Dercuano

Dercuano is a self-contained downloadable HTML tarball containing a book's worth of disorganized notes I've made over the last few years. As an alternative option for computer systems incapable of handling a downloadable HTML tarball, I've hacked together an inferior PDF rendering of it as well, which comes to some 4000 pages, formatted for comfortable reading on hand computers.

Buried among the errors, red herrings, and ratholes, there are numerous wonderful insights (perhaps even a few of them original), many fascinating facts about the world (many of which are true, and a few of which are original observations), and a wide variety of inventive ideas about what is possible and what could be done, in particular ideas about how to improve the world with new hardware and software — a few of them workable. I've published little of it previously.

Disclaimer, preface, and warning

Mostly, I made these notes for myself, though with the intention of someday getting most of them into shape for publication, but lacking the discipline imposed by regular publication, that's probably not going to happen. It may not happen anyway. So, fuck it! Here it is, incomplete as it is — I hope you enjoy it!

Beware, this is (almost) all wrong

Much of what is written here is wrong in a variety of ways.

- Some of it is factually wrong (for example, on many occasions I confused the vector space $GF(2)^{32}$ with the very different field $GF(2^{32})$ of degree-32 polynomials over GF(2));
- some of it was factually correct at one point but has since become outdated;
- some of it is okay at a factual level but has led me to incorrect conclusions due to my misunderstanding of the relationships between the facts;
- some of it is just a farrago of incoherent sentence fragments;
- some of it is a collection of atomic facts that are individually coherent and could, in theory, be assembled into a meaningful whole, but so far have not been;
- some of it documents the embarrassingly long path of reasoning by which I eventually argued myself around to a reasonable conclusion which was, in retrospect, obvious from the start; and
- some of it, perhaps most of it, amounts to getting distracted from the most important aspects of an issue by some minor detail.

On the other hand, some of it is correct. Of the correct part, most is unoriginal — sometimes I'm just taking notes on well-established concepts, and sometimes I'm laboriously rediscovering things that are already obvious to others — while some small part is original. Unfortunately, I don't know which part.

Most of these notes are about things I barely understood, or didn't really understand at all, when I wrote the notes. In some cases, I later came to understand them better, but in other cases I've lost even what

understanding I had. Nearly every note is incomplete; of those that are complete, very few have been checked for correctness or revised for readability. So, beware.

Many of the dates are only approximate.

Dercuano is scholarly work in progress, but not a completed scholarly publication

One of the distinguishing features of scholarly publications, as currently understood, is that they are consciously situated with regard to the existing state of knowledge: they are aware of the state of the art; build on its successes (rather than falling victim to known pitfalls); they explicitly describe how they relate to that existing knowledge, declaring which pieces of its foundation are sourced from existing work and what its novel contributions are; and they give credit to existing scholarly work.

By and large, I appreciate these values, and I would like to do work that practices them. Sometimes, in the past, I have. Dercuano is not such a work. It is full of cases where I rediscovered known ideas (sometimes incorrectly) and cases where I think something is true, due to other people's previous work, but I don't remember who demonstrated it, or in many cases, precisely what they demonstrated. In many cases there's existing work in a field that I haven't done the work to understand; often I find that attempting to rederive such work from first principles is the best way for me to understand it, and much of Dercuano consists of such attempts. This is not due to malice, but simply because doing scholarly work properly is a lot of effort, and I haven't finished that work, and in fact I've given up on ever finishing it for most of the notes in Dercuano. From a scholarly perspective, Dercuano is best understood as a collection of unfinished notes on ideas that mostly seem promising and merit further investigation, which could lead to a scholarly publication, rather than a scholarly publication in itself.

The work that leads up to a scholarly publication invariably involves a great deal of information-gathering, experimentation, thinking, revision, and usually discussion before reaching the point of actually representing an advance on the state of the art. When you begin learning about a topic, you have no idea what the state of the art is, what is true or false, or what will work; bit by bit, you find these things out. Sometimes this process is recorded, for example in laboratory notebooks, but it usually remains secret, in part because of all of the embarrassing errors during the process. Preregistration of clinical trials is starting to reduce this secrecy in medicine, but it would be wonderful to see more people doing more of their thinking in the open. Dercuano is an example of what I would like to see more of: scholarly work exposed and done in the open even before reaching the level of a scholarly publication. I am fortunate to have been in the position where I could do this.

Size and public-domain dedication

On 2019-12-28 as I write this, the Dercuano tarball is 3.6 megabytes and contains some 1.2 million words in 882 notes, about 3500 paperback pages' worth of text. The PDF rendering mentioned above uses a page size slightly smaller than standard for improved readability on hand computers.

As far as I'm concerned, everyone is free to redistribute Dercuano, in whole or in part, modified or unmodified, with or without credit; I waive all rights associated with it to the maximum extent possible under applicable law. Where applicable, I abandon its copyright to the public domain. I wrote and published Dercuano in Argentina.

The exception to the above public-domain dedication is the ET Book font family used, licensed under the X11 license (p. 3783). This doesn't impede you from redistributing or modifying Dercuano but does prohibit you from removing the font's copyright notice and license (unless you also remove the font).

(The source repository also contains some other fonts which are used to produce a PDF, but those are not included in the HTML tarball.)

Gitlab

At this writing, there's a replica of this repo on Gitlab.

Notes

2007

• Why John Backus Was on the Wrong Track (p. 2722) 2007 (updated 2019-05-05) (48 minutes)
• Some notes from playing 20q.net (p. 1246) 2007 to 2009 (22 minutes)
• Air conditioning (p. 1665) 2007 to 2009 (21 minutes)
• I think I understand how to use libart's antialiased rendering API now (p. 409) 2007 to 2009 (10 minutes)
• Barcode receipts (p. 2359) 2007 to 2009 (6 minutes)
• A 2007 overview of matrix barcodes (p. 1094) 2007 to 2009 (2 minutes)
• Bicicleta maps (p. 582) 2007 to 2009 (2 minutes)
• Using bytecode won't make your interpreter fast (p. 226) 2007 to 2009 (26 minutes)
• C bad (p. 2832) 2007 to 2009 (4 minutes)
• The coolest bug in Ur-Scheme (p. 1007) 2007 to 2009 (2 minutes)
• A stack of coordinate contexts (p. 2987) 2007 to 2009 (9 minutes)
• A cute algorithm for card-image templates (p. 1946) 2007 to 2009 (2 minutes)
• Double ended log structured filesystem (p. 1653) 2007 to 2009 (4 minutes)
• Notes on reading eForth (p. 1398) 2007 to 2009 (9 minutes)
• Notes on reading eForth 1.0 for the 8086 (p. 541) 2007 to 2009 (5 minutes)
• Emacs22 annoyances (p. 3197) 2007 to 2009 (4 minutes)
• A comparison of prices for different forms of energy (p. 3097) 2007 to 2009 (2 minutes)
• Enumerating binary trees and their elements (p. 1445) 2007 to 2009 (4 minutes)
• Erlang musings (p. 2789) 2007 to 2009 (3 minutes)
• Error Reporting is Part of the Programmer's User Interface (p. 2323) 2007 to 2009 (18 minutes)
• Eur-Scheme: a simplified Ur-Scheme (p. 876) 2007 to 2009

