kJ into heating air from 20° to 75° means you need to heat about 3 kg of air to deliver that energy; at 1.2 kg/m³, that's 2.5 m³ of air you need to pass over the meal's worth of food, or 510 kJ or 7.5 m³ per person per day, 5.9 W. You might need to double that if some food goes bad. It's still a factor of 20 to 40 smaller than the reservoir you need for the refrigerator.

In a situation of a prolonged outage of municipal services, dehydration is probably also a reasonable weapon to have in your arsenal against food decay, corpse decay, and feces, although if you're going to be dehydrating feces with hot air you probably want to use a separate dehydrator from the food dehydrator, and you might also want to use some kind of scrubber on the output air to keep the smell down. (This in turn suggests you might want to use a closed-loop system like the one modern condensing clothes dryers use.) Dehydrated feces can be burned, stored, or more easily composted than fresh feces, especially diarrhea, and if you can sterilize them in the process, all the better.

Cooking

My stove is, unfortunately, electric. Cooking a meal involves, minimally, heating the food to the right temperature and holding it at that temperature until it's cooked. The temperature is invariably between 40° and 100°. Some meats can be cooked *sous vide* at temperatures as low as 60°, at least once they're sterilized, but many vegetables require 90°. Kidney beans in particular are dangerously poisonous if cooked below about 95°.XXX

The traditional means for holding the food at the right temperature is to continuously apply heat to it, while it's losing heat to the environment by another route, so that the thermal equilibrium is around the desired cooking temperature, but other approaches are possible; for example, you can use a thermos or hooikist to maintain the temperature passively, or a thermostat together with some insulation to maintain it more actively, as crockpots, *sous vide* cookers, and my oven do.

Typically a meal's worth of food for a person is about 500 g, and it's largely water, with a specific heat in the neighborhood of water's. Heating it from 20° to 80° thus requires 20 kilocalories, 84 kJ, which is 2 minutes in a 700-watt microwave oven at full power. Thermal losses might push the energy required higher, perhaps to 150 kJ. Three meals a day then require 450 kJ per person per day, or 5.2 W, very close to the 510 kJ required to dehydrate the food garbage.

Indoor climate control

Due to deplorable construction techniques, a refrigerative air conditioner of 2000 watts or more is necessary in many Buenos Aires apartments to maintain the temperature at bearable levels. 2000 watts of input produces about 4000 watts of heat removal (CoP ≈ 2), but typical duty cycles are about ⅓ on a 24-hour basis, meaning that you only need to remove 1300 watts on average (115 MJ/day). Typical set points are in the 18°–26° range; 24° is about the most I can take.

Ice vests

Workers in very hot environments, such as some parts of power plants, often use ice vests, which either have ice packets in the vest or coolant tubes in the vest running to an ice backpack containing some phase-change material at or below 20°, typically water ice at 0°. This allows you to shunt the 100 W or so of heat that your body produces into the ice rather than finding a way to reject that heat into a hostile environment. If you are adequately insulated, that 100 W, or up to

2000 W if you're exercising hard enough, is all the ice vest needs to absorb.

Usually ice vests are used for short stints, like an hour or two, but an ice vest that could last 8–12 hours would be very useful in the Buenos Aires summer. An hour at 100 W is 360 kJ, or a bit over 1 kg of ice, so a 12-hour ice vest would require about 13 kg of ice, which would be an uncomfortably heavy backpack.

As an alternative to indoor climate control, an ice vest with easily interchangeable ice packs, or even that you could leave plugged into a flexible coolant line as you move around your apartment, could be lightweight, and it would require less energy than air conditioning, since it would only need to absorb the heat produced by your body, not the sunlight flooding in through the windows or the hot air seeping in under the door.

Showering

The building has a central electric hot-water system with a huge stainless steel tank, so my hot water didn't actually go out during this power cut, but it would during a longer cut. My shower delivers about 250 mℓ/s of water at typically about 40°, but needs to be able to reach 45°; further temperature range is undesirable, as water above 45° can scald you before you can react. I typically shower for about half an hour a day, which is perhaps longer than most people, and works out to about 450 ℓ of fresh water that would have otherwise flowed unmolested past Buenos Aires into the Atlantic, where it turns brackish in the estuary of the Rio de La Plata.

450 ℓ of water at $\Delta T = 25$ K is 47 MJ per person per day, or about 540 W.

Summary of thermal energy needs

So here are the controlled heat flows per person, with a per-day average. This is not the electrical energy, but the thermal energy.

Use	W (avg)	MJ/day	target	
Air conditioning	1300	115	20˚	cooling
Refrigerator	220	19	4˚	cooling
Ice vests	100	8.6	20˚	cooling
Showering	540	47	45˚	heating
Cooking	5.2	0.45	100˚	heating
Dehydration	5.9	0.51	75˚	heating
total	2171.1	190.56		

#+TBLFM: @8$2..@8$3=vsum(@2..@7)

So the first thing to notice is that air conditioning actually accounts for 60% of the total, and the problem gets substantially easier if we can eliminate it, for example with ice vests or better building envelope design. The second thing to notice is that the high-temperature heat applications are very low-volume, while the high-volume heat application, showering, is very low-temperature.

Possible reservoirs

What combination of thermal reservoir designs could we use to satisfy these needs? We can use thermal mass or phase-change materials, and we can recharge the reservoirs from different sources of

heat and cold.

We can consider the hot reservoirs and cold reservoirs separately, because they are

Cool reservoirs

Although ice vests could in theory use a higher-temperature phase-change material, you pretty much need water ice in even larger volumes for food refrigeration, and probably any other phase-change material would be both more massive and more expensive. So it's probably best to just use ice for the phase-change cool reservoir. 28 MJ of ice is 84 kg of ice per day, of which 8.6 MJ or 26 kg is for your ice vest; a week's store of ice would be 590 kg, almost a cubic meter. This is a substantial-sized home appliance, especially with the extra volume needed for cooling extra people.

The difficulty with water ice is that you need something below 0° to get it, unless perhaps you make clathrates or something at a slightly higher temperature. Although some very dry places do reach such temperatures during the night — and you might be able to do a bit better still with reflective optics and some evaporative cooling — here in Buenos Aires, this pretty much requires active refrigeration, either with a compressor or some other form of refrigeration, like a vortex tube or an ammonia-absorption refrigerator.

(An ammonia-absorption refrigerator powered by solar thermal energy is quite a reasonable possibility.)

But it's quite common for the temperatures to reach cool and even chilly levels during the night; as I write this, for example, it's 18° outside. If you could accumulate a large mass of 18° material during the night, for example by passing night air through it, you could use that for indoor climate control during the day, even if not directly for food refrigeration. But how much mass would you need?

Supposing that it's in the form of water bottles at 18°, which you then allow to warm up to 23° as you pass air over them in order to sink the undesired daytime heat. To compare apples to apples, we'll suppose we're using this to cool your no-longer-ice vest rather than to air-condition your house, so we only need 8.6 MJ. But 8.6 MJ / ((23 - 18) calorie / g) = 410 kg instead of the 26 kg for the corresponding ice. (The other 58 kg were for cooling food down to 4°, for which the 18° water would be counterproductive.) Cooling the 410 kg of water back down at night involves passing at least 8.6 MJ / (5 K · 1.01 kJ/kg/K) = 1700 kg = 1400 m³ of 18° air over them. That's 66 ℓ/s or 139 cfm if you do it in the 6 coolest hours, which is a quite feasible airflow rate, but one that will require forced air in any reasonably-sized system.

If you have a phase-change material that changes phase at a temperature between 18° and 23°, you could use that instead, and maybe you could get it down to 50 kg or something. Unfortunately, the only things I'm aware of that fits the bill is certain expensive grades of paraffin and some outrageously expensive metals.

The potential advantage of using a second cool reservoir at a more moderate temperature is that you can replenish it in relatively simple ways, like with a box fan running at night, rather than a compressor or vortex tube or something. But it's probably not worthwhile, since you need the larger, colder cool reservoir for food preservation anyway.

Hot reservoirs

On the other hand, the system should almost certainly use separate reservoirs for heat: one for the ≈1 MJ daily of cooking and dehydration heat at 100°, and another one for the ≈50 MJ daily of hot water at 45°. Both of these temperatures can be easily obtained from solar thermal energy; the equilibrium radiation temperature of "one sun" is 94°, which is to say that thin things on Earth's surface only fail to reach 94° when they're at right angles to sunlight because they have air blowing around to cool them off, and "two suns" — the intensity of sunlight you get from direct sun plus a flat mirror — gets you to 163°. Anything up to "ten suns", which would get you to 379°, is considered a "low solar concentration ratio" and is easily achieved.

Small high-temperature reservoir

If we have to gather the 11.1 W of cooking and dehydration heat during 6 hours of sun exposure — a reasonably pessimistic figure — then we need 44 W during that time, which is 0.044 m², a 210-mm-square area. In order to be able to cook and dehydrate at other times of day, we need to transfer the heat from the absorber (which is of a size somewhere less than 0.04 m² to achieve the required temperature, and somewhere larger than 0.004 m² so that the optics aren't too complicated) to some kind of reservoir. Bricks, for example, or sand. The easiest way to move this heat around is with some kind of coolant, and the easiest one that has no trouble with temperatures from 20° to a bit over 100° is air.

If we add a bit of pad, let's suppose that the reservoir itself is at 120° when full and stores 3 MJ of heat that are released when it cools down to 100°, at which point we consider it "exhausted". Storing 3 MJ in 20 K of ΔT in a material with, say, 1 J/g/K, means that it needs about 150 kg of active mass, say about 1500 ceramic tiles of 100 g each, which will occupy on the order of 0.15 m³ of volume including air spaces between them. This will have on the order of 1.5 m² of surface area around it through which it can lose heat to the environment with its ΔT of about 90 K above ambient. We'd like it to lose no more than, say, 1 MJ during 18 hours when it's not warming up, which is a rather demanding 15 W or so, 9 W/m², or 0.1 W/m²/K. It's probably not safe to use organic insulators like polyisocyanurate, styrofoam (33 mW/m/K; see Deep freeze (p. 1465)), or straw (90 mW/m/K) at these temperatures, but fiberglass should be fine. I don't have fiberglass's insulance handy, but let's say it's 50 mW/m/K. Then you need 500 mm of fiberglass around your thermal reservoir to reach such a demanding specification. This is somewhat unreasonable.

So let's add a lot more pad. Let's let our reservoir be at 200° when full and store 20 MJ of heat by cooling down to 100°. Now it needs to be 200 kg, which would be a cube 58 cm on a side at 1 g/cc, with a surface area of 2.1 m². Say we can afford to lose 16 MJ (leaving 4 MJ) during 18 hours, which is 250 W (better not keep it indoors in the summer) at a ΔT of 130 K, which works out to 120 W/m² and 0.9 W/m²/K. (50 mW/m/K) / (250 W / 130 K / 2.1 m²) = 55 mm of fiberglass insulation, which is eminently feasible, comparable to what my refrigerator uses.

You can't, of course, support 200 kg of tile or whatever on

580×580 mm of fiberglass and maintain the fiberglass's insulance. But you can suspend the mass in a frame in the middle of the fiberglass, hanging it by metal wires. 1mm-diameter music wire would in theory be enough, but probably more like 8 such wires would be advisable to keep the suspended frame from shifting around and opening gaps in the fiberglass.

If you can use a phase-change material with a transition temperature between 100° and 200°, you might be able to simultaneously reduce the mass, and the volume, the working temperature of the reservoir, the variability of the temperature, and the surface area through which heat is lost. Alkali nitrates and typemetal occur to me as possibilities.

The absorber that heats up the air to heat the reservoir

Peak shaving and TOU metering

Some electrical utilities, like PG&E in California, are introducing time-of-use metering, where they charge you more for electricity used during "peak" hours than during "off-peak" hours. While this is still a long shot from true demand response, it should create a market for appliances such as refrigerators

Studies support authority

Kragen Javier Sitaker, 2017-04-10 (2 minutes)

If the powers that be are sensible, then studies will show objective evidence that actions they take have positive effects, but not their negative effects, because the negative effects can be designed to not be objectively verifiable for a long time.

As a clear example, official crime statistics showed a drop in the murder rate in the first years of the Argentine dictatorship in the 1970s. It was known that the state was also fighting against "subversion", meaning a couple of armed Marxist insurgencies. But the people who were kidnapped and murdered by the police — some for being Marxist insurgents, others for being merely suspicious, or for having children that could profitably be adopted by military families — did not show up in the official murder statistics. During this time, a friend of mine was arrested, interrogated, and raped by the police. Her rape did not appear in the official statistics.

Some ten thousand "disappearances" and murders were documented, using the official records kept by the military, after the return to democracy. Another twenty thousand people are said to have disappeared during this time, but we do not have good evidence to know how many of them are victims of the dictatorship whose records were destroyed and how many were killed by non-government organized crime, how many abandoned their families and set up new identities elsewhere, and how many died in accidents and whose bodies were never found.

Bubble display

Kragen Javier Sitaker, 2017-01-24 (updated 2017-08-03) (1 minute)

A bubble in gel scatters light. I think it scatters an amount of light proportional to its cross-sectional area, which is proportional to the square of pressure. If so, the average amount of light scattered from the bubble is a function of the RMS of the pressure, rather than the average pressure; oscillating pressure will increase the total light scattered.

Gel without bubbles can operate as a fiber optic, restricting light to within itself by total internal reflection.

By connecting a piezoelectric hydrophone to a bubbly gel column, you can generate a traveling wave in the column. But if the column is closed, you can generate a *standing* wave, in which bubbles in some parts of the column move back and forth, while bubbles in other parts merely grow and shrink. I think you can in fact generate an arbitrary superposition of standing waves simply by taking the Fourier transform of the desired display scattering function. Then you can illuminate the gel column with total internal reflection.

A somewhat better approach is probably to illuminate the column with a small duty cycle so you don't have to deal with the multiple nodes and antinodes.

The delta from QEmacs,with only 88 commands, to a usable Emacs, is small

Kragen Javier Sitaker, 2013-05-17 (2 minutes)

I downloaded and built QEmacs. It's a good enough Emacs I could almost use it! Which is inspiring, since it was an individual spare-time project by one person, even if that one person is Fabrice Bellard. So I thought I'd take some notes on its deficiencies to see if it's fixable, or how much more work would be needed to make something really usable.

• Crashes sometimes in help. Open qe_g, C-h b q
• open a C file and type
typedef struct node {
and QEmacs takes you to the beginning of the line. Follow that up with `enum {` and it happens again.
Type `typedef int buf[4];` and it happens again. I think this is just part of a general problem it has with indenting C.
• Yes, it can open a text file of nearly 300 megabytes. But going to the end of the file is slow.
• Doesn't support M-^, M-;.
• C-x C-e (compile) tries to execute the make command in the directory where qemacs started, not where the file is.
• repeated C-k doesn't append to the latest kill-ring item as it should, so you can't use it to cut blocks of text.
• M-q takes you out of your paragraph, so you can't just keep typing.
• Redisplay is visibly slow and not double-buffered.
• Doesn't support ~ in filenames.
• Doesn't support M-/
• Control-backspace is "help" instead of "backward-kill-word".
• When there's pending keyboard input, it wastes time updating the screen with already-stale state!
• Undo works in individual buffer changes, rather than commands, which is quite suboptimal with M-q and also with undoing typing.
• Doesn't support prefix arguments. M-5 M-6 M-g prompts you for a line number.
• M-y (yank-pop) causes subsequent C-y to yank the same thing. Maybe this is an improvement.

Still, it's impressive how much like Emacs it can feel with only 88 commands!

Interval radiosity

Kragen Javier Sitaker, 2016-07-27 (1 minute)

You can think of radiosity rendering as something like seeking the first eigenvalue of a transformation matrix; each vector element identifies the luminous flux at a particular point in space oriented in a particular direction. The transformation matrix identifies the transformation function of this six-dimensional light field as it propagates through space and bounces off objects, along with whatever sources of illumination are needed. This vector must necessarily be of very high dimensionality in order to provide a reasonable approximation, but it may be possible to do a reasonable job by subdividing space and directionality recursively using interval arithmetic until you reach an adequate approximation.

A minimal window system

Kragen Javier Sitaker, 2018-04-27 (updated 2018-10-26) (12 minutes)

See also Window systems (p. 1335).

For whatever reason, windowing systems are de rigueur for personal computing systems. What's the smallest one you could build? Computers are fast enough now, since about 2000, to redraw the whole screen every frame, so there's no need to faff about with hacks to avoid redrawing parts of the screen. We just have to keep a cap on how many times per frame we draw each pixel, on average.

A pull shared-memory windowing system

Each application shares a memory segment with the window system. The window system has a list of windows, which it can reorder, each with four numbers: (dx, dy) for the window origin and (sx, sy) for the window width and height. Each frame, the window system composites the application windows together into the framebuffer, using the painter's algorithm. This involves copying rows of pixels from the shared memory segments into the framebuffer, some of which will be overwritten later with other pixels. Each application also has an input queue for keyboard, mouse, and frame events. Keyboard events always go to the topmost window; mouse events go to the topmost window that contains the mouse, except that the mouse-focused window stays fixed while the mouse moves with a button held down.

Frame events indicate the completion of a frame, telling the application that it is now free to scribble over the window buffer used in that frame. Atomic pointer writes allow the application to update its window to a different framebuffer (in the same shared-memory segment) for resizing or double-buffering.

Two possible worthwhile enhancements: support (premultiplied) alpha; don't draw windows that are invisible because they are completely off the screen or completely covered by another window, and (combined with that optimization) divide the screen into 32×32 pixel "subscreens" or tiles that are drawn independently. The first enhancement gives you not only window transparency but also a crude approximation of shaped windows; the second should keep the compositing overdraw to a minimum under most circumstances.

A push tile-stream windowing system

Each application sends the window system a sequence of commands, which can include requests to position or size its window or tiles of pixels to draw in it. The window manager sends back a sequence of events.

If the IPC mechanism supports transferring ownership of blocks of memory (or, sort of equivalently, immutable data) then the tiles need not be copied between memory spaces. If they are, say, 32×32 tiles of 32-bit pixels (4096 bytes each), then a 3840×1024 screen would be 120×32 such tiles, 3840 of them in all. If the drawing command itself is an (x, y, w, h, framenumber) tuple with 16-bit fields, the 3840 tiles work out to 38400 bytes of messages, while the pixel data is a bit over

15 megabytes, 409.6 times larger. Sending 15 megabytes in 3840 write() calls on Linux on my laptop would work out to about 300ns · 3840 = 1152µs for the calls plus 171ps · 15728640 = 2689µs for a total of 3.8 milliseconds — a somewhat excessive amount of time, especially when you consider that the window system needs to read all those bytes, too, taking roughly as long.

A simple test program on Linux is able to create 65000 4096-byte memory mappings for a 4096-byte file in 290ms using mmap(), or about 4.5 µs per mapping. (It fails when it attempts to create more than that.) This means that mmap() is actually a bit slower than copying for such a small mapping, but it doesn't get any slower when the file goes up to 8 megabytes. A different operating system might make somewhat different performance tradeoffs, but there's no strong reason to suspect that Linux's implementation is profoundly suboptimal.

There's the question of whether the tiles should be fixed-size and whether they should be required to be pixel-aligned on a grid. If we take as a priority that the window system should be efficiently nestable, the answers are no — we want intermediate window servers to be able to pass along drawing commands as they arrive, but they may not draw a full tile, and they may be offset so that tiles that are pixel-aligned in the window aren't pixel-aligned on the screen.

This architecture is not nearly as amenable to alpha-blending.

Performance thoughts

Consider the tiled pull design on a 128×32-tile four-mebipixel screen with an average of two drawable windows per tile — some tiles have only one, while other tiles have window overlaps and translucent overlays. It needs to read 8 mebipixels (32 mebibytes) from window buffers and write them into the 4-mebipixel (16 mebibytes) output image, but the tiles are 4096 bytes and thus fit in cache, so this will probably only amount to 16 MiB of write traffic to main memory, for a total of 48 MiB.

My laptop can manage about 2 GB/s of large memcpy traffic on one core and about 4 GB/s across all four cores. At 60fps that's a budget of 67 MB of memcpy traffic per frame — this is cutting it pretty close, because it means 75% of the CPU's RAM bandwidth would be devoted to just filling the screen. It also includes an "Intel HD graphics" engine with 16 execution units, which you could imagine might be capable of blitting quite a bit faster. Wikipedia confirms that the GPU has 25.6 GB/s of memory bandwidth.

This approach requires only some 8192 blit commands per frame rendered, leaving about 2 µs to process each one. Even CPython function calls would be fast enough, as they take only about 200 ns on one core. However, if the commands a CPython program was sending were one level lower — individual scan line segments — there would be roughly 32 times as many comands, and CPython performance would be inadequate.

As it happens, Numpy is capable of doing this kind of thing, because it has mutable multidimensional arrays. A quick test finds that copying 128 MB of RAM via numpy takes 64 ms, which works out to 2 gigabytes per second. However, doing a million small blit operations in this way took 5.4 µs per blit, which is too slow by more than a factor of 2.

```
def draw(n):
 for i in range(n):
  j = (i % 200) * 5
  fb[j:j+5, 0:8] = fb[:5, :8]
```

Factoring out the source image, as if that were realistic, got it down to 3.9–4.0 µs.

```
def draw(n):
    src = fb[:5, :8]
    for i in range(n):
        j = (i % 200) * 5
        fb[j:j+5, 0:8] = src
```

So I could maybe make it work, barely, by taking advantage of multicore, or with a smaller screen, like 1Mpix, or like 30fps. Or by giving up on the small-subscreen approach and doing more precise occlusion calculations to do bigger blits and eliminate overdraw. (My laptop is only 1920×1080.)

If we have 3ms to draw the screen with an overdraw factor of, say, 2 due to alpha, then our 2 GB/s gives us 6 MB.

Vectorizing precise rectangular occlusion calculations

For more precise rectangular occlusion calculations, we could imagine a scan line as a sequence of (pixelcount, sourcewindow) pairs, and a screen as a sequence of (linecount, scanline) pairs. To compute a scan line, we can sort the window vertical edges (dx and dx+sx) and walk from left to right across the scan line, maintaining a Z-ordered heap of windows under the current pixel position, yielding spans when the topmost window changes. A similar calculation for window horizontal edges yields spans of identical scan lines, although it may not be a priori clear which scan lines are going to be identical; it might be better to use an identical-span-merging procedure on the sequence of generated spans, both horizontally and vertically:

```
def coalesce(spans, reducer=operator.add):
    c = None    # Current span
    for k, v in spans:
        if c is None:
            c = k, v
            continue

        pk, pv = c
        if k == pk:
            c = k, reducer(v, pv)
        else:
            yield c
            c = k, v

    if c is not None:
        yield c
```

This constant-space algorithm is a generalization of run-length

encoding, `uniq`, and `uniq -c`, and is actually the reduce phase of map-reduce, assuming the sorting in between the map and reduce is already taken care of. (God damn it, I'm going to end up programming in Rust after all, aren't I?) For simple data, like `list(zip(floor(arange(128)/10), ones(128)))`, it takes about 5µs + 750 ns/item.

To make this work with some windows having alpha, for each span, we need to store either the whole window stack or enough of the layers on top to reach opacity, rather than just the topmost window. If there is no alpha and everything is opaque, it's overdraw-free.

The whole computation doesn't quite fit into the map-reduce mold because, although the windows map to pairs of edges, there's a computation in between to find the differences of the sorted list.

There's a way to express this algorithm, for the addition case, in three lines of Numpy, but I hesitate to describe it as "straightforward" because I keep putting bugs in it when I implement it:

```
def coalesce(ks, vs):
    last = concatenate((ks[1:] != ks[:-1], [True]))
    v = cumsum(vs).compress(last)
    return ks.compress(last), concatenate(([v[0]], diff(v)))
```

In APL, given the inputs in k and v, I think that would be something like this:

```
(L/k) ,[1] w[0],(1↓w)-¯1↓w←(L←((1↓k)≠¯1↓k),1)/+\v
```

except that that doesn't handle cases where k and v have different data types, and also I haven't tested it because LinuxMint doesn't come with APL.

For largish arrays (1e8 trivial items) on my laptop this takes 11 ns per item, about a 20th of a 200-ns Python function call; for a 256-item array, it takes 75 µs (290 ns/item); for a 512-item array, it takes 80 µs (160 ns/item, or about 20 ns per additional item), while for a 65536-item array, it takes 805 µs (12 ns/item). This suggests some slight nonlinearity and a rather hefty Numpy overhead of about 70 µs (about 350 Python function calls) per call. This makes it faster than the longer generator version above for more than about 90 items, but potentially an order of magnitude slower for small cases.

A more assembly-style imperative Numpy implementation might do a better job by reducing memory allocations. For example:

```
def coalesm(ks, vs):
    last = ones(len(ks), dtype=dtype('bool'))
    not_equal(ks[1:], ks[:-1], last[:-1])
    v = cumsum(vs).compress(last)
    result_v = zeros(len(v), dtype=v.dtype)
    result_v[0] = v[0]
    result_v[1:] = v[1:]
    result_v[1:] -= v[:-1]
    return ks.compress(last), result_v
```

This is somewhat faster on large data sets — the earlier version takes

about 19 ns per item to count the duplicates in `floor(arange(1e8)**.1)`, while this version takes about 11 ns. Both take 11 ns per item for trivial int arrays. It is, if anything, about a microsecond *slower* for small problems, as you would probably expect.

We should use end-to-end optimization algorithms for 3-D printing design

Kragen Javier Sitaker, 2015-09-03 (14 minutes)

I just spent a few hours designing and printing things in PLA with a US$400 Prusa Mendel RepRap, using a workflow that goes like this: OpenSCAD → Slic3r → Pronterface → RepRap → break them. I think this is the wrong approach, for a couple of reasons.

Printing problems I've seen

The RepRap does not realize your 3-D model with perfect precision or reliability. Here are the ways I've seen it fail:

• Printing on dirty glass, or glass that's not hot enough, the bottom layer can peel up from the glass when pulled by tension from the extruder. This may be corrected by subsequent layers, or it may generate a runaway positive feedback loop as the extruder crashes into the debris, peeling more and more of it.
• Of course anything needs a sufficient area of contact with the printing bed to anchor it during printing.
• When the bed is insufficiently well leveled, printing the first layer in some places will not deposit any plastic and may cause the pinch wheels to lose their grip on the filament. This could be remedied in software by using a thicker bottom layer in models with a large X and Y extent.
• Sometimes, particularly with a horizontal overhang, Slic3r tries to delineate a layer boundary by depositing filament on top of empty space. This works up to a point, particularly if it starts on top of non-empty space and then goes out a very short distance onto empty space.
• A tall, skinny model can start to flex with the extruder as the extruder drags across the top of it; this results in a sort of backlash. This is relatively innocuous when you're depositing 10% infill, but when you're depositing 100% infill, it can result in the plastic mounding up, which creates positive feedback — the mound of plastic obstructs the extruder further, which results in further bending and sometimes even getting unstuck from the bed.
• Any kind of obstruction can result in lost steps in X and Y, since the RepRap runs entirely open-loop.
• Depositing a horizontal surface on top of an open space (either one in the model or one generated from infill) always sags somewhat; the extent of the sag, and whether further layers on top of it are able to become fully solid, both vary somewhat. It's easy to end up with just a set of parallel threads that don't cohere into a surface.
• Sometimes narrow vertical walls encounter the same fate: just a set of parallel, unconnected threads. I think that when I saw this, it was from an infill setting that was just on the edge of instability being driven over the edge by the cooling blower.
• I saw one design that drove the X drive belt into one of the support

beams when it drove the Z-axis up past 110 mm. We aborted the print before it could break the printer. Apparently the electronics and Pronterface don't enforce a sufficiently safe bounding box in Z.
• Layers that are too discontinuous (that is, that consist of separate islands that are too small) suffer from the unavoidable imprecision in start and stop times of the extruder. Sometimes this results in prints completely failing, as the extruder wiggles around in the air millimeters away from the actual workpiece, perhaps spewing spaghetti.
• Very small layers can remain so molten that the achievable overhang drops dramatically.
• Warping during cooling can delaminate the piece and peel it up from the build platform.
• Vibration of the machine produces small but visible and palpable horizontal displacement errors.
• For some reason, polygons bulge at their vertices ("corner blobbing"), with the result that their outer edges are concave. Perhaps the extruder stops for a moment before changing direction.
• Horizontal or nearly-horizontal surfaces that are supposed to be solid sometimes come out porous, due presumably to miscalibration of filament diameter, and sometimes to other kinds of failures mentioned above on top layers.
• Stringers, of course, which are partly a problem of getting your forward and reverse pinch wheel settings right to prevent ooze, and also of having a toolpath that isn't too discontinuous; and you can wiggle the extruder around to break existing stringers sometimes. Skeinforge has a setting to try to build separated vertical "towers" each a few layers at a time, rather than potentially creating stringers between them on every layer, but unfortunately this needs a model of the extruder in order to work properly.
• Too small of a base area can make it too easy for the model to unstick from the glass.

Often one problem leads to another: maybe flexing leads to mounding, which leads to lost steps, which leads to spaghetti spewed into the void.

All of these problems can be solved with software, and e.g. Skeinforge has settings you can use to solve them already. So what am I suggesting that we do differently?

We can automate solving these problems so you don't have to use trial and error to get a working print.

Design Rule Checks

Semiconductor fabrication has had decoupling between the design and fabrication steps since about 1980, using the methodology designed by Carver Mead and Lynn Conway. As I understand it, which might be wrong, this works as follows. First you design your masks in software with some kind of abstraction of the process steps provided by your fab; then you simulate the circuits to get a good idea of analog performance; then you send the masks (originally on tape, thus the term "tape-out") to the fab, who produces some number between 10 and 100 000 of your new design, which you can test a few weeks later.

A crucial aspect of this process is a thing called "design rule checks", which you run on your masks before simulation, and which the fab

also runs on your masks before doing any photolithography. DRCs are mechanically checkable requirements which, if met, that ensure that your circuit will come out working properly despite the limitations of the fabrication process, things like "no wires less than 2Λ wide" and "minimum 2Λ spacing between wires". If your layout passes the DRCs specified by the fab, it's dramatically more likely to produce a working chip.

Shapeways publishes a sort of set of DRCs (they call them "design guidelines" or "printability checks") for STL files that you'd like them to print; for example, their ceramic page says, among other things:

Max bounding box: 340 × 240 × 170 mm and X + Y + Z ≤ 400 mm
Min bounding box: X + Y + Z ≥ 120 mm
Min density: 5% material density
Max wall thickness: 15.0 mm thick
Min embossed detail: 2.0 mm high & wide

There are another ten parameters describing what kinds of models they can print, at the STL level of abstraction. They do some of these DRCs (density, bounding box, wall thickness, model integrity) when you upload a model, while others are done manually.

But I'm thinking about DRCs a layer of abstraction down from there, because none of the problems I've seen with RepRap prints are things that printability checks would have caught, except for the bounding-box violation I mentioned above.

I want DRCs that are checks you run on your final G-Code that would detect problems like these:

• Excessively steep overhang (with different thresholds for cantilevered overhang and void-spanning overhang);
• Overhang deposited in the wrong order (spaghetti spewed into the void);
• Bounding box violations;
• Insufficient time to cool before printing another layer on top;
• Insufficient margin for error in filament diameter (resulting in possible mounding or possible unwanted porosity); and
• Ooze-producing patterns of movement (e.g. traveling immediately after shutting off the extruder)

Simulation and Optimization for Toolpath Design

To a great extent, you could use AI search techniques to find a toolpath that most closely approximates the desired shape (as expressed in an STL file) without violating DRCs, and then to optimize the toolpath for metrics like minimal plastic use and maximal speed. If you take this a little further, you find yourself simulating the plastic as it comes out of the extruder and cools, rather than using rules of thumb about allowable overhang, slenderness, and cooling time, with dozens of parameters that you have to tweak until you get reliably good prints.

(I'm assuming here that the thermodynamics and mechanics of the plastic coming out of the extruder can be characterized with a smaller set of parameters, ideally parameters that can be measured to a few significant figures rather than attempted via trial and error.)

But really you'd like to optimize things besides plastic use and print speed, while keeping the shape as a given. For example, maybe you'd

like to optimize strength or smoothness along with plastic use. But what is "strength"? That depends on the situation.

Why Are Long Bones Curved?

A lot of our long bones, like femurs, tibias, ulnas, and phalanges, are frequently subject to compressive stress. Since they're long and slender, an easy way for them to fail under compressive stress is by buckling: bending to one side or the other, giving the compressive stress progressively more leverage against the tensile strength on the outside of the bend, until the bone breaks. It's well known how to maximize resistance to buckling for a given slenderness of strut: make the strut as close to perfectly straight as possible, so that a greater force is needed to initiate buckling.

So why are all these long bones curved, since a broken bone is such a serious injury and so important to prevent?

I suspect that the answer is that early buckling, far from increasing the danger of broken bones, decreases it. The long bone's diaphysis acts as a spring, absorbing up to a certain amount of energy without damage, and limiting the forces experienced by other parts of the bone and the body until the energy and displacement are very large.

Now, I thought this was just a crank hypothesis I'd dreamed up, but it turns out that actual scientists published basically this idea in 1988: JE Bertram and AA Biewener, and they've been cited 149 times ; they cited other forms of it published in 1984.

So long-bone curvature is actually an advanced design technique for making bones and bodies less brittle. It was evolved by exploring the possibilities thoroughly with genetic algorithms, and has produced remarkably resilient and strong skeletons for our bodies by the judicious use of an unremarkable mineral.

Simulation and Optimization for Shape Design

I printed a connector to connect two plastic coke bottles together, with a vertical axis. It had a coke-bottle thread (PCO-1810) on each side, and a lip in the middle. The print took 45 minutes; as soon as I got two bottles into it, it delaminated, each bottle keeping its section of the thread.

I rotated it to horizontal, took the opportunity to thin out the lip a bit, and printed it again. As soon as I got two bottles into it, it delaminated again, but this time that meant it split lengthwise; still unusable.

I gritted my teeth and added massive ugly discs girdling the pipe. This pumped the print time up to 75 minutes, put a bunch of extra plastic in places that weren't weak, added ugly cylinder corners that made it look like a ray-gun plumbing fitting, and made the knurling on the bottlecap model I was using inaccessible to your fingers, but it was an easy few lines in OpenSCAD. This time it withstood several double-bottle insertions, only failing once I tried to really crank two bottles down onto the gaskets to see if I could get it to seal, and it only cracked instead of failing completely like the older models. It used almost three meters of filament.

Much of the problem, of course, is that PLA is comparatively weak compared to the polypropylene normally used for bottlecaps, but

more — it's brittle, in the sense that it can't be stretched very far before it breaks. But that's true of hydroxyapatite, too.

Suppose, instead, we were optimizing a feasible toolpath to provide strength *and resilience* with constraints to provide a lip against which the bottles could seal, without obstructing the bottles' threads (including as they screw in) or necks, and resisting movement of the bottles in all six degrees of freedom.

A first cut at the problem could be a huge block of solid plastic with bottle-shaped cutouts in it; a sufficiently large block would provide the required strength. (FEM simulation would be needed to find out how large.) Then, simply removing material from that block in different places would reduce the amount of plastic needed. Hill-climbing search might steer us to remove plastic less stressed by the bottle neck being screwed in tightly; some possible removals would reduce strength while improving resilience, while others would result in infeasible toolpaths. The ultimate result would surely be lighter-weight, more resilient, and more aesthetically pleasing than what I have sitting on my desk now, and it would take much less time to design and produce.

What it means that HTML is "not a programming language", and why the ignorant sometimes think otherwise

Kragen Javier Sitaker, 2019-09-09 (updated 2019-10-01) (24 minutes)

XXX tone down the arrogant pedant attitude

(Edited and considerably expanded from my comments on the orange website.)

What does it mean for something to be a "programming language"? It might seem like a trivial discussion of semantics, but as it turns out, it's important to care for semantics in order to have a conversation that conveys information, which is necessary for having culture.

Moreover, the real question here is not one of word definitions, but one of ontology: what kinds of categories exist in the real world? If we attempt to reason with incoherent categories, such as "non-elephant mammals plus mosquitoes", we cripple our reasoning. Reasoning with such categories, we are likely to believe that mosquitoes probably bear live young and produce milk, even if we haven't been able to observe these phenomena yet, and be unable to use observations of elephants to reject false hypotheses about mammals.

In the 20th century, after thousands of years of effort, the humans finally succeeded in formalizing the notion of an *logical procedure* or *algorithm* in the construct of a *computer program*, and the implications of this discovery touch on some of the most profound questions about the limits of the knowable, the foundations of mathematics, and even the nature of the physical universe; and subsequent experiments rapidly disproved many long-held philosophical notions about the nature of human thought. The concept of a *programming language* is emerging as fundamental to this far-reaching intellectual breakthrough.

Dismayingly, a recent article in IEEE Spectrum incorrectly described HTML as a programming language, so it seems to me important to clear up the confusion.

Popular confusion about programming languages

One person eloquently defended the popular confusion as follows:

> People don't care for semantics. If you write it and it causes a PC to do something (even if it's just to show a website), it's a programming language. Doesn't need to have branching, variables, etc... (not to mention that HTML includes JS and CSS) `print "hello world"`, `<b>hello world</b>`, same difference.

This seems to amount to the position "my ignorance is as good as your knowledge".

Unfortunately, this proposed definition of programming languages includes CSV, JPEG, Word, and URLs. Does that mean that anyone

who snaps a photo on Instagram is a programmer? This does not seem to be in accordance with the usual meaning of the word "programmer". Is it "programming" to write a dunning letter in Word? It seems to me like a qualitatively different activity.

Upon being presented with this argument, the misguided-egalitarian admirer of foolishness responded as follows:

> And yet people don't call them "programming languages", while they do call HTML that — so that even if HTML is not a programming language, there's still a not formally expressed difference that people can intuitively grasp with those other things...
>
> You can't program most things in SQL either (not without some modern extensions that make it Turing complete), but it is still considered a programming language...

So what is it that really distinguishes an ontologically coherent category of "programming languages" from other things, and why are the ignorant so frequently confused into thinking HTML is a programming language? What is this "not formally expressed difference" that "people can intuitively grasp"? And how much *can* you program in SQL, anyway?

The deep essence of programming languages

Programming languages are all more or less equivalent; although they have a variety of paradigms, and although they are supplied with a variety of I/O facilities, you can program more or less precisely the same set of *computations* in all of them. This is called "Turing-completeness".

Consider the differences between C, Forth, Smalltalk, Prolog, Fractran, Lisp, Brainfuck, Haskell, VHDL, amd64 machine code, Malbolge, Scratch, Octave, Python, and R: some of these do not even have branching or loops or variables, but they are all programming languages; none of them can compute anything that any of the others cannot.

The exception might be things like Turner's "Total Functional Programming", which excludes nonterminating computations without, he hopes, excluding much of practical interest; Excel, excluding the macro language, also has this limitation, but in Excel it is more onerous.

By contrast, you can't compute so much as a polynomial or NAND in HTML. That is to say, you can't program at all in HTML. So HTML is not a programming language. The same is true of CSV, JPEG, URLs, and Word documents (except insofar as Word documents might include macros).

You might say that HTML includes JS, but this is wrong. English does not include Latin, although, e.g.†, phrases like "*inter alia*" and "*et cetera*" can be used in English, and it's not uncommon for an English sentence to quote a Latin motto. Similarly, HTML does not include JS and CSS, just as it does not include the URL syntax, and Python does not include SQL or HTML; they are six separate languages.

† *exempli gratia*

An example of a borderline case: tabulating polynomials in SQL

It's fairly uncommon for people to call SQL a "programming

language", but you actually can program quite a bit with SQL; even without the recursive common table expressions alluded to above by the promoter of vulgar misconceptions, you can do surprisingly complex computations with it, and even define functions in the form of views, as long as they are finite. Certainly neither NAND nor evaluating polynomials poses any difficulty for SQL. In fact, here's an example of *arbitrary* polynomial evaluation in SQL which works in MySQL, MariaDB, Postgres, Oracle, and SQL Server:

```
select x, sum(a * power(x, e)) from data group by x;
```

In SQLite, you easily can evaluate a *particular* polynomial, or, with a bit more hassle, any polynomial up to some finite degree, but evaluating an *arbitrary* polynomial would seem to be out of reach without using recursive CTEs. Here's an example of how to do this for polynomials up to the fourth degree without recursive CTEs:

```
select x, sum(a * case e when 4 then x*x*x*x
                         when 3 then x*x*x
                         when 2 then x*x
                         when 1 then x
                         when 0 then 1 end) from data group by x;
```

The identifier `data` provides the polynomial to evaluate and the points at which to evaluate it; this can be a table or, in most dialects of SQL, provided directly inline. In SQLite, for example, in this case evaluating $5x^4 + 2x + 5$ at the points 0, 1, 2, and 3:

```
select x, sum(a * case e when 4 then x*x*x*x
                         when 3 then x*x*x
                         when 2 then x*x
                         when 1 then x
                         when 0 then 1 end)
from (select 3 as x union select 0 union select 1 union select 2) xt,
     (select 4 as e, 5 as a union
      select 0, 5 union
      select 1, 2) t
group by x;
```

This syntax works in other database engines, but in, for example, Postgres, you can instead simply say

```
select x, sum(a * power(x, e))
from (select 3 as x union values (0), (1), (2)) xt,
     (select 4 as e, 5 as a union values (0, 5), (1, 2)) t
group by x;
```

MySQL (5.5.62, at least) has `power` but requires the more verbose literal data syntax:

```
select x, sum(a * power(x, e))
from (select 3 as x union select 0 union select 1 union select 2) xt,
     (select 4 as e, 5 as a union
      select 0, 5 union
      select 1, 2) t
```

```
group by x;
```

Note, though, that even the Postgres version of this is somewhat repetitive; to evaluate the polynomial at 100 points, we would have to put 100 numbers and 192 more words into the source code. While this is not as bad as HTML, where we would have to evaluate the polynomial ahead of time (for example, with pencil and paper, or with SQL, or with an actual programming language) it still means that there are things that are easier to program in languages such as Fractran or Malbolge than in SQL — without recursive CTEs, that is.

With recursive CTEs, you can do it compactly, though fairly awkwardly, because recursive CTEs *do* make SQL Turing-complete:

```
with recursive redonditos as (select 0 as x union
                              select x+1 from redonditos where x < 99)
select x, sum(a * power(x, e))
from (select 4 as e, 5 as a union values (0, 5), (1, 2)) t, redonditos
group by x;
```

This works in Postgres (9.5.14) and, with the change explained earlier, in SQLite 3. MySQL doesn't support CTEs, at least as of 5.5.62.

Excel without macros, Coq, and GNU MathProg are other languages that can compute large classes of interesting functions but are not Turing-complete.

What kinds of generalizations are valid about programming languages?

The first and most important fact about programming languages is the Turing Tarpit Principle: they are all equivalent, in the sense that *any of them can compute any algorithm*, which is to say, anything any of the others can compute; but that does not mean that it is equally easy in all of them. ("In the Turing Tarpit," observes Fred Brooks, all computable functions are "possible, but nothing of interest is easy." "Turing Tarpit" languages like Malbolge perversely elevate this to a design goal, and so it took several years for someone to figure out how to write a working loop in Malbolge.)

In particular, the Halting Problem applies to all of them: you cannot always compute whether a program in them will continue to loop forever on a given input, or whether it will eventually terminate. Turing gave an airtight but somewhat lengthy and mindbending proof of this in 1936.

The Collatz conjecture in Python; does this program halt?

But a very simple argument that shows that this is at least very difficult is searching for counterexamples to the Collatz conjecture. In Python:

```
cn = lambda n: 3*n + 1 if n % 2 == 1 else n // 2
(x, n, m, p) = (1, 1, 1, 0)
while True:
    if m == 1 or cn(m) == 1:
        print("{} → 1 in {} steps".format(x, 2*p if m == 1 else 2*p+1))
        (x, n, m, p) = (x+1, x+1, x+1, 0)
    else:
        (n, m, p) = (cn(n), cn(cn(m)), p+1)
        if n == m:
```

```
        print("{} loops without reaching 1".format(x))
        exit()
```

This produces lines such as the following:

```
1 → 1 in 0 steps
2 → 1 in 1 steps
3 → 1 in 7 steps
4 → 1 in 2 steps
5 → 1 in 5 steps
6 → 1 in 8 steps
7 → 1 in 16 steps
8 → 1 in 3 steps
9 → 1 in 19 steps
10 → 1 in 6 steps
```

The Collatz conjecture says that this sequence, where the successor of a number n is $3n + 1$ for odd n and $\frac{1}{2}n$ for even n, reaches 1 if you start at any positive n. Lothar Collatz proposed this in 1937, but nobody has found a proof of it yet, nor a disproof. If the conjecture is true, then the program above will run forever, continuously printing lines of text, if it isn't halted externally. If it is false because there exists a Collatz cycle that doesn't include 1, the program will halt by invoking `exit()`. If it is false because it finds a Collatz sequence that increases without bound, it will instead run forever without printing anything, if it doesn't run out of memory first.

Nobody knows which of these three is the case, despite some 80 years of effort from many of the most famous mathematicians and physicists; at least one book has been published on the subject. (It is entitled *The Ultimate Challenge*.) That is, 80 years of research by many people has not been sufficient to predict the behavior of the 11 lines of code above. And you can translate that code into *any programming language*. (However, it is known that if there is a counterexample to the Collatz conjecture, it is larger than 87×2^{60}, so your translation may involve multiple-precision arithmetic and therefore be several pages of code. Python has arbitrary-precision arithmetic built in.)

The Collatz conjecture in non-Turing-complete languages

You cannot translate it into CSV, JPEG, HTML, URLs, Excel without macros, SQL without recursive CTEs, Coq, MathProg, or Turner's Total Functional Programming. However, you can translate *the computation within the loop* into most of these, at least with numbers limited to some finite size (such as 128 bits or 256 bits); that is, you can translate this part:

```
cn = lambda n: 3*n + 1 if n % 2 == 1 else n // 2
if m == 1 or cn(m) == 1:
    print("{} → 1 in {} steps".format(x, 2*p if m == 1 else 2*p+1))
    (x, n, m, p) = (x+1, x+1, x+1, 0)
else:
    (n, m, p) = (cn(n), cn(cn(m)), p+1)
    if n == m:
        print("{} loops without reaching 1".format(x))
        exit()
```

For example, here is a fairly horrific but apparently correct† translation into SQL (without recursive CTEs), tested in SQLite3 and Postgres:

```
select case when nextx then x + 1 else x end as x,
       case when nextx then x + 1
            else (case n % 2 when 1 then 3*n + 1
                                    else n / 2 end)
       end as n,
       case when nextx then x + 1
            else (case newm % 2 when 1 then 3*newm + 1
                                       else newm / 2 end)
       end as m,
       case when nextx then 0 else p+1 end as p,
       case when nextx then 0=1 else n = newm end as exit
from (select (m = 1 or newm = 1) as nextx, x, n, m, p, newm
      from (select x, n, m, p,
            case m % 2 when 1 then 3*m + 1
                            else m / 2 end as newm
            from (select 16 as x, 4 as n, 1 as m, 2 as p) state) a) b;
```

From there it is a matter of finding some external way to initialize the computation and repeat it until it results in your translation of `exit()`. (And, as Turing argued, this is a generalized property of all programs, not just this Collatz program — as long as you have infinite memory, any of them can be rendered into an even more limited form where each execution step is just a lookup in a finite table of next actions.)

However, even in this limited form, you cannot translate the Collatz program into HTML, CSV, JPEG, or an URL. So, in that way, things like Excel without macros and SQL without recursive CTEs are still *programming languages*, even though they aren't Turing-complete, while things like HTML are not.

† Implementing multiple-precision arithmetic in SQL is left as an exercise to the reader. Maybe you can use `DECIMAL` — in Postgres, `select power(2::decimal(30), 64) - (power(2::decimal(30), 64) - 1)` works correctly, but that syntax is a Postgres extension to SQL.

The Collatz program in SQL with recursive CTEs

In Postgres 9.5.14 the query

```
with recursive collatz as
   (select 1 as x, 1 as n, 1 as m, 0 as p, 0=1 as exit union
    select case when nextx then x + 1 else x end as x,
           case when nextx then x + 1
                        else (case n % 2 when 1 then 3*n + 1
                                                else n / 2 end)
           end as n,
           case when nextx then x + 1
                        else (case newm % 2 when 1 then 3*newm + 1
                                                   else newm / 2 end)
           end as m,
           case when nextx then 0 else p+1 end as p,
           case when nextx then 0 = 1 else n = newm end as exit
    from (select (m = 1 or newm = 1) as nextx, x, n, m, p, newm
```

```
        from (select x, n, m, p,
              case m % 2 when 1 then 3*m + 1 else m / 2 end as newm
              from collatz where not exit) a) b
    where x < 100)
select * from collatz;
```

appears to work, producing 1634 rows in 23 ms.

In SQLite 3.11.0, subqueries cannot refer to recursive CTEs, and it's not obvious to me how to reformulate this query to eliminate the subqueries.

Rice's Theorem

We could describe the above program as computing a partial function of the integers, namely how many Collatz iterations it takes to reach 1 from each integer. It's a *partial function* in that the program might fail to produce an answer for a given input if that Collatz sequence increases without bound. Rice's Theorem extends Turing's proof of the Halting Problem's incomputability to say that there is no algorithm to prove any nontrivial property of the partial function computed by given Turing machines, and thus by given programs in any Turing-complete programming language. The definition of "nontrivial" is amazingly wide.

Computational complexity

There is additionally an issue related to *computational complexity*: in programming languages it is easy to write a program that will take a very long time to run, even if it terminates.

The conclusion: programming languages mean trouble

This means that it is very easy to, in some sense, get ourselves in trouble in any programming language — to produce a program intended to do something in particular, but not be able to tell whether the program does in fact always do that. This leads to the widely-remarked-on phenomenon of buggy software.

Does this mean programmers are awesome and Web designers are not?

No. If we can extract any value judgment from this, it is rather the opposite: it means that programmers are constantly tripping over their own feet attempting to accomplish even seemingly-trivial tasks in their programs. This is the motivation behind the design of non-Turing-complete languages like Coq, GNU MathProg, URLs, HTML, Excel, and SQL (at least until recently): by steering clear of Rice's Theorem, we can ensure that our constructs behave in predictable ways, can be analyzed in certain ways, and can be changed in predictable ways. In the history of the WWW, this was called the "Principle of Least Power"; HTML was deliberately designed to not be a programming language due to experience with using programming languages like PostScript and TEX to represent documents.

In building any system, you should do as little as possible in programming languages and as much as possible in passive data formats like HTML.

The ongoing struggle to navigate between the Scylla of programming by copy-pasting boilerplate and the Charybdis of Rice's

Theorem has given rise to a fruitful and active area of research that continually expands the set of borderline "programming language" cases; the SQL example above shows one of the most successful cases. However, HTML is nowhere near that borderline. It is a format for passive documents consisting of marked-up text.

Perhaps some of the ignorant confuse HTML with programming languages because it's written in plain ASCII text

I have occasionally heard people saying HTML is a programming language. But they're just wrong. Presumably most people at some point thought the world was flat; we shouldn't attempt to explain away their error by saying that they meant something different by "world" or "flat" than we do. Some people think vaccines cause autism; this isn't actually because they're using the word "vaccine" or "autism" in a different sense than we are. They're just wrong. (As for the people who think organic food contains no chemicals, I'm not sure; I think some of them are just wrong, while others are in fact just using a nonstandard definition of "chemical", meaning something like "pure chemical" or "industrially produced chemical".)

In the same way, people are just wrong if they think HTML belongs to the set that includes C, Forth, Smalltalk, Prolog, Fractran, Lisp, Brainfuck, Haskell, VHDL, amd64 machine code, Malbolge, Scratch, Octave, Python, and R, rather than to the set that includes CSV, JPEG, Word, and URLs. Similarly, bash clearly belongs to the former set, and Excel (without macros) and SQL arguably do.

In a lot of cases, they seem to be reasoning based on shallow surface features like the use of plain ASCII text files. (You can see several examples of this even in the original thread discussing the issue on the orange website.) This is similar to the neural network that learned to recognize photos of tanks based on whether the photos had been taken on a sunny day or a cloudy day, or the people who think I'm "hacking into systems" when they see me using a terminal emulator — an understandable error from the ignorant and foolish, but not one we should allow to confuse our own thinking.

After all, to an illiterate person, a page full of random letters and spaces looks much the same as a page of a novel or a page from a legal brief, and quite visibly different from, for example, a painting of the Virgin Mary or a pornographic sculpture. We would not therefore assert that the legal brief is "fiction", nor the page of random letters "legalese". But an unlettered peasant might make such an error, just as they might assert that the Earth is flat.

This, I think, is the "not formally expressed difference" that "people can intuitively grasp": if you don't know how to read it, an editor window full of HTML looks similar to an editor window full of JS, and different from an editor window with a Microsoft Word document in it, because the font has a fixed width and all the letters are the same font size. That's what people intuitively grasp.

The surprise is to find that the editors of IEEE Spectrum have fallen to such abysmal levels of ignorance.

Is it bad to be ignorant?

It is *unfortunate* to be ignorant, not *reproachable*. Reproaching someone for their ignorance is contemptible, like reproaching poor people for their poverty or sick people for their sickness. But to *spread* ignorance is to impede others from escaping that unfortunate situation, and that *is* reproachable. It is malfeasance as surely as robbery or deliberately infecting people with diseases.

Where did the Rubius comic book come from?

Kragen Javier Sitaker, 2017-01-10 (4 minutes)

It was 2015-10-13. Holy shit, I had future shock. I'd just bought a hardcover comic book (A4 size, full color, sewn in signatures) of Rubius. The Youtuber. At a newspaper stand.

Who is Rubius? He had 14 million subscribers on YouTube; now, 2017-01-10, he has 22.6 million. Has there ever been a public access cable show with 22 million fans? Mostly they're gaming videos. He describes it as follows: "My channel of Gayplays of Minecr... Wait. No. My channel is of Gayplays in general, but I never play anything predefined. Some days you'll find horror games, others fun games, others indie games, etc., but I don't only upload Gayplays!"

I have no idea what "gayplays" are.

I'd heard of Rubius previously because when he had come to Argentina the year before, 2014, there was a problem when his fans showed up at the airport.

Paul Visscher estimated that he easily makes 7 or 8 figures per year with his six million views per video.

I'm just surprised to live in a world where a gamer uploading videos to YouTube is merchandising his brand via comic book spinoffs.

I looked into the economics of the comic book slightly. I bought the book for US$9.50. The printing is done, not somewhere in Asia, but by Cartoon S.A. in Salta, Argentina. The Argentine copy I have says it's the second edition (which I think means "printing"), printed in 30,000 copies. The artist is María Dolores Aldea, aka Lolita Aldea. She posted the first 10 pages in PDF on her web site, from which we can see that the Spain version of the book is printed by Unigraf SL, a Spanish company, in Catalonia, on the Mediterranean coast of Spain, near Valencia. They also print invitation cards and personalized paper napkins.

Cartoon S.A. is a little harder to figure out, but it looks like they mostly do graphic design and printing for brochures and stuff like that.

It seems like the "publisher", as distinct from the two and presumably more printing companies, is the "children and young adult" imprint of Grupo Planeta. It doesn't seem to be a vanity press like, say, Blurb or Lulu. It was founded 70 years ago.

So, I'm thinking that Editorial Planeta ("Planet Publisher") probably bought personality rights from Rubius and are paying royalties to him and the cartoonist. Most of their kids' books seem to be cartoon books where they licensed the characters from someone else: Maya the Bee (although the original book is out of copyright, the book looks like a spinoff from the TV series), Violetta, Pixar's Planes. Apparently this is their second Rubius book; the first one was "The Troll Book".

The thing that surprised me was not so much that there is a guy who is well-known among Spanish-speaking video game fans — his videos are in Spanish — but rather that he was *so* well-known that

random newspaper stands on the street were selling comic-book spinoffs from his YouTube channel. This was future-shockish to me. Again. Like in 1994 when suddenly the number of internet books in bookstores went from like 3 to like 300 in the course of a few months, or 1996 or 1997 when suddenly advertising had URLs in it. It's kind of mindblowing to me that a gaming channel on YouTube is now a licensable brand on the same level as Disney shows and Pixar movies. And this was apparently their "most commented" book in the "young adult" category, although the Violetta and Maya and Planes books are in a different category; *Violetta. En mi mundo* is one example.

It's also interesting that this 70-year-old press is outsourcing the actual printing of these books to random graphic design storefronts in different countries.

Notes and calculations on building luxury underground arcologies for whoever wants them

Kragen Javier Sitaker, 2013-04-17 (updated 2019-08-27) (66 minutes)

Arcosanti was Paolo Soleri's project to build the city of the future in the Arizona desert. The Venus Project is Jacque Fresco's project to build it in the Florida swamps. They have been noticeably less successful than other efforts such as Burning Man, which gives the appearance of having been inspired more by *Mad Max: Beyond Thunderdome* than *Star Trek*, or Dubai. One of the cornerstones of Soleri's vision was the "arcology", a kind of building-sized self-sufficient city.

Here I try to imagine what kind of arcology I would like to live in.

Some of this will probably seem outdated in a short decade or two, in particular my concern for energy conservation. Rather than seeing a movement toward energy self-sufficiency in small groups, I think we'll see something like another decade of energy scarcity, ending around 2026, as bigger and bigger fractions of the globe are devoted to harvesting solar energy, now that it's finally become cheaper than fossil-fuel or nuclear energy.

The population density question

A basic question about such structures is how much population density they can accommodate. For self-sufficiency, they must necessarily use no more energy than they can harvest from their environment; in the simplest case, with no deep drilling and fracking to harvest geothermal and no nuclear reactors, this is merely the solar energy available to them.

The NREL Solar Resource Maps show a photovoltaic solar resource of 125–250W/m² in the US, which they have unfortunately chosen to state in non-SI units as 3–6 kWh/m²/day.

This is necessarily the energy supply before the inefficiencies of conversion to electricity; the solar constant above the atmosphere is only 1400W/m², the sun only shines at most half the time for 700W/m², and it's not direct all of that time; reaching 250W/m² *after* photovoltaic conversion would imply panel efficiencies of 50%, which has not yet been achieved.

A human being normally needs to eat 100–120 W (unfortunately typically rendered in non-SI units as 2000–2500 kcal/day), equivalent to about 5–6 mg/s of carbohydrates or protein, in addition to micronutrients; but micronutrient needs can be satisfied at an insignificant energy cost.

(For brevity, I'll frequently use the Chinese 人 to mean "person" in what follows.)

Dividing these two numbers, we have an *absolute maximum* population density of about one or two people per square meter in temperate areas like the US. A standard 100-meter-square city block could then accommodate some ten or twenty thousand people, which works out to one or two million per km². Wikipedia tells me this is

much higher than any real city:

City	人／km²
maximum for self-sufficiency	1500000
[Friendship Village, Maryland][2]	32000
Delhi	29000
Ahmedabad	22000
Manhattan (in New York City)	27000
Chennai	26000
Mumbai	23000
Paris	21000
Cairo	18000
Buenos Aires	17000
New York City	10600
Taipei	9600
Shenzhen	8600
San Francisco	6600
Hong Kong	6500
Tokyo	6000
Los Angeles	3000

However, real solar plants (see the "Utilities → Food" section below) don't even approach 100% conversion efficiency, nor does any known means of conversion of sunlight to electrical, chemical, or mechanical energy. Typical large-scale electrical efficiencies are 16% for the sunlight that hits the panels, but the panels are placed some distance apart so they don't shade each other when the sun angle is suboptimal — since panels are so much more expensive per m² than sunny land, emphasis is placed on not wasting panels, rather than not wasting land — so typical yields are more like 11W/m² for Optisolar's Sarnia project, 6.25 ac/MW = 40W/m² for Nevada Solar One, 15.5MW/85 acres = 45W/m² for SunEnergy1's Duke Energy project.

There are currently-shipping mass-producible thin-film panels that hit 20%, space-deployed very expensive multijunction semiconductor panels that hit 40%, and concentrating solar can hit the usual 35–40% for large fixed steam turbines. There are some potential nice synergies here: photovoltaic panels, including multijunction panels, are nearly black, so the sunlight that photovoltaic panels fail to convert to electricity is mostly converted to heat rather than reflected, which means you can use it to make steam, and concentrating the light means you can justify the use of much more expensive photovoltaic cells, but if you're concentrating more than one or two suns on your cell, you'll need some kind of active coolant to keep the cell from melting — such as steam! So in theory you might be able to hit 50% or 60% conversion efficiency with the combination, but nobody's done it yet.

Modern life involves using energy beyond the bare necessity for survival, generally quite a lot of it, mostly bought on the market rather than harvested for direct use. A self-sufficient arcology would probably have to be less efficient in its material energy use than the average person in a modern society, who takes advantage of economies of scale and specialization in many kinds of goods. The USA DOE EIA AER estimates 2011 marketed energy use in the USA at 97.30 quadrillion Btu/year, another absurd non-SI unit; this

quantity is actually 3.243 terawatts; if we figure 311.8 million people, that's 10.4 kW per person, the equivalent of about 100 slaves per person, Buckminster Fuller's "energy slaves".

Let's assume that the overall solar conversion efficiency hits 30%, rather than 50% or 65% or staying at 16%, and that the overall electrical energy use of the inhabitants of the arcology is one-third lower than current US marketed energy use, for the following reasons:

- They don't need to heat or cool their houses actively or separately; the arcology's surface area per person is much smaller and well-insulated, and it uses primarily passive climate control.
- They spend very little or no energy on actively chilling their food; the arcology provides a cold reservoir which provides this service free.

- They spend no electrical energy on daytime lighting, because light is provided more efficiently through a system of lightguides.
- Because the arcology is self-sufficient, they don't need to spend much energy on transporting goods to it, or transporting themselves to goods.

If we need 10.4 kW per person, each person would need 83 m² at 125 W/m² or 42 m² at 250 W/m², giving a density of some 12000–24000 人/km². If we double this, on the assumption that we'll lose a factor of 2 in efficiency to generalization, we get 6000–12000 人/km².

XXX what about the factor of 5 in efficiency you lose to current PV cells? Huh? I don't think the NREL figures cover that! RECALCULATE EVERYTHING. unless NREL *does* cover that.

XXX if I just multiply everything by 5 it stops being an arcology at all. Possible optimistic assumptions:

- maybe solar energy efficiency will improve, so that you get, say, 33% of the light, instead of 20%, due to combining concentrating solar with photovoltaic?
- maybe people in an arcology won't use as much energy, because people outside an arcology use a lot of energy to heat and cool their houses and foods, about half of it; so perhaps they'll use 33% less.

With these two 2:3 optimistic assumptions, you use only 4/9 of the current energy and therefore need only 4/9 of the land area.

XXX recalculating again from first principles: current low-cost PV panels are 16% efficient, and current utility-scale PV capacity factors range from 10% (in Germany) to 29% (in California) or a bit more, with the US average being around 24%. (See Japan can achieve energy autarky via solar energy, but not much before 2027 (p. 2819).) Those factors are normally calculated relative to a nominal "solar constant" of 1000 W/m², so a 20% CF means 20% · 16% · 1000 W/m² = 32 W/m². This means that 10.4 kW is **325 m²**, quite a bit more than 42. This gives a density of only 3000 人/km². So it looks like the NREL figures *didn't* account for PV inefficiency.

This is 10× the threshold population density where the EU defines an area as urban but about one sixth the population density of Buenos Aires.

XXX food refrigeration is perhaps a fundamental utility service!

42 m² by itself is a fairly comfortable, if smallish, apartment. So

this kind of "arcology" could comfortably be constructed, at first, as a city block of single-story construction, which means you could bootstrap it fairly incrementally; you don't have to start with a megastructure.

But if you want a megastructure — especially a pleasant one — it's far cheaper to build parts of it all at once, due to certain economies of scale.

Envisioning universal luxury dwelling

Contrary to the usual Cold-War-era utopias, I don't envision an above-ground mass of megalomaniacal architect-ego-worship, nor some kind of giant right rectangular parallelepiped with sad little rectangular holes in its bare gray concrete walls, nor gleaming cubes and towers — I'd prefer to leave the above-ground surface as a park, with crops, meadows, trees, perhaps a forest with some babbling brooks, and keep the human habitation beneath the ground. Sunlight can easily be brought downstairs with the occasional translucent artificial stone cemented in place below the dirt-line, and ventilation requires a few wide ventilation towers, which can be constructed in organic shapes and beautified with vines.

Subterranean dwelling is not a new idea, going back of course to Paleolithic hunter-gatherers, and featuring in many science-fiction stories, but here I explore why it's historically been marginal (mostly confined to extreme conditions and military surplus reuse), why we now have the option to change that, and how completely fucking awesome it could be.

Underground construction is tricky and expensive, particularly in wet areas where the water table approaches the surface. Here in Buenos Aires, each construction site excavation vents a continuous stream of seepwater into the gutter, proceeding, I suppose, from a pump down at the bottom of the pit. Water tends to trickle and seep in through porous materials like concrete, needing continuous pumping to keep it from eventually filling your living space. Less porous building materials (e.g. concrete sealed with water glass or resins) reduce the seepage, but they don't eliminate it. Even missile silos in the Great Plains fill up with water when left unattended.

There are also risks like collapses, poisonous and asphyxiant gases, and explosive gases; these three can be minimized during construction by digging a pit instead of a cave, but in many places, further measures must be taken after construction to prevent them.

But underground construction has advantages. Aside from the benefits of being able to enjoy the land surface as a park, underground construction is silent, naturally temperature-stable, and much less vulnerable to terrorist bombing — perhaps not a concern wherever you live at the moment, but that's what people here in Buenos Aires thought until Hezbollah blew up the Israeli Embassy and AMIA in the 1990s.

Suppose, though, that instead of a single story of underground construction, we have ten stories, but still one person per 80 or so square meters of ground area (6000 人/km², comparable to the density of Tokyo, in between Los Angeles and San Francisco or Hong Kong). Now the average person has 800m² of live/work/storage space, some of it shared with others, plus 80m² of park; the average couple has 1600m².

This is enough for a sort of underground termite mound of palatial mansions. A normal bedroom may occupy some 16m²; 50 of them will fit into 800m². Every man, woman, and child could easily own their own 12-bedroom mansion.

Hearst Castle, that classic of robber-baron gilded-age excess with its 56 bedrooms, occupies some 8400m², so 800m² of floor per person is enough for truly palatial living. The question is whether we can make that kind of thing affordable to everyone.

Excavation volume and costs

Summary: it looks like it costs about US$30k/人 to dig the hole using current mining methods, although that's still really far from the fundamental efficiency limits.

Volume: 3200m³/人; weight: 7000Mg/人; energy: 1.4GJ/人 or US$20/人

If the average height of a story is 4m — with some ceiling height variety to allow some rooms to be cozier and others more majestic — this is 400k(m³) of excavation, some 3200m³ of excavation per person, perhaps 7000 tons of dirt and stone to remove. I have no idea how to estimate the economic cost of this, except that it is one of those things that has truly enormous economies of scale, since big strip-mining steam shovels are vastly cheaper per ton of rock than little backhoes; but the *energy* cost of listing 7000 tons by an average of 20 meters is some 1.4 gigajoules.

Energy is commonly priced in yet another non-SI unit, the megawatt-hour (MWh), at typically around US$40 wholesale (US$11/GJ), and two to five times that retail. A megawatt-hour is about 3.6 gigajoules, so we're talking about an energy cost of excavation of some US$20 per person.

(Looking at it another way, at 125 W/m², 1.4 gigajoules per 80m² is about 39 hours' worth of energy production.)

Landscaping excavation techniques would cost US$1.5M/人

Some random web site says that typical excavation costs are US$299.64 to US$423.77 per cubic yard (another non-SI unit of some 0.764 m³), which would place the cost of excavation of the above at some US$1.3–$1.8 million per person. However, I'm fairly confident that that's a backhoe cost, not a strip-mining cost, while what I'm envisioning is more a strip-mining kind of operation (or "surface-mining", as the miners like to call it these days), followed by construction and surface restoration.

Strip-mining excavation techniques: US$30k/人, 4 months

The Global Surface Mining company web site boasts of a trial where one of their surface-mining machines removed 830 tonnes of limestone per hour of operation. At this rate, you could excavate the 7000 tons for the habitation of one person by using one machine for a single ten-hour shift; excavating an entire 100-meter-square city block, digging self-sustaining luxury homes for 125 people, would take some one to four months.

But how much would that really cost? An online Open Pit Mine Model seems like it might be more relevant:

This mine is an open pit mine producing 5,000 tonnes ore and 5,000 tonnes waste per day. The total resource to be mined is 18,715,000 tonnes. Ore is hauled 1,068

meters to an ore stockpile. Waste is hauled 535 meters to a waste rock dump. Rock characteristics for both ore and waste are typical of those of granite or porphyritic material. Operating conditions, wage scales, and unit prices are typical for western U.S. mining operations. ... November 2007

Some further figures drawn from that model:

Hours per shift	10
Shifts per day	2
Days per year	312
Total Hourly Personnel	38
Total Salaried Personnel	15

Supplies & Materials	$/tonne ore	$2.07
Labor	$/tonne ore	1.96
Administration	$/tonne ore	0.82
Sundry Items	$/tonne ore	0.48
Total Operating Costs		$5.33

Total capital costs	$15,988,500

More than half the total capital costs are equipment, including a single 4½-cubic-meter hydraulic shovel. There are two four-kilowatt pumps included, presumably because of the water seepage I mentioned earlier; that's a heck of a lot of seepage.

So these guys are spending US$5.33 to remove two tonnes of rock (one tonne of ore and one tonne of waste), plus their capital cost. If we were to use the same equipment and methods to dig a 40-meter-deep hundred-meter-square hole, removing 875000 tonnes of rock and soil — let's just call it a million tonnes — then it would have an *operating* cost of US$2.7 million, and at 10 000 tonnes per day, would take 100 days, almost four months. If you divide by the 312/365 days they work, you get 117 days.

If you divide that among 125 people, it's US$21000 per person. Not insignificant — certainly much greater than the US$20 per person that is the inherent cost of the energy to just lift the soil up — but not an overwhelming cost in the world of construction, either.

But wait! I haven't accounted for the capital costs yet. If we figure an interest and depreciation rate of some 20% per year — high for the US, but probably reasonable for much of the world — we end up spending about 6% of the capital cost on interest and depreciation. That adds up to about US$960k, bringing the total cost to about US$3.7M, or US$30k/人. (This is assuming, perhaps optimistically, that capital line items like "Engineering & Management" and "Buildings" represent things you could sell without too much loss at the end of the operation.)

About a third of that cost is labor, and the population of the dwellings is more than double the size of the digging crew, so it seems likely that you could reduce the money cost by a third by means of DIY, or perhaps half or more, if you use methods that are more labor-intensive and less capital-intensive.

It seems possible that a larger-scale excavation operation would be more efficient, but given the number of equipment items of which only a single item is present, it seems likely that a smaller-scale one would not reduce the cost by much.

These fairly enormous capital equipment investments probably explain why underground construction is not traditional, because without them, it's not only dangerous but ruinously expensive.

Alternative to excavation: build a hill

As an alternative that involves moving less dirt, and might help with water seepage, you could build your arcology essentially above ground, but then cover it with dirt. The dirt sloping away from the center will encourage the water to run off, and so the water table won't rise toward the center of the hill as much as you think it might; and you can run drain pipes underground to provide passively-safe drainage and seep protection for the buildings inside.

This is basically your classic science-fiction pyramid-shaped arcology, but with a layer of dirt on top of it, and with its outer walls restricted to a slope of at most 30° above the vertical in order to keep the soil from slumping off. Since in this case the base will be four times as wide as the height, the bh/3 pyramid volume formula in this case reduces to $16h^3/3$, times or divided by some minor deviation from squareness. If you want it to have the $125 \times 80m^2 \times 4m \times 10 = 400k(m^3)$ volume of the previous excavation, it needs to be about 42 meters tall and 170 meters wide at the base; if its surface is covered in three meters of soil (vertically, not perpendicularly), that's about $85000m^3$ of soil, or about $677m^3$ per person, less than a tenth of what you'd have to remove for the excavated version.

A circular mound is slightly taller, narrower, and with less surface area; a triangular or kidney-shaped one would be the opposite.

While this might seem more handicapped-accessible than the purely-underground version, you could of course add small hillocks to that version to provide ramp or elevator access, or ordinary small buildings, as in the Terra Vivos entrance near Barstow.

In the USA, it used to be that once a hill was 1000 feet (almost 305 m) tall, you could call it a "mountain" (although the USGS no longer has such a hard-and-fast rule). So if you scale this proposal up by a linear factor of 8 (an area and population factor of 64, a volume factor of 512), you get 8000 people living inside an artificial mountain, each with an average of 25600 m^3 (6400 m^2). The construction cost per person would remain similar.

Concrete: US$14000–45000/人

Once you have a gigantic hole in the ground, or a building site for a hill, before you can landscape its roof into a park and start building mansions and cathedrals inside, you have to build that roof, and also stop up the seepage from the walls. As far as I can tell, the essentially universal technique at this point in history is to use reinforced concrete, made with portland cement, for floor, pillars, and ceiling, and either concrete or something similar for the walls to keep the water out.

It's conceivable that some other kind of construction technique could work and be cheaper, but I don't know of a candidate.

The surface area of a 100m×100m×40m hole in the ground would be $(20000 + 4*4000)m^2 = 36000m^2$, so each cm of thickness of concrete means $360m^3$, or about 900 tonnes, or 7.2 tonnes per person, of concrete that will be needed. The surface area of a 170m×170m×42m pyramid would be $(170\times170 + 170\times170\times\sqrt{5}/2)m^2$

= 61000m², 610m³/cm, 1.47Gg/cm, or 11.7 tonnes/cm/人.

Unfortunately, I don't have any idea how thick concrete needs to be for this kind of construction. If I guess (I hope reasonably?) that it needs to be some 20cm thick, we end up with:

	total concrete	total concrete	concrete mass/人
square pit	7200m³	18000 tonnes	144 tonnes
pyramid hill	12200m³	29000 tonnes	230 tonnes

These numbers are smaller than the amount numbers for the amount of rock and dirt that need to be removed from the hole, by about two orders of magnitude, so I assume that the labor cost to put this amount of concrete in place will be small compared to the labor cost to dig the whole. Nevertheless, concrete costs US$100–200/tonne, so we're looking at a materials cost per person of US$14000–45000.

The cement in concrete costs about 330–660kWh/m³, which is to say 1.2–2.4GJ/m^3, to produce. At US$11/GJ, this is a very small fraction of the dollar cost of the concrete. At 10.4kW/人, that's about 33–66h/人/m³, so we're looking at about 80–160 days of the arcology's population's usual total energy usage to produce the cement; or, if the arcology were to produce its own cement, 40–160 days of its own energy harvest. In practice, it's probably not reasonable to expect the arcology to be self-sufficient before it's built!

You can probably strengthen the walls substantially and avoid the need for internal support pillars by making them not flat — like an eggshell, they should be everywhere convex outward, except possibly t the bottom — and veining them, like a leaf, an insect's wing, or a plastic injection-molding.

Once you're done with the excavation and sheathing it in concrete, you're done with the parts of the traditional construction process that benefit enormously from economies of scale. Everything past this point can be done incrementally without dramatically increasing its unit cost.

Possible future concrete alternative: biocementation

I was interested in Magnus Larsson's 2009 "Dune: Arenaceous Anti- Desertification Architecture" proposal a few years back to cement desert sands using urea, Bacillus pasteurii bacteria that ferment it into alkaline carbonate, and calcium chloride to form calcite from the carbonate; but nothing seems to have come of it, and the process seems to produce hazardous quantities of ammonia, as anyone who's inadvertently fermented urea can tell you. So it might be a cheaper alternative at some point, but isn't yet; watch Ginger Krieg Dosier's startup "bioMASON" to see if it works out! (Dr. Dosier Tweeted me that in her process, the "by-product is captured in a closed loop system", by which I assume she means they make their bricks in a hermetically-sealed chamber and bubble the ammonia through a sulfuric-acid solution, or maybe just dissolve it in water and recycle it into new urea.)

If it does work out, we can expect the result to be as hydraulic as portland cement, slightly less porous, and perhaps significantly cheaper. You don't need a cement mixer, the raw materials are urea and calcium chloride, and you may be able to use aggregate in-situ by soaking it with the water-soluble cement components. Portland

cement costs US$110/ton, and comprises between a quarter and half of the mass of concrete, and therefore about a third of its cost. Urea costs about US$400/ton, while calcium chloride costs about US$200/ton; but the resulting calcium carbonate will not include most of their mass, since the chloride ion and the majority of the urea (both its amines, which is to say, everything except its carbonyl) are merely waste products.

Even if it's possible to substitute raw piss for industrial urea, it would not reduce the cost substantially. Piss is only about 1% urea, So you'd need 100 tons of piss per ton of urea, and I think you get 1 mole of carbonate per mole of urea, which is to say 60g of carbonate or 100g of calcium carbonate per 60g of urea — that's assuming the other oxygen comes from dissolved O_2, not from more urea molecules — so you'd need 60 tons of piss per ton of cement, or 8600–14000 tonnes of piss per person. At a rate of 1–2 ℓ of piss per person per day, this would amount to 12–38 millennia of piss production. Gathering the piss of millions of people for the construction project would cost more than simply buying industrially-produced urea.

Reinforced biocement would seem to pose a couple of major problems. The first, which may not matter in this application, is that calcium carbonate expands and contracts very little with heat, while portland cement has an expansion coefficient similar to that of the reinforcing steel, so reinforced lime cement will tend to crack when exposed to thermal stress — which hopefully subterranean construction won't experience! The second is that chloride ions can corrode the reinforcing steel even in extremely alkaline environments, so to reinforce biocement with steel, you probably need a source of calcium other than calcium chloride. Unfortunately, the other soluble calcium salts that occur to me (calcium bromide and calcium iodide) are much more expensive, and furthermore, I'm not sure they wouldn't cause the same corrosion.

An alternative that's been sometimes explored in the past, which might solve both problems, is reinforcing concrete with bamboo rather than steel. You need a higher fraction of bamboo than steel to reach the same strength, but I'm pretty sure chloride doesn't degrade the cellulose that gives the bamboo its strength.

Possible concrete alternative: submarine electro-accumulation

As reported in the March/April 1980 *Mother Earth News*, you can get a concrete-like substance by electrolytically extracting minerals from seawater on submerged wire armatures; futurist architect Wolf Hilbertz founded companies in the 1970s and 1980s to commercialize the project for, among other things, healing reinforced concrete that had been damaged by corrosion. The resulting accretion on the cathode, principally composed of aragonite and brucite, is known as "seacrete" or "biorock"; it can grow about 5cm/year, and the efficiency is about 400–1500g/kWh (100–400kg/GJ). The strength is comparable to concrete when accreted at 5–100mA/ft² (50–1000mA/m²); typically you use 12V.

If it were logistically feasible to use seacrete to construct the arcology, the 144–230 tonnes needed per person would therefore cost 350–2000GJ, or US$4000–23000.

However, discussions on the Seasteading fora debate this, claiming the real efficiency is closer to 50g/kWh (14kg/GJ). If this is correct,

it would push the cost an order of magnitude higher than concrete.

Utilities

To keep the structure fit for human habitation, it's necessary to provide light and clean air at comfortable temperature and humidity; to exhaust or consume CO_2; to prevent the growth of toxic or allergenic molds; to haul away garbage; to provide food and drinkable water; to provide means of ingress and egress; to limit the spread of vermin such as cockroaches, fleas, mosquitoes, mice, and rats; to contain, ventilate, and neutralize eruptions of noxious chemicals (say, when some poor dummy foolishly mixes bleach with ammonia while cleaning — or just when someone has a night of farts with a lot of hydrogen sulfide, or burns his toast); and to deal with sewage, ideally by composting and refining it. It's also highly desirable to provide electrical energy, internet access, individual climate control to taste, hot water, compressed air, and vacuum suction for cleaning, not to mention some way to wash your laundry and stuff.

Many of these problems are simply slightly-larger-scale versions of the problems that face large contemporary apartment buildings, but some are not, and some admit better solutions than the traditional ones.

The compact shape of an arcology makes such utilities easier to provide. In the 100×100×40 pit, for example, you have 400k(m^3) of space within a 74-meter radius; you never have to lay more than 74 meters of pipe or duct to reach anywhere. The corresponding distance in the pyramid is 119 meters.

Light: skylights, lightguides, and electricity at night

The most obvious question about living underground: "Won't it be too dark?"

It depends. It can be a great deal brighter than many current dwellings. Aboveground, nobody lives in a glass house, because if you stop convective and radiative cooling with glass, you get a massive greenhouse effect, and you can rapidly reach dangerous temperatures — think of a toddler locked in a closed car in the sunshine. In above-ground passive solar design, according to Daniel D. Chiras's *The Solar House: Passive Heating and Cooling*, typical allowable glazing on sun-facing walls ranges from 7% to 12% of the floor area, depending on issues like thermal mass, overhang, and local climate.

That means that the above-ground passive solar houses we think of as "luminous" and "bright" are already between 88% and 93% dimmer than direct sunlight, just in order to remain at a livable temperature without outrageous amounts of heating and air conditioning!

And traditional construction techniques (the picturesque clapboard and adobe houses we all know from landscape paintings) more or less adhere to these limits.

The skylights: 4m²/人

Bringing 10% of the sunlight underground *would* more or less imply that 10% of the land needs to be skylights. (You can also illuminate electrically, but this adds the 80–85% inefficiency of the photovoltaic panel to the 85% inefficiency of the LED or fluorescent tube, giving you a total of 97–98% loss and therefore requiring 30–50 times as much land area; better to bring the light inside directly when you

can.)

However, first of all, the skylights don't need to look like windows. They can, and should, take the form of massive glass or glass-like sculptures, frosted luminous stones, clear-bottomed waterways, or gigantic artificial formations of quartz, sapphire, fluorite, or salt crystals; quartz crystals can be grown at a millimeter per day with the hydrothermal method, and giant thick, but hollow, glass or acrylic vessels can be filled with a cheap material with a similar refractive index, such as water. LiTraCon-style embedding of optical fibers in an opaque matrix can even produce mostly-opaque rocks which nevertheless conduct a substantial fraction of the light that strikes them down into the ground.

Second, we only really need to illuminate the rooms we're in. If each of our 125 inhabitants is, most of the time, in a room of some 3×6 meters, we only need some 2m² of skylight per person — let's say 4m²/人 to be safe, for a total of 500m² out of some 10000m² — and beam the light down to where we want it using light pipes, either fiber optics or air-core metallic lightguides. They don't have to be very high-quality fiber optics, since the light only has to travel some 40 meters at worst, and losing half of it over that distance is tolerable, as long as it doesn't damage anything (e.g. melting it). That is, you could lose 3dB/40m, or 75dB/km, and be fine.

Generally it's a lot easier to increase illuminance than to decrease it, so it might be a good idea to have a few skylights that focus sunlight to provide more than one sun of illuminance for high-illuminance applications.

How to carry light down to the depths: lightguides

Lightguide illumination has been deeply investigated already as a way to illuminate buildings, and it works.

For solid fiber-optic lightguides, I think the *circumference* of the lightguide must be proportional to the absorptivity of the material, or a bit more, to prevent overheating; this would seem to suggest bundles of thin lightguide cables so you can blow air through them. The total power absorbed in the fibers will be quite significant, at least if you don't use high-quality glass: if you're collecting 500m² of sunlight at the surface, that's about 500kW, and if you absorb half of it in the fibers, you need to dissipate 250kW from the fibers. Liquid-core lightguides could use the liquid itself as the coolant, providing hot-water heating from the light absorbed from the lighting system.

Typical optical fibers used today for communication have attenuation of about 0.3dB/km, which is about 0.012dB in 40 meters; so if you managed to use them, they would absorb only about 0.3% of the sunlight, or 1.5kW, so you could use about 30× less of them, by circumference, than of some cheaper material. However, they cost a lot more than 30× as much, they're a lot trickier to connect, and they'd need complicated light-gathering and great care taken with the highly concentrated sunlight within them, so it wouldn't be worth it except perhaps for special applications, like solar surgery or welding.

Ocean water attenuates at about 10dB/75m or 5dB/40m, despite its particulate content, so transparent pipes full of pure water might work fine as light pipes for this purpose if you don't bend them too sharply, as long as the pipe material's refractive index isn't too much

higher than the water's. (On the other hand, other published attenuation coefficients for seawater point at more like 10dB/40m in even the clearest waters; apparently it depends on the wavelength range you consider. Some book on the Chesapeake Bay says, "Lorenzen (1972) estimated the attenuation due to water alone to be 0.038 m^{-1}, though his measurements were for deep ocean conditions, in which measurements generally commence at depths > 5 meters."; this works out to be 0.17dB/m, or 6.7dB/40m. Pope and Fry's 1997 measurements find absorption coefficients varying by wavelength from 0.00442/m at 417.5nm, which they point out is "more than a factor of 3 lower than previously accepted values...unquestionably a result of contamination by [the other experimenters'] stainless steel cell", up to 1.678/m at 727nm; I don't even know how to interpret an absorption coefficient >1, but if the other one meant what I thought it did, it's 0.019dB/m or 0.77dB/40m, which is quite acceptable. If too much of your light at depth were blue, you could use fluorescence to reconvert some of it to yellow; I used to have a dark green plastic bottle that fluoresced bright yellow in the light of my blue LED, but wouldn't fluoresce in ultraviolet light at all.)

Fiber optics have the advantage that you can "switch" them by filling junctions with liquid water, which allows light to flow instead of suffering total internal reflection.

I don't know if you can get reasonably cheap glass, acrylic, or polycarbonate of sufficient clarity. Apparently Toshikuni Kaino et al. (Applied Physics Letters 41, 802 (1982)) describes an acrylic (PMMA) plastic with a 50dB/km loss, which would be ample. Apparently this is what is now known as "POF", is widely available, and costs US$0.25/m in 1mm inner fiber diameter, but that stuff has unacceptably high losses of up to 200dB/km; so I suspect the answer is no.

Alternatively, you might be able to use an air-filled pipe lined with aluminum, aluminized mylar, silver, or gold, to a thickness of a few dozen atoms. The trouble is that you lose energy on every reflection. Aluminum is only, at best, about 92% reflective in the visible, so you lose 0.36dB per bounce, while gold reaches 97% in the red, thus losing only 0.13dB, but absorbs a lot of blue and even yellow light. Silver nearly hits 97% across the visible. With sufficiently wide light pipes, say bigger than 50cm, these could maybe perform better than fiber-optic light pipes full of water.

What to do with light in the depths: luminaires

The actual luminaires illuminated by that the sunlight delivered through the lightguides can be of almost any form. You can illuminate the water in an indoor fountain or pool, a crystalline object such as a large salt crystal, or anything made of frosted glass. A planar lightguide made of glass could even out the illumination over a large surface made of something like marble bonded to it. Or you could backlight a water-cooled LCD display as a sort of virtual window.

Fluorescence and filters (dichroic or otherwise) can be used to alter the colors of the lighting.

Dimmer lighting with lightguides

You might prefer to have dimmer lighting some of the time, even during the day; for example, many computer screens are more readable in dim light. Direct sunlight, like sunbathing on the beach, is

around 100klux; full daylight out of the sun is around 15klux; a cloudy day is around 1klux; a typical office is around 400 lux; a typical living room at night is around 50 lux; you can see when things are illuminated with around a millilux; and you can see light sources down to a few nanolux.

Accordingly, if you choose to light your office like a typical office during the day, instead of using 4m² of skylight for yourself, you'll only be using 0.04m², leaving more for other arcologists.

Fallback lighting with LEDs and fluorescents

You can, of course, use electricity to get lighting at night or when you want more light than is available from the sun. The best LEDs are around 200 lumens per watt, and a lux is a lumen per square meter, so to reach 15klux with those you'd need 75 watts per square meter, and about US$75 per square meter. Fluorescent lights are a little lower in efficiency, but also in cost.

10.4 kilowatts is enough energy to run quite a lot of incandescent lights, too, but you probably want to avoid doing much of that, just because it will contribute undesirably to heating, adding extra heat that needs to be removed.

Underground rain-forest gardening

One of the key features of historical luxury homes has been their gardens. But, aside from the park at the surface, it might seem that we don't have sufficient lighting to maintain hundreds of square meters of lush gardens per person; after all, to preserve the surface, we're only letting a small fraction of the sunlight into the arcology.

But, if our purpose is lush vegetation rather than high agricultural productivity, a small fraction is plenty.

Photosynthesis and productivity in different environments, vol. 3, (ed. John Philip Cooper), has on p. 20 a graph of "relative illuminance", showing that on the floor of an evergreen oak forest, illuminance was only some 5% of full sunlight, while in the ten meters above the floor of a tropical rain forest, illuminance never exceeded 2% of full sunlight, only reaching 5% at some 20 meters; at the forest floor it was more like 0.5%. (He also provided absolute numbers for PAR, or "photosynthetically active radiation": 5–50 "cal cm^{-2} d^{-1}", which I suppose is cal/cm²/day; these non-SI units, sadly, are ambiguous, as there are two separate units of energy known as the calorie, which differ by three orders of magnitude). *Tarsiers: past, present, and future*, (ed. Wright, Simons, and Gursky) cites "Grubb and Whitmore, 1967" for the observation (p. 39):

> At the forest floor, rain forests have low relative illuminance of visible light, often less than 1%.

Frances Baines, in the Daintree ancient tropical lowland rainforest in Queensland, measured 2klux in the shade, where she was examining ultraviolet illuminance on reptiles, compared to 90klux "in the sunlit area". She notes, however:

> It is interesting to note the wide range of temperatures, light levels and UVB light levels available on the forest floor – all within feet of each other, and constantly changing as the sunlight moves through the canopy above.

This is consistent with some 2% average illuminance.

So, plants adapted to life in forests below the canopy could be gardened productively with minimal amounts of light, if its spectral composition isn't too far off. Every square meter of light captured at

the surface could be distributed to feed 50 or 100 square meters of underground gardens simulating a rain-forest understory, with its ferns, mosses, shrubs, insects, and reptiles.

You'll probably need substantial ultraviolet, though, so soda-lime glass and water won't cut it as light-pipe materials.

Exhausting CO_2

People and fires produce carbon dioxide, which acidifies your blood, makes your lungs feel like you're suffocating, and would eventually replace all the oxygen in your air and suffocate you. But for plants, CO_2 is an essential nutrient, which they struggle mightily to extract from the air; normal air is only 0.039% CO_2 (up from 0.032% CO_2 in 1960). If you feed them air with 0.1% CO_2, they can grow 50% faster and produce 12% higher yields. You can deal with sustained breathing of air with 1% or 2% CO_2, but normally you want to try to keep it to 0.2% or so. Your own exhalation is about 5% CO_2, totaling about 1kg/day (12mg/s); 1% CO_2 is enough to kill some insect pests.

Also, in some places, CO_2 will seep out of the ground, and you need to ventilate spaces fast enough to keep it from building up. This is particularly tough underground, because CO_2's molecular mass of 44 is much higher than the molecular masses of nitrogen and oxygen (30 and 32). It's so much denser that you aren't going to be able to do it with convection at any kind of safe temperature. You have to do it with chemicals or air pumps.

Compost also produces CO_2.

So you'd ideally want to route a lot of CO_2-rich air to surface greenhouses, both to reduce the CO_2 emissions of the arcology and to promote the productivity of its crops, ultimately using nearly all of the produced CO_2 (average 1.4g/s across all 125 people, not counting sources other than respiration) into the biomass in the greenhouse. But that turns out not to be possible, as explained below.

The numbers above suggest that you need to change the air in a room after you've breathed at most a twenty-fifth of it. If the room is 3m×3m×6m, it contains about 54m² and 54kg of air, and it needs to be replaced every time you emit 0.2% × 54kg = 108g CO_2, which at 12mg/s, is 150 minutes — an air change every two and a half hours. However, as shown below, other considerations require an air change several times more often than that!

Nuclear submarines and space stations sometimes have "scrubbers" consisting of metal oxides (CaO, LiO) which absorb CO_2 from the air, producing carbonates; and houseplants can also absorb CO_2. These might be useful for resiliency purposes, but they probably aren't necessary for day-to-day living.

Clean air

It's necessary to replace the air in a room several times an hour to keep it habitable, due to accumulation of other things than CO_2: humidity, bad smells, dust, and heat. A list of uncertain provenance gives numbers that range from two air changes per hour (that is, 2m³ of air per m³ of room volume per hour) for a warehouse, up to 15–60 for kitchens, or 20–30 for spaces like bars, taverns, clubhouses, and repair garages.

(Dust, aside from being potentially allergenic, can also be explosive.)

This suggests that, for luxury, you need at least 10 air changes per hour in the rooms where you are, and more if there's a crowd or things are on fire; and at least 4 air changes per hour in the rooms where you aren't, which will be the vast majority of the arcology and therefore dominates the total ventilation need.

If you figure that all of this air needs to come from the outdoors, which seems like a conservative but perhaps not unreasonable assumption, that's the full 3200m³/人 of air, every 15 minutes (≈1mHz), or roughly 3.2m³/人/s, or 400m³/s across the whole arcology. In the non-SI units usually used for HVAC work in the US, that's 850 000 cfm, which is a fucking hell of a lot of air, all of which has to go through highly-efficient heat exchangers to prevent excessive heat loss. That's not hard to do, since you can easily lay hundreds of meters of ducts, but it's something to keep in mind.

The Passive House guidelines require not exceeding 30m³/人/hour, which means 0.008m³/人/s, "to avoid overly dry air", because "humidifying the air within the ventilation system is to be avoided for reasons of hygiene". You're obviously going to be violating the crap out of both of these recommendations, along with most of the rest of the Passivhaus program, because although it's awesome, it's designed for ordinary buildings, not underground cities.

Changing the air so often means your breath will be useless for feeding plants unless you concentrate it further, but whatever.

Ventilation power

A small US$80 six-inch fan does 400CFM, which is to say, 0.2m³/s. You need sixteen thousand times that, which would, linearly extrapolating, cost US$1.3 million of fans.

More digging around suggests that you can order custom-built 3.5PSIG 50 000CFM blowers, of which you'd need 17, but if you have to ask, you can't afford one. At 3.5 PSIG, which is to say 24 kPa difference input to output, each of these would be outputting 570 kW, for a total of 10MW, or 77kW/人 — way outside our energy budget, even before factoring in motor losses!

That means that if you really want to do 400m³/s, you need to do it at more like 1kPa, not 24 kPa. A table of duct sizes suggests that for 50 000 cfm (24m³/s), you should use a 41" (104cm) round duct, which will have a frictional loss of 0.67 inches water (160 Pa) per 100' (30.5 m).

If you used 17 such ducts for 40 meters of input and 17 more for an equivalent distance of output (a combined total of 104cm * π * 80m = 4400m² of galvanized sheet metal), then you'd have 426 Pa of pressure dropped in those ducts, for "only" 171kW. That gets us down to just over 1kW per person, which is manageable but still seems high. Despite the chances of infiltration by movie villains, it seems like it might be worthwhile to use still larger ducts in order to further reduce the energy usage, noise, and surface winds; and perhaps very wide, flat ones, so you can make them work effectively as heat exchangers. (They have to be wide way out of proportion to their flatness.)