(13 minutes)
• Forth looping (p. 2025) 2007 to 2009 (16 minutes)
• Free software debugging (p. 136) 2007 to 2009 (2 minutes)
• IRC bots with object-oriented equational rewrite rules (p. 838) 2007 to 2009 (6 minutes)
• Gaim group chat (p. 2677) 2007 to 2009 (3 minutes)
• Interesting features of the GNU assembler Gas (p. 3000) 2007 to 2009 (2 minutes)
• The Gelfand Principle, or how to choose educational examples (p. 1967) 2007 to 2009 (8 minutes)
• Git data (p. 2823) 2007 to 2009 (5 minutes)
• Git learnings (p. 3268) 2007 to 2009 (3 minutes)
• High-risk behavior in context (p. 1485) 2007 to 2009 (5 minutes)
• HTML is terser and more robust than S-expressions (p. 562) 2007 to 2009 (4 minutes)
• Learning low level stuff is not just fun, but also useful (p. 815) 2007 to 2009 (5 minutes)
• A filesystem design sketch modeled on Lucene (p. 1624) 2007 to 2009 (43 minutes)
• Designing a Scheme for APL-like array computations, like Lush (p. 661) 2007 to 2009 (4 minutes)
• Microfinance (p. 2875) 2007 to 2009 (6 minutes)
• Developing Win32 programs on Debian (p. 609) 2007 to 2009 (12 minutes)
• Nested inheritance (p. 340) 2007 to 2009 (2 minutes)
• Copyright status of the Oxford English Dictionary: relevant data (p. 82) 2007 to 2009 (3 minutes)
• Polycaprolactone (p. 1813) 2007 to 2009 (3 minutes)
• Notes on running QEMU on Debian Etch (p. 1646) 2007 to 2009 (3 minutes)
• Running your regular desktop in QEMU? (p. 292) 2007 to 2009 (3 minutes)
• Quasiquote patterns (p. 3021) 2007 to 2009 (9 minutes)
• Notes on Raph Levien's "Io" Programming Language (p. 1740) 2007 to 2009 (10 minutes)
• Rich programmers (p. 805) 2007 to 2009 (4 minutes)
• Does SAAS make it harder to ship? I doubt it. (p. 1049) 2007 to 2009 (7 minutes)
• Schimmler parallelism asymptotic gain (p. 294) 2007 to 2009 (1 minute)
• Studies in Simplicity (p. 500) 2007 to 2009 (5 minutes)
• A survey of small TCP/IP implementations (p. 2616) 2007 to 2009 (4 minutes)
• Food miles imply insignificant energy costs (p. 2187) 2007 to 2009 (4 minutes)
• Maybe Counting Characters in UTF-8 Strings Isn't Fast After All! (p. 2992) 2007 to 2009 (15 minutes)
• Tagged dataflow (p. 405) 2007 to 2009 (2 minutes)
• Why Thunderbird is inadequate for opening a 7-gigabyte mbox (p. 980) 2007 to 2009 (2 minutes)
• The Problem: Writing With One Access Pattern, Reading With Another (p. 3004) 2007 to 2009 (19 minutes)
• Programming paradigms for tiny microcontrollers (p. 2104) 2007 to 2009 (6 minutes)

• The AL programming language, dimensional analysis, and typing: do different dimensions really exist? (p. 731) 2007 to 2009 (2 minutes)

• User-per-group (UPG), umask, and "Permission denied" on shared Git repos via ssh (p. 2481) 2007 to 2009 (4 minutes)
• ML's value restriction and the Modula-3 typing system (p. 1763) 2007 to 2009 (3 minutes)
• Vanagon mail (p. 2032) 2007 to 2009 (3 minutes)
• What's wrong with ../../? (p. 2304) 2007 to 2009 (2 minutes)
• Win32 startup (p. 2439) 2007 to 2009 (2 minutes)
• wood and stone personal digital assistants (p. 3191) 2007 to 2009 (6 minutes)
• Writing math in Unicode with the Compose key (p. 1863) 2007 to 2009 (2 minutes)
• Index set inference or domain inference for programming with indexed families (p. 1434) 2007 to 2009 (updated 2019-05-05) (27 minutes)
• Additive smoothing for Markov models (p. 2429) 2007 to 2009 (updated 2019-05-19) (11 minutes)
• OMeta contains Wadler's "Views" (p. 842) 2007 to 2009 (updated 2019-05-20) (13 minutes)
• Improving "science" in eSpeak's lexicon (p. 188) 2007 to 2009 (updated 2019-06-27) (15 minutes)
• bytecode interpreters for tiny computers (p. 2847) 2007-09 (61 minutes)

2008

• The economics of solar energy (p. 1175) 2008 (27 minutes)
• On hanging out with cranks (p. 1715) 2008-04 (4 minutes)
• Smoky day (p. 3010) 2008-04-19 (4 minutes)
• Predictions for future technological development (2008) (p. 341) 2008-04-19 (11 minutes)

2010

• mechanical computation: with Merkle gates, height fields, and thread (p. 2494) 2010-06-28 (36 minutes)

2012

• How should we design a UI for a new OS? (p. 1159) 2012-10-10 (updated 2012-10-11) (4 minutes)
• Pensamientos acerca de diseñar un calefón solar (p. 117) 2012-10-15 (2 minutes)
• Más pensamientos acerca de diseñar un calefón solar (p. 1713) 2012-10-15 (5 minutes)
• Passively safe solar hot water (p. 1333) 2012-10-15 (updated 2012-10-16) (6 minutes)
• Storing dry bulk foods in used Coke bottles (p. 2145) 2012-10-15 (updated 2012-10-21) (5 minutes)
• In what sense is e the optimal branching factor, and what does it mean for menu tree design? (p. 2483) 2012-12-04 (3 minutes)
• Worst-case-logarithmic-time reduction over arbitrary intervals over

arbitrary semigroups (p. 1021) 2012-12-04 (5 minutes)
• a logarithmic-time alternative to summed-area tables for reducing arbitrary semigroup operations over arbitrary ranges (a generalization of RMQ segment trees) (p. 1190) 2012-12-06 (updated 2013-05-17) (10 minutes)
• How can we take advantage of 16:9 screens for programming? (p. 1982) 2012-12-17 (2 minutes)
• Giving Golang a second look for writing a mailreader (in 2012) (p. 290) 2012-12-17 (updated 2013-05-17) (2 minutes)