XXX figure out ducting and heat exchanger heat loss

Filtering

It may also be necessary to filter air coming in from the outside to remove smoke, volcanic ash, carbon monoxide, ozone, or other

pollutants.

Mold

XXX

Garbage

The traditional approach to garbage in big apartment buildings was the garbage chute: a nearly-vertical shaft with a door on each level into which you would dump your garbage bags, emptying into a bin in the basement. This seems to have gone out of style; XXX I don't know why.

The approach taken in the apartment buildings I've lived in in Buenos Aires in the last few years is, instead, either for each inhabitant to carry their garbage separately to the curb for pickup, or (especially in larger buildings) to have a garbage can on each level, which the building caretaker empties each day, typically dirtying up the freight elevator.

Garbage in general is a pretty big problem for would-be self-sufficient communities; simply stated, a group that generates garbage is not really self-sufficient. The universe has no garbage, only recycling. But full recycling in a modern society is quite difficult, and probably requires a group much bigger than 125 people.

Nevertheless, we can make substantial improvements over the typical state of modern urban life, within the scale of this single modest building.

A 2008 New York State study found the following composition of the garbage of the residential and commercial/institutional sector:

paper	33%
glass	4%
plastics	14%
metal	7%
"organics" (food?)	23%
textiles	5%
wood	3%
other	11%

The total is 18.3 million tons; if the state contained 19 million people, that's one ton per person per year, or 28mg/s/人. With that in mind:

		mg/s/人
paper	33%	9
glass	4%	1.1
plastics	14%	3.9
metal	7%	1.9
"organics" (food?)	23%	6.4
textiles	5%	1.4
wood	3%	0.8

| other | 11% | 3.0 |

Of these, paper, wood, textiles, and "organics" can all be composted for fertilizer, a process which dramatically reduces its mass over the course of some six months to two years. Plastics can be recycled into other plastic (especially if PET), melted into structural material, or burned for energy and CO_2 for the greenhouses. Metal and glass can be profitably sold outside the arcology for scrap, or recycled within. This leaves only "other", much of which could also be used for structural material; but if not, we're left with 3mg/s/人 of dumpit, 375mg/s in total, or almost 12 tonnes per year for the arcology as a whole, perhaps 6m³.

Since this "other" contains nothing that could plausibly rot, and hopefully nothing that's chemically unstable, it doesn't need to be taken out immediately. You could quite reasonably take out the arcology's garbage once a month instead of once a day, to keep it from piling up; or if you decided you had to let it pile up, you would have enough space to pile it up inside the arcology for 68 millennia. Given the likely future strategic value of material resources in garbage, this is probably a good idea.

In my book, that essentially removes garbage as a problem for self-sufficiency, as long as composting can be made to work, which turns out to be pretty easy.

Composting garbage

From the above, we get an estimate of 64% of garbage as compostable, a total of 18mg/s/人, or 2.2g/s. Of this, some 6.4mg/s/人 is "organic", which presumably means "wet"; that probably shrinks by some 75% if you dry it out, which you probably want to do before you compost it, reducing it to 1.6mg/s/人, and reducing the total to 13mg/s/人 or 1.6g/s.

This compost, if managed as "hot" compost and watered and turned properly, takes some 1–3 months before it's ready for use as fertilizer. If you take the high end of that range, 3 months, you can see that you have some 13 tons of compost (say, 13 m³), plus water, constantly fermenting. This is an eminently, almost trivially manageable quantity, and it will diminish further once I get to discussing sewage, since much of this compost will be diverted to sewage treatment.

This is, however, a size of compost heap that will benefit from a mechanical compost tumbler, regular temperature and humidity checks, and XXX

Food

As I mentioned before, you, individually, need to eat 100–120W or 5–6mg/s of carbohydrate and protein to survive.

Soy: not enough of a miracle, needs 1000m²/人

Soy, one of the highest-yielding crops, yields on average about 45 bushels/acre/year (12 picometers per second), and each bushel yields 11 pounds (5kg, 141 g/l) of oil and 48 pounds (22 kg, 620 g/l) of meal, which is about 80% carbohydrate and protein. 620 g/l * 12 pm/s * 80% = 6.1 micrograms/m²/s, which means you need about 1000m² of soy to feed you, a quarter of an acre. Not much!

Well, that's unfortunate, because you only have 80m², and that has

to include your solar panels and skylights too. You're too low by a factor of about 12.

Sugarcane

Sugarcane is one of the most energy-efficient crops. Experimental small plots in Brazil, says WP, have yielded 250 tonnes/hectare/year (25 kg/m²/year, or 790 micrograms/m²/s). Suppose you can raise it in greenhouses with enriched CO_2 and fertilization and everything; how much can it feed you? Suppose, like Louisiana's farmers in 2011, you get 230 pounds of raw sugar per ton of cane, 11.5%, and suppose that's basically 100% carbohydrate. That's 91 micrograms/m^2/s, which is 15 times better than soy! You're saved! Barely!

But, well, you do need some protein. And 25 kg/m²/year is way beyond normal; normal is 7. Those Louisiana farmers were delighted to get 9.6. 25 was the NPK-fertilized trial in Brazil reported in Bogdan's 1977 *Tropical pasture and fodder plants*, and it's anyone's guess whether you can really reproduce that.

How can it be that 80m² provides 10kW of XXX oh, of energy, not of electricity.

Fungus

You may be able to supplement your diet with fungus. Quorn, for example, is made from the hyphae of the *Fusarium venenatum* soil mold, processed to remove RNA and DNA.

Ingress and Egress

Somewhat to my surprise, it appears that it's actually possible for an arcology to comply with, say, the Pennsylvania fire code, because the fire code doesn't actually require you to be able to get out of a building in a reasonable time; it just requires you to be able to get to the other side of a firewall (an "exit") in a reasonable time, and from there to outside the building (an "exit discharge").

The fire code's guidelines on number and width of doors seem reasonable:

- at least two exits (four would be better);
- at least 28 inches (71cm) width for each exit; probably 2m is better.
- "exits shall be so arranged that the total length of travel from any point to reach an exit will not exceed 150 feet (45 m)", or 200 feet (60 m) if sprinklers installed.
- "The capacity in number of persons per unit of width for approved components of means of egress shall be 60 persons. Buildings protected by automatic sprinkler systems shall be allowed 90 persons per unit of width;" here a unit of width is basically the 71cm mentioned earlier. For 125 people, then, two exits is almost sufficient, and two double-wide exits is quite sufficient.
- maximum slope of an exit ramp: 8.33%. Unfortunately this would demand that you run almost 500m to get up and out of the pit arcology using the ramp.

The fire-code occupancy guidelines for housing occupancy is to assume at least one occupant per 125 square feet (11.6m²) of bedroom. If each person did actually dedicate a quarter of their 800m² to bedrooms, you'd end up with 200m² of bedroom per person, with the rather absurd result that you'd need to build means of egress for some 17 times the sustainable occupant load of the arcology — almost 2200

people. That means you'd need 36 "units of width" on the exit stairways. The "units of width" measure is a little bit nonlinear, and it turns out that, with four exit stairways, you could manage it if each one were 4.6 meters wide. Four stairways of 4.6 meters wide, by themselves, should be no problem. However, should someone decide to set up a classroom or dining area or something in one of their rooms — something with fewer square feet per person — they could easily exceed the 2200-people "occupancy" limit!

Certainly, exits sufficient for emergency use by thousands of people should be adequate for regular use by 125 people.

Moving-sidewalk ramps carrying you rapidly up from the lower stories to near the surface, in the case of the below-grade arcology, would seem to be a good idea.

Water

A bacteriostatic water tank at the top of the arcology, filled with chlorinated water, can provide on-demand pressurized clean cold-water supplies to all residents.

Where do you get the water? Well, maybe you can use a municipal water supply, but that's not very self-sufficient. You can use a well, if you're in a zone where the groundwater is safe and abundant. Or you can harvest rainwater or moisture from the air.

As mentioned later, the usual Burning Man figure is that you need about 8 ℓ/人/day, or 93 microliters/人/s. Spread over 80m²/人, that's 1.16 nm/s of rain you need, or in the non-SI units typically used by meteorologists, 37 mm/year or 1.43 inches/year. There *are* parts of the world that get less than that: much of the Sahara and the Atacama, and small parts of Arabia, the Australian Outback, Nevada, Greenland, and Siberia, and presumably Antarctica; but *most* of the Sahara, of Arabia, of the Gobi, and so on, get more rain than that.

But suppose you don't? Suppose you're in the middle of the Sahara? You have to condense water out of the air, either using a thermal store (radiate away heat at night and store the cold in a water tank, then use the cold water to condense more water on the surface of a pipe, warming up the cold water until the next night) or, in the worst case, using an electrical heat pump, aka an air conditioner. The electrical heat pump needs to be able to lower the temperature of the air to its dewpoint, at which point its coefficient of performance is probably closer to 1 than the usual 2 — it's burning 1 J for every J of

heat that it manages to pump away from its cold side. [Condensing water takes] about 2.26 MJ/ℓ; at 93μℓ/人/s, that's 210W/人, an easily payable energy cost.

So you can totally build a viable arcology in the middle of the Sahara, just as long as the Tuaregs are cool with it.

Stored supplies for resiliency

It seems inevitable that some of the people attracted to such a community will be interested in resiliency against external shocks, such as terrorist attacks, economic collapse, or military occupation. So it might be worthwhile to investigate how much storage space you need for emergency supplies.

A year's worth of water: 2.9m³/人, 360m³ total

Of all the groups who store up for emergencies, the Mormons are the most extreme; they are recommended to keep three months' worth of food on hand, and normally a year's worth. Of all the supplies you need, oxygen is the bulkiest, but for the time being, let's exclude the emergencies that require you to use stored oxygen! Water is next. How much water do you need?

At Burning Man, in the desert, you needed about 8 liters of water per person per day. A year's worth, then, is 2.9m³/人, which is an almost insignificant fraction of the 3200m³/人 we're talking about. You could probably get by with less, since arcology air isn't desert air, but why bother?

If you had a centralized water tank with storage for the whole arcology, you'd need only 360m³, which is about 7 m in diameter. While this would provide great resiliency against external supply disruptions, it would only provide limited resiliency against internal prisoner's-dilemma problems; see "Community issues" below. A centralized water tank can also provide gravity-feed water pressure for the majority of the arcology, as described above under "Utilities".

Community issues

As anyone who's attended a condo association meeting knows, cooperating with your neighbors can be by far the hardest part of living in a community. And the more common resources you share, and the less trusting your neighbors are, the harder this is.

So it seems that the problem of growing a community to create the arcology is likely to be at least as difficult as the physical architecture; you could say that's what sunk Arcosanti.

Gradient overlay

Kragen Javier Sitaker, 2018-04-27 (2 minutes)

Let's say some color component, say red, is a linear function of pixel position (x, y) in some region: $r_i = a_0x_i + b_0y_i + r_0$. This is an arbitrarily oriented linear gradient. Now, if we α-blend this red r_i with some other red r_j painted over it with some opacity α, we get $r_k = (1 - \alpha)r_i + \alpha r_j$. This gives us a new gradient:

$$\begin{aligned} r_k &= (1 - \alpha)(a_0x_i + b_0y_i + r_0) + \alpha(a_1x_i + b_1y_i + r_1) \\ &= ((1 - \alpha)a_0 + \alpha a_1)x_i + ((1 - \alpha)b_0 + \alpha b_1)y_i + (1 - \alpha)r_0 + \alpha r_1. \end{aligned}$$

That is, the three components of the gradient (r, a, b) blend according to the alpha-blending equation just as if they were colors. Except really they are nine components; in some sense a linear gradient is a transformation matrix from (x, y, 1) space into (r, g, b) space. These matrices then react to alpha-blending in the same way that individual color vectors do: $(1 - \alpha)M + \alpha N$, at least if this α is constant and not a gradient as well.

This means that if we have several layers, each of which is divided into disjoint regions, each painted with a linear gradient with a constant alpha, we can compute the intersection regions of the single-layer regions in different layers, and compute the resulting gradient for each of those intersection regions, then render the resulting gradient.

For things like drop shadows, it would be nice to have gradients of alpha, as well, so that things can be gradually feathered into complete transparency. Linear alpha multiplied by a linearly varying color gives us a quadratic gradient.

Saturation detector

Kragen Javier Sitaker, 2013-05-17 (3 minutes)

Ferromagnetic materials have very high magnetic permeability, but saturate at some point; in some cases, especially for extremely ferromagnetic materials like the electrical steel used in transformers, the transition is quite abrupt.

A major problem in the historical development of radio was the "detector": some way of converting the high-frequency AC signal of the detected radio wave into a DC or low-frequency signal that could be used, for example, to activate a solenoid. This was eventually solved by the development of the vacuum-tube diode and later the semiconductor junction diode, but before that, there were a number of Rube Goldberg contraptions, some of which remained in use for a long time in special circumstances: the "coherer", which sintered metal particles together with the RF energy and then measured the DC resistance of the result; the "cat's-whisker detector", a delicate Schottky diode made with a point contact between a finely-pointed wire and a crystal of a semiconductor such as galena, iron pyrite, carborundum, or even the iron oxide on a razor blade of a "foxhole radio"; Marconi's "magnetic detector", which used the nonlinear hysteresis behavior of moving iron wire to convert an RF magnetic field into a tiny DC voltage; and Fessenden's "electrolytic detector", which used the electrolytic formation of a layer of bubbles on a fine platinum wire electrode to preferentially impede current in one direction. Somewhat related is the "mercury-vapor rectifier", which uses the enormous difference in work function between mercury and graphite to conduct in only one direction.

It occurs to me that the saturation transition in low-hysteresis electrical steel could be used to form a detector for frequencies up to some limit, as follows. You bias the primary winding of an iron-core transformer almost to saturation with DC, then superimpose the AC signal on it. The part of the AC signal opposing the DC bias will dip into the high-permeability region and will therefore see strong inductive effects --- a high impedance, either inductive (in the case of an open-circuit secondary winding) or resistive (in the case of a dummy load connected across the secondary). The part of the AC signal in concert with the DC bias will experience much smaller inductive effects, perhaps two orders of magnitude less.

This should give you an entirely-solid-state "detector" that works without any semiconductors or vacuums.

I think this device is limited in frequency only by hysteresis and eddy-current losses, which increase linearly with frequency. In this application, though, much larger losses are acceptable than in the usual applications of transformers: a 1%-efficient detector is still usable. Wikipedia tells me that laminated-steel transformers with especially thin laminations are still sometimes used at 10kHz, so I am guessing that this detector should work usably with a steel core up to some 100kHz, and with ferrite or powdered iron, up to 1GHz.

You should be able to substitute a permanent magnet for the DC bias, eliminating the need for a power supply.

Negative weight undirected graphs

Kragen Javier Sitaker, 2019-11-01 (8 minutes)

The classic shortest-path algorithms on graphs such as Dijkstra-Moore, Floyd-Warshall, and Bellman-Ford are commonly applied specifically to digraphs. In particular, Bellman-Ford is much slower than Dijkstra-Moore for graphs of any reasonable size, but is guaranteed to be correct on a more general class of graphs --- those including negative arc costs, but not negative cycles.

The usual reduction from weighted graphs to weighted digraphs replaces each undirected arc with a pair of antiparallel arcs of equal cost. Unfortunately, from Bellman-Ford's point of view, this transforms a negative arc cost into a negative-cost cycle. So, what's the best way to find lowest-cost paths in a weighted *undirected* graph with negative arc costs, but no negative cycles?

Manfred Weis discussed this in the Bellman-Ford context last year. He found a transformation from an undirected weighted arc into five directed arcs (three zero-weight) and two new vertices that seems to have the right properties. And Johnson's algorithm is another known approach. To my surprise, this seems to be a somewhat active research area.

I thought it should be straightforward to modify the Floyd-Warshall algorithm to handle this situation. But now that I think about it further, I'm not so sure.

Floyd-Warshall, like Dijkstra-Moore and Bellman-Ford, proceeds by successive relaxations, but those relaxations amount to adding a possible intermediate node k to the set of all possible paths. The central step in Floyd-Warshall is

$$d_{ij} \leftarrow d_{ij} \wedge d_{ik} + d_{kj}$$

where $\wedge$ is the binary minimum function. This amounts to considering whether the best known path from i to j can be improved by chaining together the best known path from i to k with the best known path from k to j; at the point that the algorithm does this update, all paths through all nodes preceding k have already been taken into account. (So doing this update for a given k and all i, j ensures that k and all the nodes before it have been taken into account.)

That is, either node k isn't an intermediate node on an optimal path from i to j, or it is; the two possibilities are handled by the two operands of $\wedge$. In some sense, the possible paths Floyd-Warshall considers between any two vertices are the powerset of all the vertices. In particular, this means that non-simple paths --- those that visit the same node more than once --- are not contemplated, except that a path is (in some sense vacuously) permitted to pass through either or both of its own endpoints.

Let's consider 2-cycles, paths from some node p to some other node q back to p, without any intermediate nodes. These can only exist in digraphs. (Cycles in either graphs or digraphs can only include the same arc once.) If our weighted digraph represents a plain weighted graph in the way described above, the two costs are equal; if they are

positive, this cycle cannot form a part of any optimal path (since you could improve the path by removing it), but if they are negative, they form a negative-cost cycle that means that there is no shortest path anywhere reachable from them. But this does not carry over to the original undirected graph: it may well have no negative-cost undirected cycles, because the single undirected arc is not a cycle.

So, either way, if we're trying to apply Floyd-Warshall to an undirected graph, we'd like to avoid considering these 2-cycles.

I thought I saw a simple way to do this, but now I'm not so sure. I thought it would be straightforward: just don't create paths from i back to i with only a single intermediate k. But now I see that paths from i back to i that run through multiple intermediate k nodes will necessarily start out as paths with only a single intermediate k.

A couple of ideas:

• When you decide to overwrite an optimum cost using nodes prior to k with an optimum cost going through k, you could compute how many arcs are on that path; say, start with an array of path lengths p_{ij} entirely filled with ones, and when you update $d_{ij} \leftarrow d_{ik} + d_{kj}$, also update $p_{ij} \leftarrow p_{ik} + p_{kj}$, which may amount to either increasing it or decreasing it. This enables you to add a special case: when considering updating a cost $d_{ij} \leftarrow d_{ik} + d_{kj}$, you can check whether either d_{ik} or d_{kj} is a length-2 cycle (i.e., the two coordinates are equal and $p_{kk} = 2$) and just not update in that case.

(There's an algorithm which stores the actual paths in rope form rather than just their lengths, but if you want the paths rather than their lengths, using ropes is no faster than the standard next-pointer modification of Floyd-Warshall for path reconstruction, and it needs more space.)

• But why bother with p? Including cycles in your candidate optimal path is never beneficial: either they have positive cost and you can eliminate them, or they have negative cost and the optimal path fails to exist. You could just decline to include cycles altogether by the simple expedient of not considering the possibilities $i = k$ and $j = k$. Then the algorithm will compute the lowest-cost *simple* path between each pair of nodes.

Well, not quite! It turns out that it can still unintentionally consider cycles in the following way. Suppose that the lowest-cost path from a to c goes through b, and the lowest-cost path from c to d also goes through b. If k = b before k = c, in the b step, we will compute a d_{ac} and a d_{cd} that each depend on going through b. Later, in the c step, one of the candidates we will consider for d_{ad} is $d_{\mathrm{ac}} + d_{\mathrm{cd}}$. If this is cheaper than $d_{\mathrm{ab}} + d_{\mathrm{bd}}$, which can happen if there's a negative-cost cycle between b and c, we may take it. The same logic shows that the approach in point 1 is also flawed.

However, I assert without proof that it does still consider all the simple paths, even if it considers some nonsimple paths as well.

Here's the implementation of Floyd-Warshall I was using, which appears to work in cases without negative-cost cycles:

```
def floydwarshall(edges):
    V = {u for u, v, w in edges} | {v for u, v, w in edges}
    inf = float('inf')
    d = {(i, j): inf for i in V for j in V}
```

```
    for u, v, w in edges:
        d[u, v] = min(d[u, v], w)

    for k in V:
        for i in V:
            for j in V:
                d[i, j] = min(d[i, j], d[i, k] + d[k, j])

    return d
```

For reproducibility and to attempt the possibility #2 above, I modified it as follows:

```
def floydwarshall(edges):
    V = {u for u, v, w in edges} | {v for u, v, w in edges}
    inf = float('inf')
    d = {(i, j): inf for i in V for j in V}

    for u, v, w in edges:
        d[u, v] = min(d[u, v], w)

    # Sorted order so that cases where the algorithm doesn't give
    # incorrect results at least get repeatable results:
    for k in sorted(V):
        for i in sorted(V - {k}):
            for j in sorted(V - {k}):
                d[i, j] = min(d[i, j], d[i, k] + d[k, j])

    return d
```

I was generating the graphs to run it on with this routine:

```
def randomgraph(n, m, o=10, p=1):
    rv = []
    existing = set()

    for i in range(m):
        u = v = None
        while u == v or (u, v) in existing:
            u, v = random.choice(n), random.choice(n)
        existing.add((u, v))
        rv.append((u, v, random.randrange(o)-p))

    return rv
```

Fast gsave

Kragen Javier Sitaker, 2018-11-27 (5 minutes)

I was reading *TeX: The Program*, and in §§220 et seq. explaining *eqtb* and in particular §§268–284, I found the solution to implementing PostScript's `gsave` operator efficiently in an interpreter, a solution that's more efficient than either deep binding or the usual approach to shallow binding.

`gsave` saves the drawing parameters on a stack of drawing parameters, including not just the current path, but also things like the current clipping path, the current line dashing pattern, the current line join, the current line width, the current color, and so on, which change relatively rarely. Later, they can be restored with `grestore`. This allows code inside the `gsave`/`grestore` pair to change these parameters with impunity.

Now, the standard shallow binding approach to this problem is to allocate a new saved-graphics-context object on the saved-graphics-context stack, copy the entire current-graphics-context to it, and then continue. To restore, you copy the saved-graphics-context on top of the stack over the current-graphics-context. This means that accessing the variables in the current graphics context is fast, because they're always in the same location in memory in the current-graphics-context. (A slight variation of this accesses those variables directly on the top item on the stack, thus making access to them indexed off the stack pointer, which was slower on old machines but is pretty much just as fast nowadays.) But, with this approach, `gsave` and `grestore` are fairly slow.

The deep-binding alternative, as I understand it, is to maintain the graphics context as a stack of setting-value pairs. To access a graphics-context variable, you search down the stack until you find it. This is slow, but `gsave` and `grestore` are much faster, since they don't need to copy anything. But it's somewhat hairier than deep binding in its original Lisp context, where you're pushing some new bindings onto the stack, because `gsave` doesn't have a list of graphics parameters to override; it just arranges for later graphics parameter changes to be pushed onto the stack.

How can you implement this? Presumably you need to tag each name-value pair on the graphics parameter stack with the `gsave` level it belongs to. `gsave` increments the level and saves the stack pointer, and operators like `moveto` or `setlinejoin` first search the stack to find an entry, then check to see if its tag matches the current level. If it matches, they can just overwrite the value with the new value; if it doesn't match, they need to push the new level on the parameter stack. `grestore` then restores the stack pointer and decrements the level.

So variable access is slow, but `gsave` and `grestore` are fast, since they hardly do any work. This is not a good tradeoff because you commonly do several graphics operations per `gsave`/`grestore` pair, often very many, and those operations typically access several graphics parameters each.

But wait. What if we don't have to search the stack to find the current value? This is the TeX approach. The value of, say, glue between paragraphs (`par_skip`) is stored in `eqtb[glue_base+2]`, which turns

out to be `eqtb[1+256+256+1+2100+10+257+1+2]`, which is `eqtb[2884]`, a constant memory address. But the item stored at that address includes not just the value of the glue parameter, but also the save level it came from. You can ignore that when you're reading it, but when you're setting it, it tells you whether you need to save the old value on the stack or not. Then `grestore` (in TeX, "unsave") iterates over the save-stack items, restoring their old values, until it hits a level boundary.

This means that variable access is pretty fast, `gsave` is fast, and `grestore` only does a small amount of work proportional to the number of parameters that must be restored — comparable to the work done in overwriting them in the first place.

Unfortunately I don't know how to generalize this to a wider class of problems. It's perfect for dynamically-scoped variables and for propagating a potentially large class of top-down properties down a tree during a tree traversal. It's useful for graphics contexts, where it offers a much better alternative to copying a whole graphics context because you want to change a few things in it and a noticeably better alternative to changing a few things in it and then changing them back. But it isn't useful for, for example, Emacs buffer-local variables or efficiently cloning a heap object from a prototype.

Topics

Xor 1 to 1 hashing

Kragen Javier Sitaker, 2017-07-19 (updated 2017-08-03) (10 minutes)

Suppose you want to map, say, 32-bit words to 32-bit words in an apparently random but easily computable and guaranteed 1-to-1 way, such that you can generate an apparently random sequence by applying this mapping to subsequent values of a counter.

A very simple way to do this is to do a boolean matrix multiply by a nonsingular but otherwise random bit matrix. The roles of multiplication and addition here are taken by AND and XOR, i.e. multiplication and addition in GF(2) — in the 8×8 case, this is the MMIX MXOR instruction. Because of linearity, this will always map 0 to 0, but it can map any nonzero value to any nonzero value.

As a 4-bit example, we can take the following product:

```
0 1 0 0  b3
0 1 1 0  b2
1 0 1 0  b1
0 1 1 1  b0
```

If $b_3b_2b_1b_0$ is 0001, we get 0111; if $b_3b_2b_1b_0$ is 0010, we get 1010; if $b_3b_2b_1b_0$ is 0011, we get 0001 ⊕ 1010 = 1011; and so on. All 16 possible 4-bit bitvectors are produced in this way, but in the somewhat apparently random order 0000, 0111, 1010, 1101, 0110, 0001, 1100, 1011, 0100, 0011, 1110, 1001, 0010, 0101, 1000, 1111. It's not extremely random — for example, the low-order bit simply repeats the sequence 0, 1, while the high-order bit simply repeats the sequence 0, 0, 1, 1 — but it isn't obviously ordered either. And it has the advantage that the sequence can be accessed in an arbitrary order. Because it's all linear, the mapping can also be inverted, which may be an advantage or a disadvantage depending on the context.

Empirically, about 30% of 4×4 bitmatrices are singular, and also about 30% of 8×8 bitmatrices and of 16×16 bitmatrices. This was surprising to me; I am going to conjecture that the actual number is 1/e.

In discrete domains like GF(2), there's no such thing as an ill-conditioned matrix.

As a longer example, consider this 8×8 matrix:

```
1 0 1 0 1 0 1 0
1 1 0 0 1 1 0 1
0 1 0 0 1 1 1 0
1 1 0 1 0 0 1 0
1 1 1 1 0 0 1 0
0 1 0 1 1 1 0 0
0 1 0 1 1 0 1 1
0 1 1 1 0 1 0 0
```

(More compactly, we could say [170, 205, 78, 210, 242, 92, 91, 116] or "ªÍNÒò[t".)

If we apply this matrix to successive counter values, it generates the sequence [0, 116, 91, 47, 92, 40, 7, 115, 242, 134, 169, 221, 174, 218, 245, 129, 210, 166, 137, 253, 142, 250, 213, 161, 32, 84, 123, 15, 124, 8,

39, 83, 78, 58, 21, 97, 18, 102, 73, 61, 188, 200, 231, 147, 224, 148, 187, 207, 156, 232, 199, 179, 192, 180, 155, 239, 110, 26, 53, 65, 50, 70, 105, 29, 205, 185, 150, 226, 145, 229, 202, 190, 63, 75, 100, 16, 99, 23, 56, 76, 31, 107, 68, 48, 67, 55, 24, 108, 237, 153, 182, 194, 177, 197, 234, 158, 131, 247, 216, 172, 223, 171, 132, 240, 113, 5, 42, 94, 45, 89, 118, 2, 81, 37, 10, 126, 13, 121, 86, 34, 163, 215, 248, 140, 255, 139, 164, 208, 170, 222, 241, 133, 246, 130, 173, 217, 88, 44, 3, 119, 4, 112, 95, 43, 120, 12, 35, 87, 36, 80, 127, 11, 138, 254, 209, 165, 214, 162, 141, 249, 228, 144, 191, 203, 184, 204, 227, 151, 22, 98, 77, 57, 74, 62, 17, 101, 54, 66, 109, 25, 106, 30, 49, 69, 196, 176, 159, 235, 152, 236, 195, 183, 103, 19, 60, 72, 59, 79, 96, 20, 149, 225, 206, 186, 201, 189, 146, 230, 181, 193, 238, 154, 233, 157, 178, 198, 71, 51, 28, 104, 27, 111, 64, 52, 41, 93, 114, 6, 117, 1, 46, 90, 219, 175, 128, 244, 135, 243, 220, 168, 251, 143, 160, 212, 167, 211, 252, 136, 9, 125, 82, 38, 85, 33, 14, 122].

Shuffling

One particular use for such arbitrary, randomly-accessible permutations is shuffling — for example, generating a random but repeatable ordering of a playlist. This allows you to resume the shuffled playing at some later time while only storing your position in the playlist and, possibly, the matrix — which, in the 8×8 case, can be represented as a 64-bit number such as 12848028463340370089. (The 32-bit case instead requires a 1024-bit number.)

Only a tiny minority of all possible permutations can be generated by this method. (For example, for the 16×16 case, there are about $10^{2871^{88}}$ possible permutations of the $2^{16} - 1$ nonzero values, but this algorithm can generate only about 10^{76} of them.) Is this subset "fair" in the sense that every nonzero value is equally likely to be second in the permuted sequence?

Special cases

The identity matrix exists, of course, as does a bit-reversal matrix, and every other mere permutation; reflected-binary Gray code (RBGC) is generated by the identity matrix with an extra bit set to the right of the diagonal, and its inverse is the full upper triangular matrix with all bits on the diagonal or to its right set.

```
1 0 0 0   0 0 0 1   1 1 0 0   1 1 1 1
0 1 0 0   0 0 1 0   0 1 1 0   0 1 1 1
0 0 1 0   0 1 0 0   0 0 1 1   0 0 1 1
0 0 0 1   1 0 0 0   0 0 0 1   0 0 0 1
Identity  Reverse    Gray   Inverse Gray
```

Homomorphism for XOR

Because this mapping is linear, it's a homomorphism for XOR (addition in GF(2)), but of course not for other operations such as those in $GF(2^n)$. For example, consider the matrix given earlier:

```
1 0 1 0 1 0 1 0
1 1 0 0 1 1 0 1
0 1 0 0 1 1 1 0
1 1 0 1 0 0 1 0
1 1 1 1 0 0 1 0
```

```
0 1 0 1 1 1 0 0
0 1 0 1 1 0 1 1
0 1 1 1 0 1 0 0
```

We map 10 (0x0a, LSB in the last row) to 169 (0xa9, LSB being in the last column), 11 (0x0b) to 221 (0xdd), and 1 (10 ⊕ 11) to 116 (0x74). And 169 ⊕ 221 is exactly 116.

The inverse matrix is:

```
1 1 1 0 1 0 1 0
1 1 0 1 1 1 1 0
0 0 0 1 1 0 0 0
0 1 0 0 1 0 1 1
0 0 0 1 1 1 0 1
1 0 0 0 1 1 0 0
0 1 1 0 1 1 1 1
1 1 1 0 0 1 0 1
```

And, using this inverse matrix, we can easily do the reverse mapping; it maps 116 back to 1, 221 back to 11, and 169 back to 10.

An interesting question is whether the use of AND as the multiplication function is necessary to get this homomorphism.

Reverse-engineering the matrix from the sequence

For an N×N matrix, given the mappings for any N linearly independent values, you can reconstruct the matrix. What if you are just given M sequential output values, without knowing the corresponding inputs, only that they are sequential counter values? I think you can extract the last roughly lg(M) matrix rows but not necessarily all:

```
>>> m = bitmatrices.random_nonsingular_matrix(8)
>>> v = [bitmatrices.mxor(m, i) for i in range(20, 29)]
>>> [v[i] ^ v[i+1] for i in range(len(v)-1)]
[30, 38, 30, 64, 30, 38, 30, 141]
>>> v
[1, 31, 57, 39, 103, 121, 95, 65, 204]
>>> m
[25, 239, 222, 170, 205, 171, 56, 30]
```

The LSB row of the matrix, 30, appears as a difference between half of the adjacent pairs of output values: four of them. The XOR of the last two rows, 56 ⊕ 30 = 38, appears in two positions. There are two other differences, 64 and 141, which are respectively the XOR of the last four and the last three rows, but I think there is no way to distinguish those; and I think the other rows could be anything at all.

I'm not entirely sure because there seems to be a bit more information leaked: we can see that the last two bits of the index changed in the sequence [00, 01, 10, 11, 00, 01, 10, 11, 00], so we know that the selected subset of the first six rows of the matrix (which, as it happens, are just 170 and 171) XOR to 1 at the beginning of this subsequence. But we already know that those first six rows must span

a subspace including 1 (supposing our matrix is nonsingular) because we can see that the subspace spanned by 56 and 30 (or 38 and 30) does not include 1.

What might Diamond-Age-like phyles look like in the real 21st century?

Kragen Javier Sitaker, 2014-04-24 (9 minutes)

Neal Stephenson's *The Diamond Age* famously speculates on a future society dominated by tribal groups like the Ashanti Nation and the Neo-Victorians, nations whose members live distributed around the world rather than within a single territory. In the novel, Stephenson calls these tribal groups "phyles". What might phyles look like in the real 21st century?

Current protophyles

The case of the United States of America is interesting. The USA (population 300 million) is one of the few nation-states — perhaps the only one — which levies income tax on non-resident citizens, although currently only those with particularly high incomes. As a sort of compensation for this, a US passport makes it easy to travel to most of the world's territory, even obtaining work visas in many places; and in many cases, the US Embassy or Consulate will intervene if a US citizen encounters legal trouble or needs legal help in a foreign country. Additionally, the US military forces, consisting of some 1.5 million people, occupy parts of about 25 other countries†. In part because of these factors, some 3–6 million of the world's 200 million expatriates are US citizenso.

† The US has military deployments in some 150 countries, which is nearly all of them, but only the US and Afghanistan have over 100 000 US troops; only those countries and Germany have over 50 000; only those countries, South Korea, and Japan have over 20 000; only those countries, Italy, and Kuwait have over 10 000; only those countries and the UK have over 5000; only those countries and Australia have over 2000; and only those countries and Belgium, Spain, Turkey, and Bahrain have over 1000 US troops.

The case of the Romani is also interesting, largely by contrast. The Romani, unlike the USA, control no territory, and have controlled no territory for some 700 to 1000 years; but they are bound together not just by a language (with some two million speakers) and social customs, but also a separate, parallel justice system, the kris-romani. (The kris originated within the Vlax Romani, and has spread to some parts of the Romani diaspora influenced by the Vlax.) The Romani have suffered conflicts with much more populous indigenous peoples during their centuries living in Europe, including mass enslavement, mass killings, childhood kidnapping, mass deportation (most recently in France in 2009 and 2010), and so on, but also including day-to-day discrimination.

Perhaps their position vis-a-vis such events could be improved by better coordination in order to negotiate with national governments collectively. Imagine, for example, if France recognized the Romani as a sovereign state; the 2010 mass deportations of Romani which provoked no particular reaction from Bulgaria and Romania, to

which the Romani were deported.

The Church of Jesus Christ of Latter-Day Saints, also known as the Mormon Church, is a worldwide organization of some 14 million people, more than a third of whom live in the US. Some one-third of this number are "active" members. They tithe, in general, 10% of their income to the church, a centrally controlled hierarchy, which prepares its plans to establish a worldwide theodemocratic government after the predicted collapse of secular government in the days before the Second Coming of Christ. Members who do not tithe cannot enter the temple, even to attend weddings of family members. The church's net worth is estimated at US$30 billion. Most people born into Mormon families remain Mormon, and nearly all male Mormons spend two years proselytizing overseas in the care and 24–7 surveillance of the church, funded by their own money, an experience which strengthens their bonds to the church; at any given time, some 50 000 Mormons are missionaries in this way, at some 340 missions throughout the world. As a result of this proselytism, the church is still doubling in size every 15–20 years. In addition to the 50 000 missionaries, the church has some 100 000 other volunteers.

Among other services, church maintains a "bishop's storehouse", which provides goods to poor people in exchange for service to the church; in theory, these goods are available to non-Mormons as well.

The church's earlier attempts to assume temporal authority in the 1830s through 1858 resulted in wars with the USA and the assassination of its founders. Until 1927, the church's "endowment" ceremony, required of its missionaries and those who would wed in the church, included an oath to "pray to Almighty God to avenge the blood of the prophets upon this nation".

Dubai is a sort of inverse case: 80% of Dubai's population consists of expatriates, who do not enjoy the rights of citizenship in Dubai. The UAE in general does not recognize *jus soli* citizenship, so citizenship in Dubai is a sort of inherited élite status distinguishing a powerful indigenous upper class from a large class of people who, by birth, have diminished legal rights.

The Roman Catholic Church is, in some sense, the remnant of the Western Roman Empire. It operates a worldwide hierarchy with a variety of relationships with other sovereign states; sometimes its local leaders ("bishops" or "archbishops") are supported by local governments, chosen in part by local governments, or both, and sometimes not. It has territorial control over only a single square mile, the Vatican City.

Triads?

Freemasons?

http://nymag.com/daily/intelligencer/2013/07/bart-strike-shows-privatizations-dark-side.html talks about the upper class abandoning public transit in the Bay Area:

> In the Bay Area, many high-earners have already moved on to what amounts to a private services grid. They get to work on corporate shuttles, go out at night using Uber or Lyft cars, and use services like Seamless to bring food and other necessities to them. They've accepted the public sector's dysfunction as a given, and they've already abandoned it for most basic services.

The CEO of Avego strenuously objects in the comments to being lumped in with luxury services like taxis and Uber:

Avego allows people to carpool together and share the cost of the ride. The only thing Avego is doing is providing efficiency and reducing the cost of commuting for both rider and driver. Is this a bad thing? In fact, BART costs the average rider $0.35 per mile (that's their pricing model, if I remember correctly). It's not a particularly cheap network to begin with, although I grant you, it's a great system and San Francisco needs it and I love the good public transport San Francisco has, in general.

But you say Avego could never afford to charge less that the Public Transit system? In fact, the Avego network does (unlike the Ubers and Lyfts and others, which do cost about 5-7x higher than public transit). The cost works out to about $0.20 per mile, below BART's own rate.

It's a little naive to think that technology necessarily makes things more expensive. In Avego's case, we're dramatically lowering the cost of the commute, and, particularly in these difficult economic times, cutting waste and reducing people's cost of living while also improving their quality of life counts for a net win.

http://www.nytimes.com/2013/05/18/technology/financial-times-site-is-hacked.html?pagewanted=all&_r=3& describes the Syrian government's arm's-length relationships with computer crackers who advocate its cause, similar to what Myhrvold was talking about in his Strategic Terrorism paper.

http://www.theatlantic.com/international/archive/2013/07/if-your-government-fails-can-you-create-a-new-one-with-your-phone/278000216/ has lots of interesting points about supplementing states with ad-hoc smart mobs, such as:

But when states fail to deliver governance goods, communities increasingly will step up, digitally. This shouldn't be surprising, given how much excitement there is around the prospect that e-government will significantly improve the capacity of even rich governments to deliver services. However, what we're talking about here is about more than service delivery: it is about the capacity of communities to set rules, stick to them, and sanction the people who break the rules. A sovereign state is one that can implement and enforce policies. When states don't have these capacities, a growing number of communities use digital media to not only provide services, but to do so in a way that amounts to the implementation and enforcement of new policies.

Is there an incremental union find algorithm?

Kragen Javier Sitaker, 2019-10-01 (8 minutes)

The union-find data structure, sometimes called a disjoint-set forest, is a well-known data structure that pops up in, for example, constructing minimum spanning trees; it efficiently supports the operations *component*(*n*) and *connect*(n_1, n_2). You are guaranteed that *component*(*n*) == *component*(*m*) if and only if there is a (possibly empty) set of past *connect* calls that create a path between *n* and *m* — if the *connect* calls create arcs in a graph, they are in the same component. Moreover, you can intersperse *component* and *connect* calls freely without losing efficiency, and the structure uses only O(*N*) space, where *N* is the number of nodes, not even the number of arcs.

However, the standard structure does not support edge *deletion*, only edge *creation*. It seems probably impossible for a structure with the same space performance to support such an operation, since its size must remain unchanged as O(*N*) despite the creation of O(N^2) edges, any of which can later be deleted. But is there a way to support edge deletion with "reasonable" performance?

The standard union-find data structure

Here's an implementation of the standard union-find algorithm I wrote last year as part of a maze generation program in Golang:

```
// Data structure for rapidly determining whether two maze cells are
// already connected.
type Unionfind map[Cell]Cell

func (u Unionfind) root(c Cell) (root Cell) {
        parent, ok := u[c]
        if !ok {
                return c
        }
        root = u.root(parent)
        u[c] = root
        return
}

func (u Unionfind) Connect(start, end Cell) {
        u[u.root(start)] = u.root(end)
}

func (u Unionfind) Connected(a, b Cell) bool {
        return u.root(a) == u.root(b)
}
```

For convenience, this implementation uses a Golang `map` to store the parent pointers; you can use a plain array of integers if you identify your nodes with integers, size the array to be big enough, reserve a distinguished integer to mean "nil", no parent, and initialize by filling

the array with "nil". (Alternatively, instead of setting root nodes' parents to a nil value, you can make them their own parents.)

Analyzing the performance of this algorithm is difficult enough that I am not going to try (though there is an extensive literature on the subject), but you can see that `root()` is O(1) whenever it is called a second time on the same node without an intervening `Connect()` call that would change its return value, because it recurses at most once. In such a case it does two `u[c]` lookups in the map, the second of which fails, and one (redundant) `u[c]` update.

For this algorithm variant ("path compression without union by rank"), CLRS gives a worst-case running time of $\Theta(n + f(1 + \log_{n} n))$ for $n - 1$ `Connect` calls and $\frac{1}{2}f$ `Connected` calls (p. 571). When $f \gg n^{2}$ this function is very nearly $n + f$; when $f \ll n$ it is $n + f \lg n$; and when $f \approx n$ it is about $n + f \ln n$. The "path compression with union by rank" variant is asymptotically faster, but it requires a great deal of extra bookkeeping information and has a larger constant factor; it uses twice as much space and, until n is fairly large, it's also slower. If f is much larger than n, it's slower even then.

A logarithmic-time union-find with edge deletion (or maybe not)

Suppose that, instead of parent pointers, we maintain, for each node, a linked list of edges, each indicating a lower-numbered node that it is directly linked to. Now `Connect()` merely has to determine which node has the higher number and add the edge to that node's edge list, but `root()` becomes infeasible except by groveling over the entire set of nodes repeatedly. To avoid this, we add the parent pointers back in, but in the form of an additional linked list of edges on each node — but these edges are edges between components, not just between nodes. These are established using essentially the same rule as before, with the additional proviso that they must point from a higher to a lower node, like the edges between nodes. So now `Connect()` must create both a between-nodes edge and a between-components edge, and unlike before, it does not delete a between-components edge.

Every edge (in the between-nodes list or the between-components list) has a list of dependent between-components edges attached to it. If that edge is removed, its dependents are also removed; and since those dependents may have further dependents, those further dependents are also removed. When a between-components edge is created, it becomes a dependent of the between-nodes edge that was created at the same time (if any), as well as all of the between-components edges that were followed for its creation. The logic of `root()` now must handle the situation of multiple "parent pointers" (that is, between-components edges); it always follows the pointer that points to the lowest-numbered node, since this (XXX I think) is guaranteed to be the most-recently-created surviving parent pointer.

XXX If a between-components edge is deleted because it depended on another between-components edge that has been deleted, but it was added together with a between-nodes edge, should it be recreated from its original between-nodes edge?

Hmm, I was thinking that I could replace the single-hop parent

pointers with a logarithmic number of parent pointers, each traveling up the parent chain by a power of 2, or roughly so, sort of like a skip list, in order to keep the space and time overhead both bounded at logarithmic. But I'm not sure any variant of this approach will work at all.

Merging union-find structures?

Suppose you have built two union-find structures on the same set of nodes by applying two some potentially large sets of *connect* operations. How can you compute the union-find structure that would have been computed from the union of those two sets of edges?

One way to do it is to determine whether the second set contains any edges that bridge components that are separate in the first set — which is to say, whether there are any pairs of nodes that are connected in the second set but not the first. If so, you can apply additional *connect* operations to the first set to unify them.

To connect, in the first structure, all the pairs of nodes that are connected in the second set, it is adequate to connect each node to either its root or its parent (in both cases, in the second union-find structure). That is, the parent pointers provide adequate information for this task; they are a compressed summary of the original second set of edges.

This merge operation suggests that we could build a binary tree of union-find structures in which, at the leaves, we have individual edges (that is, union-find structures containing only a single edge). Then, to remove an edge, we null out its leaf and propagate the merge operations back up to the root.

Unfortunately, although we need only walk through O(lg E) nodes, we are doing O(N) work at each node. It would be faster to just recompute the union-find from scratch, unless there are many more edges than nodes.

Golomb-coding operands as belt offsets likely won't increase code density much

Kragen Javier Sitaker, 2017-06-15 (updated 2017-06-20) (6 minutes)

Suppose we want a really compact format for representing computer programs. Historically speaking, stack-based representations tend to be the most compact, even though not all operands can be implicit; typically you have a ratio of about one stack manipulation to one computational operation. I thought maybe we could do better, with a construction like the Mill's Belt, and so I did the quick rough analysis below to see what gains were likely; it turns out that you can roughly match 5-bit stack code with a variable-bit-length operand coding, but not clearly beat it.

The idea is that instead of referring to input values implicitly by their position on the stack, you refer to them by how long ago they were produced. At a given point in code with no control-flow join points (jump destinations that can be reached by more than one jump or by non-jumping control flow) each non-constant value was either provided as an input at entry, produced at a single lag into the past. Consider, for example, this piece of assembly code, which copies a byte from stdin to stdout under Linux:

```
_start: mov $__NR_read, %eax       # literal constant  #0
        mov $stdin, %ebx           # literal constant  #1
        mov %esp, %ecx             # use input #-1
        mov $1, %edx               # literal constant  #2
        int $0x80                  # operation: system call with four args #3
                                   # inputs are #0, #1, #-1, and #2
                                   #            (.-3, .-2, .-4, and .-1)
        test %eax, %eax            # result of operation #5 (.-1) #4
        jz exit                    # jump conditional on result of #4 (.-1)
        mov $__NR_write, %eax      # literal constant  #5
        mov $stdout, %ebx          # #6
        mov %esp, %ecx             # input #-1
        mov $1, %edx               # #7

        int $0x80                  # #8 (using #5 (.-3), #6 (.-2), #-1 (.-9), #7
o (.-1))
```

Here we have ten references to non-constant values that are inputs to four subsequent operations (two system calls, a comparison, and a conditional jump). Some of the non-constant values are the result of a previous operation; others are references to the value of %esp at the entry to this code, some time in the past; and others are references to previously introduced constant values. The offsets into the past at which these references occur are distributed as follows:

```
.-1 4
.-2 2
.-3 2
```

```
.-4 1
.-9 1
```

Here's another example, a complete subroutine on amd64:

```
   20 0000 53            pushq   %rbx            # (subroutine prologue)

olast value)
   65 003a C3            ret
```

Here we see the following distribution of offsets into the past for value references:

```
.-1 5
.-2 2
.-5 1
.-8 1
.-9 1
```

If we sum both tables, we get this:

```
.-1 9
.-2 4
.-3 2
.-4 1
.-5 1
.-8 1
.-9 2
total 20
```

So, what probability distribution are these spans drawn from?

This gives a first impression that the probability of a reference going N steps back declines exponentially in N, which is to say, the span is geometrically distributed. The optimal encoding for geometrically encoded data is Golomb coding, which reduces to unary coding in the case where the exponential parameter is 2, which is pretty much what it is here.

If we encode those 20 spans in unary, they consume (+ 9 (* 2 4) (* 3 2) 4 5 8 9 9) = 58 bits, an average of 2.9 bits per operand; this is pretty close to the same density we would get on MuP21 or GreenArrays stack code with its 5-bit operations. This leads me to believe that 5-bit stack operations are already quite close to the optimal density for operand encoding.

(If we assume that the real distribution is exactly the one the encoding is optimized for, we would get exactly 2 bits per operand on average. But it's probably not.)

However, bytecode normally uses a whole byte per operation. To get such slightly-under-3-bits-per-operand density in stack code, you definitely need your stack manipulation operations to occupy less than 8 bits, because that will get you about 4 bits per operand.

(You would have to elaborate the model a bit to handle merging control-flow, such as at the tops of loops and after conditionals, and to handle functions, and I don't think this will be difficult, but the likely gains are not large enough to motivate me.)

A possible way to rescue this: suppose that for two-operand instructions, one of the operands is *always* implicitly the previous result, and you use a separate one-operand "belt manipulation" copy instruction in the rare cases where that isn't what you want. If these copy instructions are uncommon enough, this could get your average well below the 5.8 bits of operands per computational instruction implied by the above, maybe down to 3 or below.

Isotropic nonlinear texture effects for letterforms from a scale-space representation

Kragen Javier Sitaker, 2019-09-10 (16 minutes)

I was walking by some of those goofy hipster chalkboard signs in my *cheto* neighborhood today and noticed that a lot of them are produced from a bunch of relatively simple transformations of letterforms: outlining, drop-shadowing, color gradients, and so on. It occurred to me that it's probably feasible to mechanically explore restricted but visually interesting sets of such transformations in the form of DAGs of a simple algebra.

In many cases, it would be ideal for the transformation to be shift-invariant (s-i), rotation-invariant (i), resolution-invariant (r-i), and bounded-amplitude (b) — that is, transforming a shifted, rotated, or resampled image should produce the shifted, rotated, or resampled transformation of the original image, and that it should be possible to compute bounds on the brightness of the pixels in the transformed image, at least given bounds on the brightness of the images in the original image. Moreover, if you want to do image approximation for style transfer (see Image approximation (p. 2394)) it might be helpful for the transformation to be differentiable with respect to some set of parameters. These restrictions reduce the space of possible transformations in a way that should dramatically accelerate stochastic exploration and mathematical optimization.

Note that it is quite explicitly *not* a goal to restrict ourselves to *linear* transformations.

This is quite similar to, and inspired by, the abundance of excellent work in recent years on computer vision using artificial neural networks.

(See also An algebra of textures for interactive composition (p. 1283) and Cheap textures (p. 736).)

Colors

In the below, I generally speak of "images" as two-dimensional regularly sampled grids of scalar numbers. This is most apt to grayscale images; the simplest way to incorporate color images is to treat them as three separate images, one each for red, green, and blue.

The basics: isotropic scale-space representation

Given a sampled image, you can convolve it with some linear filter to get a transformed image; this transformation is shift-invariant (s-i) from the definition of convolution. If the filter's impulse response is isotropic, which is to say rotation-invariant (i), this transformation will be isotropic. If the linear filter f_s has a scale parameter s such that f_{ks} gives the same linear filter resampled to a new sampling grid k times larger, then you can satisfy the resolution-invariance criterion. You can derive reasonable amplitude bounds on the resulting image

from amplitude bounds on the original image and on the filter's impulse response.

A particularly appealing filter is the Gaussian, the scaled function e^{-r^2}, both because it's the only isotropic separable filter and because it can be very inexpensively approximated using CIC or Hogenauer filters, called repeated box blurs in image processing — independent of the radius, a quadratic approximation to the Gaussian (up to a constant scale factor) takes only six subtractions per pixel, given a dimension-indepenent third-order two-dimensional prefix sum (aka summed-area table) of the image, which requires six additions per pixel to compute, and in general about four times as much space as the original image.

(An additional desirable property is that Gaussian convolution is closed under composition: the composition of two Gaussian convolutions is a third Gaussian convolution whose scale parameter is simply the sum of the scale parameters of the two.)

This is the standard scale-space representation used in machine vision since the 1960s, the two-dimensional analogue of the one-dimensional Weierstrass transform used in analysis (and in particular function approximation) since the 1800s.

So you can use Gaussian convolutions with arbitrary constant radii as elementary operations in your algebra of transformations without risk of producing an inefficient, anisotropic (¬i), shift-variant (¬s-i), resolution-dependent (¬r-i), or unbounded (¬b) transformation. Moreover the transformation is differentiable with respect to both the input image and the scale parameter.

Another class of scalable isotropic filters that admit especially efficient implementations of convolution are flat† circles — circular boxcar filters. These are less efficient than Gaussian convolution, especially as kernel sizes grow, but, as discussed in Real-time bokeh algorithms, and other convolution tricks (p. 2661), they still admit much more efficient implementations than are generally known in the literature, on the order of 1–3 additions and subtractions per scan line in the kernel, or less if polygonal approximations are used.

Flat circle convolution is i and r-i except for aliasing artifacts, b, and s-i. It's differentiable with respect to the input image, but it's imperfectly differentiable with respect to the scale parameter; the flatness constraint requires the circle to expand by discrete pixels, which create discontinuities in its derivative. I feel like you should be able to make a differentiable version by lerping between circles of adjacent radii; using the above-linked algorithms, such a filter can be implemented at much less than twice the cost of a single flat circle convolution, since the two circles will be equal on most scan lines.

† "Flat" in the sense that all points within the support of the filter have the same "height".

Nonlinear morphological operators

Another class of shift-invariant, resolution-invariant, and bounded-amplitude transformations on images with efficient interpretations are the nonlinear morphological operations of erosion ⊖ and dilation ⊕; if used with an isotropic "structuring element" or kernel, such as a flat circle, these operations are isotropic. These, too, have been used in machine vision since the 1970s. As described in Some notes on morphology, including improvements on Urbach and

Wilkinson's erosion/dilation algorithm (p. 216), Urbach and Wilkinson published an algorithm that can evaluate these operators with flat kernels at only slightly higher computational cost than the linear convolution with flat circular kernels described in the previous section, and it's straightforward to shave off another factor of 2 or 3 from Urbach and Wilkinson's algorithm in most cases.

So you can use erosion and dilation with flat circles with arbitrary constant radii as additional elementary operations; as with the isotropic convolution cases, this poses no risk of producing an inefficient, anisotropic, shift-variant, scale-variant, or unbounded transformation.

Combining operators

Arithmetic pixelwise combination

Given constant images and the above elementary unary operations on images, we can combine them pixelwise using most of the standard mathematical operators: +, -, ×, ∧ (minimum), ∨ (maximum), and in some cases ÷, if appropriate bounds can be shown to hold for the input images. (But not %.) In particular, note that pixelwise-nonlinear ×, ∧, and ∨ permit the realization of nonlinear image filtering operations even without the use of any nonlinear neighborhood operations such as the morphological operations.

Moreover, you can apply a number of unary operations pixelwise, such as exp, sin, cos, atan, and in some cases ln.

Bounds-preserving operators

However, I think the above set of combining operators is somewhat suboptimal with respect to its boundedness and efficiency. It's true that you can compute bounds on $a + b$ or $a \times b$ given bounds on a and b, but if you're randomly assembling DAGs in this algebra, a lot of them will randomly have very large or very small bounds. It would be desirable to have a similarly expressive set of operations in which, if both inputs are bounded to some range, the output is too.

In particular, consider the case of a, b, $c \in [0, 1]$. Then these continuous, pixelwise combining operations preserve that bound:

- $1 - a$
- $\frac{1}{2}a + \frac{1}{2}b$
- $\frac{1}{2}a - \frac{1}{2}b + \frac{1}{2}$
- $a \times b$
- $a \vee b$
- $a \wedge b$
- $a + b \times (c - a)$ (lerp)
- $\lg(1 + a)$
- $2^a - 1$
- $\frac{1}{2}\sin(\omega a + \varphi) + \frac{1}{2}$
- 0 if $a = 0$ else $a/(a + b)$
- 0 if $a = 0 \vee b = 0$ else $2/(1/a + 1/b)$ (scaled resistors in parallel; soft minimum; harmonic mean)
- $\sqrt{(a)}$
- a^k, more generally

Of these, all but ∧ and ∨ are everywhere differentiable; those may happen to be differentiable in a particular case. It might be possible to

use the harmonic mean above or $\sqrt{(ab)}$, the *geometric* mean, in place of $a \wedge b$, but it's not a very good substitute.

Anisotropy

The algebra of image filtering above can express a wide range of effects, but since all of its operators are isotropic, it can't express anisotropic effects, which for better or worse include calligraphic stroke emphasis (including goofy hipster ironic Victorian puffery effects) and drop shadows. By adding just a simple shift operator to the algebra, $s_{m,n}(p) = (x, y) => p(x - m, y - n)$, we can gain a wide variety of such anisotropic transformations, while still guaranteeing b, s-i, and r-i—except for aliasing artifacts. Differentiability suffers from the same kind of aliasing artifact as the flat circle convolution, and similarly bilinear interpolation is sufficient to mostly restore differentiability. However, bilinear interpolation suffers from its own artifacts, having to do with the lousy approximation the triangle kernel is to a sinc.

To fully restore differentiability, we need a differentiable interpolation operator, such as quadratic spline interpolation, which additionally is a much better approximation of sinc. It requires nine multiply-accumulates per pixel, though perhaps I can strength-reduce that to three, or one if it is separable or close enough.

To account for both the computational cost and the anisotropy we would like to minimize, it may be a good idea to include a special penalty term for the use of the shift operator in cost functions used for mathematical optimization.

Dynamical systems

Discrete time

In addition to static graphs of image transformations, we can think about evolving an image over time. One simple way to do this is to iterate a transformation some number of times — that is, run it with its previous output as its new input. This can give rise to interesting behavior even with very simple transformations. (This is also one of the motivations for seeking combining operations with output bounds the same as input bounds.)

Continuous time

However, the number of times the transformation runs in that state-machine scheme is necessarily discrete — and such discretized time means that the result cannot be differentiable with respect to time. As a possible alternative, we can use a transformation to define an *ordinary* differential equation that specifies the temporal evolution of the image: the pixelwise difference between the original image and the transformed image gives the pixelwise time derivative of the evolution. (It can be seen that, except for numerical approximation errors, this will never lead the pixel outside the smallest interval containing both its own range and the range of the transformed pixel; so if both are [0, 1], it will remain within [0, 1].) Then we can use garden-variety Runge–Kutta numerical integration of ordinary differential equations to compute the image's evolution, time step by time step, with high precision.

This makes the resulting image differentiable with respect to the

time parameter — somewhat by fiat, as it were — and allows us to vary that parameter continuously.

Differentiable crossbars

In the above I've mostly talked about the DAG of image-processing operators as if it descended from heaven. But there occur to me three major ways to handle this:

- Expose image-processing operators directly to a user, whether through an API, a GUI, or some hybrid, and let them play around.
- Generate DAGs randomly, possibly using genetic-programming techniques, or exhaustively, possibly using some kind of heuristic breadth-first search.
- Use a fixed topology that is nevertheless flexible enough to generate a wide variety of effects.

The third approach is the one taken by most current artificial-neural-network research, usually through "fully connected layers" (complete bipartite graphs) and "max-pooling". Fully connected layers of n neurons from m inputs involve multiplying a vector of length m through an $n \times m$ matrix — for every pixel in your image, if you're doing something convolutional.

Telephone networks originally worked using fully connected switchboards: any jack could be patched to any other jack by the operator by inserting a wire into both jacks. But this scaled poorly with the size of the network, so they changed to crossbar switching.

A crossbar switch is a small permutation matrix; it might have four inputs and four outputs, although in the Telephone network all these connections were initially bidirectional. Each of the 16 crossing points could be closed (1) or open (0). In this way, any input can be connected to any output, and indeed every input can be connected to some output at once when the matrix is 75% sparse.

The trick is that multiple layers of many of these crossbar switches can produce any permutation of the inputs on the outputs. (A sorting exchange network is the special case of this where the crossbars are 2-input 2-output switches.) Consider a layer of four input 4×4 crossbars, each with one output connected to each of four output 4×4 crossbars. This is sufficient to connect any of the 16 inputs to any of the 16 outputs, but it cannot produce all possible permutations — you cannot have two inputs on the same input switch connected to two outputs on the same output switch. All circuits are busy.

Introducing an intermediate "hidden" layer of four more 4×4 crossbars, with a similar fully-connected arrangement, does, I think, give you all possible permutations. (A simple counting argument shows that it *could*, while no arrangement of eight 4×4 crossbars can — $4! = 24$, and $24^8 = 110{,}075{,}314{,}176$, while $16! = 20{,}922{,}789{,}888{,}000$, but $24^{12} = 36{,}520{,}347{,}436{,}056{,}576$; but clearly there are many ways to get the same output permutation by routing circuits through different hidden-layer crossbars.) There is some savings here: a single-stage 16×16 crossbar would contain 256 contact points, while this three-stage network contains only $12 \times 16 = 192$ contact points. Adding further crossbar-switch stages to the network increases the economy.

What I have in mind here is using 4×4 matrices as differentiable crossbar switches. Applied pixelwise to four input images, such a

crossbar produces four output images as linear pixelwise functions of the inputs, and so a few layers of such stages can substitute more economically for the fully-connected layers in traditional artificial neural networks.

The output of these stages is then fed to some set of fixed-function units attached in a fixed topology to the crossbar outputs: lerp, multiply, average, max, min, Gaussian blur, shift, and so on. In this way, the continuously-differentiable "crossbars" substitute for the discrete connection topologies we might otherwise have to search through.

We can apply an optimization penalty for weights that are far from 0 or 1, perhaps later on in the training, as is conventionally done in topological optimization. In this way we can give the crossbars an incentive to sparsify, and thus we can stop computing functions that aren't contributing to the results.

In a world with ubiquitous surveillance, what does politics look like?

Kragen Javier Sitaker, 2014-04-24 (11 minutes)

There's been a lot of discussion about how the NSA is spying on everyone in the world, which is a huge civil-rights problem. If everything you've ever written to a lover or a friend, every file you've ever downloaded, and a minute-by-minute record of your whereabouts as determined by your phone, is archived forever, someone who wants to blackmail you can probably find something in the archive to offend any particular group they want you to offend, prosecute you wherever you happen to live, and therefore make demands on you. So the NSA, or anyone with access to their archives, will have extensive influence on world politicians throughout the next half-century, even if their spying were to stop tomorrow.

Beyond the utility of such an archive as a means of coercion *per se*, it can be used to amplify more traditional means of coercion. It's common for political leaders and even rich people to employ bodyguards and keep their whereabouts private in order to frustrate kidnapping and assassination attempts. But, even if your cellphone records from your teen years don't reveal where you're likely to vacation with your family, even if your bodyguards are always at your side day and night, and even if the NSA and their Russian counterparts don't have the political backing to blow you up with a Hellfire missile or shoot you with a quadcopter-mounted rifle, the social-graph data of who you know will provide ample "soft targets" --- a tactic that has already been used, for example, in the FBI's malicious prosecution of US journalist Barrett Brown. (They raided his mother's house and filed trumped-up charges against her: "obstruction of justice," for not knowing he had his laptop at her house. She pled guilty.)

Any government agency armed with a computer-generated list of your thirty-two closest friends and family members can surely find one of them who is poorly guarded and easy to kidnap or threaten. By this means, social-graph data amplifies traditional means of coercion.

You might think that regulatory and administrative oversight of the NSA can solve this problem. I don't think it will, for two reasons.

First, the NSA is already in a strong position to retaliate against any politicians that attempt to rein it in, using blackmail.

Second, if the NSA doesn't do it, other agencies will. Current computer security is extremely poor; a smart kid in Iran can probably manage to download cellphone location records of people in the US en masse; and the relevant social-graph information is largely public on Facebook. As has been the case with bombings for over a century, our best defense is that not very many people want to do it badly enough to dedicate the necessary part of their life to the problem.

However, as with bombing, given that this is now a viable path to geopolitical power, there will be no shortage of organized groups (such as the US military and the militaries of other countries) who organize themselves to take advantage of the opportunity. Indeed, any entity seeking power through coercion who fails to take advantage of these opportunities will probably be subverted by entities that do.

There's still the matter of budget. If we stipulate that the information is readily available, how much does it cost to turn it into a Big Brother Database that enables this kind of coercion? (Let's assume the agency pays for this itself instead of using storage it borrows without permission.)

There are currently about 7 billion people. Each of them might have 1000 social connections that matter; these social connections range over several orders of magnitude of importance. If you need 16 bits to represent the importance of the relationship and 40 bits to identify the person who is related to, that's 56 trillion bits, or 7 terabytes. A one-terabyte disk currently costs about US$100, so storing the world social graph — if you could get hold of it — would cost you about US$700 of disk. You'd probably want to store it with some redundancy to handle disk failures, indices might add another factor of 2, and motherboards, power supplies, etc., might add another 25%. All in all we're talking about a budget of some US$2500 to store the world social graph, assuming you can get hold of it.

However, disk prices are still in an exponential fall, halving every 15 months. In three years, in 2016 or so, the price will be around US$600, and three years from then, US$150.

The next step, presumably, is the location information database. The Earth is about 20 million meters from pole to pole, so locating someone on Earth's surface to within one meter — good enough for targeting a bomb — requires about 50 bits of information. Let's round up to 64, 8 bytes. Collecting this information every ten minutes for a typical 30-year lifetime adds up to 12.6 megabytes per person, or 88 petabytes in all: about US$9 million of disk storage at present, shrinking to US$1 million around 2020 and US$1000 around 2035 (although the population will be somewhat higher then, so the cost will be slightly higher). But this information is highly compressible, so these cost numbers might be high by an order of magnitude or so.

However, even if you collect this much information originally, you don't have to retain it all for it to be useful. If you summarize to the three most common places in which a particular person can be found, then instead of 12.6 megabytes per person, you only need 24 bytes per person, or 170 gigabytes for the world population, about US$20.

Collating multiple sources of location information might inflate the 12.6 megabytes by a factor of three or so. For example, license-plate cameras, gait recognition from security cameras, public-transit card tracking, ticket-purchase information from airlines and long-distance bus lines, private jet flight plans, and location information on social-media postings can all provide supplementary location information. Disagreements among these sources might point to cases where someone's trying to hide something. For example, if someone's cell phone jumps from one city to another at over 200 kilometers per hour, they've probably taken a plane, and there should be a flight record unless they're traveling under an assumed name.

This kind of information also supplements the online-gathered social graph with information about who you move from place to place with (perhaps you're riding in their car) and who you lend your car to.

So what about the Blackmail Communications Database? This is more difficult. A basic version might be some ten 100-byte SMS messages per day per person, some 1000 bytes. 1000 bytes per day per person over 30 years is about 11.0 megabytes per person, similar in size to the location information database; you also need the metadata of who the message was to and when it was sent, which perhaps inflates it by 10% or 20%, so let's say 13 megabytes. If you also include IM and email, you might have another order of magnitude on top of that, or 130 megabytes. (Some people send more, some send less.) That brings us up to almost 900 petabytes for the world: US$90 million.

Any spy agency in the world with a billion-dollar budget has surely already done these calculations and has been running this program for years.

At some point in the near future, perhaps around 2020, DNA sequencing will be as inexpensive as license-plate scanning is today. Whenever you touch an object that isn't yours, such as a doorknob or hot-water tap, or release bodily fluids such as urine into a public receptacle, you'll be taking the chance that it's sampling your skin cells. Combined with the location database, this will rapidly provide a clear picture of the genetic ancestry tree of living humans, which can be added to the social-graph database to provide a more complete picture, including corrected biological paternity data. That is, you'll be able to infer whose biological father, grandfather, or great-grandfather is someone other than who it's conventionally assumed to be.

In its full form, the genome of a human being is 3 gigabasepairs, or 750 megabytes, although this is highly compressible. But you don't need 750 megabytes to uniquely identify a person; you only need a judiciously chosen 66 bits to provide a unique identifier with high probability. Reliably inferring biological relatedness probably requires more bits, but I don't think very many more.

This data, interchangeably with other biometric surveillance data such as facial recognition and gait recognition, will eliminate anonymity and pseudonymity for anyone who traverses public spaces, at least from the agency or agencies that have access to it.

This seems to point to a fairly dystopian future, one in which a friendship with, or relatedness to, a powerful person could get you kidnapped or murdered to coerce their compliance, and in which access to a relatively small and easily copied database is sufficient to provide this ability to the NSA --- and whoever manages to steal a copy of it from them. What are our options for avoiding this?

You could try to keep your part of the social graph secret: don't post it on web sites, say. But that doesn't help if the other people you know, or the people who see you together, go ahead and post their photos online.

Today there are companies whose business is to deanonymize web visitors http://www.forbes.com/sites/adamtanner/2013/07/01/heres-some-co
ompanies-who-unmask-anonymous-web-visitors-and-why-they-do
-it/ and to sell listings of sightings of a given license plate

http://www.forbes.com/sites/adamtanner/2013/07/10/data-broker-offers-new-service-showing-where-they-have-spotted-your-car/ so you can tell where a car has been. These services will get more comprehensive, cheaper, and more numerous, as improving fabrication and analysis technology progressively drives down the cost of providing them.

Caustics

Kragen Javier Sitaker, 2018-08-18 (updated 2019-11-08) (8 minutes)

A group of students at EPFL have started a company called Rayform to make objects with customized caustics (both reflection and refraction), using materials such as PMMA, aluminum, and glass to form their "caustic generators". This turns out to be a centuries-old Japanese art form known as "magic mirrors"; the originals were copper mirrors hand-scraped to produce customized caustics under the influence of copper's elasticity and a varying material thickness, legendarily so that underground Japanese Christians could escape religious persecution; the principle by which these "diaphanous mirrors" or "makkyo" worked was not understood until the 1960s, although they had been manufactured in Japan and also China for thousands of years. This prompted a couple of thoughts from me tonight. First, what about sunlight automicroscopy? Second, how about cheaper fabrication technology?

See also files Gauzy shit (p. 2985) and Caustic simulation (p. 1454).

Sunlight automicroscopy

Sunlight reflecting off a convex surface projects a magnified image of whatever colors or patterns are on the surface; this is easily seen with, for example, a Red Bull can. Sunlight is about 100 kilolux, while sunlight shadows can vary but are typically around 3–10 kilolux. So even if the reflected light is spread over a 20× larger surface than the reflective convex object, it still has brightness comparable to the ambient light. And the projected image is substantially larger than the patch on the surface that it is projected from — in the aluminum-can case, all the spread is in a single dimension, so it can be on the order of 20× larger, while the correspondingly bright reflection from a sphere would have a linear magnification factor of only 4–5 before becoming undesirably dim.

However, the caustic-shaping technique can potentially rescue the method — in the geometrical-optics approximation with point-source illumination, it can focus the light from an arbitrary area onto a point or line of zero area, thus achieving infinitely bright illumination. Rayform's demo videos seem to show focusing of more than one order of magnitude.

Point-source light reflecting from a surface whose normal varies over some angle θ will in turn vary over the angle 2θ. The sun subtends about half a degree, so the reflection from a curved surface patch will subtend about half a degree more than the curved surface, which blurs the projected image somewhat. However, this is a limit on the angular resolution of the microscopy method, not its spatial resolution. And narrowing the sunbeam by passing it through a pinhole that subtends less than half a degree from the point of view of the generator.

The nonzero angular size of the sun also provides the limit on the brightness increase available by focusing: the projected focus spot will have, at minimum, the same angular size as the sun, as viewed from

the point on the generator that is generating it.

Another limit on this technique is the diffraction limit: as the concave facet producing the focused spot becomes smaller, the produced beam has a larger divergence. I think that roughly to achieve half a degree divergence — the best you can do with a half-degree-wide sun light source — you need a facet of diameter roughly $\lambda/(\frac{1}{2}\sin(\frac{1}{2}°))$. This works out to about 126 μm for 550-nm light. This *is* a spatial resolution limit.

The facet can be a concave paraboloid section, in which case it produces a point caustic, but if it is less concave in one direction, it will spread out its light to produce a line caustic subtending some arbitrary angle at some arbitrary rotation.

Setting the spatial and angular resolution limits equal, maybe we would like 126 μm to subtend about ¼° of the curve of the convex surface, which gives us a radius of about 29 mm. Spheres or cylinders with a diameter smaller than 58 mm will have an unnecessarily coarse angular automicroscopy resolution limit, larger than ¼°, imposed by diffraction of light from their facets; those with a larger diameter will have an unnecessarily coarse spatial automicroscopy resolution limit, larger than 126 μm, imposed by the apparent size of the sun.

If we want these 126 μm facets to project pixels at about 72dpi — 350 μm, a lower limit for comfortably readable text, although older computer terminals and printers used a slightly coarser 8 vertical pixels per 6lpi line, giving 530 μm — then we want 350 μm to subtend ½° as seen from the surface of the mirror. This gives a projection distance of 40 mm, which seems rather small to me, so maybe 100 mm would be better, which gives blurry 870-μm projections. Since each facet can project an arbitrarily oriented line, rather than just a point, you only need about, say, 5 of them per letter. This means our 29-mm-radius shiny sphere with its 10500-mm² surface area, holding about 850 000 facets of 0.0124 mm² each, can project about 170 000 letters, about 40 or 50 pages' worth of text.

This may not be reasonable — the pixels may be too crowded together. Consider that if the facets are all just directly pointed away from the center, the spots they project will be ½° apart as seen from the surface — which is to say, they will all kind of blur together, unless you stack some of them on top of each other, which is of course what Rayform does.

How bright are they by default? Consider a mm² in the center of the sunbeam, which is reflecting its light onto a screen in shadow positioned a negligible angle to the side of it. This mm² subtends 34 milliradians (1.98°) and so its projection will subtend 78 mrad (4.0°), which means that at 100 mm it covers an area 6.9 mm × 6.9 mm, which is 48 mm². So it will be 48× dimmer than the direct sunlight: 2100 lux, visible on a 10 kilolux shadow background but far from overwhelming. But areas illuminated by several times this 126-micron-wide minimum will be considerably brighter than the shadow.

How much spatial precision do we need to make the surface reflect like this? Suppose we're willing to tolerate ¼λ deviations. Well, at 555 nm, that works out to 139 nm (≈ 5.5 micro-inches). This is a relative radius error of 4.8 parts per million. Regular ABMA bearing balls of grade 100 have a surface finish smoothness of 5.0 micro-inches (127 nm), but to get roundness of 5 micro-inches, you have to go

down to grade 5. That isn't even the lowest grade, but grade-5 bearing balls don't come as large as 58 mm; they only go up to 2 inches, which is 50.8 mm.

Turning a spherical surface with a radius of 29 mm into a 127-micron-wide paraboloidal facet with its focus at 100 mm requires changing the curvature radius from +29 mm to -200 mm. At +29 mm, the middle of the facet would be 69 nanometers proud of planar; at -200 mm, it would be 10 nm below. This seems like I must have some kind of calculation error, since it seems inconceivable for such a small difference to produce a precise focus.

Cheaper fabrication technology

First off, what about using sugar glass instead of PMMA or soda-lime glass for the refractive pieces? Instead of polishing it with rouge, you could polish it with water.

Second, how about using electropolishing to remove tiny, precisely controlled amounts of metal, leaving a smoothly varying surface, while leaving a mirror finish? Electroplating at around 1000 A/m² deposits chromium at something like 100 nm/minute, so it seems like thickness control down to the level of less than a monolayer should be feasible. This is also potentially useful for making large mirrors out of invar or similar, then aluminizing or silvering them.

A failed attempt to make squares cheaper to compute

Kragen Javier Sitaker, 2019-07-09 (updated 2019-07-11) (4 minutes)

Could you cheaply generate a lazily filled square table using the method of differences?

The squares are the sums of the odd naturals; $5^2 = 25 = 1 + 3 + 5 + 7 + 9$, for example. The simplest way to tabulate the sequence of squares $y = x^2$, or for that matter any polynomial function, is using the method of differences, here using three columns because the sequence is quadratic:

```
2   1   1
2   3   4
2   5   9
2   7  16
2   9  25
2  11  36
2  13  49
```

Here each number is the sum of the number to its left and the number above it, except the first row.

This is not a very appealing way to find 28^2, though.

Consider, though, if we want to tabulate $y = (3x)^2 = 9x^2$. We can tabulate this sequence with the same algorithm, but starting from a first row that is multiplied by 9:

```
18   9   9
18  27  36
18  45  81
18  63 144
18  81 225
18  99 324
18 117 441
18 135 576
18 153 729
```

This has gotten us somewhat more quickly to $27^2 = 729$, which is very close to knowing 28^2; specifically, the difference is $2 \cdot 27 + 1 = 55$, so $28^2 = 729 + 55 = 784$. We could have gotten there even faster by tabulating $y = (9x)^2 = 81x^2$ in the same way, starting with a first row multiplied by $9^2 = 81$:

```
162   81   81
162  243  324
162  405  729
```

That is, this setup allows us to leap ahead as we tabulate squares, skipping eight out of every nine items. We could leap by tens, or by hundreds, or by 27s, or by any other number. And once these squares are tabulated, we can keep them tabulated and not recalculate the ones needed to get us close to our objective.

This suggests a general procedure for finding your way to a given square with a logarithmic number of N-digit additions: first leap by the largest power of 3 less than the number, twice if necessary; then the next-largest power of 3, twice if necessary; and so on, until you're leaping by 1s. So, for example, to square 451, first find the square of 243, then 324 (leaping by 81), then 405, then 432 (leaping by 27), then 441 (leaping by 9), then 450, then 451. This involves 12 three-digit additions, which is worse than the standard partial-products approach, but only by a factor of 4. And it's the same 12 operations we'd need to find the 451st term of an arbitrary quadratic sequence, not just $y = x^2$. And maybe some of those values would be already tabulated if this isn't the first number we're squaring.

However, there's a missing piece here. When we arrived at 27 leaping by 9s, our computational state said:

```
162   405   729
```

To leap by 1s again instead of 9s, we need to somehow get from that to this:

```
  2    55   729
```

The 2 is easy — it's the same 2 on the first line of the leaping-by-1s square sequence — but where do we get the 55 from?

I'm pretty sure that the second column we need to slow down by a factor of 9 is a linear function of the previous computational state (162, 405, 729), and I think you can derive that linear function from Newton's divided-differences form for the underlying polynomial.

But I suspect it really only depends on the 405 in this case. 55 is 55 because it's $2x + 1$. 405 is 405 because it's $18x - 81$. So 55 is $2(405 + 81)/18 + 1 = 405/9 + 10$. Extending this to arbitrary quadratic functions (which potentially have a different second-order difference) might involve taking the 162 into account: it's the 2 of our original second-order difference multiplied by the square of our speed.

This is kind of shitty, though, because we were hoping to avoid multiplying a two-digit number by itself, and to get there we ended up dividing a three-digit number by 9, which is *harder*.

A filesystem design sketch modeled on Lucene

Kragen Javier Sitaker, 2007 to 2009 (43 minutes)

IN PROGRESS:

- finish writing
- describe segment directory structure
- list awesome features

I've been thinking about using something like Lucene's index file structure to build a filesystem suitable for lots of small files, similar to Reiserfs's goals.

I've been using Reiserfs for a project recently, and I've been pretty annoyed at its lack of performance predictability for interactive use; for example, when I `find | wc -l` on a certain Reiserfs directory tree that contains 18GB in about 500 000 files (see the section "murdererfs problem" for exhaustive detail), it takes 9 minutes. So I was thinking about how to avoid this.

To some extent, lack of performance predictability is an unavoidable feature of disk-based filesystems; access to a random byte that's in the buffer cache costs maybe 100ns, while access to a random byte on a spinning-rust disk unavoidably costs somewhere around 8ms, which is 8 000 000 ns. Since the disk is (generally) much bigger than the buffer cache, an adversarial program can always choose its next requested byte from a block that's not in the buffer cache, thereby receiving terrible performance, 80 000 times worse than if it were to read data that was already in memory.

So it's not possible to design a filesystem to have consistently good performance for all possible access patterns, even for read-only access; read/write access complicates things even more. Instead we should design a filesystem that has consistently good performance for the *common* access patterns. As explained above and in the "murdererfs problem" section, reiserfs fails at this in the case of `find -print`.

This is an exploration of how to do better, and why; but first, why not.

Spinning Rust is Obsolete

Now, it's possible that Flash SSDs will make this all irrelevant, as they become large and inexpensive. I suspect that spinning-rust disks will remain relevant for a while longer, for the following reasons.

First, there's Moore's Law and its effect on pricing. For the last 15 years, disks have doubled in capacity every 15 months, while chips have doubled in capacity only every 18 months. Flash has improved its density relative to feature size quite a lot during that time (that is, bits per square lambda; lambda is now 45nm, I think) and has become economically important enough to get access to the latest fab technology and have almost zero NRE expenses per unit. However, I am guessing that from now on it won't improve any faster than process sizes do. At present 8GiB of Flash costs about US$20 (US$2.50 per GiB) and comes on a single smallish chip (that fits in a Micro-SDHC card). At the standard Moore's Law rate of 18 months

per lambda-halving, we should see 32GiB of Flash for US$20 in a Micro-SDHC form factor around 2012, 128GiB for US$20 around 2015, and 512GiB (550GB) for US$20 around 2018.

By contrast, 500GB disks currently cost US$80, or US$0.16 per GiB. If they continue on their 15-month exponential growth curve, then 2018 will be 7 doublings in the future for them, and so we should expect to have 64TB disks selling for US$80 in 2018, or US$0.00125 per gigabyte. That's a 30× lower price per bulk gigabyte, as against 15× today.

More surprisingly, though, in 2018 we should expect to have 4TB or 8TB disks selling for US$20, just as we have 40GB disks selling in that price range today. Today buying a US$20-$40 disk instead of a US$20-$40 flash card costs you perhaps a factor of 5 in capacity; in 2018 it would cost you a factor of 8 or 16, if these predictions hold. This reduces the market available for small Flash devices.

Second, in the time between now and 2018, even the existing 15× price premium for Flash is too much for many applications. It's likely that Flash will spend many years (in systems bigger than your thumb) occupying a middle layer of the memory hierarchy, in between DRAM (US$10/GB, 100ns) and spinning rust (US$0.16/GB, 8 000 000ns). Right now Intel's 80GB SSD has access times of about 130 000ns, according to Bonnie++, and it costs about US$550 (according to a Google search; all the other prices here are from Pricewatch), which is about US$6.70/GB. Presumably this price will come down soon; I'm mystified that people are buying these things already. Maybe database journaling?

Anyway, so Flash will be filling the price/latency tradeoff gap between RAM and disk, much as disks and drums used to fill the price/latency gap between core and magtape. (Again, this is in computers bigger than your thumb. In small systems, Flash makes things possible that were simply impossible before: in the past it made possible MP3 players, cellphones that shoot video, and in the future it will make things possible we haven't thought of yet.)

The third reason that disks will remain relevant for a while is that [a lot of the current SSDs actually use a lot of power] [TH], which neutralizes one of Flash's big potential advantages. Hopefully this will get better soon.

[TH]: http://www.tomshardware.com/reviews/ssd-hard-drive,1968.html "there is indeed one Flash SSD that beats the living daylights out of any hard drive now"

murdererfs problem

This section should contain enough information to either reproduce my performance problem or figure out why I have it and you don't. It probably contains too much detail to be interesting otherwise.

I have a 30GB-max Reiserfs 3.6 filesystem (using ordered data mode, size 8192) in an 18GB sparse file on ext3fs, which I defragmented by using `cp` to make a fresh (presumably sequential) copy of the file before running this test. I'm running a fairly stock Ubuntu 8.10 Intrepid Ibex system with its standard 2.6.27-9-generic i686 (32-bit) kernel, on a 1.6GHz Celeron E1200 system with an Asus P5KPL-AM motherboard, 2GiB of RAM, and a Western Digital

WD50000AAKS-75A7B0 500108-MB hard disk, attached via SATA (although the kernel claims it's configured for UDMA/133).

Running Bonnie++ on the underlying ext3 filesystem, once with 12240M and once with 10240M of data, I got about 64000K/sec block writes with 30% CPU usage, 75000K/sec block reads with 16% CPU usage, and 102 random seeks per second with 1% CPU usage.

I mounted the filesystem, for the first time since reboot, and ran `find reiserfs-mount-point/ | time wc -l` (actually I used a different piece of software that's slightly different from `wc -l`, but that shouldn't matter.)

It took 9:07.38 elapsed time to get the 538 055 filenames from the reiserfs filesystem the first time. (Almost half of the files are directories; there are 100 directories at the top level, each of which has around 2000 subdirectories; most of these subdirectories contain a single file, but some contain several.) Repeating, it took 0:08.54 elapsed time, 64× as fast. I was running `iostat 5` in another terminal while doing this; during the first read, `iostat` reported between 100 and 220 "tps" during the first read, and between 800 and 1300 "Blk_read/s". There was also write traffic during this time, but it stopped shortly after the test was over, so I am guessing it is due to reiserfs.

The system was generally idle otherwise, with under 2% CPU usage.

The pathnames totaled 25.8 megabytes.

As I have said, no filesystem can have good read performance for every access pattern, and it can't have consistent read performance for every access pattern unless it does so by always hitting the disk (i.e. not caching). However, I do not think `find` is such an unusual access pattern that it does not need optimizing for, especially since murdererfs's raison d'être is explicitly to handle the "lots of small files" pattern better than ext2fs.

It *does* handle this pattern a lot better than ext2fs (or ext3fs anyway), which needs something like six times as much time to do the same `find` (on a different machine!), and additionally wan't any faster the second time around.

According to `iostat`'s man page, a "block" is 512 bytes, so 1000 blocks is 500kiB. So reiserfs is running a 75MB/s disk at 0.5MB/s, less than 1% of its maximum speed. The useful data it retrieved was 538 055 filenames and inodes. An inode is about 128 bytes, so there were about 69 megabytes of inodes, and the filenames totaled 4.9 megabytes, for a total of 74 megabytes of *useful* data being read. (The filename and inode data would be entirely sufficient to answer the `find` query, although directory entries might have another 5 megabytes of inode numbers, which serve only as pointers to find the inodes.) But 0.5MB/s for 9:07 (547 seconds) is 270 megabytes, so only about 30% of the data Reiserfs read from the disk was actually useful for answering the query.

If all of that data were stored sequentially on the disk, it would take 1.0 second to read the filenames and inodes, or 3.6 seconds to read all of whatever other useless data Reiserfs decided to read. If it were scattered in 1000 pieces, requiring 1000 random seeks, it would take 11 or 14 seconds to read it. But apparently Reiserfs managed to require about 55 000 separate disk transactions: roughly one transaction (and 0.5–1 seek, since it was getting 100–200 transactions per second) per

ten files!

ext3fs manages to do substantially worse.

Common Access Patterns

A filesystem should have *fast*, *consistent* performance for *common access patterns*, as well as providing a way for applications to "escape" from the filesystem's tradeoffs by providing *predictable* performance for applications that want to roll their own --- by storing their data inside a big file they structure as they please. Here's a list of the common access patterns I think are important to be consistently fast:

- Sequentially reading a large file that was sequentially written. (Almost all filesystems do well at this.)
- Sequentially reading a large file that was randomly written. (Most filesystems do well at this; LFS implementations, and ext3fs during part of the 2.6 series, sometimes fail badly.)
- Sequentially writing a large file.
- Sequentially creating and writing a large number of small files in the same subdirectory tree. (None of the filesystems I know do well at this.)
- Sequentially reading a large number of small files in the same subdirectory tree.
- Statting or opening a file, given a path from the root of the filesystem.
- Reading the metadata of a large number of files in the same subdirectory tree.
- Random read/write access within parts of a single file.

I think an approach based on Lucene's index structure can provide reasonably good, but above all consistently not bad, performance for all of these access patterns, while providing the usual POSIX filesystem semantics.

The Design

The filesystem is a bag of variable-length (key, timestamp, data) triples. There are three kinds of key: pathnames, inode numbers, and extent numbers. The data associated with an *extent id* is an inode number and a list of variable-length (offset, contents) pairs, each of which gives a block of data stored at that offset in the file to which it belongs. The data associated with an *inode number* is a list of (variable-length) pathnames that point to that inode. The data associated with a *pathname* is more complicated, but usually it is the file's metadata --- basically, most of the results of `stat()`.

Writing to the filesystem consists of adding more triples to the bag with a newer timestamp than the triples already in the bag. To get data about a file, you look up its pathname in the bag, and (if you want its contents) look up its extent ids in the bag too. To list the contents of a directory, you search for triples whose keys are pathnames in a certain range.

When there are multiple triples in the bag with the same key, you just get the triple with the latest timestamp and ignore the older ones. Eventually they will be removed by "merging", as explained below.

This is not a great match to traditional Unix filesystem semantics, since the file data is actually stored with the directory entry. So when a pathname is a hardlink to an already-existing file, instead of storing

the usual metadata, it just stores a *broken heart* containing just the inode number of the file. When we try to get a file's metadata and come up with a broken heart, we look up the inode to find out what pathnames point to that inode; the first one of them has the actual file metadata. So we look up that pathname to get to the file.

The tricky thing in such a system, which pretends to be a normal Unix filesystem where file contents and metadata are separate from a bunch of interchangeable directory entries, but actually stores them as a single unit, is how to handle deletion of the "primary" directory entry for a file with multiple hardlinks. To handle this case, we add three triples:

XXX we'd need less write bandwidth if we separated inodes, atimes, and filesystem paths.

- a new version of the inode triple with its first entry removed;
- a new version of the new primary directory entry, updated to contain the file metadata instead of a broken heart;
- a new version of the triple for the old primary directory entry, which has a special "deleted" marker instead of file metadata or a broken heart.

This isn't the simplest approach, but it's not fiendishly overcomplex.

Segments

The triples are stored in segments. A segment is a sequence of triples sorted by key, compressed with LZF, and stored in a contiguous sequence of disk sectors. Each segment is normally around one megabyte in size compressed, which should decompress to around 2.5 megabytes of data. This size is chosen because reading less than about a megabyte of data from disk is pretty much a waste of a seek, but decompressing the segment (necessary to read its contents) might take 5–10ms of CPU time. XXX not sure; compress in subsegment chunks? The sort order sorts the different kinds of keys apart: inode numbers are all together, not interspersed with pathnames, and extent ids are all together, not interspersed with inode numbers and pathnames.

I'm not sure whether the slots the segments are in should be fixed-size; presumably that entails a certain amount of wastage.

There's a segment directory, which sort of like the superblock. For each live segment, it lists the key of the first and last key in the segment, the timestamp of the newest triple in the segment, and the segment's location on disk. My new 500GB disk might be expected to contain up to around 500 000 segments at any given time; keys are probably mostly around 64 bytes; timestamps are perhaps 8 bytes; disk addresses are perhaps 8 bytes. Consequently this is about 80 bytes per segment, or about 40 megabytes for the entire disk. This can easily be kept in RAM.

To look up a single key:

- Find all the segments `seg` in the segment directory for which `seg.first_key <= key <= seg.last_key`. Sort them by timestamp, with the newest segments first. Start with `found_timestamp = 0`, where 0 is a value that is less than any real timestamp.
- For each segment in the list of candidate segments, if its

`latest_timestamp` is earlier than `found_timestamp`, bail out of the loop; neither it nor any of the later segments can contain newer data for that key. Otherwise, load the segment from disk (if necessary) and decompress it (if necessary) to see if it contains the key with a timestamp greater than `found_timestamp`. If so, remember the triple and set `found_timestamp` to the timestamp of the found triple.
• Now you have in hand the latest triple for that key.

The algorithm for finding all of the keys in a range (a "range query"; e.g. files in a directory) is similar, but can't bail out of the loop early. It is built on an algorithm for finding the first key after a given key ("get next"); there is an analogous algorithm for finding the last key before a given key ("get previous").

Segment Merging

Clearly the efficiency of this scheme, for read, largely boils down to not having very many overlapping segments, so that you don't have to consult very many segments for each query. If the segments are perfectly nonoverlapping, then only a single segment ever needs to be fetched and examined to answer a single-key probe. So opening and reading a single-extent file (in the common case where it has only one directory entry) would require a single seek to fetch its metadata, then a single seek to fetch its contents. (Although see below under "extents and extent ids".) Listing the contents of a directory (and `stat()`ing all of the files) would simply involve reading the one or more segments covering that directory's key space.

However, when we add new triples, we do it by putting them into a new segment. So whenever we write to the filesystem, even to update an atime, we create overlapping segments.

The solution is to periodically --- well, more or less constantly --- *merge* segments. A merge takes some number of segments that partly overlap --- say, between 5 and 10 --- and turns them into roughly the same number of non-overlapping segments by merging them into a single sorted sequence of keys, while dropping outdated triples, and then chopping that sequence up into some number of new segments. This merge operation should take around 400ms: say, 70ms to random-seek to 8 overlapping segments, another 110ms to read their 8MB of data, another 100ms (overlapped) to decompress it into 20MB, 6ms to merge it into 20ms of sorted data, another 200ms to recompress it into 8MB, and another 110ms (overlapped) to write it in a sequential run of new segments. The segment directory on disk need not be updated until that is necessary for some other reason.

On a machine with 8 idle processors (which should be most desktop computers most of the time, starting with desktop computers sold in 2011), the recompression step could be done in 8-way parallel, cutting the time by 175ms.

Merging should clearly be done preferentially to fairly young segments that cover a comparatively large part of the keyspace, since they will tend to cause slowness to many more queries; and it is preferable to do it to segments that are already in the buffer cache and decompressed.

So one strategy that might work reasonably well for merging under load would be to merge after answering a query that required too many seeks --- specifically, merge exactly the set of segments that were needed to answer that query. In the above scenario, this would

leave only the 6ms of merging, the parallelizable 25–200ms to recompress, and the overlappable 110ms of writing --- so maybe 30ms on CPU and 110ms talking to the disk.

That isn't optimal in general, though; it's pretty wasteful to merge a very young, sparse, and therefore wide segment with a bunch of old, dense, and narrow segments; in the limit, you end up with the first half of the young segment, followed by the first half of an older segment, followed by the contents of a yet older segment, followed by the second halves of the other two segments. It's much more profitable to merge segments that are similar in density.

Every byte written to a new segment, if not superseded, must be eventually read, merged, and written into some new, denser, merged segment N times before reaching its final resting place in a very dense segment. This would seem to mean that only 1/N of the disk write bandwidth is available for writing new data! This may be ameliorated somewhat by churn, but it remains the case that to get a disk from empty to mostly full with this scheme, the data must be copied N times.

For 500 000 total segments and average 8-way merges, randomly distributed data would need to go through 6 or 7 steps to reach a totally non-overlapping state.

However, the inode numbers are not natural keys; it's probably possible to keep their segments from overlapping very much by the simple expedient of allocating them sequential serial numbers from a space large enough that it never gets exhausted. (Again, atime may play havoc with this.) (This may be a reason to go back to the traditional Unix approach of storing the inodes separately --- you'll have new filenames inserted between old ones much more often than you'll have inodes inserted.) And for all but the smallest files, it's the extents that really matter. My original data set, for example, had 538 055 files totaling 18GB; their filenames totaled 4.9MB; their uncompressed inodes presumably were 67MB. So the presumably mergey metadata is only 1/300 of the total, while the hopefully nonmergey file contents data is the rest. See below about "extents and extent ids" for how those are handled.