2013

• Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) 2013-04-17 (updated 2019-08-27) (66 minutes)
• Food storage (p. 2706) 2013-05-11 (updated 2013-05-17) (54 minutes)
• Illuminating yourself with 10 kilolux of LEDs to combat seasonal affective disorder (p. 527) 2013-05-17 (5 minutes)
• Alastair thesis review (p. 1784) 2013-05-17 (1 minute)
• Charge transfer servo (p. 3017) 2013-05-17 (2 minutes)
• Cheap shit ultrawideband (p. 2776) 2013-05-17 (10 minutes)
• Harvesting energy with a clamp-on transformer (p. 1952) 2013-05-17 (7 minutes)
• Clickable terminal patterns (p. 859) 2013-05-17 (2 minutes)
• Only a constant factor worse (p. 1648) 2013-05-17 (16 minutes)
• Use crit-bit trees as the fundamental string-set data structure (p. 1498) 2013-05-17 (3 minutes)
• Critical defense mass (p. 2170) 2013-05-17 (14 minutes)
• Cycle sort (p. 2344) 2013-05-17 (1 minute)
• How can we usefully cache screen images for incrementalization? (p. 1077) 2013-05-17 (18 minutes)
• Dollar auctions and tournaments in human society (p. 884) 2013-05-17 (7 minutes)

Comb filtering PWM

Kragen Javier Sitaker, 2019-10-28 (4 minutes)

A phase-correct PWM signal has a lot of its energy at the fundamental PWM frequency and, typically, more at its harmonics --- though *which* harmonics depends on the duty cycle it's producing at the moment. A unity-gain feedforward comb filter has nulls at a fundamental frequency and its harmonics --- if the gain is negative, then it has a null at DC and at all multiples of the fundamental, while if the gain is positive, then it has a null at only odd multiples of the fundamental (and a gain of 2 at DC).

Typically the PWM harmonics are thought of as undesirable noise on the PWM signal. The good news is that, at a constant PWM output level, *all* of the PWM noise is at these harmonics; so, if we could notch them out, PWM could perfectly reproduce our desired output voltage or current.

There are many ways to do this, but in particular I wanted to explore using transmission-line comb filters. A transmission line leading to an open circuit will feed a delayed copy of its input back to that input; this is a unity-gain feedforward comb filter. A 10-meter coaxial transmission line with a typical propagation speed of 0.5*c* will add a signal delayed by about 130 ns to its input.

(I'm a little bit vague on exactly how this needs to be hooked up in a circuit to get the desired effect, in particular for a high-power signal where efficiency is important.)

Suppose that your PWM frequency is 7.5 MHz, carefully locked to this delay. Then the transmission-line comb filter will cancel the first, third, fifth, seventh, and higher odd harmonics from the PWM signal, leaving only the even harmonics.

If this filter can be cascaded with a second similar filter made with a 5-meter coaxial transmission line, that will cancel the second, sixth, tenth, and higher 2*odd harmonics from the PWM signal, leaving only the harmonics divisible by 4.

A third such filter made of 2.5 meters of such line will cancel the remaining harmonics not divisible by 8: 4, 12, 20, 28, and so on.

A fourth such filter made of 1.25 meters will cancel the remaining harmonics not divisible by 16: 8, 24, 40, and so on.

At this point the first 15 harmonics of the PWM signal have been perfectly reactively canceled; the first unfiltered harmonic is the 16th, at 120 MHz.

By adding a delayed copy of the PWM signal to itself four times, we can make a stairstep approximation of the desired signal, with I think any of $3^4 = 243$ different voltage levels; there is a small remaining amount of quantization noise remaining at 16 and more times the PWM carrier frequency.

Ten-meter-long delay lines might sound impractically large, but Horowitz & Hill tell us that old oscilloscopes commonly used a dual-core coax with two signal lines in a double helix inside the outer shield; the signal propagation along the helix was what you would normally expect for signal propagation along a normal coaxial cable center. If this helix were 20 mm in diameter and the coiled wire were 1 mm wide (including insulation), each 2 mm of delay line would

provide 31.4 mm of delay, so 10 m of delay would fit into a length of only 640 mm.

How would you maximize the energy density of a capacitor?

Kragen Javier Sitaker, 2016-07-27 (5 minutes)

How would you maximize the energy density of a capacitor?

This is the formula for capacitance:

$$C = \varepsilon A / d$$

That A/d is "area over distance". So permittivity $\varepsilon = C d / A$, which means it has units equivalent to farads per meter. Specifically, $\varepsilon_0 \approx 8.85$ pF/m. A farad is a joule per square volt.

The energy content of a capacitor at a given voltage V is $E = CV^2/2$; its maximum energy capacity is $CV^2/2$ where V is its maximum voltage.

Permittivity, then, is one characteristic of a dielectric that determines the energy capacity of the capacitor. Energy stored scales linearly with permittivity; double the permittivity means double the joules per square volt. The other relevant characteristic is its dielectric strength, which is measured in volts per meter; when the field strength reaches its dielectric strength, you get avalanche breakdown and your capacitor is, usually, destroyed. Energy capacity is quadratic in dielectric strength: twice the dielectric strength means that an otherwise-unchanged capacitor can withstand twice the voltage, and thus contain four times the energy.

The maximum voltage is $V = d S$, where S (a variable name I just made up) is the dielectric strength (or "breakdown field" or "breakdown voltage") of the dielectric.

So the energy capacity of a capacitor is proportional to the square of the dielectric strength and of the permittivity of its dielectric. What else does it depend on?

Well, clearly it depends on the area of the plates and the separation between them, since those are also factors in the capacitance. It would seem that you can make your capacitor arbitrarily large in capacitance by making its plates bigger and closer together, and indeed real-world capacitors range over 12 orders of magnitude of capacitance, of which almost all is due to variations in these factors. You eventually run into a limit in capacitance once your dielectric layer is only a few atoms thick, as in double layer capacitors.

But, holding the dielectric *volume* constant, the area of the plates and the separation between them doesn't affect the *energy capacity* at all!

Consider how the energy capacity varies with plate area and plate separation.

As I said before, the maximum energy capacity is $E = CV^2/2$, where $V = d s$. So this works out to

$$E = d^2 S^2 \varepsilon A / 2d = d A S^2 \varepsilon / 2$$

Now d A is just the volume of the dielectric! So for a given volume of dielectric, it doesn't matter whether you have a high-voltage, low-capacitance capacitor or a low-voltage, high-capacitance one; the energy stored is the same. And $S^2 \varepsilon / 2$ gives you the energy per unit volume!

That means that, for example, air has a dielectric energy capacity of

about 40 joules per cubic meter (½(3 MV/m)² · ε_0/2), while glass, with a relative permittivity of 4.7 and dielectric strength of about 10 MV/m, can hold ½(10 MV/m)² · 4.7 · ε_0 ≈ 2000 joules per cubic meter. Tantalum pentoxide has not only a remarkable relative permittivity of about 25, but also a dielectric strength of 400 MV/m, giving about 18 MJ/m³. (And that's half of why tantalum capacitors explode when you overload them. The other half is that most tantalum capacitors are made of an explosive mixture of manganese dioxide and tantalum.)