Extents and Extent ids

XXX need special case for merge and/or lookup; should extent id include length?

An extent id consists of an (inode number, offset) pair; so retrieving the extents associated with an inode consists of a range query. The data associated with it in the filesystem is some number of bytes of the file contents, starting at that offset. So to retrieve the contents of a file, you just retrieve all extents identified with that file's inode number; to retrieve file contents starting at an arbitrary offset, you use the "get previous" algorithm to find the last few extents that start at or before that offset, and take the most recent one that is long enough to reach that offset.

Extents have a maximum length, which I think should be around 32kiB, for several reasons:

• If extents had unbounded length, potentially into tens of gigabytes, they would create segments of unbounded length; this would impede random reads from the middles of files.

• If extents had unbounded length, then reading the byte at location 28920620234 in a file would require reading all of the extents starting at locations 0 to 28920620233, of which there could be up to 28920620234, because until you have read them all, you never know if the next one is going to be a 28920620234-byte long extent that's newer than all the ones you've seen so far. Limiting extents to 32kiB means you only have to fetch the extents beginning in the previous 32kiB in order to make sure you have the current version of the file data.

Making the maximum length too small, however, will impede compression efficiency and impose too much scatter-gather overhead.

In a contiguous bulk write, you'll lay down segments consisting entirely of new extents (already in order) and new versions of the file's metadata with updated size and mtime. These segments, after a merge, will keep the extents in order, and the extent segments will be "dense" in the sense that no other segment will ever overlap their key space, except when it updates that same file. Consequently that data will never need to be moved on disk unless it's updated.

When partial updates of a file are written to disk, they will be in a separate segment from the original data; the file is "fragmented". Eventually a merge will bring all of this data together; this is "online defragmentation".

Continuous snapshotting

If you don't delete triples with timestamps older than some cutoff date, you can roll time back to any arbitrary point in the past since that cutoff date, at some overhead cost to reads of data that's been updated since then. This permits a variety of useful features:

• online database table backup (you don't have to worry that the file is being modified while you back it up, giving you inconsistent backups; just backup a snapshot)
• file undeletion
• general undo
• filesystem change auditing ("what did that install just change?")

View Updating

If you have some application that wants to maintain some data that's dependent on the data currently in the filesystem --- say, locate (although with this filesystem, `find` might be fast enough to render `locate` obsolete), or a full-text indexing system, or something like `make` that runs instantly, that application currently has to function as follows. At startup, it scans the entire filesystem, or the subtree it cares about, in order to compare them to its database. As it scans, it uses `inotify` to request notifications of any future changes. Then it has to sleep, waiting on notifications, for a long enough time to justify the expense of its startup scan.

Things like these are analogous to "materialized views" in a database: a full-text index is a "view" of the files it indexes, a compiled program is a "view" of the source code that makes it up. So I'm calling this general problem "view updating", because it's analogous to the problem of updating materialized views in a database.

By contrast, on this filesystem, the segment directory contains a latest-timestamp for each segment, and most segments should contain data written during a fairly narrow time window, so you can efficiently retrieve all of the segments containing data written since some recent timestamp (if it hasn't already been merged with older segments.) And all of the data is efficiently reverse-mappable: if you find that there's a new extent, you can look up what pathnames it belongs to quite quickly, even if the mtime in the inode hasn't been updated (e.g. because the update followed another update in the same second).

This allows you to run view-updating programs on-demand, or from `cron`.

Filesystem Resizing

Resizing a mounted filesystem is fairly straightforward, either to expand or shrink it, and doesn't pose any special risks due to power failure at the wrong moment. Expanding the filesystem just adds some free space for use in new segments; the segment directory needs to be expanded correspondingly. Shrinking the filesystem requires relocating (and, if possible, merging) the segments in the region to be freed.

Use as Full-Text Index

If you have a bunch of (word, document_id, position) triples, you can encode them as pathnames: "#{word}/#{document_id}/#{position}", and create those paths as empty files. The efficiency of operations such as bulk-create, merge, and lookup should be comparable to the efficiency of the same operations in Lucene, although the inodes will make it somewhat worse.

Directories with Lots of Descendants

There is a case where this design is slower, even unpredictably slower, than standard designs like ext3fs: `ls`, when you're in a directory that has a lot of descendants. In theory, `ls` at the top level of the filesystem has to scan through the entire space of pathnames (you could potentially have billions of pathnames) in order to extract the dozen or so immediate descendants of the root directory. However, there's a reasonably efficient way to solve this problem.

Let's assume for the moment that the pathname segments are nicely merged so that there are no overlapping segments. Now we need to consult the segment directory to find out which segments might contain pathnames under, say, the root directory. But the first-and-last-key information we get this way actually contains enough information to know that most of these pathname segments don't contain any transitions between children of the root! For example, a segment that begins with `/usr/lib/perl/5.8.8/regcomp.h` and end with `/usr/lib/python2.6/xdrlib.py` doesn't contain any children of / or even `/usr` --- only descendants of `/usr/lib`.

So this gives us a worst-case bound: at worst, we only need to fetch one segment per child of the directory we're listing. For the `ls /` case above, this amounts to 120ms. However, only large subtrees (over around 100 000 pathnames) will actually push the next child

into another segment, so at worst, we only need to fetch one segment per *large-subtree* child of the directory we're listing.

out of place XXX

The advantage of storing things in this way is that it optimizes for the common case:

• statting a file through its primary directory entry (and most files have only primary directory entries) only requires a single contiguous read from the relevant spot in the segment. (How you find that spot is explained later. It may require a few seeks.)
• reading or creating and writing the entire contents of a subdirectory tree

Intra-segment structure

The data inside a single segment will normally decompress to around 2.5MB, but if the compression ratio is good, it could be considerably larger, like 20MB or more. But decompressing even 2.5MB of data will totally blow your cache, so you don't want to do that too much if you can avoid it.

So the segment is compressed in about 16 "sub-segments" of about 64kiB of compressed data, each prefixed with an (uncompressed!) length field and the first key in that segment, and containing some number of whole triples. This allows you to find the right sub-segment (assuming you only want one sub-segment) in about 16 cache line fills, and then decompress it into your L2 cache.

There is a SHA-256 sum of the uncompressed data inside of that data, at the end of the subsegment, in order to make it possible to verify that the data hasn't been corrupted by memory, disk hardware, or the decompression/compression step.

For large extents, the sub-segments will contain about two maximal-size extents each. Small data, such as inodes and pathnames, might be 128–256 bytes per triple uncompressed (and 40–80 bytes per triple compressed). So a sub-segment might contain a thousand or more triples. To allow finding the right triple quickly, the triples inside a sub-segment form a sort of skip list --- each one is prefixed not only with its own length but with some number of "pointers" giving the length of the sequence of 2, 4, 8, etc., triples that it begins. These pointers can be two bytes (they need to be fixed-width so they're easy to backpatch) and they add about 2000 bytes to the uncompressed data. This allows search inside a sub-segment to use at most about 20 probes.

XXX now we have three levels of index using different structures: the segment directory (which presumably has some in-memory indices of its own), the sub-segment directory, and the skip list. Maybe these could be unified?

XXX Are segments placed in fixed "segment slots" implying slack space at the end? Like what, 10k?

At the end of the segment, there's a SHA-256 of the SHA-256s of the sub-segments to allow early detection of serious segment corruption.

fsck

The filesystem has some internal invariants: the list of pathnames at an inode should match the set of pathnames that have that inode number; the size in the inode should match the

stat() (inode number, mode, number of hard links, uid, gid, size or device ID, atime, ctime, mtime)

Durability

It's highly desirable that the filesystem not lose committed data when the machine loses power suddenly.

Group commit. Micro-segments. NVRAM/network backup/Flash.

Why Transparent Compression

Segments are compressed before being written to disk and decompressed when read from disk. This has several benefits.

First, it decreases the amount of disk bandwidth needed. The disk interface is still fairly slow; the machine I'm testing this on can sequentially write to the disk, as I've said a zillion times already, at 64 megabytes per second. Also, if I understand correctly, it can do 1600 million 32-bit memory transactions per second, which is 51.2 gigabytes per second.

Second, it means we don't care very much about the representation efficiency of the on-disk data structures. We don't have to agonize over how many bits to allocate to the inode field or how to represent numbers efficiently or how to represent pathnames efficiently or how to avoid storing a separate uid, gid, ctime, and mtime for each small file in a large directory.

As an example, I made a list of 2000 pathnames from my Reiserfs partition. (Yes, that did take 20 seconds.) Raw, the pathnames are 57kB (or 121kB if you include the mount point at the beginning of the paths instead of starting them with "./"). Compressed with the `frcode` program from GNU findutils 4.4.0, a program carefully designed to compress precisely such sequential lists of pathnames, it is reduced to 18kB. But compressed with LZF (a general-purpose high-speed compressor), it's 13kB, and compressed with gzip, it's 10kB. The compressed numbers don't change significantly depending on whether the pathnames include the mount point.

So the effort that went into writing `frcode`, and its corresponding decompressor, and the ";login:" article about it, and maintaining it over the years, has been wasted, and actually counterproductive; if `findutils` used `gzip` (or originally `compress`) instead, it would have been getting better compression all along. Still, `frcode` is only about 200 lines of code; but there are many carefully optimized but very specific representations like that, scattered around the system.

I tried another example that wasn't so successful: compressing an executable versus *compressing a hexadecimal dump* of the executable --- two hex digits in place of each byte in the original executable, with no newlines or offset numbers. The original executable was 34kB; hexdumped and compressed with LZF it was 28kB; compressed with LZF without hexdumping, it was 21kB. (`bzip2` was able to compress it to 16kB, which is perhaps a reasonable estimate of the actual entropy

of the data. It did only slightly worse on the hexdump version, like 17kB.) So hexadecimal-encoding frustrated LZF's ability to extract redundancy to some degree, but LZF was still able to remove more redundancy than the hexadecimal encoding added.

As a third example, I made a *list of 1533 numbers* that were the sizes of files in a directory tree. Encoded as ASCII decimal numbers separated by newlines, they took 6.6kB; binary-encoded as 32-bit integers (none of the files happened to be 4GiB or over), they took 6.1kB; the list of ASCII numbers compressed with LZO was 4.5kB. (LZO-compressing the numbers in their binary form put them at 4.9kB.) So there's no gain in space-efficiency in this case from using binary encoding, and actually a substantial loss --- barely a win over just using ASCII decimal numbers. (Note that ASCII decimal numbers also have no arbitrary size limit.)

Third, compressing segments means that groups of small, similar files in the same directory can be compressed as a group, as can groups of inodes. Long experience with the `.tar.gz` format has shown us that this is a win, often a significant one. Storing the file contents in extents separate from the metadata means that both the files' contents and the metadata are intermixed with a minimal amount of foreign data in a different format.

Fourth, by removing, in most cases, the need for applications to compress their data files, it can make those data files easier for users to reverse-engineer, modify, and use for other purposes. For example, Gnumeric's data file format is `gzip`ped XML. I made a simple spreadsheet with 45 cells; the Gnumeric data file was 2kB, the uncompressed XML was 13kB, and the LZF-compressed data file was 3kB. Clearly the 6× reduction in bulk is worthwhile; but a Gnumeric designed to run on an LZF-compressed filesystem, where `gzip` saves only 30%, could reasonably have chosen a different path. (Obviously Gnumeric is pretty far down this path already by using XML to store spreadsheets.)

Fifth, it effectively increases the size of the buffer cache substantially, increasing the buffer cache hit rate dramatically.

Sixth, it effectively increases the size of the disk substantially for no effort on the part of the user or their application software. (This is the traditional reason for filesystem compression, but I think it's less important than the previous four.)

Seventh, it may improve the security of whole-disk encryption. This is a disadvantage too --- it makes data recovery more difficult.

Compression Isn't Too Costly

Despite all the advantages I ascribe to transparent disk compression in the previous section, we wouldn't want to use it if it made the filesystem too slow. It turns out that it shouldn't.

`gzip -1c` on one of the CPUs of the 1.6GHz Celeron E1200 gets about 3.3× compression at about 20MB/s input. At `-9` it gets about 3MB/s and gets (on a test file, i.e. my reiserfs image) 3.9×, i.e. about 15% smaller. `gzip -d` decompresses at about 60MB/s output, and is about 15% faster when the input data is compressed with `-9`.

These are pretty expensive, CPU-wise. But if we assume that typical computers in the next few years will have more CPU cores than hard disks, and that compression and decompression of independent segments can be partitioned into embarrassingly-parallel

tasks, it might be reasonable.

However, `gzip` (LZ77) is not one of the fastest lossless compression algorithms out there. There are other algorithms around that beat the living shit out of `gzip` for speed.

LZW is no longer patented, and supposedly [compresses at 50 kilobytes per second on a 386] [TIFF], which runs maybe 12 million 32-bit instructions per second --- maybe 250 instructions per byte --- so you'd expect it to run on one of the Celeron's CPUs at about 50 megabytes per second. However, Thomas and Woods's `compress` program only compresses at about 10 megabytes per second on the same machine, half as fast as `gzip -1c`, and only compressing by 2.7×. LZW was discovered in 1984; it's about 2K of code to implement.

LZO and LZF are two new LZ77 variants with, like LZW, low CPU usage. LZF is being used in the kernel for suspend to disk.

LZO was supposedly a third the speed of `memcpy` at decompression on a Pentium 133 --- 20 MB/sec to `memcpy`'s 60MB/sec --- and four times slower for compression. On my same machine that I was testing with earlier, `lzop` 1.02rc1 (using liblzo 2.03-1) compresses at 64—100 megabytes per second and decompresses at 143 megabytes per second. It compresses by about 2.7×, slightly better than `compress`'s LZW. Apparently [in 2002 on a 200MHZ Pentium] [ACT] `lzop` 1.00w took 1.47 seconds to compress (and 0.99 to extract) a corpus that `gzip` 1.2.4 (with no options, which seems to be about `gzip -6` these days, 10 megabytes per second) took 15.57 seconds to compress.

That means LZO used to be 10.6× as fast as `gzip -6` at compression at the time, but now it's only 3–5× as fast. Maybe `gzip` got better, but also it seems that LZO's performance has gotten relatively worse --- it was 20MB/sec on a Pentium 133 and only 3–5× faster on a 1.6GHz four-issues-and-retires-per-cycle processor, which does 1600 million memory transactions per second instead of 66 million?

LZF is even faster. It only compresses by about 2.4×, but it compresses on the same hardware at 77—138 megabytes per second and decompresses at 138—199 megabytes per second. (I built liblzf-3.4 with `./configure && make -j3` with GCC 4.3.2-1-ubuntu11, which used `-g -O2 -O3 -funroll-all-loops`.) I don't understand the algorithm well enough to see if it could be optimized more or run on a GPU, but the current version is a small amount of C and seems to include CRC32 checking.

The TWI and I²C buses and better alternatives like CAN and RS-485

Kragen Javier Sitaker, 2018-06-28 (updated 2018-07-05) (24 minutes)

Most AVRs support "TWI", their slightly bastardized version of Philips I²C. In theory, this should allow you to hook up any number of AVRs (and maybe other devices) on a shared two-wire bus (SDA and SCL), or up to 113 of them, anyway, and communicate at 400 kbps. It even supports address-recognition wakeup, even from deep sleep modes that don't run a clock to the TWI interface — it uses the bus clock itself for wakeup!

In particular, the ATMega328P used in Arduinos supports it.

Actually, it turns out that only slave devices need addresses; because masters can initiate both reads and writes, they do not need addresses. So you could connect an infinite number of masters to the bus. Fat lot of good that'll do you, though, if they can't talk to each other!

What I was thinking with this is that if you want a bunch of GPIO pins, more than the Arduino has, or want to control more power than the Arduino can, it might make the most sense to add some more chips on a TWI bus in order to add those GPIO pins. This could potentially also give you modularity — you can plug boards together with just four wires, as long as you don't have slave address conflicts, which will probably happen around 10 devices without some mechanism to assign addresses dynamically.

I don't think the I²C bus deals with chips running at different voltages.

Fatal problems with I²C

As I dig more into this, it seems increasingly impractical as a way of building a modular system that is easy to extend, for the following reasons:

• Address assignment: aside from the occasional awful IC with a fixed I²C address or only a few bits assignable, even randomly assigned addresses over the whole 7-bit space will give you collisions after 11 devices, on average. To avoid this, you have to intervene to assign addresses by hand, but even then, Elliot Williams says he's never seen as many as 20 devices on an I²C bus. Some kind of daisy-chaining arrangement like JTAG uses would be a lot better.
• Voltage incompatibility: I²C high is 0.7 Vcc or above, which means that the 3.3 V power rail isn't high enough to be high on a 5V system. There's a standard technique to work around this with a discrete MOSFET per pin.
• Speed: 400kbps is pretty slow. This results in part from the single-ended nature of the I²C bus.
• Fanout: the drive capability you need to make your I²C bus work depends on the speed you're running it at and the total capacitance of the devices attached to it. If you have too much capacitance attached for the drive current of a device, you can't make it all the way down to 0.3 Vcc (its low level) in time. 5 mA should be fine for a couple of

devices but maybe not 10 devices, depending in part on signal routing, and the standard specifies 400 pF as the maximum. And you need stronger pullups if you have more devices, which of course requires still stronger pin drive.
• Bus hangs: there's a known bug in I²C where resetting a master in the middle of a transfer can leave a slave hanging the bus indefinitely. SMBus fixes this with timeouts.

Addresses

You would think that with 7-bit addresses, you would get 128 devices, but the address 0000 000 and the 8 addresses 1111 xxx are reserved, so you actually only get 119 devices. And actually 0000 xxx are reserved for other purposes, though Atmel doesn't document this, so you only get 113. 0000 000 is for broadcast. The bus arbitration algorithm provides strict priority among slave addresses; the broadcast address is the highest-priority possible address.

Bit rates

An address packet is 9 bits long, and following an address packet, you can transmit any number of 9-bit data packets, each bearing 8 bits of data. There are an additional two bit-times at the beginning to indicate the START condition and two more at the end to indicate the STOP condition. This ought to mean that you can transmit 20000 one-byte packets per second, or up to 44000 bytes per second in large transmissions.

The AVR implementation supposedly supports clock stretching, and indeed depends on it in order to give interrupt handlers time to respond.

The bit rate is set by the TWBR register to (CPU clock frequency)/(16 + 2 · TWBR · prescaler), which puts a maximum bit rate of 1/16 of the clock speed. For clock speeds over 6.4 MHz (including the maximum internal RC oscillator speed of 8 MHz) this should not be a consideration, but systems that use lower clock speeds to get better power consumption might be limited. (And apparently the CPU clock needs to be at least 250 kHz for TWI to work at all). In theory this only affects communications that include the slow chip.

The possible prescaler values are 1, 4, 16, and 64.

Electrical limitations

For reliable operation, the AVRs' 20 mA drive needs to be able to discharge all of the input capacitances on the bus at well over 400 kHz — say, in a microsecond. Worse, the pullups need to be able to charge them, and the drive needs to be able to fight the pullup. This suggests that only a couple of thousands of pF of input capacitance on the bus can be tolerated.

However, some other devices have smaller drive capabilities.

Chip support

Bit-banging I²C or TWI seems very challenging, due to requirements of bidirectional open-collector pins with slew rate limiting and spike filtering. It seems like something you could do with an external chip, but that's kinda what we're trying to avoid

here.

AVRs have interrupt support for TWI, but the interface involves one interrupt per byte transferred, and occasionally more. At 400 kbps and an 8 MHz CPU clock, you have at least 180 cycles between successful complete byte transfers.

The slave address register TWAR can be set to whatever address you want.

The ATmega328P, like its smaller variants the ATmega48A, ATmega48PA, ATmega88A, ATmega88PA, ATmega168A, ATmega168PA, and ATmega328, supports a single TWI bus on pins 27 and 28, or balls 4B and 4A in its UFBGA incarnation. The ATmega48/88/48PB/88PB/168PB supports a single TWI bus on pins 27 and 28. The ATmega16U4 used on the Arduino for its USB interface, and its larger version the ATmega32U4 (also the core of the Adafruit Feather), support a single TWI bus on pins 18 and 19. The ATmega8A supports a single TWI bus on pins 27 and 28. The ATtiny20 has a TWI bus for slave mode only on pins 6 and 3 (out of 14), pins 12 and 15 of its 20-pin VQFN, balls 2B and 2B of its UFBGA, or balls 3C and 5C of its 12-ball WLCSP. The ATtiny40 has a TWI bus for slave mode on pins 16 and 13 (out of 20), or 11 and 14 in VQFN.

The ATmega328P comes in a 4 mm square VQFN and a 4 mm square, 0.6 mm thick UFBGA, but no smaller packages. This is smallish but even the UFBGA is 8 times the size of the ATtiny20 12-ball WLCSP mentioned above.

The obsolete ATtiny2313's USI claims to support TWI, but without slew rate limiting and spike filtering, and it sounds like you pretty much have to implement the protocol in software. It is not clear to me that this will work, and definitely it is not interrupt-driven.

The ATtiny25/45/85 and ATtiny13/ATtiny13V do not support TWI, just SPI. (I think the 25/45/85 may have a 2313-like USI.) The ATTiny4/5/9/10 don't support either TWI or SPI.

More detail on the ATtiny20

The ATtiny20, despite being slave-only, is especially appealing for adding I/O lines to a distributed system linked by a TWI bus because its WLCSP incarnation is 1.56 × 1.40 mm and 0.54 mm thick, and its UFBGA (like the VQFN for the ATtiny40) is 3 mm square. Even its TSSOP and VQFN are only 5 mm square.

The ATtiny20 additionally supports 10-bit extended addresses and address masking, although that isn't useful without a similarly capable master to communicate with.

This tiny size still has a substantial current drive capability, though; at a drop of 0.8 volts, it can sink or source the usual 20 mA per pin at 5 V or 10 mA at 3 V, except on its reset pin. Running at lower voltages lowers the possible current substantially.

Digi-Key sells ATtiny20s in most packages from 56¢ in quantity 1, but the WLCSP costs 92¢.

Non-AVR chip support

Many other things nominally support I²C, although apparently compatibility problems are not unusual. Many EEPROMs support I²C — this is the main use of I²C actually — and the popular Cypress

CY7C68013A/CY7C68014A/CY7C68015A/CY7C68016A EZ-USB FX2LP 8051 supports 100 or 400 kHz I²C, for example, but only as a master; it can use this for booting from an EEPROM at startup. The popular ultra-low-power TI MSP430G2x53/MSP430G2x13 microcontroller supports I²C; not sure how much of the rest of their family does.

As an example of EEPROMs that support I²C, consider the AT24C32/64, with 4096 and 8192 bytes, respectively, 5 mm × 4 mm in SOIC or 3 mm × 4.5 mm in TSSOP. These use 3 of their 8 pins to set the I²C address of the EEPROM to 1010xxx (so you can gang up to 8 of them on a bus) and support the 400 kHz rate at 5 V. They support writes of up to 32 bytes at a time, or longer if what you want is a 32-byte ring buffer.

These EEPROMs have their own internal charge pump for erasing, so they need only a single supply. They can drive 5 mA and have 8 pF of input impedance, which works out to 50 kΩ at 400 kHz, so in theory support fanout of about 50. This is much less than the total of 119 from the address limits.

The other microcontrollers I'm most interested in are the STM32 family, the LPCxxxx family, and the ESP8266/ESP32 family, just because they seem to be the most popular at the moment (other than PICs, which I would prefer to avoid entirely).

The STM32F0 does support I²C, including 10-bit addresses (and some even have two I²C interfaces), and it's even functional in "low-power stop modes", which I guess means it can turn the chip on. I think it's only 3.3 volts, though, which seems like it could pose interoperability problems. The cheapest STM32 at Digi-Key is the STM32F030F4P6, which goes for US$1.30, down to 59¢ in quantity. The cheapest STM32 with CAN is the STM32F042F4P6, which is US$2.18 down to US$1.07.

The LPC1769 naturally supports I²C, and actually supports more than one bus per chip, I think.

The ESP32 supports I²C.

The TI DRV8830 is a 6.8V 1A H-bridge chip controlled over I²C.

Other peripherals? ADCs probably don't make sense (the AVRs have ADCs built in, and higher-speed ADCs are too fast for the I²C bus; they would need to just be high-precision, low-speed ADCs) but things like LCDs, DACs, and high-power switches ("drivers") might make sense. Also radios, of course. H-bridges or ESCs would be super nice. RAMs might be useful too, even if a bit slow. How about other radios, including LoRa and BLE?

The ONSemi NCP5623 is a linear I²C RGB LED driver that can drive three LEDs at up to 90mA on 2.7 to 5.5 V using current mirrors, but with only 32 PWM levels. I can't figure out how its address is determined or what its PWM frequency is.

The ONSemi LV8498CT is a voice-coil motor driver IC with I²C control; it's basically a current-mode 10-bit DAC running up to 150 mA at 5 VDC. Its slave address is 0110011, so you can only use one of them on a bus. I can't figure out how fast or slow it is.

The ONSemi LV5236V is a 24-channel 5V I²C LED driver with 5-bit PWM and/or up to 50–100mA per LED, or maybe 30 mA per LED controlled by a DAC, I can't tell. It's 5.6 mm × 15.45 mm. It has five address pins, so you can set its address to any 10xxxxx. Digi-Key will charge you US$3 for one, which works out to 12.5¢ per

LED.

Maxim has an LM75 I²C temperature sensor with three address pins to configure its address to any 1001xxx address.

Alternatives to I²C

SMBus

SMBus is a slight tweak on I²C which adds a few requirements to prevent hung or powered-off components from screwing up the bus, but it doesn't solve the fundamental problems.

CAN

The CAN bus sort of seems to be designed as an answer to some of these problems, but for some reason CAN bus drivers are expensive, and anyway they don't solve the problem of address assignment.

JTAG

JTAG has the desirable attributes of being daisy-chained and thus partly avoiding the problems of address assignment and fanout. It uses four or five wires, not counting power supplies: TCK, TMS, TDI, TDO, and optionally TRST*; you chain TDO of one chip to the TDI of the next, but you run TCK and TMS to all the chips, thus still potentially having fanout limits.

TMS is "test mode select", which clocks in a sequence of bits to drive the JTAG controller state machine. In particular, the sequence 11111 will always drive the state machine to its reset state, where it will remain as long as it gets more 1 bits; from there, the introduction of strategically placed zeroes into the TMS data stream can navigate it to other states, five of which are stable on 0 (i.e. have 0-edges to themselves). TMS bits are clocked in on the rising edge of TCK, and then the resulting states can cause TDI bits to be clocked into things on the falling edge of TCK.

The reset via TMS is somewhat fault-tolerant in the sense that a single spurious 0 is not sufficient to transition the state engine to take any action; three more 1s in succession will successfully drive the state machine back to the reset state.

At times, depending on the state of the JTAG state machine and the "current instruction", TDI is clocked directly to TDO, converting a whole chip into just a single clock delay. At other times, a shift register is interposed between TDI and TDO, but which one depends on both the JTAG state machine and the current instruction — it can be the current-instruction register or a data register determined by the current instruction. Two of the aforementioned five stable states, Shift-DR and Shift-IR, are the ones that interpose shift registers.

The instruction register is required to be at least 2 bits because there are 4 required instructions: BYPASS (all 1s), EXTEST (once, all 0s, but then they decided that was a bad idea), PRELOAD, and SAMPLE, which may be the same as PRELOAD.

The TDO line is supposed to be "set to its inactive drive state except when the scanning of data is in progress", which turns out to be when the chip is in Shift-DR or Shift-IR state. This allows you to share TDI and TCK between chains and wire their TDO lines together, using a separate TMS for each line to select which one will

be active.

Two other optional states in the rather complicated (16 states!) state machine permit either overwriting the shift register from data held elsewhere (i.e. moving data from an internal register into the shift chain) and overwriting data held elsewhere from the shift register.

Although the state machine is complicated, the standard actually includes a circuit diagram showing that you can implement it with 32 NAND gates and 8 D flip-flops, under 200 transistors.

I like this idea of using a sequence of bits to maneuver a state machine around, and I like the idea of bucket-brigading a bunch of bits through a daisy chain, but I don't like the fanout of TMS and TCK, even though they're always driven by the bus master, and so in the worst case just need a couple of big Darlingtons. I really like the idea of altering the bucket-brigade topology at runtime by bypassing some devices in order to prevent latency from the bucket brigade. I don't particularly like the separation of TMS and TDI, which seems unnecessary — JTAG ends up needing 6 wires if you include power, while CAN and I²C make do with only 4.

A hypothetical super-JTAG

What if you could redesign JTAG?

Bit-stuffing nonsense

To unify TMS and TDI, a very simple kind of bit-stuffing could use a sequence of 5 1 bits as a magic resynchronization/reset sequence, and when transferring data, send nybbles of 4 arbitrary bits preceded by a non-optional 0, thus preventing the magic sequence from occurring regardless of the data being transmitted, at only a 25% overhead.

Following the magic reset sequence, or indeed following a single 1 following a nybble of data, we could maybe have a variety of different states.

To provide addressing of individual slave devices, one possibility is to have a state that decrements a fixed-width little-endian hop-count address field, for example of 8 bits; if the borrow is set at the end, it means it rolled over from 0 to 0xFF, which means you're the intended destination! This entitles you to overwrite whatever payload data may follow, so that when it eventually gets shifted around to the master again, it contains your reply.

If we want to get rid of the clock line too, we might want a different kind of bit-stuffing that ensures frequent transitions.

A better, connection-oriented approach for unicast

Consider a simpler approach in which the bus master repeats these three steps repeatedly: 1. establish a connection to a slave node; 2. communicate with it; 3. terminate the connection. In a daisy-chain topology, step 1 could be as simple as sending a time-to-live count byte, or even an unary-encode count, which gets decremented on its path through the chain; intermediate nodes would change to a "passthrough" state and forward the data, bit by bit or byte by byte. Steps 2 and 3 could then be distinguished using, for example, HDLC bit-stuffing, constant-overhead byte stuffing, or SLIP framing.

Hmm, I guess that isn't very different from the previous approach, actually, except that in this approach, I was thinking not to forward packets that didn't need to be sent on further. Instead, the slave

addressed would simply send reply data back to the master. It would be more like a traditional serial connection than a packet-switched network, or SPI, or the ISA bus.

You could also have a special broadcast address for addressing all slave nodes at once, or within network latency anyway; and barrier synchronization of the master waiting on all slaves could be achieved by yet another kind of packet which a slave only passes to its successor if it is in "waiting" state.

At 1Mbps, which should be easy to reach, and one byte of buffer per node, the latency of a 256-node daisy chain would be 2048 bits: 2 milliseconds. This might be too much latency to replace Fabnet. 10Mbps should be electrically easy to reach but might be a larger computational load.

If the data is differentially encoded on a single twisted pair — as in RS-422 or RS-485 — a dc bias on this pair can be used to provide power from one board to another. This is more suitable for board-level connections than chip-level connections. As I've argued previously in Exploration of using RF current sources instead of ELF voltage sources for mains power (p. 642), a constant-current supply meshes nicely with daisy-chaining boards together, and allows the use of thinner wires. Consider using 24AWG copper phone-line wire, as I suggested there, 510μm in diameter, 1.8 g/m, 84mΩ/m, with a constant-current supply running up to 48V at the 3.5 A maximum for that kind of wire. This gives you a maximum of 168 W for the overall system, although of course anything that needs more power than that could use a separate power supply.

This allows you to do both power and data on just two wires from each board to the next, but the final board needs a final pair of wires to be brought back around to the master to complete the circuit. So each board needs four terminals in the end. You could reduce the number of cables by 1, and potentially isolate and partly tolerate connection errors, by using a four-wire cable from each node to the next, two of which are merely the return path and are wired straight through from the downstream socket to the upstream socket.

Differential bus connections like the CAN bus require only two connections per board, but can't also supply power at the same time. So CAN bus boards end up requiring at least four terminals, too.

RS-485

RS-485 is the basis for the Fabnet bus used in Peek's dissertation. It's a multidrop version of RS-422, which is a differential version of RS-232. Because they use terminating resistors and balanced transmission lines, RS-422 and RS-485 can reach data rates of tens of megabaud over short distances. RS-485 can be used either in a two-wire "party line" mode or a four-wire "master-slave" mode, but I think neither version has an arbitration algorithm for when multiple devices attempt to transmit at the same time.

Notes on running QEMU on Debian Etch

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

I'm running QEMU with kqemu on my old 700MHz laptop.

User-mode stuff is slowed down only slightly. This command line:

```
time for x in $(seq 10000); do :; :; :; :; done
```

takes 1.17 1.19 1.20 1.22 user seconds in emulation and 1.13 1.13 1.14 1.14 user seconds outside QEMU.

However, it takes about 100ms of system time in place of about 10ms. (The `-kernel-kqemu` flag may solve this; haven't measured.)

I had some kind of keyboard problem when I ran QEMU 0.8.2-4etch1 with `-snapshot`. Like, the keyboard just didn't work. That problem went away when I built QEMU 0.9.1 from source and started using that, but I still can't use `-snapshot` and `-loadvm` together.

Networking: `tap`

This was a bad idea (for me).

By default, QEMU uses `user` networking, which proxies network connections through normal sockets, like `slipknot` or `slirp` or `term`. (In fact, it uses `slirp`.) I thought this didn't give me a way to talk to it over the network (for example, if I'm running a web server on it).

So I thought `-net tap` could help with this, but it has some drawbacks. It requires running QEMU as root, and then the network interface on the emulated machine needs to be configured statically, e.g. in `/etc/network/interfaces`, since `-net tap` doesn't provide DHCP by default. And then you have to set up IP masquerading, more or less as follows:

```
qemu -net nic -net tap,script=ifup "$image"
```

In file `ifup`:

```
set -e
/sbin/ifconfig "$1" 172.20.0.1
echo 1 > /proc/sys/net/ipv4/ip_forward
/sbin/iptables -t nat -A POSTROUTING --source 172.20.0.0/24 -j MASQUERADE
```

This does actually work, but you have to configure the network stuff inside of QEMU: IP address, netmask, default gateway, and worst of all, DNS server. And I think it might allow other people on your LAN to masquerade through you.

What would be ideal would be bridging the virtual interface to my real Ethernet interface, but I never got around to doing this.

Networking: `-redir`

It turns out there's an easier way. I can use the default `user` networking, and if I have a web server on the emulated host on port

8080, I can say

```
qemu -redir tcp:8000::8080 "$image"
```

and connect my web browser to http://localhost:8000/.

This works beautifully. The one downside I've found is that if you're using `qemu -loadvm`, the inner virtual machine has to re-request DHCP before the redirection works.

Startup: `-loadvm`

Bootup takes an annoyingly long time. But, if you don't regularly have any permanent changes you want to save, you can use the `savevm` command to save an image of the virtual machine state after a boot, and then use `qemu -loadvm` to start QEMU in the already-booted state.

Only a constant factor worse

Kragen Javier Sitaker, 2013-05-17 (16 minutes)

I read somewhere that the "optimal" approach to buying a money-saving appliance that you're not sure how much you'd use is to keep track of how much you waste by not having it; when the total of waste reaches the cost of the appliance, you buy the appliance. This way, your worst-case expenditure is twice the cost of the appliance, and your best-case expenditure is nothing. And, with this policy, it's very likely that you'll buy the appliance if it will save you money, and you won't if it won't.

This actually works for any constant factor of the cost of the appliance. You could buy the appliance when your total potential savings reach 75% of its cost, or 200%; the underlying principle is the same. Depending on your priors (how likely it is you'll keep doing what you're doing) and your time preference for money, it might make sense to adjust the factor.

Presumably whatever benefit you'd be getting more cheaply with the appliance is more valuable than the amount you're wasting by not having it --- say, having a washing machine might save you $25 a week in laundry-service costs, but having clean clothes to wear is presumably worth more to you than the $25; and having a camper bus might save you $100 a night in hotel-room fees when you travel, but presumably if traveling isn't worth $100 a night, you wouldn't be doing it before buying the camper bus.

Some other possible strategies have, in some sense, an unlimited downside. "Never buy" can cost you an unlimited amount of money --- $100 a night for all eternity, say --- and while "buy just in case" won't cost you an unlimited amount of money, the ratio between the benefit you get and the cost is unlimited. For example, you could spend $40000 on a camper bus you never use. If you use it for just one night, you'd have gotten better value for your money by spending $10000 on a really nice hotel room. (Not that this is a reasonable strategy.)

The buy-when-costs-reach-predetermined-multiple-price strategy omits a couple of significant factors, though: the cost of owning the appliance, and its lifetime. The cost of ownership can be substantial if you have a small house and move frequently, or if it requires a lot of maintenance. (This is much on my mind at the moment, because I'm living in a small apartment --- effectively an efficiency with a storage room --- and I've moved six times in the last seven or eight months; and my refrigerator and bicycle need some serious maintenance.) These are not too hard to add in to the model, though, and you still have a strategy that guarantees you a worst-case expenditure of a constant factor of the cost of the appliance.

RAID

Another case where a constant-factor extra cost gets you something valuable is error-correction coding. For some constant factor in coding expansion, you can reduce the probability of storage errors in your data to an arbitrary degree. The simplest realization of this is "disk mirroring", where you store the same data on both disks. If one

disk dies, the other still has your data. (In theory. Right now, some of my data is on a RAID where one disk has died, and I haven't gotten around to replacing the dead disk, so I could still lose my data at any moment.)

Food buying

It's well known that you can buy sufficient nutrition for a dramatically lower cost than a normal diet. On August 16th of last year, after the national statistics bureau had created a furor by deciding on a poverty line of about AR$6 per day, I went to Carrefour on Independencia in San Telmo to price out some food and calculate the lowest-priced macronutrient-balanced diet. Here's what I came up with. None of the prices are sale prices.

	Soybeans	Salt	Sunflower oil	Flour	Total
g/day	200	5	33	430	668
kcal carbohydrates/day	54			1238	1292
kcal protein/day	280			155	435
kcal fat/day	420		297	39	756
kcal/day	754		297	1432	2483
AR$/kg	7.98	6.30	5.10	2.48	
AR$/day	1.60	0.03	0.17	1.07	2.86
US$/day (at AR$4.50)	0.36	0.01	0.04	0.24	0.64

(The whole spreadsheet, in Spanish, is at http://canonical.org/~kragen/comida.gnumeric. Due to rampant inflation, Argentine prices have gone up since then.)

The idea is that you boil the soybeans with a little salt, or maybe sprout them, and use the flour, rest of the salt, and the sunflower oil to make what are called "tortas de parrilla", a sort of unleavened flatbread which is commonly for sale in the streets here, cooked over charcoal in metal pans on shopping carts. You can see that the result is hearty; what may not be obvious is that the soybeans provide enough fiber and omega-3 fatty acids to avert what could otherwise be serious nutritional imbalances, and that their protein is of an especially high biological value, i.e. its amino-acid mix is close to optimal.

There are a couple of obvious questions about this diet:

- What about vitamins, minerals, other micronutrients?
- Don't you have to be rich to bulk-buy to get prices this good?
- Won't the lack of variety really suck?
- Isn't this going to be a lot of work?
- Isn't so much gluten going to be bad for you?

There's also the question of how much space you need for food storage.

What about vitamins, minerals, other micronutrients?

The flour (whose extremely low price is, I think, a result of government subsidies) is fortified with a variety of vitamins as required by law. But all-in-one multivitamin pills cost about US$0.02 per day, or AR$0.09 at the time, and provide all the

micronutrients we're known to need. So it's possible to solve the micronutrient problem very cheaply.

Don't you have to be rich to bulk-buy to get prices this good?

Bulk buying is indeed necessary, although all the prices above are for units of one kilogram or less. (You might be able to get better prices if you buy in *real* bulk.) It turns out, though, that even if you're actually so poor that you can't ever afford to buy US$5 of food at a time, you can work up to bulk buying with a constant-factor-worse strategy. If you're buying sunflower oil, say, by the 250mℓ bottle and getting a 20% worse price as a result, you can gradually build up a stock of sunflower oil by buying an average of, say, 10% more than you need. 250mℓ might last you 7½ days, so buy a new bottle every 6¾ days on average, rather than every 7½. Every week, more or less, you'll accumulate an extra 25mℓ of oil; after about six months, you'll be able to buy the 500mℓ bottle instead of the 250mℓ bottle, and your sunflower-oil investment will start paying dividends. Another year later, you'll be able to buy a liter at a time.

You could argue that this is not a realistic view of life in poverty; more typically you have no money coming in for a long time, like a month or six months, and then you finally get some, which you can use to buy things you've been putting off; and the critical thing to focus on is not efficiency but resiliency, i.e. making sure you have some way to get some food when you need it. This actually just happened to me, and I went to the supermarket and bought two kilograms of rice, some mayonnaise, butter, spaghetti, rice, *pears*, and so on, after living for much of the last weeks on whatever dried foods I had stored up and whatever my girlfriend bought for herself. But I'm getting ahead of myself.

Won't the lack of variety really suck?

The lack of variety is a more serious problem. It tempts you to go off-budget and eat an AR$5 hot dog or something, because you just can't face the thought of another lunch consisting of soybean pancakes. And there may be health problems caused by such a monotonous diet, even if they don't come from deficiencies of known macro- or micronutrients; for example, there might be a pesticide used on the soybeans that your body can tolerate if you're eating 200g of dry soybeans once a week, but not every day, or you might be getting some vitamin in a form that your body finds particularly hard to absorb.

The same constant-factor-worse strategy applies, though. If you can manage to buy 10% more soybeans than you're eating, then after a short time, on some shopping trip, you can buy another nutritionally similar low-priced food instead --- around here, that would be lentils, split peas, or garbanzo beans, or possibly polenta or whole-wheat flour. As long as you can keep buying a constant factor *more* than what you're eating, whether it's 5%, 10%, 50%, or 100% more, the variety of foods stored in your pantry will continue to increase, and therefore so will the variety of your meals.

(Practically speaking, you might also want to spend some of that constant factor on things other than macronutrients: spices, MSG, onions, sesame oil, herbs to plant, and so on --- things that go a really

long way to rendering otherwise unpalatable dreck edible. Tonight, for example, I ate about 100g (dry) of boiled split peas, which were AR$8.50/kg and therefore cost about AR$0.85; I added an AR$1 packet of dried soup stock, which is mostly MSG and salt but also had some basil and garlic flavor, and it made a huge difference. Ajinomoto has a line of mixed-condiment packages that are similar but even cheaper. The one I used earlier today came in a package of 12 5-gram packets for AR$4.85, I believe, so each packet costs AR$0.40.)

This also gradually reduces the risk of hunger shocks where you have nothing to eat for a few days, or weeks, because of an unexpected expense, delay in getting paid, or jump in prices. That is, if applied assiduously, the constant-factor-worse strategy eliminates some serious risks to your food budget.

Building up a stock in this way also increases the probability that you'll be able to buy food when it's on sale or even gratis.

This ignores, though, the cost of storage and the limits of lifetime --- as the constant-factor-worse appliance-buying strategy does. If you eat 200g of soybeans a day and buy 100% more, 400g (or, more practically, buy 2kg of soybeans every five days), your stock of stored soybeans will grow at 200g per day. If you somehow followed this strategy for a year, you'd have 73kg of dried soybeans stored. How on earth are you going to store 73kg of dried soybeans? And stored flour will eventually go rancid, especially if it's whole-wheat flour.

This *is* a real limit, but it's not as bad as it sounds, unless you're bouncing from one temporary accommodation to another, as I am. (In that case, maybe you should ask a friend to store your soybeans and stuff in their house.) See below about space requirements.

Independent of how consistent or inconsistent your food buying and income is, you can adjust how much of your constant factor is going into building up a stock for the future and how much is going into buying "luxury" foods that are more expensive than the bare minimum. I think the optimum fraction for building up a stock for the future, in the absence of storage and lifetime considerations, would be about half of the total. As shown above, this is feasible if you're spending more than about US$1.28 per day on food. The total investment needed to build up a one-year stockpile would be about US$234.

Isn't this going to be a lot of work?

No, soaking and boiling soybeans and frying up griddle cakes is not a lot of work. It requires planning and discipline, which can be difficult, but it doesn't take much time or toil.

Buying 10% or 20% or 100% more food than you would have been buying otherwise and bringing it home and putting it away is more work, but it's not much more work. It's about 10% or 20% or 100% more work. It's only a small constant factor worse.

Isn't so much gluten going to be bad for you?

Most people digest gluten well. Some people don't. Some people are so sensitive to it that they have to avoid it entirely or face serious health problems. Avoiding gluten increases the cost substantially, and because of the vitamin fortification, increases the risk of micronutrient shortages. From the same spreadsheet, here's my

cheapest gluten-free version:

	Polenta	Brown rice	Soy beans	Salt	Sunflower oil	Total
g/day	240	180	200	5	33	658
kcal carbos/day	691	562	53			1306
kcal protein/day	108	58	280			445
kcal fat/day		45	420		297	762
kcal/day	799	665	753		297	2514
AR$/kg	5.56	5.17	7.98	6.30	5.10	
AR$/day	1.33	0.93	1.60	0.03	0.17	4.06
US$/day (@AR$4.50)	0.30	0.21	0.36	0.01	0.04	0.90

That is, cutting out gluten increases the price of the minimal diet by about 42%, to almost a dollar a day.

Won't food storage take a lot of space?

Earlier, I said that by buying a constant factor more than what you eat, you will gradually build up a stockpile, which will allow you to buy food only when it's on sale, buy food in bulk for better prices, and keep a wide variety of stored food on hand to avoid dangerous dietary monotony. But such a stockpile takes up space. Is it an unreasonable amount of space?

I'll investigate this, plus the question of managing stored food lifetimes effectively, in depth in another post. For now, the outline is this:

These foods will last at least a year in storage. At the 600 to 700 grams of stored food per day described above, a year's supply is about 237 kilograms. That's a small enough amount of food that you could store it under your bed, in your coffee table, or possibly in shelves that already exist. So if you're not moving around a lot, it won't take up an unreasonable amount of space.

240 kilograms is enough to have about four kilograms each of about 60 different foods, so it can provide plenty of variety.

Double ended log structured filesystem

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

I use a sort of log-structured filesystem for my notebooks. I fill the notebooks in chronological order (more or less) from the second page to the last page. (The first page is left blank at first.) Everything is under some heading; the current heading is repeated at the top of every page, with the date, but sometimes there are several headings on a single page. The headings are underlined so they're easy to see looking at the page.

So I can find things by paging through the recent pages and looking at the headings. When that gets to be too much, I append a new "table of previous contents" section, under a heading just like everything else; it lists all the headings, with dates, since the last "table of previous contents". The first page contains a list of tables of previous contents, with their dates, so that I can find them relatively quickly. This allows me to find my notes more quickly by reading through the few pages that are full of tables of previous contents, rather than leafing through all the pages in the book looking for headings.

If I were a disk, which I'm not, this would be a reasonably efficient scheme for writes: regardless of how much stuff I have to write, I could append it all in a single write to the end of the currently-written data, possibly including a new table of previous contents, then update the "superblock" on the first page with a pointer to the new table. So writing any amount of data less than a notebookfull requires a seek to the end of the previous ToC, possibly a read of data following it, a write of the new data, and possibly a second seek and a second write to the superblock. Two seeks. Finding something in a notebook with three ToCs requires at most four seeks: one to each ToC, then another one to the data; if it's not listed in any ToC, you can sequentially scan for it after the last ToC.

With this scheme, there's a tradeoff (for either humans or for disks) between the amount of sequential scanning you may have to do (due to still-unrubricated items) and the number of ToCs you may have to seek to and read.