Diamond's dielectric strength is supposedly 20 MV/cm, or 2000 MV/m, and so even at its lower relative permittivity of 5.7, diamond-dielectric capacitors should have a higher energy density of 100 MJ/m³. Diamond dielectrics are not in current use, perhaps because as a semiconductor, even slight impurities give it unacceptably high conductance. (Or perhaps even without them? I'm not sure.)

More typical dielectrics include PZT (relative permittivity 300–5000, dielectric strength 10–25 MV/m), mica (relative permittivity 3-6, dielectric strength 118 MV/m), and fused quartz (relative permittivity 3.75, dielectric strength 30 MV/m).

Summarizing:

material	relative permittivity	dielectric strength (MV/m)	energy density (J/ℓ)
air	1	3	0.04
glass	4.7	10	2
fused quartz	3.75	30	15
PZT (low)	300	10	130
mica	3-6	118	250
PZT (high)	5000	25	14000
tantalum oxide	25	400	18000
diamond	5.7	2000	100 000

PZT is a little weird because its breakdown behavior is very time-dependent, and in a temperature-dependent way. Water, which I didn't include in the table, is even more so; it has a very promising relative permittivity of around 80, but its breakdown voltage goes to zero as time goes to infinity — eventually, apparently, a streamer will form through the water and discharge your capacitor. There are nevertheless water-dielectric capacitors in use for special purposes such as particle accelerators.

It's instructive to compare the capacitive energy densities above with more typical bulk energy storage systems: gasoline is 36 MJ/ℓ, lithium batteries are 4.3 MJ/ℓ, and lead-acid batteries are 340 kJ/ℓ. The above table suggests that diamond-dielectric capacitors might be in the ballpark of lead-acid batteries for energy storage.

The bottom line is that, among the solid capacitors commercially available today, tantalum capacitors offer an order of magnitude higher energy density for long-term energy storage.

The history of NoSQL and dbm

Kragen Javier Sitaker, 2017-04-10 (16 minutes)

The current fashion of "NoSQL" key-value stores reminds me that Unix has shipped with a NoSQL key-value store since Seventh Edition Unix in 1979, written by Ken Thompson and called dbm. Dbm files are on-disk hash tables mapping strings to strings, and they are used by many Unix programs — Sendmail and Postfix, for example, support storing arbitrary tables related to mail delivery in dbm files, and Apache supports using dbm files for many purposes. They're supported by a dbm library, which generally only works properly if at most one program has them open at a time. You don't normally connect to a "dbm server", but rather open the file and lock it.

History

The 1979 dbm interface looks like this, in modern ANSI C parlance:

```
typedef struct { char *dptr; int dsize; } datum;
int   dbminit  (const char *name);
int   store    (datum key, datum content);
datum fetch    (datum key);
int   delete   (datum key);
datum firstkey ();
datum nextkey  (datum key);
int   dbmclose ();
```

(Adapted from the GDBM docs.)

This is very simple, and it's easy to figure out how to use it, aside from an allocation issue I mention below, but you can perhaps see some problems right there in the interface — not only do `store()` and `fetch()` and the like not have a namespace prefix, making it easy to have collisions with your functions, but also they don't have a parameter to tell you which dbm file to access! That means you can only have one dbm file open at a time in a single process, but on the PDP-11 that V7 Unix ran on, the process's entire address space was only 64KiB, so you couldn't do too much in one process anyway.

The dbm file uses a scheme called "extendible hashing" to allow the on-disk hash table to grow smoothly as data is added to the file, though in a way that requires the underlying filesystem (and your backup programs!) to handle sparse files efficiently.

The original dbm was more or less replaced with Berkeley ndbm in 1986, which solved those interface problems, but, as I understand it, still used the same limited disk file format. Other more or less enhanced clones included sdbm (1987), GDBM (1990–2002), Berkeley DB (1991 to present), QDBM (2000, QDBM's successor Tokyo Cabinet, TDB, its variant ntdb, tdbm, Larry McVoy's memory-mapped MDBM (significantly enhanced this millennium by Yahoo), and a pure-Python implementation called dumbdbm.

In the original dbm interface, it isn't obvious from the API where the buffer space for the fetched data comes from, and in particular

when it will be reused — in GDBM, at least, it's `malloc`ed, and the caller must free it, even if they only cared about testing whether the key is present or not. But that would be an unlikely thing for 1979 Unix to do (it was very shy about dynamic allocation) and GDBM's compatibility ndbm interface frees it for you on the next call, whether you like it or not. I infer that probably dbm and ndbm returned you a pointer to a static buffer. And, indeed, we can see the fetch function in 1979 dbm doing exactly that; `pagbuf` is a static buffer defined (!) in `dbm.h`.

cdb

One dbm replacement is particularly interesting, because instead of being an enhanced version of dbm, it was a deliberately more limited version.

When Daniel Bernstein decided to write a secure replacement for Sendmail in 1995, called qmail, he was faced with the problem that existing C libraries were full of unreliabilities, poor performance, and security holes, just like Sendmail itself. He solved this problem by writing replacements for all of the standard C library functionality that he needed, from scratch, without any functionality he did not need, and without bugs. One of the things he needed was a rough equivalent of dbm, but he did not need dbm's ability to incrementally update an existing database. So the qmail equivalent of dbm is called "cdb", "constant database", and it consists of 329 lines of C. The read interface consists of these two functions:

```
int cdb_seek(int fd, char *key, unsigned int len, uint32 *dlen);
int cdb_bread(int fd, char *buf, int len);
```

`cdb_seek` returns 1 if `key` of length `len` is present in the file open on file descriptor `fd`, 0 if not, and -1 on I/O error, storing the length at `dlen`; `cdb_bread` then reads the corresponding value, if desired, into `buf`, returning -1 on error, including truncated files, or 0 on success.

Rather than using the extendible-hashing algorithms used by dbm, the cdb file is always divided into 256 hash buckets, described by a 2KiB table at the beginning of the file, whose format limits it to 4GiB. And the code to generate the file builds a hash table with separate chaining in memory, then writes it to the file once insertion is complete.

cdb is less featureful and presumably less performant than other variants of dbm, but because it likely has no bugs and is only about 2 kilobytes of executable code, it may be preferable at times.

Language integration

Perl 4 had native support for dbm files, and a lot of websites that graduated from storing their data in static text files started to use dbm files instead. Perl 4 was the first widely-used garbage-collected language; most of the shift from static websites to web applications in 1994 and 1995 was implemented in Perl, and many sites still didn't have Perl 5 installed.

Python, too, has shipped with support for dbm files for a very long time.

Why not just use a filesystem directory?

You might reasonably ask why people used dbm files, which after all merely map sequences of bytes to sequences of bytes, when the filesystem already performs this function. The reason is that, at the time, most Unix filesystems still used sequential search in filesystem directories for filenames, and as a result, directories with more than a few dozen files in them started to get slow. If you are going to maintain a table and then sequentially search it, you can just use a text file for that. (And Unix does, all over the place.) Also, in most Unix filesystems, files take up at least 256 bytes or so.

The Pick operating system and the ReiserFS filesystem for Linux were based on making the normal filesystem apt for this kind of purpose, rather than trying to build the facilities in userspace. Various forms of Pick are still around, but ReiserFS ran into performance limitations in the Linux system call interface, then lost its influence after Hans Reiser murdered his wife in 2007 and was not able to effectively lead the project from prison.

The filesystem interface requires at least three system calls to get the contents of a file: open(), read(), and (in the steady state, anyway) close(). Even today, Linux system calls require on the order of a microsecond, about 300ns on my machine, so about 1 µs for the three put together, which will limit you to about 300k such file reads per second on a single thread. By comparison, MDBM can manage about 450 ns per random read. One of the last controversial projects of Reiser's company was a system for batching up a whole sequence of Reiser4 operations into a single system call.

Why not SQL?

So we used dbm files for all kinds of things, including things where a relational database would worked a lot better. You might wonder why we didn't just use relational databases.

The problem is, there were no decent free software SQL databases. University INGRES was, as I recall, available, but it had its own query language ("QUEL") and didn't support SQL; its development had ended in 1985, though Wikipedia tells me that Sybase and Microsoft SQL Server were developed from that codebase. At Berkeley they were developing Postgres, which was licensed to Illustra about 1994 as an "object-relational database," and eventually sold to INFORMIX, but Postgres was slow and unreliable, and it didn't support SQL either, yet — its query language was a thing called "POSTQUEL". SQLite and MySQL and MariaDB and even Gadfly didn't exist yet.

A lot of people did build web sites and things with SQL database backends, including well-known companies like Amazon and eBay and lesser-known companies like ArsDigita, which was in many ways the prototype for Google. But they had to license proprietary databases to do it.

There was additionally the problem that relational databases were very heavyweight, like Cassandra today — you couldn't run them at all on a low-end machine, and you universally had to run them in a separate process and connect your app to them via IPC — sockets or whatever. (This was partly ideological. As Stonebraker said in the original Postgres — excuse me, POSTGRES — paper, "DBMS code must run as a sparate process from the application programs that access the database in order to provide data protection.") You

probably had to have a separate machine to run the database server on, a workstation or maybe a tower-case PC. This kind of nonsense meant that there was no possible way to use . This may be hard to imagine now that most cellphones have dozens of SQL databases in them (mostly SQLite) but consider that, even today, starting up `sqlite3` linked with glibc and opening a database, you're already using 27 megs of virtual memory:

```
USER       PID %CPU %MEM    VSZ   RSS TTY      STAT START   TIME COMMAND
user     26485  0.0  0.0  26916  3728 pts/3    T    01:47   0:00 sqlite3 hello.d
```

Until the DRAM price bubble burst in 1995 or 1996, DRAM cost US$40 per megabyte for years due to collusion in a cartel of DRAM manufacturers, so that was about US$1000 worth of memory.

(This level of bloat is probably mostly glibc's fault. The sqlite3 binary and library are under a megabyte.)

In 1994, David Hughes in Australia sparked a revolution by writing a simple SQL database he called "mSQL" (for "mini SQL") and releasing it with source code, but not as open source — it was "free for noncommercial use" only. In 1995, he founded a company he called Hughes Technologies to commercialize it. But that's another story, so I am going to return to talking about dbm.

Crash safety

In the environment Unix grew up in, a power loss was a catastrophic event, similar to a disk head crash, a datacenter fire, or a memory corruption bug in the kernel. Some other operating systems had crashproof filesystems which were designed not to lose data in the event of power loss, but Unix did not, and indeed this was one of the desiderata in the original plans for the GNU system — GNU would be better than Unix because its filesystem would have versioning and be crashproof.

Corrupting your filesystem and losing files on power loss was still common in Linux up until about 2004 or 2005, at which point ext3fs and other journaled filesystems put an end to that problem, for the most part.

Nowadays, by contrast, it is very common for Unix machines to lose power — their batteries may run out, or you may drop them on the sidewalk and joggle the battery out of touch with the contacts. By contrast, memory corruption bugs in the kernel and cellphone fires are vanishingly rare, and SSDs have no moving parts and therefore don't have head crashes.

However, if there are consistency constraints inside some file that is being written to in random places, it's possible for an inconsistent, acausal snapshot of that file to be what survives. Unix provides an `fsync()` system call to limit the possibilities for such inconsistencies — it doesn't return until all the data for the file in question is safely saved on disk. This guarantees two relevant properties:

- If `fsync()` returns and the program takes some action afterwards, such as displaying a user interface message or sending a packet over the network, then if we observe this action, then we know that the data written before `fsync()` will not be lost.
- Either all data written before `fsync()` is preserved, or no data written

after `fsync()` is preserved, or both. It is never the case that some data written after `fsync()` is preserved, while some data written before `fsync()` is lost. That is, `fsync()` serves as a "write fence".

Property #2 is necessary to guarantee the atomicity and consistency properties of transactions; property #1 is necessary to guarantee the durability property of transactions.

However, because property #1 is very expensive to provide, especially on spinning-rust disks, it is very common that programs do not bother. There was a great deal of controversy a few years back over MongoDB doing this in order to get better performance numbers, but you will of course see that the MDBM numbers I cited earlier are taken under the same conditions, and the GDBM manual explains:

…the following may be added added to `read_write` by bitwise or: `GDBM_SYNC`, which causes all database operations to be synchronized to the disk, and `GDBM_NOLOCK`, which prevents the library from performing any locking on the database file. The option `GDBM_FAST` is now obsolete, since gdbm defaults to no-sync mode.

…

Unless your database was opened with the `GDBM_SYNC` flag, gdbm does not wait for writes to be flushed to the disk before continuing. The following routine can be used to guarantee that the database is physically written to the disk file.

```
gdbm_sync ( dbf )
```

It will not return until the disk file state is syncronized [sic] with the in-memory state of the database.

Unfortunately, because omitting `fsync()` endangers not only property #1 but also property #2, it is entirely possible for a GDBM file to be corrupt after a power outage. In the case of GDBM, although I haven't verified this, I think this means that some previously stored data that wasn't being modified could be irretrievable, but not necessarily all of it.

Worse, making this work properly typically involves inserting an `fsync()` as a write-fence in the *middle* of a sequence of write operations. Doing an `fsync()` at the end can ensure that, if the execution gets that far, the data stored is not lost; but it cannot ensure that a power failure at some other point does not leave the disk file in an inconsistent state.

An extremely simple electromechanical state machine

Kragen Javier Sitaker, 2014-04-24 (16 minutes)

As I was walking out my door earlier tonight to get an empanada, I noticed that the keys had left a mark by brushing against the paint on the door, and I thought, wow, I can make pretty intricate patterns in brass entirely by accident this way. Wouldn't it be awesome if we could somehow just *draw* a computer as a two-dimensional pattern on paper and have it work?

And it occurred to me that it *is* actually practical to simply draw a state transition table and have a simple electromechanical machine implement the state machine you specified. Here's the idea.