Beatrice pointed out the other day that it would be easier for a human to write the notes sequentially from the beginning of the book, while writing the ToC entries sequentially from the end of the book. This way, all the ToC entries are in a single sequential chunk, the tradeoff between maximum sequential scan length and ToC fragmentation is eliminated, and writing still requires only two seeks.

Of course she is correct, and this might be a reasonable strategy for log-structured filesystems too, although there are usually more levels of indirection: from superblock, through various levels of inodes and directories, to the actual file extents on disk. You could probably do a reasonable job by putting a B-tree of pathnames at a fixed location of the disk, and putting the inodes and data extents contiguously somewhere else. `/var/cache/locate/locatedb` is a reasonable approximation of the contents of this B-tree; on my current laptop, it's 5.3MB,

indexing 95GB of files using 596 662 inodes (i.e. 596 662 files, although `sudo locate / | wc -l` only finds 494 488 files.).

Repacking a 5–20MB B-tree when it got too large and loose would take a significant fraction of a second on a modern disk, but on my laptop would take perhaps 10–20 seconds, due to the slowness of on-CPU disk encryption. So it might be better to defragment the tree incrementally.

Piano synthesis

Kragen Javier Sitaker, 2015-09-17 (updated 2017-07-19) (6 minutes)

Looking at this "grand piano" synth sample, I see that toward the beginning (19 cycles just after the attack has settled down a bit):

there's a fair bit of white (or rather pink) noise between the harmonics;

its fundamental is at 443 Hz at -13dB,

its second overtone at 883 Hz is 6.8dB lower,

its third overtone at 1326 Hz is the same (well, only 1.1dB lower),

its fourth overtone at 1775 Hz is a bit lower at 16.1dB below the fundamental,

its fifth overtone at 2223 Hz is substantially depressed at 23.1 dB below the fundamental (almost as low as the second subharmonic),

its sixth overtone at 2678 Hz is about 13 cents sharp (twice the inharmonicity of anything so far) and is 19.3dB below the fundamental;

its supposedly undesirable seventh overtone at 3129 Hz is almost 16 cents sharp and is 23.4dB below the fundamental;

its eighth overtone at 3597 Hz is 25.9dB below the fundamental, and inharmonicity continues to increase sharply to 26 cents;

its ninth overtone at 4072 Hz is 31dB below the fundamental;

higher overtones (which probably don't matter) continue to diminish in amplitude exponentially with their frequency.

Overall this spectrum looks a lot like an impulse train has had its fifth harmonic attenuated by about 6dB, has been low-pass filtered at about 9 dB per octave with a cutoff below the note frequency, and has had its overtones stretched out a bit, by about 9 cents per octave.

(It seems strange that amplitude would diminish *exponentially* with frequency, though. 9 dB per octave would give you amplitude diminishing *cubically* with frequency. Might be hard to tell the difference with this much noise, though.)

This suggests that my attempt to synthesize a piano with triangle waves didn't sound very piano-like because it was *too* low-pass filtered, not the opposite, which I guess I should have figured out just by looking at the waveform.

Looking at it about 500ms later, the peaks are much more separated (much less pink noise in between), everything is quite attenuated (the fundamental, which has moved down to the more correct 441Hz, is down to -30.9 dB, a decay of 27.9dB, indicating a half-life of about 55ms or about 24 cycles) and the rolloff is sharper: the second overtone is now 13.8dB below the fundamental, and the third 25dB below the fundamental. This is consonant with my understanding of the low-pass-filtering nature of the KS model, but it is being generated from a very realistic synthesized sample.

Looking at a somewhat noisy and MPEG-4-artifacted sample from an upright piano shortly after the attack, I see peaks at

119 Hz -46.7dB
247 Hz -19.2dB
370 Hz -28.4dB
491 Hz -34.0dB
614 Hz -40.5dB

739 Hz -32.1dB
866 Hz -34.2dB
986 Hz -41.6dB
1110 Hz -47.2dB
1236 Hz -44.5dB

It also has a notably high peak at 1867Hz at -45.7dB.

(Those are from a 2048-sample window. Later I got better numbers with a 4096-sample window but didn't update it, but in particular the first peak really peaks closer to 124Hz.)

These are roughly harmonics of about 123.47 Hz, which would be B2 in A440 pitch (although as I recall, the guy was tuning the piano a little flat) and which is nearly *missing* from the sound, which is probably why Débora says her upright piano sounds shitty compared to a grand.

If we figure that the two octaves from the second overtone 247Hz at -19dB up to 986Hz at -42dB represent the normal falloff, that's about 11.5dB per octave. The fifth overtone at 614Hz is attenuated some 8dB below this line, just like in the synthesized sample, and the seventh overtone at 866Hz is not particularly attenuated at all.

Looking at it after a second or two of decay, there's less noise between the overtone peaks, everything is of course much quieter (the first overtone is down to -61.8dB and the second down to -38.3), and the third and seventh harmonics have gotten much stronger relatively — stronger, in fact, than anything else! And there's a second subharmonic peak at 55Hz at a barely-detectable -82dB, presumably due to nonlinearities in the instrument. This is after about 850ms, or about 105 cycles. If we figure the overall attenuation is about 12dB, that's a half-life of about 26 cycles, which is quite similar to the half-life of the synthesized piano signal.

The initial attack is about 35ms long, and seems to be pretty similar across all the frequencies; it doesn't show the phenomenon I saw in the synthesized sample where the high frequencies start later.

So, overall, our piano recipe is:

• an attack time about four cycles of the fundamental;
• a half-life of about 25 cycles of the fundamental, shorter for higher overtones;
• about 9 to 12 dB per octave of low-pass filtering in the initial spectrum (compared to an impulse train);
• attenuate the fifth overtone by about 6dB over and above the basic low-pass filter;
• overtone tuning stretched by about 9 cents per octave from perfect harmonicity (the Railsback curve, although that curve shows that it's not linear) or perhaps significantly less for a better piano;
• beating among different oscillators for a given note at about 1Hz;
• to sound like a cheap upright piano, also high-pass the thing such that stuff below 250Hz or so is subject to a vicious 25dB/octave rolloff.

There's also some stuff about sympathetic strings and energy transfer among different modes of vibration, but that stuff doesn't really show up in my analyses. You can definitely hear it at times in the highest strings on the actual physical piano.

Nomadic furniture optimization

Kragen Javier Sitaker, 2019-12-15 (2 minutes)

Reading Papanek and what's-his-name's *Nomadic Furniture* I'm astonished by how much they've optimized to minimize the difficulty of cutting their furniture designs out of plywood sheets with hand tools, rulers, and T-squares. (Many of the designs use other materials as well.) If you're using laser-cutting or another automated sheet-cutting process like CNC plasma cutting or Maslow-style CNC routing, measuring is free; only the material and cut length, and sometimes the cut curvature and angles, add cost.

And, cutting prototypes out of cardboard with a box cutter, I find that indeed measuring takes an enormous amount of time, as does precision in cutting. An imprecise cut can be made in cardboard by hand in a fraction of a second, while a precise cut may require a minute. This totally kneecaps the otherwise amazing advantages of cardboard. (See Cardboard furniture (p. 742).)

So we should expect nomadic-furniture designs optimized for digital fabrication to look very different from those designed for 1970s manual construction. Maybe they would use a great deal more material, but cheaper material (though the original *Nomadic Furniture* or maybe its sequel were early champions of Frank Gehry's laminated-corrugated-cardboard furniture) or in thinner sheets. Maybe they would look like the fully-interlocking designs Mark Pauly's group at EPFL have been publishing at SIGGRAPH over the last few years.

Presumably, though, you'd like to use some kind of mathematical optimization algorithm to search for the lowest-cost design that fulfills some kind of requirements. The cost of fabrication might be one part of the objective, while others might include weight, maximum load, impact energy to withstand, rigidity, and fabrication time.

Simple system language

Kragen Javier Sitaker, 2013-05-17 (7 minutes)

Reading about Rust, and having just written a raytracer that doesn't use the heap and is almost trivially statically safe, it occurs to me that you could probably do a lot better than OCaml efficiency-wise, especially on modern hardware, without much more compilation complexity.

The ML type system has basically one kind of immutable container, which is like a variant record. Typically this is implemented as a type tag followed by a pointer for each value. Many types only have one variant. Types can be parametric and recursive.

Here are the most basic type definitions from my raytracer:

```
typedef float sc;               // scalar
typedef struct { sc x, y, z; } vec;
typedef vec color;              // So as to reuse dot(vv,vv) and scale
typedef struct { color co; sc reflectivity; char texture; } material;
typedef struct { vec cp; material ma; sc r; } sphere;
```

In memory, a `sphere` occupies nine contiguous 32-bit words:

```
cp.x
cp.y
cp.z
ma.co.x
ma.co.y
ma.co.z
ma.reflectivity
ma.texture
r
```

(`texture` is one byte, but on almost all platforms, it will be padded out, basically to align the `r` that follows it. If you used parallel arrays you could avoid this memory bloat.)

We can translate this same type definition into, say, OCaml:

```
type sc = float
and vec = Vec of (sc * sc * sc)
and color = vec
and material = Material of (color * sc * char)
and sphere = Sphere of (vec * material * sc)
;;
```

The semantics are very similar, but with this definition, a `sphere` is actually a graph of objects on the heap:

```
Sphere
vec ---------------------------------- Vec
material -------- Material             sc -- float
sc -- float       color -- Vec         sc -- float
                  sc -- fl sc -- float  sc -- float
                  char     sc -- float
```

That's a total of 11 heap allocations. If OCaml had unboxed floats, it would be only 5, but even 5 is a lot. If the boxed floats don't need a separate in-memory type tag (I haven't looked), while the others do, then this is a total of some 24 words, more than twice the count for the C approach. With in-memory type tags, the total is 32 words!

Now, this is clearly a problem with memory efficiency, but it gets worse. Half of those 24 words are pointers, and if the object survives until a garbage collection, the garbage collector has 12 pointers to traverse, where it could have had zero. And they're likely to be in different cache lines (perhaps segregated by size in different pages, to cut down on allocator space overhead), so if you have a lot of spheres (I don't), you miss out on cache locality.

In a dynamically-typed language, these allocations really have to be separate — there's no telling when you could replace the `Material` with an integer or something. And you might want some of the parts to be shared with other objects, either because they're mutable or because they're large. But these objects are neither large, nor mutable, nor do they vary in type (we might say "mode", to use the Algol-68 term for in-memory representation). And the cost of the implementation strategy is clearly unacceptable.

"Sum types", that is, types with multiple possible representations, more or less clearly need to be implemented with pointers:

```
type 'a mylist = Mycons of ('a * 'a mylist) | Mynil ;;
```

both because they can be recursive (while being finite and acyclic) and because their elements can vary in size.

There are, as I said, cases where you actually *want* aliasing semantics, either because of mutability or because of size; the C and Pascal approach to this — a type constructor like ^ such that `x^` means "pointer to an x" — seems to me entirely harmonious with an ML-style type system.

(You could lump mutability in with explicit pointerhood, since if you're going to be changing the color of a sphere frequently you're quite likely to want to be able to do that with a single operation instead of three; that would be useful if you wanted a language with a minimal number of features, like C; but in theory the two are orthogonal features.)

This is similar to the approaches taken by Golang and Rust, but Golang doesn't have full type inference.

By eliminating the majority of pointers from your heap, you eliminate the majority of work for the garbage collector, reduce your memory consumption, and probably dramatically improve locality of reference. This makes garbage collection substantially cheaper. It also makes other memory-management disciplines substantially cheaper — for example, single-ownership inherited deletion, or reference counting, are much cheaper when you have fewer pointers.

Golang's approach to arrays and pointer arithmetic seems basically sound, but it seems like it would work better if you could hoist array bounds checks in more cases.

So what's the simplest compiler for a reasonably complete language along these lines? We can dispense with Schemeish simplifications

that simplify the language at the cost of complicating the compiler: automatic closure of free variables, automatic tail-call detection, and call-with-current-continuation. OCaml further dispenses with polymorphic arithmetic and implicit arithmetic type conversion, showing that this is practical. Scheme and Forth dispense with syntax above the level of tokens, showing that this is practical. If you're going to have ML-style variant constructors, you can dispense with conditional statements, but you still need loops if you're not going to do automatic tail-call detection; and you still need a stack if you're going to support recursion that isn't tail-recursion. (And not supporting recursion seems to me to go beyond just "not complicating the compiler" into "turning implementation shortcuts into subtle bugs".)

So you need functions, arithmetic, recursion, pattern-matching (with iteration), type declarations, (mutable) pointers, and perhaps variables; and you probably also need arrays, even if you don't use them much, so you need array indexing; loops; assignments; and sequences of statements.

The simplest way to get loops, other than tail recursion, is to have a pattern-matching construct that repeats unless you break out of it. For example:

```
while (listnode) {
case Cons(a, b) ->
    listnode := b;
    total_weight += weight(a);
case Nil -> break;
}
```

Not sure that really compares well with C:

```
for (; listnode; listnode = listnode->next) {
    total_weight += weight(listnode->item);
}
```

Hygienic macros — i.e. rewrite rules — may be a convenient way to implement a fairly rich compiler fairly quickly.

Underwater energy autonomy

Kragen Javier Sitaker, 2019-11-25 (9 minutes)

Suppose you have built an undersea or other underwater habitat, like Jacques Cousteau, Tom Swift, or many popular science articles from the 1950s; but it's autonomous rather than having an umbilical to a surface support station. How do you get energy to run and repair your base?

The usual suspects: fission power, solar, fuel, buoys; and their drawbacks

Fission power is clearly the best option, but suppose you can't use fission power for political reasons.

If you have sunlight, you can of course use solar panels, although the water will absorb some of it. (See Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) for notes on the absorption spectra of different kinds of water.) If you're under enough water to make it difficult to see you from the surface, or from space, you will get only a tiny amount of sunlight energy.

You can periodically receive shipments of fuel, but burning fuel requires an oxidizer such as oxygen, so you need shipments of oxidizer too. As described in The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271), the best option to me seems to be sodium chlorate, but even so, you end up with only 5 MJ/kg when you include the weight of the sodium chlorate rather than the usual 43 MJ/kg we're used to on land.

By floating a buoy on the surface, it's possible to gather surface solar energy, and also some amount of wave power, as well as sucking in air for human respiration and perhaps fuel combustion. But the buoy is visible, which may be undesirable, and also exposed to damage from heavy seas, ship collisions, oxygen, and sunlight.

Underwater "kite" wind power

I think the best option in many places is analogous to kite wind power, using a reconfigurable-geometry buoy floated some distance below the surface but above the bed; when configured for high-drag geometry, it pulls on its tether, which is gradually let out, generating power; when the tether is nearly exhausted or it's too close to the surface, it's reconfigured for a lower-drag geometry and reeled back in at a much lower energy cost than what it generated when it was being let out. This is much easier than the equivalent task in the air because the velocities are lower, the forces are much higher, the rope length and therefore snapback potential energy is lower, and it's easy to reconfigure the "kite's" buoyancy for a particular altitude under the water.

(I think passive altitude control via buoyancy control is much more difficult in water than in air; the density of air varies sufficiently with pressure for a balloon to hover within tens of centimeters of a constant height as the rubber holds its own volume relatively constant; on the other hand, in a submarine, water density varies only

very slightly with pressure, but higher pressure will tend to collapse your swim bladder and reduce your buoyancy further.)

Cables under tension can carry an amazing amount of power. Consider gel-spun UHMWPE, with its 2.4 GPa yield stress (see Dyneema (p. 123)). At 10 m/s, a snappy but not insane speed (22 miles per hour, in medieval units), 2.4 GPa is 24 GW/m², which is 24 kW/mm². According to Induction kiln (p. 2352), AWG20 [copper] wire can safely carry 5 amps and is 0.812 mm in diameter (not counting the insulation), or 9.7 megawatts/volt/m²; so, reaching the same 24 GW/m² with it requires 2500 volts. At 100 m/s, the UHMWPE cable carries 240 GW/m² = 240 kW/mm², which requires 25 kV in the electrical wire. Copper weighs 9 g/cc, about 9× what UHMWPE weighs.

Lower cable speeds require proportionally more tension and thus more cable thickness to deliver the same power.

Regular air kites

A regular air kite might be better in some sense, particularly at those underwater sites, such as those at the bottom of medium-sized lakes, that have no significant water currents. It could be made of a hydrophobic material, floated to the surface of the water by slight inflation, and then floated to kite height by further inflation with hydrogen or helium. Once in the air it can expand substantially to a size much larger than the underwater structure.

In The Suburbean: a minimally-mobile dwelling machine with months of autonomy (p. 1271), it is proposed to store some 500 MJ of energy in half a tonne of Li-ion batteries to provide a month's worth of 180-watt autonomy without access to air, in a habitat equipped with, among other things, 25 kW of winches. Suppose that the kite pulls 100 kilonewtons, which is a bit over ten tonnes (42 mm² of UHMWPE, or maybe 100 mm² = 1 cm² to have a safety factor), and rises to a height of only 200 m in order to avoid interfering with aircraft; and suppose that the wind at that height is generally 20 m/s. That provides a megawatt or two of power, enough to fully charge the batteries in five to twenty minutes, although it requires some kind of apparatus in the lake habitat capable of storing megawatts of power.

So, like a ball python, this underwater habitat could lurk unobserved at the bottom of a still, dark lake, reaching out to replenish its energy from its environment once or twice a month; but instead of swallowing a rat, it silently flies a kite for a few minutes in the middle of the night.

Hovering submarine assemblages

As I described previously in "hovering kite assemblages" (?) a flying machine large enough to simultaneously be at altitudes with winds in different directions can use those differing wind directions to maintain tautness in the tethers between its various otherwise disconnected parts, to control its direction of movement, and to generate energy to power it, in particular keeping it from falling out of the sky. Similarly, a group of tethered submarines at different depths could harness the differing directions of deep-sea currents at those depths to generate energy and control their direction of movement. (Lift in that case is unnecessary.)

In a sense, that's what a sailboat is doing: harnessing energy from the relative movement between the air and water to move in any direction, including tacking upwind.

Lift/drag calculations

The hydrodynamic force of a fluid flowing past a body can act on it in almost any direction; in general it is proportional to the density of the fluid, the square of the impact velocity, and the cross-sectional area of the body perpendicular to the direction of the flow, and has an additional factor which I think is actually the "drag coefficient". Conventionally it's resolved into a scalar in the direction of the fluid flow called "drag" and a two-dimensional vector perpendicular to it called "lift".

In a constant flow in the absence of any other applied force, drag gradually accelerates the body to the velocity of the flow, causing the hydrodynamic force to disappear. This leads to an interesting phenomenon where the power produced at zero velocity and maximum force is zero, and the power produced at zero force and maximum velocity is also zero; maximum power is somewhere in between, specifically at one third of maximum velocity. (Unless the drag coefficient changes, which it does.)

Because drag is complicated --- the coefficients vary with flow speed and viscosity, and not even continuously or monotonically --- I hesitate to pronounce anything too pompous about this, but *very roughly* this suggests that water currents tend to produce about a thousand times as much force and power as wind of the same speed; for wind to provide the same force, it needs to go 32 times as fast, but to provide the same power, it only needs to go 10 times as fast. Or, changing a different variable, wind needs a thousand times as much area to press on to be equivalent to a water current of the same speed.

Air conditioning

Kragen Javier Sitaker, 2007 to 2009 (21 minutes)

Why This Is Important

According to the EPA's figures, 75% of residential energy use in the US in 2001 was for heating things up and cooling them down in fairly brute-force fashions --- of 9.86 quadrillion BTU, only 2.40 quadrillion were spent on anything else. [0] And essentially all of that is unnecessary.

Only about a fifth of total energy consumption in the US is residential [1], so this 75% is only about 16% of the total; but I think it is only slightly exaggerated from usage patterns in the US economy as a whole. I estimate that 50% of overall US energy consumption is spent on indoor climate control.

I don't have good numbers for the rest of the world. I assume they're roughly similar.

As global warming increases the amount of severe weather people must cope with, the importance of effective indoor climate control will increase; and fighting global warming will require the reduction of energy consumption. Additionally, sufficiently effective indoor climate control can render uninhabitable regions habitable and, if scalable to large buildings, enable the cultivation of a wider range of crops than the local climate would normally allow.

Argentine Air Conditioning

Here in Argentina, air conditioners are rated in "frigorías". One frigoría is one kilocalorie per hour, which is about four BTUs per hour. They recommend 50 frigorías per cubic meter. (This is a little strange, since you'd think you would pick your air conditioner capacity by the amount of heat that comes into your house per hour, rather than the amount of heat your house can hold. But I digress.)

Our apartment is 80 m², and about 2.75 meters in height, which means it contains about 220 m³, and therefore should need about 11000 kcal/h of cooling capacity. This is a bit of a problem for two reasons:

• Air conditioners are expensive more or less in proportion to their cooling capacity, and a 2250-frigoría unit costs $1550 ($0.69 per frigoría), while a 3000-frigoría unit costs $2040 ($0.68 per frigoría). The largest off-the-shelf unit I found was 8000 frigorías, and it cost $5000 ($0.63 per frigoría). At this rate 11000 frigorías would cost us $6930 (US$2200), which seems like a lot of money to me. For example, it's more than three months' rent.
• Air conditioners also use energy more or less in proportion to their cooling capacity, with variations in the neighborhood of 30%. The 8000-frigoría air conditioner uses 3540 watts of electrical power, which would be 16 amps if it's properly power-factor corrected. (I know that's not the amount of heat it's removing, because a kcal/h is only about 17% bigger than a watt. I'm a little confused because I thought that it normally cost more than a watt to remove a watt of heat, but all the air-conditioning units' datasheets claim that they

remove a little over two watts of heat per watt of power used.) So 11000 frigorías should be 4868 watts of electrical power, or a little over 22 amps, more than half of the total of our main circuit breaker. If we assume a duty cycle of 40% during the summer, that's 1947 watts on average during the summer. If we were paying US$0.10 per kilowatt-hour, which is in the neighborhood of what the price would be if residential power weren't heavily subsidized, 4206 kWh would cost us US$420.60, or AR$1324. The current residential electrical rates are about $0.04 per kWh, which would bring the price to only $168.20, but that's still enough of a cost to want to minimize it.

Water Tanks to Sink the Heat During the Day: What Size?

So I've been thinking some more about my 'desert cool and water economics' kragen-tol post from more than a year ago. Suppose we wanted to be able to sink 11000 kcal/h of electrical power for 40% of each day during the summer into some kind of heat storage tank (say, full of water) and then radiate it into space at night. How big of a tank would we need, and how much area? How much surface area would we need for heat-exchanger coils to suck 11000 kcal/h of heat out of the air during the day?

The first question is the easiest one. In the last few days, the highs have been around 28°C and the lows have been around 18°C. Suppose we want to lower the temperature of the air from 32°C to 22°C, which is 10 K of difference. So the water must start out cooler than 22°C and end up cooler than 32°C. Suppose we can start with water at 16°C and end with it at 30°C. Then we can get 14 kcal of heat out of the air per liter of water that flows from the cold tank through the heat exchanger into the hot tank. So 11000 kcal/h would be 790 liters per hour. I've hypothesized needing this cooling power for 9.6 hours (40%) out of each day, which means that each tank would need to hold 7580 liters of water, which is 7.58 metric tons and 7.58 cubic meters.

If we kept these 7.58 metric tons of water indoors, and didn't need any extra space for insulation, we would need 5.5 square meters of floor space for them, or about 2.3 meters square. That's about 7% of our total floor space, and that 7% should be no more and no less constant across dwellings than the figure of 50 frigorías per cubic meter.

Water Tank Size Is Less Sensitive To Temperature

The same amount of water can sink more heat, and sink it more quickly, when the difference between the air temperature and the cool-water temperature is greater. If the cool-water temperature stays at 16°C and I want to cool the air from 28°C, I can only sink, at most, 12 kcal per liter of water. But if the air temperature is 40°C, I can sink 24 kcal/L, twice as much heat for the same volume of water.

So while a conventional air conditioner needs to be sized for the amount of heat it needs to extract on the hottest days, and therefore cares a lot about how hot they are, the design of such a reservoir device should be relatively insensitive to the maximum temperature.

So, even if the 16°C number is correct, I might be able to get by with a much smaller amount of water, simply because the 11000-frigorías number is only relevant on the very hottest days --- if even then.

The Exhaust Heat Exchanger

Cooling the water at night can happen in essentially three ways: evaporation, conduction, and radiation. I think evaporation is limited in its applicability (it won't help colonize the Grand Erg Occidental, and it will get expensive if water does) although being able to use brackish water might broaden its applicability.

This leaves conduction and radiation. Radiation has the major advantage that, on dry nights, the heat sink is the cosmic background radiation at a temperature of about 3 kelvins, so it might be possible to cool the water quite cold, perhaps even to freeze it. (This probably involves using an intermediate heat transfer fluid with a lower freezing point, but it's tractable.)

The basic radiation law is Stefan's Law or the Stefan-Boltzmann law:

```
Q/t = e{sigma}A(T_hot^4 - T_cold^4)

e is the emissivity, a number between 0 and 1 indicating how close
to an ideal black-body radiator the object in question is (at the
relevant wavelengths).  I think it's (1 - albedo) at the relevant
wavelengths.
Sigma is the Stefan-Boltzmann constant: 5.67e-8 W/m²/K^4
Q is the heat transferred.
t is time.
T_hot and T_cold are the temperatures of the hot and cold bodies,
measured in kelvins.
```

So if our e is, say, 0.75; T_hot is at least 16°C (289 K); T_cold is insignificantly small; t is, say, 8 hours; and we want the Q to be 100Mcal (11000 kcal/h * 9.6 h); how much emitting area do we need?

100Mcal is 420 MJ, so the required heat dumping rate is 14.5kW; T_hot^4 is 7.0e9 K^4; so we have

```
14.5kW / (0.75 * (5.67e-8 W/m²/K^4) * 7.0e9 K^4) = A
m² * 14.5e3 / (0.75 * 5.67e-8 * 7.0e9) = A
m² * 14.5e3 / (0.75 * 5.67 * 70) = A = 49 m²
```

So I'd need about 7 meters square of roof space to beam the heat from my little apartment back out into space at night, plus enough pipes and aluminum to keep it all warm. And on cloudy nights, it wouldn't work. Note that 49m² is more than half the floor area of the apartment.

Conduction, on the other hand, requires little extra equipment (just a fan and some flaps to direct air from the outdoors through the same heat exchanger used to cool the indoors) and is known to be feasible.

Cost of Space

We can estimate the "cost" of losing the space at 7% of our rent: for us, $150 per month, or $1850 per year. So it costs us $40 per month during the life of the thing, and as long as the electrical rates are so deeply subsidized, it would actually cost us almost all of the $150 amount. We're not in a particularly expensive area of Buenos Aires, but areas outside the Capital Federal are cheaper still. So for people in areas that cost less per month per square meter, it might save them money each month. Even for us, it might cost less up front than a $7000 refrigerative cooler, at least if it doesn't break the floor and can be adequately insulated without building anything really expensive.

Heat Exchanger Area

I don't really have a clue what size of heat exchanger I would need. Presumably it would be a few times bigger than the heat exchanger that an air conditioner would use, because the temperature difference between the coolant and the air is smaller.

Tank Insulation

The hot water tank must retain its heat until it can be exhausted into the great outdoors at night, if it is inside; and the cold water tank must retain its cool until it can be exhausted into the indoors during the hot day, if it is outside. In the winter, their roles would be reversed. (Beatrice suggested reversing their roles during the winter. I need to think more about this.) Insulating materials like fiberglass typically have thermal conductivities around 0.04 W/m/K. If a cubical tank contains 5.28 cubic meters, it's 1.74 meters on a side, and therefore has 18.2 m² of surface area, so that's around 0.72 m W/K, and I've been hypothesizing about a 20 K temperature difference, so that's 14.4 m W. We need to divide that by enough centimeters of insulation that the resulting uncontrolled heat flux is small compared to the average 4400 kcal/h (=5100W) heat flux that the thing is designed to control. If "small" means 5%, that's 510W, which means we need 2.8 cm of insulation.

3 cm of insulation around cubical tanks seems like it might be a much more reasonable proposition than welding up some giant dewar flasks for the thing, which would presumably need to be round instead of some more convenient shape. (Right?) That's roughly a cubic meter of fiberglass (or whatever: cork, cotton, felt, "mineral wool", styrofoam, are all in the same ballpark; silica aerogel could cut the space by half, and straw would double it) to insulate all ten cubic meters of reservoir.

Phase Change Materials Instead of Water

Water has a very high specific heat, so using most other materials for the hot and cool reservoirs in place of water (air, say, or iron, or concrete) would increase the weight required, rather than decrease it. (And solid materials have the additional problem that they're kind of inconvenient to move between the warm reservoir and the cool reservoir.)

However, materials that change phase in the relevant temperature range --- say, solid to liquid, or liquid to gas --- have a much higher effective specific heat than any substance. If we were trying to cool

the apartment from by heating water to 1°C from -1°C, for example, we could dump half a calorie per kilogram of ice going from -1°C to 0°C, then 80 calories per kilogram as it melted, then a calorie per kilogram of water going from 0°C to 1°C. This allows you to reduce the weight of water you need by more than a factor of 40. If previously you would have needed five metric tons, now you only need 123 kg.

(Air conditioners in the US are often rated in "tons", which are tons of ice melted per day. Before refrigerative air conditioners were invented, you would cut ice out of frozen lakes in the winter and store it in an "icehouse", insulated by straw, all year round. So this idea of using phase-change materials as heat reservoirs is nothing new.)

(Note that this works even if you want to cool the air from 25°C to 20°C.)

But this only works if the relevant reservoir can be induced to keep its temperature at the melting or boiling point of the reservoir fluid, or oscillate back and forth across it. If you can dependably get access to a reservoir of below-freezing cold, you can use this approach with water; otherwise, you might have to use a material whose phase change temperature is somewhere more convenient. (If it can be actually inside the range where you want to maintain the air temperature, you don't need tanks and stuff. You can just put the stuff out where it can conduct heat to the air, like in the wall or on the coffee table or whatever.)

There are all kinds of research going on on phase-change materials as lower-mass heat reservoirs. See, for example, J.R.Gates's phase-change material home page:

http://freespace.virgin.net/m.eckert/index.htm

They also have this nice thermostatic property, which has been used to calibrate thermometers for centuries, that they tend to heat up things that are colder than their phase-change temperature, and cool down things that are warmer.

This is Nothing New; Why Was It Rejected Before?

Obviously, indoor climate control with insulated heat reservoirs, passive solar design, phase-change materials for reservoirs, and so on, is nothing new. Adobe houses, stone castles, dugout houses, soddies, caves, iceboxes using ice stored since the winter in the icehouse, walls shared between houses to prevent heat loss, and so on, all go back generations if not millennia or longer. But they were all abandoned in the developed world over the last few decades. Why were they abandoned, and what makes me think they're worth recovering?

They were abandoned for several reasons:

- Fashion. In "Pioneer Pride", I seem to recall reading my great-uncle abandoned his Western New Mexico dugout because his new wife didn't feel that it was a "proper house." It wasn't what she was used to, what she'd grown up with. This is the problem the Viridians are tackling; green design has to be hip in order to get uptake.
- High cost of labor. The traditional techniques involve a lot of heavy material hauling, and most of it isn't easily automatable. (Adobe

bricks are still mixed by hand, made by hand in wooden frames, then stacked by hand to dry.)
• Inflexible construction techniques. You can build a wooden balloon-frame house anywhere you can haul the wood, but you can only build a cave house where there's a cave.
• Low cost of energy. As we've eagerly depleted the Earth's fossil-fuel endowment without much concern for the environmental effects, we've kept the cost of that energy quite low, so it's seemed sensible to use cheaper construction techniques and save space rather than spend money to save electricity. And electricity subsidies like those in Argentina, while they might be helpful for development, make this worse.

I think there are a number of new developments that make these approaches relevant again:

• Fashion. Energy conservation, and green design in general, are trendy in much of the world. Hopefully they'll stay that way for a few decades.
• More extreme weather. As global warming increases the extremes of heat and cold we must survive, even people who cling to 1950s climate-control technologies will benefit by complementing them with more efficient approaches.
• Better materials. Even glass and steel are major improvements (in cost and flexibility) over many traditional materials, but we also have stainless steel (making large Dewar flasks possible), silica aerogel, PVC, fiberglass, styrofoam, fiberglass-epoxy composites (making large transparent water tanks possible), low-emissivity glass, stainless steel, aluminum, and copper pipes and fins (making heat exchangers efficient), rammed earth, straw bales, and on and on. In this case, the large amount of thermal mass (in the form of water in a PVC tank insulated with styrofoam) occupies a tiny fraction of the size of adobe walls.
• Better designs. Dewar flasks, window overhangs, double-paned windows, and so on.
• Less-labor-intensive construction techniques. We can now excavate and build earth berms with small-scale earthmoving equipment.
• Inexpensive computer control. It's now inexpensive and reliable to have a microcontroller turn a water pump or two on and off a few times a day, monitor some pressure sensors, control some fans, open or close some air control flaps, open or close curtains or louvers to regulate the amount of solar heat gain, and raise an alarm in case of pump failure or pipe leakage. This means that it should be straightforward to control air and radiant temperature indoors as effectively as with a traditional climate-control system.
• A possibly rising cost of energy. Certainly the cost will rise here; it may double or quadruple or more.

http://www.eia.doe.gov/emeu/recs/recs2001/detailcetbls.html#total In particular, see page 3 of the total consumption PDF: ftp://ftp.eia.doe.gov/pub/consumption/residential/2001ce_tables/enduse_consump2001.pdf

Of the 9.86 quadrillion BTU, 2.21 quadrillion are spent on air conditioners and refrigerators, which someone might argue aren't really part of "climate control".

[1] US Department of Energy Energy Information Administration (DOE EIA) Monthly Energy Review, December, 2007

http://www.eia.doe.gov/emeu/mer/consump.html In particular, the third page of section 2, "Energy Consumption by Sector", p.27: http://www.eia.doe.gov/emeu/mer/pdf/pages/sec2.pdf

Currently this shows a 9-month total for 2007 of 16.43 quadrillion BTU for the residential sector, out of 76.16 quadrillion overall; there's another 13.84 quadrillion attributed to the "commercial" sector, which has roughly similar seasonal and source energy usage patterns, suggesting that a large part of its energy consumption is also devoted to indoor climate control.

However, that total also includes 30.87 quadrillion BTU of energy used by the "electric power sector" --- 40% of the total --- and presumably that usage is roughly proportional to total usage of electricity.

So my best estimate is that (0.75 * (16.43 + 13.84) / (76.16 - 30.87)) = 50% of US energy consumption is devoted to climate control.

Immutability-based filesystems: interfaces, problems, and benefits

Kragen Javier Sitaker, 2019-02-08 (updated 2019-03-19) (23 minutes)

Git provides a sort of immutable Merkle-graph filesystem which saves all previous versions of all files; every version of every file ("blob") is identified with its SHA-1 hash. It's hierarchically structured, with a similar property for subdirectories ("trees"): iff two subdirectories, or two versions of the same subdirectory, are recursively identical, their hashes will match. This is true across time and across hosts.

You could imagine a variety of functionality based on a filesystem with such an interface. Git provides some of it: for example, it eagerly eliminates duplicate files, so that storing a hundred identical versions of a subdirectory tree in Git costs no more than storing a single one, and storing a hundred nearly-identical versions costs only slightly more. (Storing a hundred nearly-identical versions of a file is optimized using a different, heuristic, mechanism). It provides rapid access to previous snapshots of the filesystem (though, unfortunately, usually through a stateful interface.) It provides relatively efficient synchronization of Git repositories over the network, using the hashes to identify which data needs to be transferred, and what data the receiver already possesses and can thus use to compress the data being sent.

Possible uses

But in addition to duplicate-elimination, historical snapshot access, and efficient network synchronization, such an interface can be used for a variety of other purposes, including consistent-snapshot backup, software downgrade, lazy file reading, userland hashing, polling for generalized change notification, build systems, and maybe even transactional filesystem updates.

Consistent-snapshot backup

Consider backing up a database server, for example. Database servers are designed so that, if the power fails, after a reboot, they will not have lost any data — under some reasonable assumptions about write ordering which are sometimes violated by actual disks, resulting in permanent data loss. So you would think that backing up the files or raw disk partitions they store their data in (sometimes called "tablespaces") would enable you to recover to the point in time when the backup was taken.

Unfortunately, backups are not taken at a point in time; it takes a certain amount of time for the backup process to read from one end of the tablespace to the other, during which time the database server may be writing data. So the data at the end of the tablespace will be of a more recent vintage than the data at the beginning, producing inconsistencies. This can result in useless backups, a fact discovered by many novice database administrators, to their dismay, only after a data-loss disaster.

(SQLite and Berkeley DB have instructions in their documentation

providing an order in which active database files can be backed up safely, but for many databases no such order exists.)

One of NetApp's selling points in 1996 — at the point that their entire website still had a bright yellow background — was that you could take backups of databases. You put the tablespaces on one of their fileservers (then marketed as "FAServers", now "filers") and, instead of backing up the live database, you make the fileserver take a snapshot and then do the backup from the snapshot, not from the constantly-mutating firesystem.

Such a backup from a consistent snapshot would be a useful application of any snapshot-capable filesystem. If you can take the snapshot of the underlying block device rather than the filesystem, for example using AWS EBS's snapshot tools, that may work as well, but it's vulnerable to a certain very common class of filesystem implementation bugs — it's similar to recovering the filesystem after a system crash, and if the filesystem doesn't actually provide the sequencing guarantees it claims to provide, the tablespace could be inconsistent anyway. Also, successfully mounting the snapshot of the live filesystem often requires the ability to modify it to correct inconsistencies in the filesystem itself (e.g., replaying filesystem journals) which requires copy-on-write functionality if it is to both be fast and not violate the integrity of the snapshot.

Git doesn't provide this functionality because it doesn't offer an API that any database servers use to store their data.

Software downgrade

Upgrading software is a constant necessity, both due to the insane epidemic of software security holes and to provide new functionality users want. But upgrading a system you depend on is always somewhat risky: the upgrade may break it, in subtle or obvious ways. Being able to reset the whole filesystem to a previous snapshot can reduce this risk greatly, as it does on AWS EBS, and I think this functionality can be provided more cheaply at the filesystem level than the block device level.

Lazy file reading

When I open a large file in Emacs, it copies the entire thing into virtual memory — it doesn't necessarily have to fit into RAM, but at least into swap by way of RAM. This is necessary because, while I'm editing the file, something else may be modifying the file while Emacs has it open, and in such a case, Emacs wants to be able to detect the conflict and offer options for resolving it. If it only read the file into memory lazily, as parts of it were requested, it could not do this. Even if I'm just scrolling through the file, you could imagine a modification in the middle of the file that results in "torn reads" — where one data block is from before the modification, while the following data block is from after it, and their juxtaposition results in inconsistent results.

It is for this same reason that incorrectly upgrading active shared libraries — which are memory-mapped by ld.so — can result in core dumps.

If Emacs could, instead, open a *current snapshot* of the file, trusting the filesystem to not permit modification of any of the data in the snapshot instead of eagerly making a copy of the whole thing, it could

open files of any size instantaneously.

As described in "Proposal for the Implementation by Xanadu Operating Company of a Full-scale Semi-distributed Multi-user Hypertext System", 1984-04-25:

> Separate processes which request the retrieval of the same orgl at the same time are each given different berts which reter to the orgl. Associated with each orgl is a count of the number of berts which currently refer to it. If one of these processes then makes an edit change to the orgl, a new orgl will be created. The process's bert will be made to refer to the new orgl and the old orgl's reference count will be decremented. By this means, the other processes will not "see" the change, and their berts will still refer to the same V to I mapping as previously. Any information about the orgl's state which the other processes might have been keeping externally will not be invalidated by the one process's edit operation.

Also, Emacs depends on filesystem metadata modification to know if modifications have happened since it read the file; this is not entirely reliable, particularly on filesystems whose modification time granularity is 1000 or 2000 milliseconds. Checking a filesystem-maintained hash of the file would be considerably safer.

Userland hashing

If you want to know if any of the files installed by any of your Debian packages have changed, you can run the `debsums` command to compute secure hashes of them, comparing them against the hashes in the original packages. Unfortunately, this is slow, because it has to read all the file data. If the filesystem provided a trustworthy hash — in 2019, maybe we'd choose SHA-256 rather than SHA-1, among other things to preserve a 2^{128} security factor even in a postquantum future — this would be instantaneous, as long as the filesystem's hashes themselves were not out of date.

Additionally, though, if you wanted to maintain a list of the hashes of some files using some other algorithm (for example, BLAKE2B), you could associate them with the filesystem's file hashes rather than merely with filenames. When a file's filesystem hash changed, you would know that you needed to recompute its BLAKE2B hash. This is in a sense a special case of the "build systems" item below.

Alternatively, the filesystem itself could maintain potentially more than one hash for each file.

Polling for generalized change notification, like inotify

The inotify API in Linux allows a running process to be woken up asynchronously when a file is changed or when any file in a directory is modified; for example, `tail -f` uses this to display new lines appended to a logfile immediately, rather than polling once per second, and GUI file managers use inotify to keep their windows up-to-date with the filesystem — so that newly created files are displayed, files whose contents have changed get updated, and deleted files disappear. The only way to do this with the standard Unix API is to poll periodically, wasting energy in the case where nothing has changed, and still delaying change propagation by up to the polling period.

However, inotify is still somewhat limited. It only applies at a per-directory level, so starting to watch for changes throughout an entire subtree of the filesystem requires a recursive traversal of the subtree with a couple of system calls per directory. And it has no way to determine whether changes happened when the process wasn't

running — the GUI file manager has no way to cache its display in case it's restarted without a directory having been changed, but must laboriously re-examine the same data it examined on the previous execution.

By contrast, if there were a hash for the directory subtree and for each file within it, the file manager could validate its cached display against these hashes when it's restarted. And a filesystem watcher doesn't need to recurse through the entire tree to set up notifications — although it may need to recurse to track down the source of a notification.

Build systems

The `make` system does several things, but one big one is caching of previously-executed computations. Supposing that your compiler is deterministic (a difficult problem in modern systems, though one being tackled by Debian's Reproducible Builds project and by Nix and Guix), it will always produce the same output files given the same input files and options. `make` relies on filesystem timestamps for this, but a more reliable approach would use secure hashes of the file inputs instead, or other handles to immutable versions of the files. (And a filesystem that records the files accessed by a build step, by interposing a check on open() and similar system calls, can provide a more reliable dependency set, not depending on compilers and Makefile authors to specify the dependency set.)

Compilation steps can also potentially depend on the contents of directories, and this introduces a potential problem. For example, I just ran a compilation command with GCC which did, among other things, the following sequence of system calls, with others interspersed:

```
[pid 25870] open("../yeso/time.h", O_RDONLY|O_NOCTTY) = -1 ENOENT (No such file o
r directory)

[pid 25870] open("/usr/lib/gcc/x86_64-linux-gnu/5/include/time.h", O_RDONLY|O_NOC
TTY) = -1 ENOENT (No such file or directory)

[pid 25870] open("/usr/local/include/time.h", O_RDONLY|O_NOCTTY) = -1 ENOENT (No
such file or directory)

[pid 25870] open("/usr/lib/gcc/x86_64-linux-gnu/5/include-fixed/time.h", O_RDONLY
|O_NOCTTY) = -1 ENOENT (No such file or directory)

[pid 25870] open("/usr/include/x86_64-linux-gnu/time.h", O_RDONLY|O_NOCTTY) = -1
ENOENT (No such file or directory)
[pid 25870] open("/usr/include/time.h", O_RDONLY|O_NOCTTY) = 4
[pid 25870] fstat(4, {st_mode=S_IFREG|0644, st_size=13543, ...}) = 0
[pid 25870] read(4, "/* Copyright (C) 1991-2016 Free "..., 13543) = 13543
```

An interposition-based system that concluded that this compilation step depended on the contents and filesystem metadata of `/usr/include/time.h` would be correct, but it *also* depends on the *nonexistence* of `/usr/local/include/time.h`, among other things. If GCC had found `/usr/local/include/time.h`, it wouldn't have continued on to read `/usr/include/time.h`.

But it would be very unfortunate for the build step to be re-executed because the contents of `/usr/local/include` had changed, or worse, because `/usr/local`, `/usr`, or `/` had a change somewhere beneath them.

Fortunately, GCC didn't call `getdents()` (at least in this case), so we can automatically define the dependency more narrowly to *just* the files it specifically probed for — the rest of the directory's contents were not relevant.

Other systems whose results we might want to cache, such as the `updatedb` part of `locate`, might indeed walk an entire filesystem tree using `getdents()`. Such systems would need a bit more surgery to make their results usefully cacheable — they would need to somehow split it into separable transactions per subdirectory tree.

Transactional filesystem updates

ACID transactions are contagious; like other acids, they tend to splash on unexpected things and produce unexpected results on them. If your filesystem can provide ACID transaction updates, then you can expand the scope of whatever transactions you're doing in your program to include the filesystem. Some form of this is necessary if you want your transactions to be actually durable, rather than just "ACI", longing after the D. Providing processes in other transactions with a view of all the files as they were before your transaction began to modify them is very similar to simply providing them with snapshots from before the transaction, but it requires at least some kind of atomic validate-and-commit operation. If you're going to participate in two-phase commit at that level, it further requires the ability to lock the validation in place while you're waiting for other participants in the transaction, which means potentially denying other writers to the filesystem.

Accessing the same mutable data within transactions and also outside of transactions has some pitfalls! Beware!

Implementation issues

Given the above list of benefits, what problems do we need to solve to implement the system? We need to decide on the granularity of hashing, deal with the possibility of hash inconsistency, and figure out what to do about hashes being broken, foreign filesystems, and space exhaustion.

Granularity and splitting

As explained in more detail below, on Flash, unchanged data is necessarily copied from one place to another periodically, offering the opportunity to hash it, but maybe not an entire file at a time. Also, processes like database servers expect to be able to efficiently write individual sectors, or at least tracks (≈100 KiB), of a potentially much larger file; such an operation shouldn't have to reread the entire file to compute the new hash. So probably you want to hash data in chunks close to the size of a disk block, in the range of 512–262144 bytes, and build some kind of Merkle tree from that for larger files. BitTorrent does this, for example, hashing each "piece" of a torrent separately; the `btih:` schema in Magnet links then uses the hash of the torrent file as a whole.

For text files and other files in which blocks of data might move

around, it's desirable to be able to draw the boundaries of the Merkle tree nodes in a way that can recognize a mostly-unchanged file, even if something has been inserted or deleted. Silentbicycle's "jumprope" data structure used in his "Tangram" filesystem and the splitting system used by Avery Pennarun's "bupsplit" system are two variants on this theme.

How can the filesystem's internal hashes get out of date?

The filesystem's hashes can get out of date via bit-flip errors on the disk, via modifications of the disk's data that don't go through the filesystem (for example, if you edit the disk with a hex editor), or via bugs in the filesystem, so they need to be checked, as `git fsck` does.

If the filesystem is running on raw Flash that suffers from read disturb, all data needs to be copied to new Flash blocks periodically; this affords an opportunity to check its hashes in the process. For this to work, the data probably needs to be hashed at a finer granularity than an arbitrarily-large file. Similarly, on Flash, live blocks periodically need to be copied from mostly-empty pages into new pages so that the old pages can be erased, affording a similar opportunity.

Cryptographic agility

In retrospect, it looks like baking SHA-1 into every persistent structure in the Git universe may have been a bad idea — SHA-1 is too short to resist well-resourced attacks with Grover's algorithm, if that becomes feasible, and it has shown some worrisome signs of weakness in the last couple of decades, with some theoretical collision attacks published.