The idea (here)

Suppose you want to implement an arbitrary finite-state machine with a minimum number of "active" electronic elements (things like vacuum tubes or transistors). Here's an interesting approach, sort of inspired by Shamir's TWINKLE.

You maintain your current N-bit state in N flip-flops with complementary Q and /Q outputs; typically each flip-flop requires one or two vacuum tubes, or a locking relay, or two to six transistors, depending on your logic family and other details. You hook up the Q and /Q outputs to lamps: these days, you would surely use laser diodes or other LEDs, but in the 1940s timeframe where this scenario makes the most sense, you'd have to use something else, maybe neon lamps. The lamps give you a matrix of N rows of two lamps, one of which is on at any given time.

A reasonable value for N here might be 3 to 20.

Now you put these lamps close to a strip of paper. The lamps reflect diffusely off the paper and illuminate the environment. If there are dark blots on the paper under an illuminated lamp, that will diminish the overall illumination reflected from the lamps.

With a lens per lamp --- not necessarily a very good lens --- you can do this trick with the lamps some distance from the paper. The idea is that each lamp just illuminates a corresponding spot on the paper.

Suppose the paper is a vertical strip, divided into rows of two squares, one square for each lamp; and just as one of the two lamps in each row is lit, one of the two squares in each row is light, while the other one is dark. Now the illumination reflected from each row is the XOR or XNOR of a bit of our state and the corresponding bit on the paper. If we slide the paper vertically, the illumination will fluctuate with time as the Hamming distance between the current state and the selected subset of the bit pattern on the paper varies.

Now, instead of sliding bits of paper around, we can wrap this strip of paper around a rotating drum. As the drum rotates, the number of matching bits on these two tracks of the drum will vary, and so will the reflected light. It will reach a minimum when every lamp is illuminating a black area.

How small is that minimum? Asphalt has a visible-light albedo of

0.04; I think carbon black is a little darker than that. Polished aluminum has a reflectance of about 0.95, although I think it gets a little worse when unpolished. But basically we can have a contrast ratio of about 20 or 25 between black and white on paper without doing anything exotic. That means that if you have 5 bits and all 5 of them match, you'll have about $0.04 \times 5 = 0.2$ of the light from one bit; while if only 4 match, you'll have $0.04 \times 4 + 0.95 \times 1 = 1.11$ of the light from one bit, about 4½ times as much. So this is an easily detectable event: the ratio between a perfect match and a near match is about a factor of 4. You should be able to detect this event with a photodiode or even an electric eye.

Suppose that an adjacent track of the drum carries another pattern of bright and dark squares, containing desired new states for your flip-flops. If you have more lamps and photodetectors close to it, one per bit, they can read the pattern without leaking much light into the environment.

Now, as the drum turns, the apparatus searches for a matching state on the drum; when the reflected light level falls to a minimum, it knows it has found it, and it loads the specified new state into the flip-flops from the other track. It's probably desirable for the "pattern" bits being matched on the track to be somewhat short, so that the new-state bits are well centered under their detectors by the time the detector fires, as follows:

```
 Q /Q  newstate
--     ##
   --
   --  ##
--     ##
```

You probably do need a mechanism that prevents a misaligned match: say, N-1 bits of one pattern and 1 bit of the following one. One way is to have an extra framing "bit" that is always illuminated on both sides, marking the paper dark on both tracks:

```
 Q /Q  newstate
--     ##
   --
   --  ##
--     ##
-----
```

Alternatively, you could just space the rows unevenly, or even leave a fractional-row-sized space between patterns.

The (N+1)×3 arrangement described above is just one of many possibilities. You could just as well put all the bits on one track, and the lamps in a line; or you could put each bit in a separate track, producing 3N tracks and one bit-height per pattern, which is probably the highest-performance option; here we have three transitions:

```
Q1 /Q1 Q2 /Q2 Q3 /Q3 Q4 /Q4 Q1' Q2' Q3' Q4'
--        --  --     --     ##  ##  ##
--        --  --         -- ##  ##  ##  ##
--        --     --      -- ##  ##
```

Simple latches, without edge-triggering, probably suffice for the flip-flops, because each transition will be either to the same state or to a different state. If it's to the same state, it's idempotent, so it's harmless to execute it continuously until the marks pass; and if it's to a different state, then it will execute until the lamps display enough of the new state that the light level rises above the level that triggers the state-transitioning logic. You just have to be careful that the transition is sufficiently well-established that all the bits have changed as they should, and none is left in a metastable state.

Further variations

• The natural approach to arranging the patterns on the drum is just to put them in numerical sequence, evenly spaced around the drum, so that you execute about two transitions per revolution. But you can also repeat them so that some transitions have the opportunity to execute many times, and so that transitions that happen in sequence are placed in sequence, and of course you can repeat the entire sequence of transitions. Furthermore, you can use the drum position as an additional, less flexible state variable, so that the entire state machine cycles through different transition graphs.
• Of course, one or more of the bits used to select the pattern can actually be an input, rather than a stored bit. You probably want to make sure the input doesn't change while you're using it to choose your next state; you can sample-and-hold it, or use an actual edge-triggered flip-flop, if it can change state arbitrarily.
• It's possible to encode "don't care" bits by coloring both sides of the pattern bit, potentially reducing the number of patterns dramatically.
• If you have both "new Qi" and "new /Qi" bits on the paper, you may be able to simplify the transitioning logic to simply illuminating them when the reflected "pattern" light falls below the threshold. That is, the nonlinear element that switches between retaining the existing state and adopting a new one can be simply the power supply of the lamps illuminating these bits.
• If you have both "new Qi" and "new /Qi" bits as described above, you have the additional option of *not* switching some bits, allowing them to retain a memory independent of the state transition being executed; this can allow a dramatic reduction in the number of transitions by, among other things, allowing you to preserve "don't care" bits, and allowing different subsets of the state independently.
• Your state variables don't need to be binary --- they can have more than two stable states. Indeed, ternary variables will give you slightly more states for patterns of the same size, and may be more convenient to work with; and quaternary variables (one-hot out of four) will give you patterns of the same size, but half the lamps illuminated, and so they may be easier to do the threshold logic with.
• You can use a tape or disc rather than a drum for a more compact machine.
• For a better contrast ratio and fewer materials, you can use punched or drilled holes rather than marks.
• You could use the state where all of the bits are *reflected* (or transmitted) instead of all *absorbed* as the trigger state, but I figured that was probably harder, since the difference between

almost-all-bits-reflected and all-bits-reflected will be, say, 10% to 33%, which will be harder to discriminate reliably than the 350% or more between almost-all-bits-absorbed and all-bits-absorbed.
• Rather than using diffuse reflection and absorption, you could use specular reflection of collimated light and diffuse reflection. For example, if you're using something like a hard disk platter, a scratched or etched spot in its surface will scatter light at random, while an untouched spot will produce a collimated reflected beam from a collimated incident beam.
• If you have an additional hardware budget, you could of course replace the pattern tracks and the light detector with a counter circuit and digital comparator, leaving only the new-state tracks and a timing mark for restarting the counter.
• If you do the whole thing in a hard vacuum, you could use electron beams instead of light, which might make it faster, depending on your light source. You'd have to use an unlubricated bearing to spin the drum if you were doing this on Earth.
• Of course you can connect some of your state bits to control some other device, such as a memory, which would then provide some of the input bits.

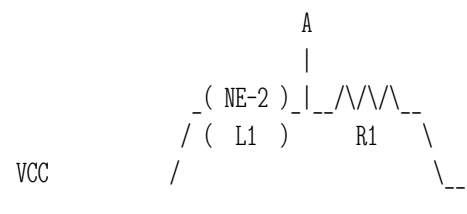
What this gets you

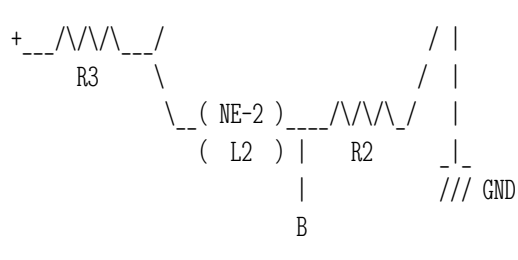
If N=4 plus one bit of input, this should give you an arbitrary sixteen-state state machine for the cost of somewhere around five to forty active elements, depending on what they are; and its speed should be limited to something like one transition per sixteen times its lamps' response time. That is, if your indicator lamps respond in 100ns, you should be able to do an arbitrary transition in 1600ns. This is dependent on actually testing a pattern every 100ns; at 5400rpm and a radius of 4cm, your patterns will need to be about 2 microns across, which means your lamps' illumination spots will need to be about that size too, and you might need to make sure they were aligned to within that precision, too. 200 microns is probably more practical if you want to be able to construct the thing without resorting to a microscope, and you can probably spin a 40-cm-radius drum at 5400rpm, practically speaking, giving you a microsecond per candidate phase transition.

The great disadvantage of this approach is that the state machine's real-time performance is fairly poor, so it can't interface directly with things like delay lines unless they're very slow indeed.

A potential 1920s realization using only neon glow lamps

I think that if you accept some further slowdown, although not quite to the level of magnetic relay logic, you can build it with a couple of 1920s neon glow lamps for each flip-flop. I haven't really played with the things, but I think that this topology gives you a flip-flop:





If "VCC" is above the striking voltage of the lamps (say 110 volts), then either L1 or L2 will ionize and start to conduct at about three milliamps; at this point the voltage across it will drop, to about 70 volts IIRC, and if enough of the remainder is dropped across R3, the other lamp will not ionize. You can measure the voltage at points A and B to see which lamp is conducting; the other one will be at zero volts. And if you apply a sufficient positive voltage at A (anything from about 50 volts up to not too far above "VCC"), you can get L1 to stop conducting if it's conducting beforehand, ensuring that L2 is conducting afterwards; and likewise for B.

This might avoid the need for separate indicator lamps, but NE-2s are pretty small, dim, and red, so your light detector has to be pretty good. However, there are other neon glow lamps that work the same way that produce more light. In extreme steampunky cases, you could perhaps even use a carbon arc lamp, which displays more or less the same bistable negative-resistance behavior that neon glow lamps do, so much so that the Pearson arc oscillator used it to power an RF oscillator circuit.

This flip-flop can be extended to multiple branches; as I sort of mentioned before, three alternatives gives you slightly better efficiency than two; six lamps in two three-branch circuits of this type can encode nine alternatives, compared to eight if they're grouped into three two-branch circuits.

So how do you connect a high voltage to A or B when one of the next-state bits gets illuminated? In today's world you'd probably amplify a signal from a photodiode to trigger a triac or SCR or something. But using neon lamps? They're slightly light-sensitive, and in their negative-resistance region, capable of amplification, so theoretically this ought to be possible, but I don't know enough of the details.

You do have the advantage that the light from the "new state" bits can be as strong as you like (although only 20 or 25 times stronger than their dark counterparts), since you're just turning the light source off when you're not transitioning to a new state, so let's suppose that we can do it with three resistors and two neon lamps for each of A and B. That means each of our N=4 bits of state consists of 6 lamps and 9 resistors, for a total of 24 lamps and 36 resistors; our bit of input requires perhaps two lamps and two or three resistors.

That leaves only the problem of detecting the darkness that triggers the transition and firing up the transition circuits. I'll guess arbitrarily that that will need five more lamps and eight more resistors, for a total of 29 lamps and 44 resistors.

It's also feasible to use electromechanical relays, of course. Modern mercury-wetted reed relays can run up to 40kHz. But they can't detect light; for that you need an electric-eye vacuum tube at least, if not an avalanche gas tube.

Sun cutter

Kragen Javier Sitaker, 2016-09-06 (9 minutes)

Could you replace a laser cutter with a focused-sunlight cutter?

I mean obviously you can burn through things with focused sunlight — I've been doing it since I was a kid — but I'm asking if you can match the performance of off-the-shelf low-power laser cutters.

The laser cutter I've been using to cut MDF cuts a 100-µm kerf positioned with 60-µm precision using a 60W laser through 3-mm MDF at 24 mm/sec, although it can handle up to I think 12 mm at lower speeds. If we figure that the divergence of the beam can't be more than about 50 µm over those 3 mm, that's about a sixtieth of a radian, 16.7 mrad, almost twice the visible width of the sun, which is about 9.3 mrad.

Optics won't work

So there are two problems here: one is to focus, say, 100 W of sunlight in an area that's less than 100 µm across, and the other is to keep the divergence of that focused beam down below, say, 10 mrad.

The very direct approach is to use a single movable parabolic reflector at a sufficiently large distance. But this will not work very well. 100 W is about 0.1 m² of sunlight at the surface, a mirror of 357 mm diameter; this is 10 mrad at a distance of 35.7 m. A geometrically-perfect image of the sun at that distance would be 9.3 mrad, which would make a 332-mm-wide image of the sun, which is substantially larger than the 0.1 mm we are shooting for.

This amounts to a spot that is 3½ orders of magnitude too wide and is 7 orders of magnitude too dim.

Getting a smaller and thus brighter image from an imaging-optics system involves shortening the focal length, as all photographers know. The desired power density here is 10 GW/m², which is (not totally coincidentally) 7 orders of magnitude brighter than sunlight.

This is somewhat problematic because the illuminance limit imposed by thermodynamic reversibility is for the focal spot to be entirely surrounded by (reflected or refracted) sun surface, that is, 4π steradians of sun. A 9.3 milliradian cone has a solid angle of about 0.27 millisteradians ($2\pi(1 - \cos(9.3\text{ mrad}))$), and so the theoretical maximum is only about 46000 suns, with 23000 suns being the limit for a point on a flat surface only being illuminated from outside the surface. This is still three orders of magnitude dimmer than the laser — and without even being pulsed!

Therefore even non-imaging optics can't help us here. We need stronger stuff than mere optics.