For most of the applications cited above, user processes don't need to access the actual hash values used to index the on-disk data; they can manipulate them through opaque handles like file descriptors, referring either to specific versions of files or to the time-dependent value of "the current state of such-and-such a filesystem entity" (from which the current version can be obtained) — although equality comparison must also be provided. Duplicate-data elimination, previous-snapshot access, consistent-snapshot backup, lazy file reading, and run-time polling for change notification could work with such opaque identifiers. However, you need some kind of stable serialization of these snapshot identifiers for software downgrade, change notification across process restarts, and build systems (across process restarts); for efficient network synchronization and userland hash verification, you additionally need to be able to get the results of a *specific* hash algorithm, because if your filesystem is giving you SHA-1 hashes and the server has upgraded to BLAKE2B, or your filesystem has upgraded to SHA-256 hashes but your package manager only uses SHA-1, you're in trouble.

There are a couple of ways to handle this. You could have the filesystem internally compute a non-constant set of hashes — perhaps the old version of a file has a SHA-1 Merkle tree hash with a blocksize of 8192, while the new version uses a blocksize of 131072, so that if you want to compare them you need to ask the filesystem to compute the other hash for one of the two, which it will store thereafter.

Alternatively, you could fix the algorithm for a given filesystem,

and allow userland processes to use the usual caching approaches to compute hashes using their favored algorithms when they need them, indexing them to individual snapshots if desired.

Compatibility with foreign on-disk filesystems

Suppose your operating system provides such an interface as its native filesystem interface. What happens when you plug in your USB pendrive with a VFAT firesystem on it? VFAT doesn't give you an efficient way to get the hash of a single file, much less an entire subdirectory tree.

I think the key is to use the previously described opaque-version-identifier interface as long as possible; as long as no userland process requests a serialized hash for a filesystem node, you can postpone hashing the file. You can still provide access to snapshots of old versions of the filesystem by buffering the old versions of modified filesystem pages in RAM, as long as some snapshot refers to them. And, once a hash is requested, the OS can retain the hash in RAM as long as the firesystem is mounted.

There may be some filesystems — btrfs, perhaps, or ZFS — which provide a reliable way to determine whether a file has been modified since the last time the filesystem was mounted. They might have some kind of generation count or journal timestamp when the file was last modified. On such foreign systems, you could either use journal-timestamp/inode pairs (or whatever version identifier you end up using) in place of hashes, or you could store a lazily-populated mapping from foreign version identifiers to secure hashes.

Space exhaustion

A serious problem with any kind of lazy copy-on-write system — whether Linux's memory-page allocation, NetApp's WAFL block allocation, Flash FTLs, or a log-structured filesystem — is that space usage is somewhat unpredictable and difficult to attribute to a single cause. Consequently, it becomes exhausted unpredictably, and then it isn't entirely clear how to respond. With the foreign-filesystem interface described in the previous section, the problem is potentially exacerbated by having to buffer old versions of filesystem data in RAM, and RAM may be much smaller than the filesystem.

This is particularly a problem when it comes to database transaction durability. A database executing a two-phase commit must check for all possible errors, especially including errors of disk-space exhaustion, during the PREPARE phase; once the transaction enters the COMMIT phase, it is too late to rollback the transaction because of being out of space. For this particular case, we can use a call to preallocate some space that we may want to write to later on, producing a conservative (pessimistic) failure indication if there may not be space available. If the filesystem can then optimize the actual data by, for example, noting that the disk block written is the same as some other disk block, so much the better — such a situation could snatch victory from the jaws of defeat, but never defeat from the jaws of victory.

Turning a delay line into a counter with a FSM

Kragen Javier Sitaker, 2018-12-10 (1 minute)

Suppose you have an FSM connected to a delay line. There should be a pretty simple transition table to make it into a counter; it just needs to somehow set its carry bit when it wraps around to the beginning again. One solution is for the FSM's initial state to be such that it emits a "start mark" or "framing mark" which doesn't otherwise appear in the initial state of the delay line.

Probably the simplest such scheme is the Internet-0 encoding scheme: 11 is the framing mark, 01 represents a binary 1, and 10 represents a binary 0 (or vice versa), and 00 is unused ("blank tape" or no transmission). This particular scheme can even work with odd-length delay lines, since once the counter sees a correctly-framed 00, it can go into a mode where it searches for the framing mark even at odd bits.

This FSM, as a Mealy machine, has seven states: carrying, waiting to carry, copying, waiting to copy, searching, framing mark 1 (the initial state), and framing mark 2. Its transition and output table is as follows:

(XXX TODO)

	0	1
A: carrying		
B: waiting to carry		
C: copying		
D: waiting to copy		
E: searching		
F: framing mark 1		
G: framing mark 2

Toward a language for hacking around with natural-language processing algorithms

Kragen Javier Sitaker, 2016-09-08 (7 minutes)

To come up with non-words beginning with "sex" consisting of an "s" followed by a real word, in bash:

```
< ~/devel/wordlist cat | while read freq word
    do case "$word" in
    ex*) echo "s$word";;
    esac
done | grep -vf <(< ~/devel/wordlist head -15000
                  | while read freq word
                    do echo "^$word\$" done) | head -45 | sort
```

This is probably the wrong way to do it. I thought it might be easier in Python, but it isn't:

```
import itertools
words = [line.split()[1] for line in open('/home/user/devel/wordlist')]
common_words = set(words[:15000])
swords = ('s' + word for word in words if word.startswith('ex'))

sorted(itertools.islice((sword for sword in swords if sword not in common_words),o
o 0, 45))
```

Python's set type, lazy generator expressions, and implicit file-line iteration are useful here, but this still ends up being kind of a lot of code, even more than the bash version, in part because genexes are pretty pointful, which is in part because Python's methods are not very useful to pass to higher-order expressions like `map` and `filter`.

Another thing to keep in mind here is that I invariably write this kind of thing incrementally, looking at the results computed by intermediate versions, in order to decide what to do next. For example, I added the filter to eliminate existing common words when "sexist" showed up in the output, and increased the cutoff from 2000 to 15000 when it continued to show up. Traditional `function(arguments)` syntax kind of sucks for this, because usually you write the arguments left to right (not least because the cursor's implicit motion is to the right as you type), and then you have to move back to the beginning to add the `function` bit. This gets even worse when we're wrapping something in a list comprehension or a generator expression.

The ideal environment for writing stuff like this incrementally would not be implicitly imperative, so that it could safely evaluate intermediate expressions without fear of damage and evaluate lazily for responsiveness without fear of confusion; it would allow you to add functions on the right; it would use map and filter functions rather than list comprehensions or generator expressions; it would use CLOS-like generic functions, with ML-like implicit currying, instead of methods so that you could use them as map and filter

arguments; and it would allow you to write the equivalent of `f(a, g(b, h(c, d)))` without matching parens.

These requirements actually make it sound a lot like Forth! But I don't think we need to descend down the rabbit hole of typelessness and syntaxlessness to get these advantages.

Here's a hack at an alternative syntax that maximizes left-to-right typability with incremental feedback:

```
'/home/user/devel/wordlist' file, split each; 1 th each -> words
words, 'ex' startswith only;
    ('s' ++) each;
    , (words, :15000 th set) contains not each;
    :45 th sorted
```

I'm not sure that's right or even parseable, but here are the things I was trying:

- `f(a, b, c)` is written as `a, b, c f`
- `x = a` is written as `a -> x`.
- `f(a, g(b, h(c, d)))` is written, with syntax somewhat borrowed from Mark Lentczner's Glyphic Script, which in turn borrowed it with a semantic change from Smalltalk, as `c, d h; b g; a f`. I'm not sure that I have the parsing rules down correctly, and it might be better to use `c, d h | b g | a f`. Also I think both of these do the wrong thing as you type the `c, d h; b` part, because it tries to apply `b` to the results of `h`, though `b` will become merely an argument to `g`; this will result in misleading feedback in the middle. (The `;,` thing in the middle there makes me think that this is really wrong and I need to rethink it.)
- For cases where the `,,;,,;` nesting-free syntax is inadequate (because you need nesting in some parameter that isn't the first one)
- `map` is called `each`. Probably it would be better to default to `flatMap`, but this code is written with the opposite assumption.
- Sequence indexing `[]` is spelled `th` (as in `4 th`, `5 th`, etc.), and sequences are lazy by default. This may not be the best spelling.
- `:` is an infix operator with the same semantics as in Python slicing, except for indexes from the end: it returns a slice object that can be used with `th`.
- Functions are implicitly curried, making it easy to write functions like `1 th each`, which means λx.each(λy.th 1 y)x in the λ-calculus.
- There are no functions as separate from methods. If we need ad-hoc polymorphism, as for `th` and sequence iteration, we use CLOS-style generic functions.
- `++` is the sequence concatenation function as an infix operator, in order to avoid semantic confusion with the `+` operator for numeric addition, which probably ought to be implicitly lifted to apply over conformable functions and sequences. I thought about using OCaml `^`, SQL `||`, Perl/PHP `.`, or Lua `..`, but all of those already carry far too much semantic baggage already.
- `(x op)`, where `op` is an infix operator, is a Haskell-style "section", meaning λy.x op y.
- `not` is implicitly lifted to operate over not just booleans but boolean-returning functions.
- `open` is called `file` and implicitly opens read-only, as in Python
- Probably opening a file for write should use some kind of IO monad

or whatever.
• `in` is called `contains`, on the theory that `common_words contains` is a sensible phrase with the right meaning.
• `split` takes a string and optionally a separator. I need to figure out how to reconcile implicit currying with optional arguments, but I suspect OCaml labeled arguments have my back, and I don't even have to use their shitty syntax because I'm not backwards-compatible with ML.
• `filter` is called `only`, so that `words, 'ex' startswith only` returns the items from `words` that start with 'ex'.
• `sorted` sorts the provided sequence, which is necessarily eager (the last input item might be the first output) but because of lazy evaluation, this only needs to loop until the first 45 items are generated.

The above suggests that it actually is necessary to have some kind of separator between a function and its arguments; in this line

```
'/home/user/devel/wordlist' file, split each; 1 th each
```

it's totally ridiculous that `each` is being applied not only to `split` but to the return of `file`. We could use `.` to apply functions and call methods:

```
'/home/user/devel/wordlist'.file, split. each, 1.th. each -> words
words, ('ex'.startswith). only, ('s' ++). each,
    (words, :15000.th. set. contains. not). each.
    :45.th.sorted
```

Or alternatively we could use `;`, but that's kind of terrible, really, because the whole point of `;` is that its left and right precedence are very different:

```
'/home/user/devel/wordlist'; file, split; each, 1;th; each -> words
words, ('ex'; startswith); only, ('s' ++); each;
    (words, :15000;th; set; contains; not); each;
    :45;th;sorted
```

My very first toddling steps in ARM assembly language

Kragen Javier Sitaker, 2019-12-10 (updated 2019-12-13) (46 minutes)

It's long past time I learned to write a little bit of ARM assembly and machine code! So I spent two hours and was able to get hello-world running, and then a few more hours and learned a bunch of other things.

Basic tools

As it happens, although this laptop is an amd64, it has cross-compilation and transparent CPU emulation stuff installed, so this works:

```
$ cat hello.c
#include <stdio.h>

int main() { printf("hello, world\n"); return 0; }
$ arm-linux-gnueabihf-gcc-5 -static hello.c -o hello.arm
$ ./hello.arm
hello, world
$
```

Specifically I have these Linux Mint packages installed:

- gcc-5-arm-linux-gnueabihf
- gcc-5-arm-linux-gnueabihf-base (its prerequisite)
- binutils-arm-linux-gnueabihf
- libc6-armhf-cross
- qemu-user
- qemu-user-binfmt

(Warning: much of the following is quoted from glibc, a copyrighted work licensed under the GNU Lesser General Public License.)

Although I do have libc6-armhf-cross installed, running dynamic executables does not work. This makes disassembly kind of a pain:

```
$ arm-linux-gnueabihf-objdump -d !$
arm-linux-gnueabihf-objdump -d ./a.out

./a.out:     file format elf32-littlearm

Disassembly of section .init:

00010160 <_init>:
   10160:   e92d4008    push    {r3, lr}
   10164:   eb000092    bl  103b4 <call_weak_fn>
   10168:   e8bd8008    pop {r3, pc}

Disassembly of section .iplt:

0001016c <.iplt>:
```

```
   1016c:   4778        bx  pc
   1016e:   46c0        nop         ; (mov r8, r8)
   10170:   e28fc600    add ip, pc, #0, 12
   10174:   e28cca68    add ip, ip, #104, 20    ; 0x68000
   10178:   e5bcfe94    ldr pc, [ip, #3732]!    ; 0xe94

Disassembly of section .text:

00010180 <backtrace_and_maps>:
   10180:   2801        cmp r0, #1
   10182:   f340 8084   ble.w   1028e <backtrace_and_maps+0x10e>
   10186:   2900        cmp r1, #0
(97,167 more lines follow)
$
```

My first steps

We can see that this is Thumb-2 machine code, with some instructions 16-bit and others 32-bit.

Buried in there is the way system calls work on ARM Linux:

```
00010aa0 <__libc_do_syscall>:
   10aa0:   b580        push    {r7, lr}
   10aa2:   4667        mov r7, ip
   10aa4:   df00        svc 0
   10aa6:   bd80        pop {r7, pc}
```

At a guess, r7 selects the system call.

And exit(2):

```
00020648 <_exit>:
   20648:   b500        push    {lr}
   2064a:   4603        mov r3, r0
   2064c:   f04f 0cf8   mov.w   ip, #248    ; 0xf8
   20650:   f7f0 fa26   bl  10aa0 <__libc_do_syscall>
   20654:   f510 5f80   cmn.w   r0, #4096   ; 0x1000
   20658:   d810        bhi.n   2067c <_exit+0x34>
   2065a:   4618        mov r0, r3
   2065c:   f04f 0c01   mov.w   ip, #1
   20660:   f7f0 fa1e   bl  10aa0 <__libc_do_syscall>
   20664:   f510 5f80   cmn.w   r0, #4096   ; 0x1000
   20668:   d800        bhi.n   2066c <_exit+0x24>
   2066a:   deff        udf #255    ; 0xff
   2066c:   4b07        ldr r3, [pc, #28]   ; (2068c <_exit+0x44>)
   2066e:   ee1d 2f70   mrc 15, 0, r2, cr13, cr0, {3}
   20672:   4240        negs    r0, r0
   20674:   447b        add r3, pc
   20676:   681b        ldr r3, [r3, #0]
   20678:   50d0        str r0, [r2, r3]
   2067a:   deff        udf #255    ; 0xff
   2067c:   4a04        ldr r2, [pc, #16]   ; (20690 <_exit+0x48>)
   2067e:   ee1d 1f70   mrc 15, 0, r1, cr13, cr0, {3}
   20682:   4240        negs    r0, r0
   20684:   447a        add r2, pc
   20686:   6812        ldr r2, [r2, #0]
```

```
   20688:   5088        str r0, [r1, r2]
   2068a:   e7e6        b.n 2065a <_exit+0x12>
   2068c:   000589cc    .word   0x000589cc
   20690:   000589bc    .word   0x000589bc
```

I'm guessing that this is the actual exiting part:

```
   2065c:   f04f 0c01   mov.w   ip, #1
   20660:   f7f0 fa1e   bl  10aa0 <__libc_do_syscall>
```

So I tried putting this in a file and compiling it:

```
        ; Attempt to write an ARM assembly program that exits
        ; successfully.
main:
        mov.w r7, #1
        svc 0
loop:   b.n loop
```

But it seems like that is completely the wrong syntax. I asked GCC for a listing please:

```
$ arm-linux-gnueabihf-gcc-5 -static -Wa,-adhlns=hello.lst hello.c
```

It obliged:

```
  1                     .arch armv7-a
  2                     .eabi_attribute 28, 1
  3                     .fpu vfpv3-d16
  4                     .eabi_attribute 20, 1
  5                     .eabi_attribute 21, 1
  6                     .eabi_attribute 23, 3
  7                     .eabi_attribute 24, 1
  8                     .eabi_attribute 25, 1
  9                     .eabi_attribute 26, 2
 10                     .eabi_attribute 30, 6
 11                     .eabi_attribute 34, 1
 12                     .eabi_attribute 18, 4
 13                     .file   "hello.c"
 14                     .section    .rodata
 15                     .align  2
 16                 .LC0:
 17 0000 68656C6C       .ascii  "hello, world\000"
 17      6F2C2077
 17      6F726C64
 17      00
 18                     .text
 19                     .align  2
 20                     .global main
 21                     .syntax unified
 22                     .thumb
 23                     .thumb_func
 25                 main:
 26                     @ args = 0, pretend = 0, frame = 0
 27                     @ frame_needed = 1, uses_anonymous_args = 0
```

```
  28 0000 80B5          push    {r7, lr}
  29 0002 00AF          add r7, sp, #0
  30 0004 40F20000      movw    r0, #:lower16:.LC0
  31 0008 C0F20000      movt    r0, #:upper16:.LC0
  32 000c FFF7FEFF      bl  puts
  33 0010 0023          movs    r3, #0
  34 0012 1846          mov r0, r3
  35 0014 80BD          pop {r7, pc}

  37                    .ident  "GCC: (Ubuntu/Linaro 5.4.0-6ubuntu1~16.04.9) 5.4.0
 20160609"
  38 0016 00BF          .section    .note.GNU-stack,"",%progbits
DEFINED SYMBOLS
                           *ABS*:0000000000000000 hello.c
     /tmp/cc20XqWG.s:15    .rodata:0000000000000000 $d
     /tmp/cc20XqWG.s:16    .rodata:0000000000000000 .LC0
     /tmp/cc20XqWG.s:25    .text:0000000000000000 main
     /tmp/cc20XqWG.s:28    .text:0000000000000000 $t

UNDEFINED SYMBOLS
puts
```

Evidently r0 contains the argument for `puts` and also the return value for `main`.

Aping the syntax therein, I tried this:

```
        @ Attempt to write an ARM assembly program that exits
        @ successfully.
        .arch armv7-a
        .syntax unified
        .thumb
        .globl main
main:
        mov.w r7, #1
        svc 0
loop:   b.n loop
```

That does build successfully; `arm-linux-gnueabihf-objdump` on the resulting executable suggests that the requested instructions were emitted:

```
(322 lines omitted)
0001049c <main>:
   1049c:   f04f 0701   mov.w   r7, #1
   104a0:   df00        svc 0

000104a2 <loop>:
   104a2:   e7fe        b.n 104a2 <loop>
(87108 lines omitted)
```

However, upon execution, the program segfaults. So I guessed wrong about *something* but without a debugger or knowing how to print things it's hard to tell what still.

Let's try building a program that exits successfully with GCC:

```
$ cat return42.c
int main(int argc, char **argv)
{
  return 42;
}
$ make return42
cc -Wall -Werror -std=gnu99    return42.c   -o return42
$ ./return42
$ echo $?
42
$ arm-linux-gnueabihf-gcc-5 -static -Wa,-adhlns=return42.lst return42.c
$ cat return42.lst
...
  21                main:
  22                    @ args = 0, pretend = 0, frame = 8
  23                    @ frame_needed = 1, uses_anonymous_args = 0
  24                    @ link register save eliminated.
  25 0000 80B4          push    {r7}
  26 0002 83B0          sub sp, sp, #12
  27 0004 00AF          add r7, sp, #0
  28 0006 7860          str r0, [r7, #4]
  29 0008 3960          str r1, [r7]
  30 000a 2A23          movs    r3, #42
  31 000c 1846          mov r0, r3
  32 000e 0C37          adds    r7, r7, #12
  33 0010 BD46          mov sp, r7
  34                    @ sp needed
  35 0012 5DF8047B      ldr r7, [sp], #4
  36 0016 7047          bx  lr
...
```

Maybe bx is "branch indirect". Also maybe I should use some optimization:

```
  21                main:
  25 0000 2A20          movs    r0, #42
  26 0002 7047          bx  lr
```

That's more like it. Can I get that to build?

```
$ cat return42-arm.s
        @ Attempt to write an ARM assembly program that exits
        @ successfully.
        .arch armv7-a
        .syntax unified
        .thumb
        .globl main
main:
        mov.w r0, #42
        bx lr
loop:   b.n loop
$ arm-linux-gnueabihf-gcc-5 -static return42-arm.s
$ file a.out

a.out: ELF 32-bit LSB executable, ARM, EABI5 version 1 (GNU/Linux), statically li
```

```
onked, for GNU/Linux 3.2.0, BuildID[sha1]=6ddb42d20b6cff668f5c6ded33b82eeda0e3bec3o
o, not stripped
$ ./a.out
qemu: uncaught target signal 4 (Illegal instruction) - core dumped
Illegal instruction
$
```

Hmm, that's not what I was hoping for. Maybe some of the other assembly directives are needed to build a runnable executable?

```
        @ An ARM assembly program that exits successfully.
        .arch armv7-a
        .syntax unified
        .thumb
        .thumb_func
        .globl main
main:
        mov.w r0, #42
        bx lr
```

It turned out to be .thumb_func. The Gas manual explains, "This directive specifies that the following symbol is the name of a Thumb encoded function. This information is necessary in order to allow the assembler and linker to generate correct code for interworking [sic] between Arm and Thumb instructions and should be used even if interworking is not going to be performed. The presence of this directive also implies '.thumb'. This directive is not necessary when generating EABI objects. On these targets the encoding is implicit when generating Thumb code."

(The manual is apparently wrong about it not being necessary when generating EABI objects.)

A little more perusing of the manual allows me to reduce this to the following:

```
        @ An ARM assembly program that exits successfully.
        .arch armv7-a
        .syntax unified
        .thumb_func
        .globl main
main:   mov.w r0, $42
        bx lr
```

Adding this line before the return instruction converts the program into an infinite loop, as expected:

```
loop:   b.n loop
```

This program runs, prints "hello, world" as hoped for, and exits:

```
        .globl main
main:   push {lr}
        movw r0, #:lower16:hi
        movt r0, #:upper16:hi
        bl puts
        mov r0, $0
```

```
        pop {pc}
hi:     .ascii "hello, world\0"
```

$ doesn't work for the half-symbols. Note no .thumb_func, and consequently it generates non-Thumb code!

```
0001049c <main>:
   1049c:   e52de004    push    {lr}        ; (str lr, [sp, #-4]!)
   104a0:   e30004b4    movw    r0, #1204   ; 0x4b4
   104a4:   e3400001    movt    r0, #1
   104a8:   fa00120e    blx 14ce8 <_IO_puts>
   104ac:   e3a00000    mov r0, #0
   104b0:   e49df004    pop {pc}        ; (ldr pc, [sp], #4)
```

Sticking .thumb_func back in there corrects this:

```
0001049c <main>:
   1049c:   b500        push    {lr}
   1049e:   f240 40ae   movw    r0, #1198   ; 0x4ae
   104a2:   f2c0 0001   movt    r0, #1
   104a6:   f004 fc1f   bl  14ce8 <_IO_puts>
   104aa:   2000        movs    r0, #0
   104ac:   bd00        pop {pc}
```

Okay, let's try something with real computation:

```
#include <stdlib.h>

int main(int argc, char **argv)
{
  if (atoi(argv[1]) == 37) printf("whoa\n");
  return 0;
}
```

This compiles to more or less the following:

```
  21                main:
  24 0000 08B5          push    {r3, lr}
  25 0002 4868          ldr r0, [r1, #4]
  26 0004 0A22          movs    r2, #10
  27 0006 0021          movs    r1, #0
  28 0008 FFF7FEFF      bl  strtol
  29 000c 2528          cmp r0, #37
  30 000e 05D1          bne .L2
  31 0010 40F20000      movw    r0, #:lower16:.LC0
  32 0014 C0F20000      movt    r0, #:upper16:.LC0
  33 0018 FFF7FEFF      bl  puts
  34                .L2:
  35 001c 0020          movs    r0, #0
  36 001e 08BD          pop {r3, pc}
  38                    .section    .rodata.str1.4,"aMS",%progbits,1
  39                    .align  2
  40                .LC0:
  41 0000 77686F61      .ascii  "whoa\000"
  41      00
```

So it looks like it's calling strtol(argv[1], 0, 10), passing the args in r0, r1, and r2, and getting the result in r0. Why it's saving r3 I have no idea. I'm guessing the `ldr r0, [r1, #4]` syntax is for indexing 4 bytes off r1 and loading the result into register r0. The rest is the same.

Does it use this same register-passing convention for varargs functions? Let's see:

```
#include <stdio.h>
#include <stdlib.h>

int main(int argc, char **argv)
{
  int n = atoi(argv[1]);
  if (n != 37) printf("whoa %d\n", n);
  return 0;
}
```

```
  21                main:
  22                    @ args = 0, pretend = 0, frame = 0
  23                    @ frame_needed = 0, uses_anonymous_args = 0
  24 0000 08B5          push    {r3, lr}
  25 0002 4868          ldr r0, [r1, #4]
  26 0004 0A22          movs    r2, #10
  27 0006 0021          movs    r1, #0
  28 0008 FFF7FEFF      bl  strtol
  29 000c 2528          cmp r0, #37
  30 000e 07D0          beq .L2
  31 0010 0246          mov r2, r0
  32 0012 40F20001      movw    r1, #:lower16:.LC0
  33 0016 C0F20001      movt    r1, #:upper16:.LC0
  34 001a 0120          movs    r0, #1
  35 001c FFF7FEFF      bl  __printf_chk
  36                .L2:
  37 0020 0020          movs    r0, #0
  38 0022 08BD          pop {r3, pc}
  40                    .section    .rodata.str1.4,"aMS",%progbits,1
  41                    .align  2
  42                .LC0:
  43 0000 77686F61      .ascii  "whoa %d\012\000"
  43      2025640A
  43      00
```

This looks pretty similar but it seems to be passing the format argument in r1, the int argument in r2, and the number of arguments in r0, to a function called `__printf_chk`. I can ape this pretty well:

```
$ cat you-arm.s
        @ Simple ARM assembly program to say "hello, Fred" when run with "Fred"
        .globl main
        .thumb_func
main:   push {r3, lr}
        ldr r2, [r1, #4]    @ argv[1]
        mov r0, $1
        movw r1, #:lower16:hi
```

```
        movt r1, #:upper16:hi
        bl __printf_chk
        mov r0, $0
        pop {r3, pc}
hi:     .ascii "hello, %s\n\0"
$ arm-linux-gnueabihf-gcc-5 -static you-arm.s
$ ./a.out Fred
hello, Fred
```

So based on the above, I can do the dumb Fibonacci benchmark program:

```
        @ Simple ARM assembly program to compute dumb Fibonacci
        .thumb_func
fib:    push {r3, lr}
        cmp r0, $0
        beq basecase
        cmp r0, $1
        beq basecase
        push {r0}
        sub r0, r0, $1
        bl fib
        mov r1, r0
        pop {r0}
        push {r1}
        sub r0, r0, $2
        bl fib
        pop {r1}
        add r0, r1, r0
        pop {r3, pc}
basecase:
        mov r0, $1
        pop {r3, pc}

        .globl main
        .thumb_func
main:   push {r3, lr}
        ldr r0, [r1, #4]    @ argv[1]
        mov r1, $0
        mov r2, $10
        bl strtol
        bl fib
        mov r2, r0
        mov r0, $1
        movw r1, #:lower16:hi
        movt r1, #:upper16:hi
        bl __printf_chk
        mov r0, $0
        pop {r3, pc}
hi:     .ascii "fib = %d\n\0"
```

This comes out as the following:

```
0001049c <fib>:
   1049c:   b508        push    {r3, lr}
```

```
   1049e:   2800        cmp r0, #0
   104a0:   d00e        beq.n   104c0 <basecase>
   104a2:   2801        cmp r0, #1
   104a4:   d00c        beq.n   104c0 <basecase>
   104a6:   b401        push    {r0}
   104a8:   3801        subs    r0, #1
   104aa:   f7ff fff7   bl  1049c <fib>
   104ae:   1c01        adds    r1, r0, #0
   104b0:   bc01        pop {r0}
   104b2:   b402        push    {r1}
   104b4:   3802        subs    r0, #2
   104b6:   f7ff fff1   bl  1049c <fib>
   104ba:   bc02        pop {r1}
   104bc:   1808        adds    r0, r1, r0
   104be:   bd08        pop {r3, pc}

000104c0 <basecase>:
   104c0:   2001        movs    r0, #1
   104c2:   bd08        pop {r3, pc}

000104c4 <main>:
   104c4:   b508        push    {r3, lr}
   104c6:   6848        ldr r0, [r1, #4]
   104c8:   2100        movs    r1, #0
   104ca:   220a        movs    r2, #10
   104cc:   f003 ff9e   bl  1440c <__strtol>
   104d0:   f7ff ffe4   bl  1049c <fib>
   104d4:   1c02        adds    r2, r0, #0
   104d6:   2001        movs    r0, #1
   104d8:   f240 41e8   movw    r1, #1256   ; 0x4e8
   104dc:   f2c0 0101   movt    r1, #1
   104e0:   f012 fa88   bl  229f4 <___printf_chk>
   104e4:   2000        movs    r0, #0
   104e6:   bd08        pop {r3, pc}
```

So I guess I can say that's the first program I've written in ARM assembly, since the others were mostly just slight modifications of GCC output. I'm still cargo-culting the saving of r3, and I probably should use a less-than comparison rather than two equal-to comparisons, and I don't know what order registers get pushed.

It segfaults if you feed it -1, and I think maybe this system is configured with apport to send the core dumps to Ubuntu or something.

A minimal -nostdlib program in ARM assembly

And here's a program that successfully invokes `_exit` via the SVC instruction instead of using the standard library, and thus can be linked with -nostdlib and doesn't make a humongous executable:

```
@ Attempt to write an ARM assembly program that exits
@ successfully with -nostdlib.  cf. return42.c.
.syntax unified
.thumb_func
```

```
        .globl _start
_start: mov r7, #1   @ system call 1: _exit
        mov r0, #42  @ exit return value?
        svc 0
loop:   b.n loop
```

This produces a reasonable disassembly:

```
$ arm-linux-gnueabihf-gcc-5 -static -nostdlib goodbyearm.s
$ ./a.out
$ echo $?
42
$ arm-linux-gnueabihf-objdump -d a.out

a.out:     file format elf32-littlearm

Disassembly of section .text:

00010098 <_start>:
   10098:   f04f 0701   mov.w   r7, #1
   1009c:   f04f 002a   mov.w   r0, #42 ; 0x2a
   100a0:   df00        svc 0

000100a2 <loop>:
   100a2:   e7fe        b.n 100a2 <loop>
$
```

So, that took a couple of hours to figure out, but it did eventually work.

Machine instructions seen thus far

Destination register always comes first.

- svc: supervisor call; in Linux we use svc 0 with the system call number in r7.
- b.n: branch always
- beq, bne: branch if equal or not equal
- bx: "branch and exchange" (not necessarily indirect; see below)
- bl: branch and link (i.e., call)
- push, pop: take sets of registers; can push lr and pop pc. Not sure how order is determined yet.
- mov: can load an immediate constant into a register or copy register to register
- movt: sets upper 16 bits of register to immediate constant
- movw: sets register to 16-bit immediate constant (or maybe sets lower 16 bits?)
- ldr, str: load or store registers to memory, supporting index-offset and I think decrement addressing modes
- cmp: can compare registers to immediate constants
- sub/subs, add/adds: can add or subtract registers, immediate constants, or both
- nop: nop.

Still mysterious: cmn.w, bhi.n, udf, mrc, negs, the whole .w and .n and "s" suffix thing, and what is this "ip" register?

Hmm, the Gas manual actually explains the "s" suffix: that means to set the flags. So presumably "add" just does an addition, while "adds" does an addition and also sets carry flags and whatnot.

write(2), and a -nostdlib hello, world

If we want to get output without stdlib, we need to be able to invoke the SVC for write(2); looks like maybe that's the system call with r7=4:

```
00021180 <__libc_write>:
   21180:   f8df c04a   ldr.w   ip, [pc, #74]   ; 211ce <__libc_write+0x4e>
   21184:   44fc        add ip, pc
   21186:   f8dc c000   ldr.w   ip, [ip]
   2118a:   f09c 0f00   teq ip, #0
   2118e:   b480        push    {r7}
   21190:   d108        bne.n   211a4 <__libc_write+0x24>
   21192:   2704        movs    r7, #4
   21194:   df00        svc 0
   21196:   bc80        pop {r7}
   21198:   f510 5f80   cmn.w   r0, #4096   ; 0x1000
   2119c:   bf38        it  cc
   2119e:   4770        bxcc    lr
   211a0:   f002 bb4e   b.w 23840 <__syscall_error>
   211a4:   b50f        push    {r0, r1, r2, r3, lr}
   211a6:   f001 f9d9   bl  2255c <__libc_enable_asynccancel>
   211aa:   4684        mov ip, r0
   211ac:   bc0f        pop {r0, r1, r2, r3}
   211ae:   2704        movs    r7, #4
   211b0:   df00        svc 0
   211b2:   4607        mov r7, r0
   211b4:   4660        mov r0, ip
   211b6:   f001 fa15   bl  225e4 <__libc_disable_asynccancel>
   211ba:   4638        mov r0, r7
   211bc:   f85d eb04   ldr.w   lr, [sp], #4
   211c0:   bc80        pop {r7}
   211c2:   f510 5f80   cmn.w   r0, #4096   ; 0x1000
   211c6:   bf38        it  cc
   211c8:   4770        bxcc    lr
   211ca:   f002 bb39   b.w 23840 <__syscall_error>
   211ce:   9d40        .short  0x9d40
   211d0:   bf000005    .word   0xbf000005
```

I don't know what all the extra stuff is in there for but presumably it covers up some impedance mismatch between the Linux system call and what the standard library behavior is supposed to be.

On this basis I achieved a stdlibless hello, world:

```
$ cat hellobarearm.s
        @ Attempt to write an ARM assembly program that hellos
        @ successfully with -nostdlib.  cf. goodbyearm.s
        .syntax unified
        .thumb_func
        .globl _start
_start: mov r7, #4   @ system call 4: write
        mov r0, #0
```

```
        movw r1, #:lower16:hello
        movt r1, #:upper16:hello
        mov r2, #(helloend - hello)
        svc 0

        mov r7, #1   @ system call 1: _exit
        mov r0, #0   @ exit return value
        svc 0
hello:  .ascii "hello, world\n"
helloend:
$ arm-linux-gnueabihf-gcc-5 -static -nostdlib hellobarearm.s
$ ./a.out
hello, world
$ ls -l a.out
-rwxr-xr-x 1 user user 964 Dec 11 02:56 a.out
$ arm-linux-gnueabihf-objdump -d a.out

a.out:     file format elf32-littlearm

Disassembly of section .text:

00010098 <_start>:
   10098:   f04f 0704   mov.w   r7, #4
   1009c:   f04f 0000   mov.w   r0, #0
   100a0:   f240 01b8   movw    r1, #184    ; 0xb8
   100a4:   f2c0 0101   movt    r1, #1

164 162 151 142 165 164 145 163 000 000 000 000 000 000 000 000
000 000 000 000 000 000 000 000 000 000 000 000 000 000 000 000
000 000 000 000 000 000 000 000 000 000 000 000 000 000 000 000
000 000 000 000 013 000 000 000 007 000 000 000 002 000 000 000
164 000 001 000 164 000 000 000 044 000 000 000 000 000 000 000
000 000 000 000 004 000 000 000 000 000 000 000 036 000 000 000
001 000 000 000 006 000 000 000 230 000 001 000 230 000 000 000
056 000 000 000 000 000 000 000 000 000 000 000 004 000 000 000
000 000 000 000 044 000 000 000 003 000 000 160 000 000 000 000
000 000 000 000 306 000 000 000 037 000 000 000 000 000 000 000
000 000 000 000 001 000 000 000 000 000 000 000 001 000 000 000
003 000 000 000 000 000 000 000 000 000 000 000 345 000 000 000
064 000 000 000 000 000 000 000 000 000 000 000 001 000 000 000
000 000 000 000
```

Although, doh, I seem to be writing to fd 0, not fd 1. QEMU confirms:

```
$ qemu-arm -strace ./a.out
30784 write(0,0x100b8,13)hello, world
 = 13
30784 exit(0)
```

read(2) seems to be syscall 3. open(2) syscall 5, and close(2) syscall 6, and maybe brk() 45 and getpid() 20.

The ARM-THUMB Procedure Calling Standard

ARM publishes this document, called the ATPCS for short. It explains the use of the registers: r0 and r1 are used for return values; r0 to r3 are used for arguments and are thus caller-saved; r4 to r11 are callee-saved general-purpose registers; r11 is also FP, the frame pointer; r12 is IP, the "intra-procedure-call scratch register"; r13 is SP; r14 is LR, the link register used by the `bl` instruction; r15 is PC. The stack grows downwards, and the stack pointer (which must be 8-byte-aligned when calling a public function) points at the last thing that was pushed, not the next thing to push. Interrupt handlers can execute on your stack, so if you have interrupts you can't depend on values you've popped staying put.

Newer versions are longer and of poorer quality, though covering more modern CPU features; fortunately I was able to find an older version, "SWS ESPC 0002 B-01" (B-01 being the version number), from "24 October, 2000", which is only 37 pages.

Original-THUMB instructions can only access r0 to r7 for most operands, so you only have 8 general-purpose registers, like the 8088;

more recent ones can access the other 8 registers but I think need longer instructions.

There are also some special uses of r10 ("SL", "stack limit" in stack-checked variants), r9 ("SB", "static base" for shared libraries and other uses of position-independent data), and r7 ("WR", "Thumb-state Work Register"), but I don't think these affect their use most of the time --- from the perspective of writing assembly code, they're mostly just more callee-saved registers, except that I guess if your assembly code is in a shared library it will use r9. More recent versions of the ATPCS eliminate SL and WR and give r9 an additional role, TR, the "thread register", for TLS I guess.

I think the definition of "IP" means that the dynamic linker is free to clobber r12 when it's doing lazy dynamic linking, so the callee may see random crap in r12 if it just got loaded. This also means it's caller-saved.

So, in summary, r4-r11 and SP (r13) are callee-saved, and everything else is caller-saved. (Except that r10 may get horked by "limit-checking support code".)

Parameter passing is what you'd expect: everything gets widened to 32 bits, except 64-bit values are split into two 32-bit values (not sure about endianness). The first four parameters go into r0-r3, and subsequent parameters are passed on the stack, first argument last. (So the argument-count passing used by `__printf_chk` above is nonstandard, which I guess is why it was calling `__printf_chk` and not `printf`.) Return values go in r0, r0-r1, r0-r2, or r0-r3, if they fit, while longer return values are returned "indirectly, in memory, via an additional address parameter." Not sure whether that parameter is passed in by the caller as a ghostly first parameter or what.

Floating-point parameter passing is different but uses floating-point registers.

The floating-point story sounds remarkably like the 8086-family story. The old FPA register set has 8 extended-precision registers (I think 12 bytes instead of the 8087's 10) that can be used as single-precision, which has recently been replaced by "VFP", "vector floating point", which has 16 double-precision registers that can be used as 32 single-precision registers instead. A difference is that they are mutually exclusive: while an Atom supports both 80387 instructions and SSE instructions, ARM chips support either FPA or VFP or neither, not both.

The assembly-language examples use a syntax closely resembling Intel syntax, with ; for comments and no %, but . to mean the current position:

```
MOV   LR, PC     ; VAL(C) = . + 8
MOV   PC, r4
```

GCC and Gas use something like this syntax by default except for the comments. The ATPCS sometimes says things like "-4[FP]" in the body text; it's not clear to me whether this is valid assembly syntax in ARM's mind, but Gas seems to be writing that as `[fp, #-4]`.

"BX" is "branch and exchange", not "branch indirect" as I thought; it uses the LSB of the address to determine whether to use ARM or THUMB instructions after the jump. There's a note: "In ARM architecture version 5T, a load (but not a move) to the PC also

restores the instruction-set state, allowing an inter-working return to be performed using LDR, LDM, or POP," which I guess means that before arm5t that wasn't the case.

Shared libraries and position-independent code

To get position-independent code, you have to use PC-relative references to all your read-only data, and you have to access read-write data by indexing off SB. This in particular means that no static data can point to any other static data without dynamic-linker intervention, even inside the same segment; and read-only data, to be sharable, can only point to read-write data by indexing off SB. I don't know how non-instruction read-only data can point to read-only data at all.

There is a delightful hack for shared libraries to find their read-write data segments in their entry trampolines: every shared library has a "library index" set at load time, and every shared library read-write data segment starts with has four pointers into a "process data table" which lists the data segments of the shared libraries. So you're supposed to do this, in THUMB code:

```
MOV LSB, SB             ; for some "low register" LSB
LDR LSB, [LSB, #my_segment]  ; 0, 1, 2, or 3
LDR LSB, [LSB, #my_index]    ; set by the dynamic linker
```

Surprisingly, section 5.8 is about Chez-Scheme-style segmented stacks (called "chunked stacks"). Too bad there's no explicit support for closures, although maybe the GCC-style trampoline hack is better than an explicit context pointer in the ABI, which would slow down every call. (Although the SB thing is pretty close to being exactly an explicit context pointer in the ABI...)

Stack unwinding

A surprising thing about the ATPCS is that it contains an unwinding spec to make it possible for zero-overhead exception handlers to safely unwind the stack, even through shared libraries, restoring all callee-saved registers just as if the functions unwound had returned normally. Even more surprising is that the recommended approach is to examine the binary code of the functions on the stack to identify their prologues or epilogues, and then either interpretively undo the effect of the prologue, or directly execute the epilogue. This is very clever, but for it to work, you need to not move the stack pointer during the body of the function the way my dumb Fibonacci code above does. If that requirement is satisfied, though, I think only a very minimal amount of auxiliary data is required to make the unwinding work.

The Gas manual leads me to believe that this is not the method currently used for unwinding, because it demands that you tell it what registers you're saving with a `.save` directive.

A bit more disassembly, exploring instruction set differences, and failing to figure out shared libraries

I wrote this C program on a different computer and compiled it

with `arm-none-eabi-gcc -S -mthumb -O`, with no `#include` files:

```
int main(int argc, char **argv) {
    printf("%d\n", atoi(argv[1]) << 3 | atoi(argv[2]));
    return 0;
}
```

The assembly code generated inside `main` looks mostly like this:

```
main:
        push    {r3, r4, r5, lr}
        mov     r4, r1
        ldr     r0, [r1, #4]
        bl      atoi
        mov     r5, r0
        ldr     r0, [r4, #8]
        bl      atoi
        lsl     r1, r5, #3
        orr     r1, r0
        ldr     r0, .L2
        bl      printf
        mov     r0, #0
        @ sp needed for prologue
        pop     {r3, r4, r5}
        pop     {r1}
        bx      r1
.L3:
        .align  2
.L2:
        .word   .LC0
        .size   main, .-main
        .section        .rodata.str1.4,"aMS",%progbits,1
        .align  2
.LC0:
        .ascii  "%d\012\000"
```

The `ldr` for the `atoi` arguments confirms that the #4 or #8 is a byte offset. The `lsl` and `orr` mnemonics were what I was really looking for, but I'm surprised not to see the left-shift incorporated into an operand, because I thought ARM supported a left-shift in every operand or something.

The `ldr r0, .L2` is presumably because the 32-bit constant address of the string at .LC0 is hard to fit into an instruction. The separate `pop` for the return address is presumably because if it used `r1` in the same `pop` it would have been popped in the wrong order (because in the instruction encoding this is surely some kind of bitfield or something, not a variable-length list of 4-bit register numbers); this also clarifies that the first thing in the `push` or `pop` list is the one SP points at within the push/pop pair: the last one to be pushed and the first one to be popped. But why didn't it just pop it into `pc` rather than using two more instructions? I suspect the answer is what I saw earlier in the ATPCS: old ARMs needed an explicit BX to ensure a switch in instruction encoding.

Previously I was compiling for `armv7-a` (by the default configuration of my toolchain on the other computer), and I wonder if that resulted

in using the freer-form Thumb-2 instruction format, in which you *can* access the high registers. Indeed, *all* of these instructions enter into 16 bits, except for the immediate operands of the call instructions:

```
$ arm-none-eabi-objdump -d shl.o

shl.o:     file format elf32-littlearm

Disassembly of section .text:

00000000 <main>:
   0:   b538        push    {r3, r4, r5, lr}
   2:   1c0c        adds    r4, r1, #0
   4:   6848        ldr r0, [r1, #4]
   6:   f7ff fffe   bl  0 <atoi>
   a:   1c05        adds    r5, r0, #0
   c:   68a0        ldr r0, [r4, #8]
   e:   f7ff fffe   bl  0 <atoi>
  12:   00e9        lsls    r1, r5, #3
  14:   4301        orrs    r1, r0
  16:   4803        ldr r0, [pc, #12]   ; (24 <main+0x24>)
  18:   f7ff fffe   bl  0 <printf>
  1c:   2000        movs    r0, #0
  1e:   bc38        pop {r3, r4, r5}
  20:   bc02        pop {r1}
  22:   4708        bx  r1
  24:   00000000    .word   0x00000000
```

We can see that the `ldr` to get the constant has been compiled as a PC-relative reference, presumably to support position-independent code --- although I'm not sure how that word is supposed to get the address of the string in it in a relocatable way?

It's not; if I instead compile with `arm-none-eabi-gcc -S -mthumb -fPIC -O`, I get this instead:

```
        ldr     r0, .L2
.LPIC0:
        add     r0, pc
        bl      printf
...
.L2:
        .word   .LC0-(.LPIC0+4)
        .size   main, .-main
        .section        .rodata.str1.4,"aMS",%progbits,1
        .align  2
.LC0:
        .ascii  "%d\012\000"
```

That is, instead of storing the address of the string, it stores the PC-relative offset from the place where the string's absolute address gets computed. The (static) linker can freely relocate the string because the .LC0 relocation will fix up the word at .L2 when the final executable or shared library is built.

With a non-Thumb non-PIC compilation `arm-none-eabi-gcc -S -O`

shl.c the code for main() is instead:

```
main:
        @ Function supports interworking.
        @ args = 0, pretend = 0, frame = 0
        @ frame_needed = 0, uses_anonymous_args = 0
        stmfd   sp!, {r3, r4, r5, lr}
        mov     r4, r1
        ldr     r0, [r1, #4]
        bl      atoi
        mov     r5, r0
        ldr     r0, [r4, #8]
        bl      atoi
        orr     r1, r0, r5, asl #3
        ldr     r0, .L2
        bl      printf
        mov     r0, #0
        ldmfd   sp!, {r3, r4, r5, lr}
        bx      lr
```

(Again, all of this is without #includes; thus the literal calls to atoi and printf.)

These are 32-bit instructions, and it seems like it's using the stmfd and ldmfd instructions (rather than push and pop) to load and store multiple values; presumably the sp! addressing mode is some kind of magic autoincrement/autodecrement addressing mode. The fact that sp is an explicit operand makes it sound like r13 is just another register and its use as the stack pointer was just a convention, but I don't think that was really true --- I think even old ARM interrupt handlers used r13 to save the registers of the thread being interrupted. (Certainly the ATPCS documents this as a thing that could happen in 2000.)

Some of the instructions have three operands instead of two, and the built-in shift I thought I remembered does see to exist here: orr r1, r0, r5, asl #3. Also it's worth noticing that these instructions are missing the s suffix in the disassembly:

```
$ arm-none-eabi-objdump -d shl.o

shl.o:     file format elf32-littlearm

Disassembly of section .text:

00000000 <main>:
   0:   e92d4038    push    {r3, r4, r5, lr}
   4:   e1a04001    mov r4, r1
   8:   e5910004    ldr r0, [r1, #4]
   c:   ebfffffe    bl  0 <atoi>
  10:   e1a05000    mov r5, r0
  14:   e5940008    ldr r0, [r4, #8]
  18:   ebfffffe    bl  0 <atoi>
  1c:   e1801185    orr r1, r0, r5, lsl #3
  20:   e59f000c    ldr r0, [pc, #12]   ; 34 <main+0x34>
  24:   ebfffffe    bl  0 <printf>
  28:   e3a00000    mov r0, #0
  2c:   e8bd4038    pop {r3, r4, r5, lr}
```

```
  30:   e12fff1e    bx  lr
  34:   00000000    .word   0x00000000
```

The Thumb assembly generated by GCC didn't have the `s` suffix on the instructions either, but the disassembly did; it turns out that Thumb instructions always update the flags, except for `mov` and `add` instructions with high registers. Also note that the disassembly spells `stmfd sp!`, as `push`, just like the Thumb version.

What about position-independent mutable data? It turns out to use the same scheme as position-independent immutable data, contrary to what I had expected from the ATPCS. I compiled this C module

```
static int accumulator;

int octal_digit(int digit) {
    accumulator = accumulator << 3 | digit;
    return accumulator;
}
```

with `arm-none-eabi-gcc -mthumb -S -O -fPIC` and got this remarkable result:

```
octal_digit:
        ldr     r3, .L2
.LPIC0:
        add     r3, pc
        ldr     r1, [r3]
        lsl     r2, r1, #3
        orr     r0, r2
        str     r0, [r3]
        @ sp needed for prologue
        bx      lr
.L3:
        .align  2
.L2:
        .word   .LANCHOR0-(.LPIC0+4)
        .size   octal_digit, .-octal_digit
        .bss
        .align  2
        .set    .LANCHOR0,. + 0
        .type   accumulator, %object
        .size   accumulator, 4
accumulator:
        .space  4
```

And this disassembly:

```
00000000 <octal_digit>:
   0:   4b03        ldr r3, [pc, #12]   ; (10 <octal_digit+0x10>)
   2:   447b        add r3, pc
   4:   6819        ldr r1, [r3, #0]
   6:   00ca        lsls    r2, r1, #3
   8:   4310        orrs    r0, r2
   a:   6018        str r0, [r3, #0]
```

```
   c:   4770        bx  lr
   e:   46c0        nop         ; (mov r8, r8)
  10:   0000000a    .word   0x0000000a
```

So we have .L2 in the code segment, just after the end of the function, which contains the BSS address of the read-write variable `accumulator`, relative to the instruction at .LPIC0. So first the program does a PC-relative `ldr` to fetch that read-only datum, and then it adds PC to the fetched datum to obtain the address of .LANCHOR0, which is the part of BSS that holds this file's zero-initialized static variables. This doesn't seem like it could possibly permit sharing the code segment, since the data at .L2 would need to be modified according to where (that piece of) BSS is positioned relative to where this code segment is mapped --- it would need a fixup by the dynamic linker.

This code also shows that the `str` instruction has its destination field on the *right*.

Without the `static`

```
int accumulator;

int octal_digit(int digit) {
    accumulator = accumulator << 3 | digit;
    return accumulator;
}
```

we get a different piece of code that refers to a global offset table; it sure isn't the scheme described in the ATPCS:

```
octal_digit:
        ldr     r3, .L2
.LPIC0:
        add     r3, pc
        ldr     r2, .L2+4
        ldr     r3, [r3, r2]
        ldr     r1, [r3]
        lsl     r2, r1, #3
        orr     r0, r2
        str     r0, [r3]
        @ sp needed for prologue
        bx      lr
.L3:
        .align  2
.L2:
        .word   _GLOBAL_OFFSET_TABLE_-(.LPIC0+4)
        .word   accumulator(GOT)
        .size   octal_digit, .-octal_digit
        .comm   accumulator,4,4
```

I mean this still seems to demand that this code be mapped at a fixed memory location relative to the `_GLOBAL_OFFSET_TABLE_` if it isn't going to be fixed up at load time. So, I don't know.

Even still, it seems like a relatively heavy price to pay for code segment sharing that instead of accessing a variable by saying

```
ldr     r3, [pc, #12]
```

you have to say

```
ldr     r3, [pc, #12]
add     r3, pc
ldr     r2, [pc, #something]
ldr     r3, [r3, r2]
ldr     r1, [r3]
```

and also have a per-reference offset stored somewhere the static linker can fix it up; and so I wonder how often it is really worth it.

Costs of accessing variables allocated statically

An interesting thing about this way of referring to variables (or that described in the ATPCS) is that it reverses the traditional costs of referring to statically and dynamically allocated variables. From the 1940s through the 1980s, accessing a statically allocated variable was cheap: it was at a known, constant address in memory, which could be baked into the instruction; while accessing a variable allocated dynamically, for example on the stack, required indexing off the stack pointer or some other kind of base pointer, which itself had some extra cost to create and maintain. (Worse, until around 1970, there were a significant number of computers where an indexed memory access required self-modifying code, because they didn't have index registers.) But in this case we see that accessing two dynamically-allocated variables can be as simple as `lsl r2, r1, #3`, while accessing a single statically-allocated variable requires a five-instruction watusi.

At first blush this sounds like a straightforward case of architectural evolution, but it isn't really. RAM is just a bunch of registers, after all. There are only a couple of minor details of the ARM architecture that contribute to this situation: it has an efficient encoding for PC-relative addressing (like amd64, unlike i386); loading from a constant pointer requires three instructions (movw, movt, ldr) instead of one; and you only have 16 registers you can address directly, while everything else is much slower, because CPU speed has zoomed way ahead of RAM speed.

Rather than a change in architecture, though, it's mostly an evolution of the execution model. It's just a different way of using the machine that prioritizes different tradeoffs. You could totally use a PDP-10 or 6502 in such a way: mostly reserve the 6502 zero page for local variables and frame pointers and whatnot rather than global variables, and index all your "statically allocated" variables off one of those registers so that separate processes sharing an address space store their mutable state in separate "segments". And although the Cortex-A7 ARM in your cellphone might have gigabytes of RAM and a deep cache hierarchy, the Cortex-M0 in a small STM32 doesn't see a whole lot of difference between its speed of accessing CPU registers and accessing the on-die SRAM, except that it may need to run several instructions to compute an address into the on-die SRAM.

Reading other stuff

ARM published an "assembler user guide" in 2001 that explains the assembly language fairly comprehensively (354 pages!). Its chapter 4 is the ARM instruction set reference, and chapter 5 is the Thumb instruction set reference. It's marked as "superseded" on ARM's unusably bad website, but without a link (that I could find) to the superseding version. On the 15th page, it explains what ARM and Thumb are; on the 16th page, it describes the register-banking scheme used to separate user and supervisor (kernel) mode. It has a wealth of information about the historical development of the instruction set, including explaining literal pools and whatnot.

However, this version of the book lacks such crucial features as 32-bit-wide Thumb-2 instructions and if-then-else blocks.

There's a decent but unfinished 15-page tutorial by Carl Burch under CC-BY-SA; it explains the -s suffix on instructions, the absence of an integer division instruction (though not the existence of extensions that have it), the built-in shift, the `umull` instruction, the limitations on `mov` immediate constants, `mvn`, `{ldr,str}{b,}`, `{ld,st}m{i,d}{b,a}`, all the ALU instructions, conditional execution, all the condition codes, all the addressing modes (including examples of scaled-register-offset and immediate-post-indexed addressing), etc.

Despite this admirable level of comprehensiveness, it's imperfect; it seems to be unfinished, stopping after explaining the above but before describing function call and return, and it doesn't cover Thumb at all. Also, the "hailstone sequence" example program has a bug in it in which the `ands` instruction overwrites the accumulator, preventing the program from ever working, and at one point it erroneously says it's jumping to the beginning of an array of doublewords. And, unfortunately, the tutorial uses ARM's assembly syntax instead of Gas's.

Azeria Labs wrote an ARM assembly cheat sheet, though it's mostly focused on breakins, and they want to charge you for the full-resolution version; it's associated with a poorly-written error-filled tutorial with totally kool diagrams. The discussion of it in 2017 on the orange website links to a lot of better resources.

Plato was not particularly democratic; ἄρχειν is not "participating in politics"

Kragen Javier Sitaker, 2014-04-24 (5 minutes)

There is a common misquotation of Plato, which recently came up yet again on Twitter:

> One of [the] penalties of refusing to participate in politics is you end up governed by your inferiors.

Or, worse:

> The price paid by good men for indifference to public affairs is to be ruled by evil men.

This is a fake Plato quote. Plato did say something kind of like this, but there's a really major difference.

What did Plato really say?

Allan Bloom's precise translation says:

> and the greatest of penalties is being ruled by a worse man if one is not willing to rule oneself.

(You could misread this as "if one is not willing to control oneself", but the Greek text doesn't admit that reading; it clearly means "is not willing, oneself, to rule.".)

Where are people seeing this fake quote?

You can find both versions of this fake quote at misquote-laundering sites like Brainyquote.

You can also find this quote in misquote-laundering web sites and publications similarly unconcerned with correctness, such as those by the Brookings Institution.

Where did the fake quote come from?

The real quote in context, from Benjamin Jowett's loose translation , is as follows:

> Wherefore necessity must be laid upon them, and they must be induced to serve from the fear of punishment. And this, as I imagine, is the reason why the forwardness to take office, instead of waiting to be compelled, has been deemed dishonourable. **Now the worst part of the punishment is that he who refuses to rule is liable to be ruled by one who is worse than himself.** And the fear of this, as I conceive, induces the good to take office, not because they would, but because they cannot help --not under the idea that they are going to have any benefit or enjoyment themselves, but as a necessity, and because they are not able to commit the task of ruling to any one who is better than themselves, or indeed as good.

This is Socrates speaking to Glaucon about three-quarters of the way through Book I of the Republic, in what's usually known as section 347c. You will note the very large difference between "refuses to rule" and "refuses to participate in politics"; anyone who endorses a candidate, after all, is participating in politics, but only the leader of the government rules.

The relevant phrase in the Classic Greek original reads:

> τῆς δὲ ζημίας μεγίστη τὸ ὑπὸ πονηροτέρου ἄρχεσθαι, ἐὰν μὴ αὐτὸς ἐθέλῃ

ἄρχειν·

(Perseus has put parallel texts online.)

WikiQuote, the free world's answer to profiteering falsehood sites like BrainyQuote, has several paragraphs of discussion about this misquotation.

At one point I misremembered Plato as saying that this was the penalty for "not being the tyrant", but that's going too far to the other extreme, to the extent of inaccuracy. The Republic talks about several different forms of government, including absolute power by one person (the "tyrant", but without the modern derogatory connotation), and there's no indication that Plato is talking specifically about seizing absolute power; ἄρχειν just means "to lead", in a very general sense, but here referring specifically to governing.

But ἄρχειν definitely does *not* mean just "to not be indifferent to public affairs" or "to participate in politics".

The older version of the falsified quote seems to be this:

> The price paid by good men for indifference to public affairs is to be ruled by evil men.

I have a vague memory that this was invented by an American political group in the mid-20th Century. The phrase "indifference to public affairs" seems to have been stolen from Hannah Arendt, in her 1951 *The Origins of Totalitarianism*, near the middle of the book, which more or less directly contradicts the fake Plato quote:

> Indifference to public affairs, neutrality on political issues, are in themselves no sufficient cause for the rise of totalitarian movements. The competitive and acquisitive society of the bourgeoisie had produced apathy and even hostility toward public life not only, and not even primarily, in the social strata which were exploited and excluded from active participation in the rule of the country, but first of all in its own class.

Starfield servo

Kragen Javier Sitaker, 2016-08-30 (updated 2018-11-07) (13 minutes)

You can use a camera to measure deep subpixel movements by using moiré patterns generated by geometrical optics, permitting extremely inexpensive sensing and servomechanisms with several degrees of freedom all the way down to submicron scales.

Suppose you have two sheets of A4-size acetate transparency film printed almost entirely black on a 1200-dpi printer, with occasional randomly placed transparent pixels piercing the otherwise uninterrupted darkness. Specifically, about one of every 2048 pixels is transparent; the other 2047 are opaque black. This means that out of all 139 million pixels on either sheet, only about 68000 are transparent.

Let's lay one of the sheets on top of the other with some integer X and Y pixel offset between them, but no relative rotation. The number of possible ways we can do this is about 9900 in X and 14000 in Y for a total of about 139 million. The odds are overwhelming that about one out of every $2048^2 = 4\,194\,304$ pixels will happen to have two transparent pixels directly on top of one another, and will therefore be transparent. If we view a bright backlight through the two sheets, we can easily detect this pixel. Each such pixel that we measure reduces the number of candidate alignments by about a factor of 2048; any set of more than about four such pixels is adequate to identify the configuration uniquely, again with overwhelming probability.

All in all, for each configuration, there are about 33 such pixels, several times more than enough.

These discrete configurations are separated by 21 microns, an inch divided by 1200.

Let's consider the more general case, where the displacement happens in more degrees of freedom and is continuous rather than discrete. Allow the sheets to rotate in two dimensions and have a perspective difference between them. In this case, almost all pixels in one sheet will overlay parts of four pixels in the other sheet, which increases the number of pixels with some light leaking through by about a factor of 4, up to about 133. It also means that we can measure more than just whether a given pixel is transparent or not; we can distinguish degrees of transparency. How many degrees we can distinguish depends on the sources of noise, but we can probably reliably measure something like 64 gray levels for the pixel. This means we can measure the displacement of any given overlapping pixel of something like a 64th of a pixel, which would increase our measurement precision to under 400 nanometers if geometric optics were the truth. But geometric optics breaks down before that point, so we probably can't do better than about a micron, at least with visible light.

Note that we're up to about 2400 bits of signal here (133 * (6 + 12)), although it's heavily redundant. In the worst case, we're trying to estimate nine degrees of freedom: the distance from the camera to the scene, two degrees of freedom of camera angle, and six degrees of freedom of relative position and orientation of the two transparency

sheets. We're hoping to calculate the relative position and orientation accurate to within about one part in 300 000, which is 18 bits; the other three degrees of freedom might need to be estimated to a similar relative precision even if we don't care. The upshot is that we need to estimate 162 bits of information from 2400 bits of data, which seems eminently feasible.

How much camera resolution do we need for the pattern of pinholes we see to be unique to that configuration? We might need enough resolution to be able to usually separate the light from different pinholes. This might require something like 256 × 256 pixels on the sensor plane, so that most of the 133 pinholes are by themselves in a row and by themselves in a column. This is a few hundred kilobits of information.

How can we make it practical to estimate this information, even if it is in principle contained in the camera image? In principle, you could simply measure the distance from the 2^{162} or so interestingly different configurations and pick the one with the lowest error. Hopefully this is not necessary in practice. Here are some techniques that will probably work:

• First identify which pixels are bright, estimating the pixel-rounded displacements from that, then compare their brightnesses to get subpixel data. For a given camera angle, scene distance, and rotation, this cuts the number of configurations down to only 139 million.
• Do the coregistration computation in Fourier-transformed spatial frequency space rather than in the spatial domain. What we're doing in physical space here amounts to multiplying the two transparencies pointwise in the spatial domain, which is equivalent to convolving their frequency spectra. If we guess roughly the right rotation, maybe we can roughly deconvolve the frequency-domain signal of the product with the frequency-domain signal of one of the transparencies, giving us an estimate of the frequency-domain signal of the other — hopefully including its phase shift.
• Instead of one single-scale pinhole field, we could divide the sheets into areas of "pinholes" of different sizes, or merely mix different sizes of pinholes together, from the 21-μm single-pixel pinholes up to 21-mm finger holes. Then we can use the much smaller number of significantly different configurations of the bigger holes to tell us what neighborhood to search in for configurations of the smaller holes, in this example through perhaps ten power-of-two hole sizes. There are only about 140 interestingly different translational configurations of 21-mm holes, about 12000 if you include 2D rotation, and half a million if you include 3D rotations. These numbers make exhaustive search feasible. (By necessity the larger holes will need to be distributed somewhat more densely, unless you try to recognize the patterns of smaller holes visible through them instead of just comparing them with each other.) Larger holes may also make the Fourier approach more feasible.
• If you're tracking motion, you can use position estimates from previous frames to find which neighborhoods of configurations to search in in a new frame. You can extend this to many simultaneous hypotheses using particle filters and the like.
• Rotations and perspective distortion are less important in small neighborhoods; if you examine a small neighborhood, you don't need

to consider nearly as many rotations. Like large holes, this might benefit from higher density of holes. Consider a circular neighborhood of radius 1150 pixels (about 25 mm), which will contain on average about four million pixels and four of these coincidental pinholes; you can rotate it by up to about 440 microradians before the pattern of pinholes changes. If you were to increase the density of pinholes in the original from one per 2048 to one per 64, then you would have four coincidental pinholes every 2048 pixels, contained in a circle of radius about 72 pixels, which wouldn't change constellations until it had been rotated by about 2.2 milliradians.

• If you compute the Delaunay triangulation of the bright points, you should be able to eliminate the necessity to try many different rotations. Many such tests on clouds of detected features are known in the computer vision literature. You can probably even hash some aspects of the feature graph.

The techniques that involve increasing the pinhole density will decrease the information available per pinhole and probably require more pixels on the image sensor, but they provide more information overall (at least until the density of holes goes above, I think, 1/e).

Sparkly surfaces

A related approach is to use the reflections from a sparkling surface illuminated from a single direction for the feedback. For example, a piece of sandstone in the sun. If the light source and camera are fixed, the pattern of sparkles gives fairly precise information about the two angles of the surface to the axis bisecting the angle between the direction to the light and the direction to the camera; the rotation of the pattern on the focal plane gives fairly precise information about the rotation of the surface *around* that axis; the position of the pattern gives fairly precise information about the translation of the surface perpendicular to that axis; and the scale of the pattern gives very crude information about the translation of the surface *along* that axis.

Of course, you have to start by calibrating the system with a massive database of sparkle patterns from that surface from many different angles.

The system as described can be improved in several ways:

• by using more than one light, ideally in separate frames of video, in order to provide redundant information and in particular to triangulate to get more precision in the imprecise dimension;
• by making the background of the sparkles as dark as possible;
• by making the bright facets themselves slightly concave, both so that they generate a brighter sparkle and so that it is visible over a smaller part of the surface's rotation;
• by making *some* facets sufficiently convex that they can be used to get an approximate angle fairly quickly, thus speeding the search for the precise position;
• by making the sparkles very sparse, so that there are always a few visible, but only a few;
• by defocusing the camera to optically convolve the sparkle pattern with a sharp-edged bokeh, permitting the use of many pixels along the border of the bokeh from a given sparkle to find its position on the focal plane to much better than a single pixel of precision, a feat which is not possible if the sparkle is perfectly focused and thus just

saturating the fuck out of a single focal-plane pixel;
• by (as described above) placing a moiré-generating screen between the camera and the sparkling surface, close to the sparkling surface, in order to distinguish displacements of a screen thread or so, which may be much less than a pixel;
• by using a combination of large facets for better angular resolution with small facets for better spatial resolution.

Riding the Sarmiento train to Once, when it was stuck in a station for a while with the doors open, I observed that moving my head by two fingerswidths (≈20 mm) caused a certain sparkle in the floor to appear; moving it two fingerswidths further caused it to disappear. The sparkle on the floor was about 3 m away from my head, suggesting an angular resolution of some 6 milliradians from simply thresholding that single sparkle; presumably you could get down to 1 mrad by comparing the relative brightnesses of several.

The sharp boundary of the sun's disc (which should be about 9.3 milliradians across, with an edge of 0.5 milliradians or less) was not evident, suggesting that the sparkle (or something, maybe some clouds) was introducing several milliradians of divergence.

Achieving a divergence of 0.5 milliradians (1.7 minutes of arc) at a wavelength of 400 nm from a blue LED requires a beam waist of at least about 0.4 mm, so if you want that much angular resolution, your facets need to be at least that big. (And your light source needs to, if not subtend that little of the field of view of the sparkly surface, at least have significant energy in spatial frequencies that high — for example, the sun's sharp boundary. A fuzzy Gaussian light source is kind of the worst case for a light source of a given size, although of course uniform ambient illumination is the worst case.)

Más pensamientos acerca de diseñar un calefón solar

Kragen Javier Sitaker, 2012-10-15 (5 minutes)

Así que la radiación de cuerpos negros no nos conviene tanto. Pero tiene una caída bastante fuerte a su frecuencia máxima; hay una frecuencia máxima, más arriba de lo cual efectivamente no hay nada de radiación. *Podría* ser posible formular una ventana que efectivamente no transmite nada más allá de, no sé, unos 8000nm, para que la pérdida de calor al cielo subirá por mucho más que unos 7% durante esa subida de 43 grados hasta 49 grados. Pero esto parece bastante difícil para mí en este momento, porque hay pocos plásticos distintos en uso común.

(En algún sentido, esto es más o menos lo mismo que un superficie selectivo común, para lo cual, para subir la eficiencia y la temperatura, queremos mucho menos emisividad en las bandas LWIR, donde emite el panel por su temperatura, que en las bandas visible, donde el sol transmite la mayoría de su energía. Pero es mucho más exigente, porque estamos buscando una subida de emisividad de alrededor de una orden de magnitud por un cambio de frecuencia de unos 2%, entre 316 y 322 K, mientras los superficies selectivos normales cambian su emisividad por un factor de solo 4 con un cambio de frecuencia de una orden de magnitud.)

Otro tipo de ventana que permite pasar el LWIR se hace de polietileno, a veces fortalecido con un mosquitero. Hay un patente acerca de esto: http://www.google.com/patents/US5493126. Una gran desventaja para nuestro propósito es que el ultravioleta solar hace mierda a polietileno sin protección en pocas meses. (Creo que es por eso que los caños de polietileno son negros, para protegerlos del sol.)

Pero bueno, todo eso me hace pensar que probablemente no es práctico hacer un colector solar para agua caliente que es inherentemente seguro contra subir a temperaturas demasiado altas. Lo típico es usar una válvula automática que mezcla agua fría con el agua caliente mientras sale del termotanque, pero también me parece que se puede resolver el problema con controlar bien la temperatura del agua que entra al termotanque. Es que hay que tener un sistema de control lo suficientemente confiable que el riesgo de muerte o lesiones serias baja a un nivel aceptable.

Mi papá también sugerió el uso de válvulas de viejas lavarropas para poder controlar el agua, lo cual me parece una idea bastante inspirada. Además del tema de un posible recicle, capaz que las válvulas que usan para reparar lavarropas serán mucho más baratas (porque más comunes) y fáciles de conseguir que otras válvulas de capacidad parecida.

También sugerió usar un termostato de una heladera para controlar las válvulas, ya que suelen ser adaptables a temperaturas así. Para mí eso será mucho más lío que simplemente usar un microcontrolador.

Sería re interesante de un punto de vista poética o artística poder fabricar la cosa entera de materiales reciclados, pero me parece que puede ser un poco difícil reciclar microcontroladores, porque se suelen deshabilitar el reprogramamiento.

Así que ahora estoy pensando en los próximos partes:

• Panel colector, de

• caño:

• caño de polietileno en espiral, atado a un par de palos o atado con plástico; o
• chapa pintado en negro, posiblemente con oxido cúprico, con caños de cobre bronceados por atrás;
• posiblemente, caja aislada para permitir que el agua pueda subir a 43 grados hasta cuando el aire está a 0 grados. Con 800W/m² de sol, esto implica una resistencia térmica de R = 0.054 K m²/W, lo cual es muy poca aislación: capaz que un simple espacio de aire con vidrio o acrílico arriba, o simplemente envolver un superficie irregular con ese polietileno suave que usan para atar cartones en pallets, atrapando un poco de aire;
• posiblemente, un reflector en vez de una caja aislada, para que la temperatura suba lo suficiente sin necesitar aislación térmica.
• válvulas de lavarropas;
• dos o tres termistores apto para uso en temperaturas entre 0 y 50, con repetibilidad de medida de un grado o menos;
• cables eléctricos para conectar las válvulas y termistores con un microcontrolador;
• un microcontrolador;
• un fuente para el microcontrolador;
• 4 barriles de 200 litros, con caños suficientes para conectarlos;
• telgopor o lana de vidrio suficiente para aislarlos hasta unos 20 cm.
• soportes de algún tipo? Soldados de acero?

Para mí, primero tendremos que armar prototipos para averiguar:

• si determinado diseño de panel puede lograr la temperatura que queremos con el sol, para cada diseño que vale la pena probar;
• como calibrar los termistores;
• qué tan grueso caño (y válvula) necesitamos para el flujo apto, para llenar el tanque dentro de poco tiempo;
• qué tanta electricidad necesitamos para operar las válvulas y el micro;
• si hay lugar en el techo de Vi para 800kg de agua;
• y qué más?

On hanging out with cranks

Kragen Javier Sitaker, 2008-04 (4 minutes)

comment to http://science-professor.blogspot.com/2008/04/someone-should-study-this.html

This is a fantastic comment thread! I especially appreciate the reference to the MJT book.

I've hung out with a few cranks in my time. One person I know, who's extremely well-respected in his field (which is not a science), is trying to publish a book on an improved version of the Titius–Bode law. I suggested that when he's sending a draft to researchers who have expressed interest, he should leave out the chapter on how the planets' orbits relate to musical scales, at least.

And I've had some lovely conversations with Ed Fredkin, a brilliant computer scientist who says, "I'm very interested in physics, but physicists are very uninterested in me being interested in physics." Maybe one of these days he will turn out to have been right, that the universe really is some kind of simple automaton. His work has gone on to inspire another famous crank, Stephen Wolfram, who (again) has done some solid academic work — before giving up altogether on academic norms like giving Fredkin credit and not suing your collaborators for publishing papers on their work.

And a few weeks ago, I had the privilege to sit next to Carl Hewitt in a meeting. Some ideas he was exploring in the 1970s have been the basis for a large fraction of the work in programming languages in the 80s, 90s, and today (Erlang, the latest hot language, is largely the latest realization of his Actors model), so he's the real deal. He gave me a copy of a paper he's working on about nonstratified inference in paraconsistent logics; I haven't been able to make heads or tails of it yet, partly because my grounding in symbolic logic is pretty weak. So what's his crank-hood? He was banned from editing Wikipedia because he kept editing physics articles to explain the importance of the Actors Model in physics. (Maybe he'll turn out to be right, but I think for now there are problems with Bell's Inequality, which is also a problem with Wolfram's ideas.)

Worse are the cases where cranks like Martha Rogers have actually gotten their crazy ideas inside the academy, destroying it from within.

(I haven't met Wolfram or Rogers.)

I have a mailing list to publish my own crazy ideas, but I try not to get too attached to them. I hope that some of them might be significant enough to turn into academic publications, but I'm constantly terrified that I'll turn into a crank myself. The major thing distinguishing me from the people I've listed above, then, would be that they have accomplished some significant things before retiring into crankhood, while I'm just some guy.

It would probably be helpful for people like me to have a guide to the warning signs of crankhood, with examples. Obviously, if this just allowed cranks to take on protective coloring and infiltrate academic mailboxes with greater ease, it would not be a public service; but if it could enable some of us non-academics to recognize

when we're being insufficiently critical of our own ideas, and perhaps in the occasional case that we have some idea that's actually worthwhile, to figure out how to distinguish it from our less worthwhile ideas and then present it in a way that its merit could be detectable — that might have the effect of actually diminishing the amount of wacko mail that comes in.

Oh, and there was this time I was at Google just after lunching with some friends there, sitting down outside with my laptop on the edge of the grounds before leaving, and the security guards were politely turning away a guy who just *had* to present his just-patented invention to *somebody*, *anybody* at Google — but he didn't actually know anybody there, and wasn't willing to disclose anything about his invention.

Reflections on rebraining calculators with this RPN calculator code I just wrote

Kragen Javier Sitaker, 2017-04-11 (4 minutes)

Over the last three nights I've written a substantial part of an RPN calculator in C in order to rebrain a four-function pocket calculator with a somewhat more reasonable calculating facility. Last night I spent about 1½ hours on it; the night before, about an hour; the night before that, about 3½ hours; for a total of six hours.

Performance and battery life projections

The basic user-level functionality mostly works on Linux with a sort of testing stub implementation of keyboard and screen, although there are a couple of egregious bugs. So it should be adequate for estimating performance.

Using it more or less continuously for 90 seconds, on Linux, compiled with optimization, executed 340,838 amd64 instructions. Just starting and stopping it executed 162,347 instructions, for a difference of 178,491, or almost 2000 instructions per second. Running it with four numeric-entry keystrokes executed 169,718 instructions, or 7371 instructions beyond setup and teardown, about 1800 instructions per keystroke; adding 3 + 4 (four keystrokes) took 168,824 instructions, or 6477 instructions beyond setup and teardown, about 1600 instructions per keystroke. If we round this to 2000 amd64 instructions per keystroke or per second, which will probably be more like 4000 AVR instructions, and if the AVR uses 8 nJ per instruction, this is about 32 μJ per keystroke (or per second).

My intent here is to replace the calculator's existing chip with an AVR or something similar, without replacing its keyboard, LCD, and maybe even battery.

Some sample batteries:

- the 300 mAh 1.2 V NiCd AA cell that powers my garden light: 1.3 kJ or 11000 hours
- a CR2032 lithium coin cell: 240mAh at nominally 3 V but down to 2 V; supposedly 192 mWh/g and 3.0 g, so 576 mWh or 691 J or 6000 hours. The datasheet makes it look like it's reasonable to suck up to about 10 or 20 mA out of the battery from time to time without unduly hurting its capacity.
- a regular non-alkaline 1.5 V AA cell: the Energizer E91 datasheet says that it's 3000 mAh down to 0.8 V if discharged at 25 mA. If it were 1.5 V until the end, that would be 16 kilojoules, which is unreasonably high since it would actually be higher energy density than the lithium cell; we can probably estimate half that or 8 kJ or 69000 hours.

I conclude that the AVR's active power draw will not consume a significant amount of battery unless the code gets a lot less efficient or I program it to do much more complicated things.

However, the AVR can run at 20 MIPS, which requires over 100

milliwatts; at this speed, it could drain some of the batteries mentioned above in an hour or two.

Possible features

So far all I've done is a basic four-function calculator, in part because the keyboard on the thing I want to rebrain is not very large. But it already offers these features above and beyond a standard four-function calculator:

- Deep expression nesting;
- Visual feedback on pending values (by displaying the whole stack, or as much of it as will fit);
- RPN syntax;
- Character-by-character number error correction.

It should be feasible to also include features like:

- Stored programs, including iterative ones;
- Named variables;
- Measurement units (i.e. dimensional analysis);
- Undo;
- Persistence;
- Vector values with broadcasting.

Topics

Range literals

Kragen Javier Sitaker, 2014-04-24 (6 minutes)

Range literals

Python syntax and semantics, considered as executable pseudocode, has a curious wart relating to ranges of numbers. Because it's so common to store data in arrays in Python (called "lists"), this wart comes up often.

This is: if we want to iterate over the numbers 1 to 15 (excluding 15), we have to write:

```
for i in range(1, 15):
    ...
```

But if we want to do something `f` with the corresponding elements of an array `arr`, we must write:

```
f(arr[1:15])
```

It's possible to store the object encapsulating those indices from 1 and 15 in another object and pass it to `arr` later. You would think you would do it like this, like in Octave:

```
idx = 1:15
f(arr[idx])
```

but actually that's invalid syntax and you have to do it like this:

```
idx = slice(1, 15)
f(arr[idx])
```

This syntax and function names are far from self-explanatory. Far better, in terms of readability, would be to write this:

```
for i in 1:15:
    ...
```

Or even this:

```
for i in (1:15):
    ...
```

And, in terms of consistency, it would be far better for the expression syntax within [] to be the same as the expression syntax outside of them. This would speed up the learning of Python.

This is one of the few obstacles to universally using Python in place of more traditional pseudocodes in the explanation of algorithms. As things are now, it is much clearer to write the traditional:

```
for i = 1 to 14
    ...
end for
```

than the Python

```
for i in range(1, 15):
    ...
```

This proposed universality of the slice syntax would simplify this, although you'd still have to explain that `1:15` doesn't include 15.

You could maybe make the argument that the extra redundancy improves the Python interpreter's error-reporting ability. That is, there are some cases where someone might accidentally write a range literal, or something like one, which would currently be a syntax error, which would give you a less clear syntax error or even broken code. I can think of a few possibler cases of this — when you want to iterate over an infinite range, for example:

```
for i in 2::
    ...
```

Or worse:

```
for i in ::
    ...
```

I think these can be basically solved by always requiring parens around the range literal, as is currently done with generator expressions, with the added looseness that the parens can also be square brackets:

```
for i in (2:):
    ...
for i in (:):
    ...
```

Negative indexing

Python's array indexing has an additional semantic wart, shared with Perl and I think originally from APL, which is that the use of negative indices counts from the end of the array. This has occasionally worsened bugs in my Python code, but mostly it's just unnecessarily mysterious for newcomers to Python.

I think a better approach would be to have a special object, called, say, `end` or `last`, which can have integers subtracted from it to produce indices that are interpreted to mean "N from the end". You wouldn't be able to iterate directly over ranges containing it, but that's not really a problem.

So, for example, you could say:

```
while line.endswith("\n") or line.endswith("\r"):
    line = line[:end-1]
```

which I think is clearer than the current real Python code for doing this. But you couldn't say:

```
for i in (:end-1):
    print line[i]
```

This would also eliminate the need for omitted indices in slices. Rather than `arr[:]`, you could write `arr[0:end]`, at a slight cost in verbosity but a great gain in clarity, at least to my eyes.

Greek letters

JavaScript allows you to use Greek letters in your variable names, which lets you write code like this (from http://canonical.org/~kragen/sw/dev3/spirals.html):

```
var Δθ = 1/r/2
  , Δr = slope * Δθ
;
if (Δr > 0.5) {
  Δr = 0.5;
  Δθ = Δr / slope;
}
if (neg) Δθ = -Δθ;

r += Δr;
θ += Δθ;
```

This code would be substantially wordier and less clear if it had to be written without Greek letters, and the same is true for a substantial amount of code that is more or less mathematical in nature. (You could argue that Greek letters are going to be intimidating for people who aren't familiar with math, but those people are going to have to learn the math before they understand the code anyway.)

I would argue that being able to use Greek letters in pseudocode often improves its clarity substantially.

An example

Here's a function from the scrypt paper, rendered in the traditional ALGOLish pseudocode from the paper, though without the LaTeX typography:

```
Algorithm ROMix_H(B, N)
Parameters:
       H              A hash function.
       k              Length of output produced by H, in bits.
       Integerify     A bijective function from {0,1}^k to {0,...2^k-1}.
Input:
       B              Input of length k bits.
       N              Integer work metric, < 2^{k/8}
Output:
       B'             Output of length k bits.
Steps:
 1: X ← B
 2: for i = 0 to N - 1 do
 3:   V_i ← X
 4:   X  ← H(X)
 5: end for
 6: for i = 0 to N - 1 do
 7:   j ← Integerify(X) mod N
 8:   X ← H(X ⊕ V_j)
```

```
 9: end for
10: B' ← X
```

Here's the Python version, with the notational improvements suggested above:

```
def ROMix(H):
    """H: a hash function producing k bits.
    Returns a function(B, N):
    B: Input suitable for H.
    N: Integer work metric, < 2**(k/8)
    returns an output of length k bits.
    Uses a bijective function Integerify from {0,1}^k to {0,...2**k-1}.
    """

    def f(B, N):
        V = [B]
        while len(V) < N:
            V.append(H(V[end-1]))

        X = V[end-1]
        for i in (0:N):
            j = Integerify(X) % N
            X = H(X ^ V[j])

        return X

    return f
```

I think this is substantially clearer than the original pseudocode version, especially if you already speak Python or C. It would be better if the inner function `f` didn't have to be named, or if the return statement could be placed before its definition (as in JS).

Passivhaus seasonal thermal store

Kragen Javier Sitaker, 2017-03-02 (updated 2017-03-07) (2 minutes)

If a house is sufficiently insulated, it need not actively reject heat outdoors, for example with air conditioners. It is sufficient to store the heat generated within by the inhabitants and their devices (lights, appliances, etc.) in a seasonal thermal store until the environment is cool enough for the heat to flow to it passively, given the opportunity.

What's the worst-case scenario? One person dissipates around 2000 kcal/day, about 100W. Household appliances are usually a few times this; let's say 400W in total.

Let's suppose we store cold in the form of ice during the winter, and that it will have to last six months.

400 J/s · 6 months · 30 days/month · 86400 s/day = 6.2208 GJ

Melting ice consumes 75 kcal/kg.

6.2 GJ/person · (1/75) kg/kcal · 4.2 cal/J = 0.35 Gg/person = 350 Mg/person

350 tons of water: 350 m^3, a little more due to the expansion of ice. At a height of 5 m, that would be 70 m^2: basically a bedroom or two of space. Or, if it were below an entire floor of 16m × 16m = 256 m^2, it'd be 1½m of height of ice. Per person. If four people live in the house, it'll be 6 meters of depth of ice below the house — 1 meter per month.

If we're talking about storing cold in a material without a change of phase, we'd have just 20° or 30° of ΔT, which is 20–30 kcal/kg, if it were water, or 7–20 kcal/kg if it were something else — in total 4× to 10× the ice, by weight — 1400 to 3500 tons per person. Nevertheless, it could be a similar volume of rock or soil, since they are some 2× to 4× as dense as ice.

In practice, it's probably possible in most places to radiatively couple to a comfortable temperature almost every day, so a six-month thermal store is extreme overkill. However, these calculations show that even a six-month purely passive thermal store is feasible.

Nova RDOS

Kragen Javier Sitaker, 2017-06-15 (22 minutes)

Bob Supnik got a revocable hobbyist license for RDOS from Dirty Genitals identical to the DEC OS/8 license

RDOS for the Nova seems to have been multitasking; it has error messages like OUT OF TCB'S and ERROR IN USER TASK QUEUE TABLE
also I am inferring a hierarchical filesystem from DIRECTORY DEPTH EXCEEDED

I'm `dd conv=swab`ing the image from http://simh.trailing-edge.com/kits/rdosswre.tar.Z
I guess this OS is from 1984 though. I wonder if it's really for a Nova?
it looks a lot more like TOPS-10 or something than it does like Unix

NUL-terminated strings, ^M for newlines, things that appear to be device names like MT0: MT1: MT2: CT0: CT1: CT2:, allusions to using matching pairs of <> in filenames (presumably to delimit the
name of the directory)
two-letter filename extensions, ALL CAPS
command flags leading with /
different file types, user-visible contiguous file allocation
misspelled error messages
SYSGEN
octal addresses
I am inferring a 16-bit word-addressed memory?
up to a mebiword of memory
horrifying interactivity: DUAL PROCESSORS (IPB)? ("0"=NO "1"=YES)
ENTER RTC FREQ (1=10HZ 2=50HZ 3=60HZ 4=100HZ 5=1000HZ)

WANT STANDARD(11 INCH) ?^M^@ENTER FORM SIZE IN LINES(1-143) ==>^@ENTER LINE NUMBER OR CR ==>^@

CHARACTER PRECEEDING A "(" MUST BE AN OPERATOR^M^@LEGAL OPERATORS ARE +, -, !, #, &, @, <, >^M^@NESTED OR MISSING BRACKET(S)^M^@")" MUST BE PRECEEDED BY A NUMBER OR LETTER^M^@
oh hey, here are "shell script commands" from DG RDOS: DELETE BADSP.RB SYS000.RB

I think this is a formatted output template: **##### TOTAL ERRORS, ##### PASS 1 ERRORS
COPYRIGHT (C) DGC 1977,1978,1979,1980,1981,1982,1984,1985ALL RIGHTS RESERVED

Here's a domacro command line:

    DUMP/V BACKUP:7 URDOS<A B C I O>.LB ALMSPD.<SR RB> BACKUP

This suggests the <> aren't directory names but limited wildcards.

Oh hey, here's some source code; I think their macro assembler defined
the instructions as macros!

.DUSR   SPT03   = 03B6          ;  3 sectors per track
.DUSR   SPT04   = 04B6          ;  4 sectors per track
```

Hmm, this error code is interesting:

```
    .DUSR   CTMLI=  321     ; TOO MANY LEVELS OF INDIRECT FILES
```

I guess "indirect files" are symlinks?

Here's some of their subroutine linkage convention:

```

        .TITLE  PARS

;
; LINKAGE & STACK STUFF
```

```
;

Here we have some documentation about their shell scripts, which are
called "domacros" and probably are the files whose names end in ".MC":

```
     DO[/H]  domacro  arg1/s1  arg2/s2  . . . .

Global /H    Help; display this message

  domacro    Name of a DO macro file
             This file may contain any commands which are valid in a
               standard CLI macro file
             It may also contain variables like %1%, %2%, etc.

  argn/sn    Local arguments and switches
             %1% in the domacro will evaluate to arg1/s1
             Up to 256 arguments are allowed
```

Backup script domacro:

Sparkle wheel display

Kragen Javier Sitaker, 2017-05-10 (6 minutes)

Maybe this should be called a "disco ball display".

If you scatter some sparkle sparsely on an uneven black plate and illuminate it with a point source, each fleck of sparkle reflects a beam off in some quasirandom direction. If you rotate the wheel around its axis, the beams from different flecks will scan in a rotating pattern; if the light source is on the axis of the sparkle wheel, the pattern is a cone, but I don't think that's the case in general.

But I don't care that much, because what I care about is what this looks like from a single, somewhat arbitrary point of view, an eye. It looks like sparkling, which is to say, brief pulses of light coming from apparently random sources scattered around the disk. If you watch long enough without moving your eye, the sparkle pattern repeats. Most of the glitter flecks have scan patterns that miss the eye entirely, but those that do not only illuminate it once.

If you map out the pattern of sparkling for a full rotation, you can turn the light source on and off at chosen times to select which flecks appear. With this approach, you can generate a moving image with a single LED, a glitter disk mounted to spin repeatably, and some sort of apparatus for reliably positioning your eye.

Multiple flecks that are simultaneously visible are a problem. If you illuminate while they are visible, you add noise to the image; if you do not, you have even lower efficiency. So ideally the number of flecks would be small enough that the average number of flecks simultaneously visible is somewhere around 1.0.

In the limit of perfectly parallel light, perfectly flat and infinitesimal flecks, and a perfectly infinitesimal viewing pupil, this would not be a problem, because each fleck would be visible for an infinitesimal period of time, so almost all would be at unique times. You could pulse the light source with a Dirac delta function in order to fit nonzero light into this zero time, so you could still see it.

But of course light sources have divergence, glitter flecks have size, flecks are curved, and pupils have size. Picking some numbers, a laser pointer might have 1.2 milliradians of divergence and 2mm of light source diameter, and might be mounted 2 meters from the spinning plate; glitter flecks might be 200 microns in diameter and not have significant curvature; and your eye might be "mounted" 1 meter from the spinning plate and have a diameter of 4 mm. Given these numbers, it seems like the 4-milliradian pupil is almost certainly going to be the limiting factor (and so you might as well use 4-millimeter or 8-millimeter flecks), but perhaps you could fix it by using a small (less than 2 mm) peephole.

You should be able to get up to 4π milliradians of angular scanning out of the apparatus, depending on the relative angles of the light, your eye, the axis, and the flecks. Unfortunately that still only gives you about 3142 pixels at 4 milliradians, which is a shitty display. Illuminating only part of the plate doesn't help; spinning the plate faster doesn't help; the issue is that you need each pixel to get its own separate timeslot in the rotation, and the timeslots are $.004/(4\pi)$ of a full rotation. Making your pupil smaller will help, and if you can

make different rotations different, that will help too.

If you add more light sources, that will help a lot, because the different light sources can activate different flecks simultaneously with no interference. Alternatively you could move the eye, the axis of rotation of the plate, or the light sources, in a controlled fashion, so that different rotations are different in a repeating pattern. So, for example, if you use an 8x8 array of light sources, a 2mm peephole, and rock the axis of rotation of the plate around at 4× slower than the rotation of the plate, you might be able to get 3142·8·8·2·4 = 1.6 megapixels. Now we're talking!

If you rotate the plate at 5400 rpm (90 Hz) and revolve its axis of rotation at one-fourth that, you get 22½ "frames" per second.

You might think that the contrast ratio between the glitter and the black background will be a problem, but I think that you can enhance that contrast ratio arbitrarily by getting further away — until the beam from the glitter fleck is as wide as your pupil, at which point you stop winning.

Then it's just a matter of mapping out which light source illuminates which spots on the disk at which position in the rotational cycle.

As displays go, this is grievously inefficient. If your disc is 50mm across and only the light falling on a 200-micron-square portion of it is being used, and that only half the time, then 62499/62500 of the light is lost. But with a sufficiently bright light source, that should be okay.

Using this approach backwards, you can recognize the fleck pattern of a particular position with a camera in order to detect the rotational position of the disc: a rotary encoder, potentially with three degrees of freedom.

Notes on Raph Levien's "Io" Programming Language

Kragen Javier Sitaker, 2007 to 2009 (10 minutes)

(This is distinct and unrelated to Steve Dekorte's "Io" programming language.)

The original paper, which I don't have a copy of, is:

Raphael Levien, 1989, "Io: a new programming notation", SIGPLAN Notices 24(12) December 1989

There is a little material about Io online, including quotes from the paper. From http://hopl.murdoch.edu.au/showlanguage.prx?exp=4671&language%oo=IO:

Coroutines

Coroutines are an important concept of computing science, but few programming notations properly support them. It is surprising how easy they are to implement in Io.

The idea of coroutines is to have two (or more) routines. When one of the routines gets to a point where it can no longer proceed (such as, when it needs more input), it is suspended, and another routine continues until it, in turn, can no longer continue (such as, when it has a value to output). Then, it is suspended and another routine is resumed.

This is used, for example, in creating a stream. A stream carries a sequence of numbers, without consuming storage. Therefore, it can be infinite. Even in the case of a finite stream, though, it has an advantage over a linked list, because computation can begin immediately after the first number is known.

The Io implementation of streams is analogous to linked lists. A stream takes two arguments. If there is no more data in the stream, it performs its first argument. Otherwise, it performs the second argument, with a data value and the continuation of the stream.

Here we define the operator `count-stream`, and bind an infinite counting stream to the variable `s`.

```
count-stream0: ~ x out;
out x ~ null out;
+x1~x;
count-stream0 x out.
count-stream: -..) ret;
ret .-9 null full;
count-stream0 0 full.
count-stream ~ s
```

S has exactly the same structure as a linked list. In fact, `writelist s` will write `0 1 2 3 4 5...` on the screen.

There seem to be some OCR errors here. I think `+x1~x` is supposed to be `+ x 1 ~ x`, and I suspect (from Raphael Finkel's book, see below) that `~` is actually supposed to be `->`. So the definition of count-stream0 should be as follows:

```
count-stream0: -> x out;
        out x -> null out;
        + x 1 -> x;
        count-stream0 x out.
```

In Scheme:

```
(define count-stream0
  (lambda (x out)
    (out x (lambda (null out)
             (%+ x 1 (lambda (x) (count-stream0 x out)))))))
```

with the following definition of %+:

```
(define (%+ a b cont) (cont (+ a b)))
```

I'm more mystified about the `count-stream` definition. From the text, perhaps the definition is as follows:

```
count-stream: -> ret;
        ret -> null full;
        count-stream0 0 full.
```

Because then s gets `-> null full; count-stream0 0 full`, which takes two arguments (as the text explains) and hands the second one off to `count-stream0`, which performs it with a data value and the continuation of the stream.

Raphael Finkel's 1995/1996 book "Advanced Programming Language Design", chapter 2, section 3, contains some more examples.

```
write 5; write 6; terminate
```

which means, in Scheme:

```