One possibility is to concentrate the light optically as far as possible, then use some other approach to deliver the power to a small area. We don't actually have to violate any laws of thermodynamics to do this; the MDF doesn't have to get hotter than the surface of the sun (5500°), and we don't have to deliver all of the energy to it, but can waste some in pumping heat around. One obviously feasible approach is to use photovoltaic panels to power the existing electric CO_2 laser, but are there more direct routes, maybe more efficient ones?

Hot fluid flow

One obvious (to me) example is to use the sunlight to heat a fluid to a sufficiently high temperature and then cause the fluid to flow through the MDF. Air is one possibility, although it might tend to catch the MDF on fire even more than the laser does. Lead, which doesn't dissolve much iron and doesn't boil until 1749°, is another possibility; at higher temperatures, copper, which doesn't melt until 1084° but doesn't boil until 2562°, or silver, which melts at 962° and boils at 2162°, might resist oxidation better. (Molten silver, however, has a tendency to attack steel.)

Air is probably going to be too difficult

How fast could air deliver power? Suppose the hot air stream is limited to 1600° in order to be able to use ordinary ceramics to control it; air's specific heat is 29.2 J/K/mol, and it weighs about 30 g/mol. Let's suppose that the MDF cools the hot air down to about 500°, so we have 1100 K to play with. Delivering 60 W then requires a flow of about 1.9 millimoles per second, which works out to about 56 mg/s, which would be 56 mℓ/s at normal temperatures — but at 1600° it's more like 360 mℓ/s. Dividing that by the area of a 50-µm-radius circle, we get the utterly implausible air speed of 46 km/s, roughly Mach 138.

(I would have liked to use metals, but even superalloys are limited to about 1000°.)

If we relax the requirements considerably, we can get into a feasible range; suppose that we make our air nozzle out of white-hot quicklime instead of regular ceramics, so that we can use air at 2600° (reducing the flow rate to 290 mℓ/s), and make the air stream 1 mm in diameter instead of 100 µm. Then we can get the air speed down to 370 m/s, Mach 1.1, which is probably feasible. (Turbulence in the nozzle just transforms into more heat in the air!) A slightly wider nozzle of 1.35 mm diameter can get your gas stream speeds down to 200 m/s, which is quite clearly feasible. But if you're blowing white-hot air on it, it's going to be really difficult to keep the MDF from catching on fire; you probably need an inert-gas atmosphere, nitrogen at least, which probably means you need to filter and recirculate it.

Lead is more feasible

Molten metal is probably a much more feasible approach; even at room temperature, it's about ten thousand times as dense as air, and that advantage increases with temperature rather than decreasing.

Lead's vapor pressure is a still-relatively-safe 10 Pa at 814° (an atmosphere is 101 kPa). Tin is a more expensive but nontoxic alternative with an even lower melting point (232°), an even higher boiling point (2602°), and an even lower vapor pressure; I think it is more vulnerable than lead to oxidation in air. The eutectic 63%-tin mixture of the two melts even lower.

If we figure that we can work from 900° down to lead's freezing point of 327°, then take advantage of its 4.8 kJ/mol heat of fusion, how much lead flow do we need? Its molar mass is 207.2 g/mol, so that's 23 kJ/kg of latent heat of fusion. Engineering Toolbox says molten lead's heat capacity is 140 J/kg/K, and we have 573 K here, so that's 80 kJ/kg of sensible heat. Together, they're 103 kJ/kg, so our

flow rate is only 580 mg/s; with molten lead's density of about 10.7 g/cc, that's only 58 microliters per second of lead.

Through a 100-micron-diameter circle, that's still 7.4 meters per second, which is some pretty healthy metal pumping action; I don't know what molten lead's viscosity is, but that won't be easy. But it's surely feasible.

Hmm, this IAEA document on nuclear reactor design says lead's dynamic viscosity is about 1 mPa·s in the temperature range considered. A Poise is 100 mPa·s. Water's viscosity at 20° is 1.002 mPa·s, so we can treat lead as especially dense water in this temperature range. This document also describes in some detail the physical properties of the lead-bismuth eutectic coolant used in many Soviet reactors. Some random engineering calculator site claims that 1 mm of 0.1 mm-diameter pipe at 58 μℓ/s should result in about 13 MPa of head loss; this is a straightforward pressure to achieve, and it amounts to a force of about 0.1 N across the area of the nozzle, and a hydraulic power of 750 milliwatts.

These numbers are all easily feasible.

Solar-pumped lasers

Another possibility is to use the sunlight directly to pump a lasing medium, such as a doped fiber; this is called a "solar-pumped laser", and there are apparently a number of them around, mostly Nd:YAG, including a megawatt one in Uzbekistan (!).

Making the CPU instruction set a usable interactive user interface

Kragen Javier Sitaker, 2015-09-17 (8 minutes)

In designing simplified computing systems for bootstrapping, one of the problems is that even once you have built a CPU and RAM, you still somehow need to bootstrap useful software into the thing. At one point this was usually done by entering an "IPL" or "bootstrap" program into the memory one bit at a time using switches, then making the CPU run, but this requires the electronic interface to the CPU and RAM to support such direct manipulation, which complicates it somewhat. Also, it's a terrible user interface.

Somewhat later, machines came with a "monitor program" in ROM, which would use the usual I/O mechanisms to interact with a user and allow them to enter the IPL program using, say, a hexadecimal keypad. The Heathkit H8 was an 8080-based computer that worked in this way. The later H89, which was a miniaturized Z80-based H8 built into an H19 terminal, substituted a terminal-based monitor program. Other PCs of the era were less slavish followers of the minicomputer tradition and typically had Microsoft BASIC in ROM, and would run that initially, sometimes giving you the option to use it to load other binary software from other media.

However, all of these alternatives involve a fairly large amount of ROM and RAM: tens of thousands of bits, if not more. An amount that would take an unreasonable amount of time to solder together out of individual transistors, let's say.

The HP 9100A took a different approach that didn't require a lot of ROM (well, except the 32-kilobit microcode!) or RAM. It was sold as a calculator, a forerunner of HP's later popular line of electronic pocket calculators (beginning with the HP-35), but it was in fact a programmable computer, just with a very small amount of read-write memory: each of its 19 registers was 14 6-bit-wide BCD digits, for 1596 total register bits. This is a very small amount of memory, but the 9100A took full advantage of it by using a 6-bit instruction set, thus supporting programs up to 266 instructions long. (I think. Maybe you couldn't store program steps in the X, Y, and Z registers. Certainly it wouldn't be very useful to do so.)

The more interesting thing about this is that the HP 9100A's instruction set was in fact its keyboard: each keystroke, more or less, executed a CPU instruction. This, plus a simple mode for storing a sequence of keystrokes in memory and an instruction set tailored to support use as a user interface, allowed it to survive without a ROM monitor.

(Unfortunately, both its keyboard and its display were tightly coupled to its processor; there was no mode that allowed a program to interactively process keyboard input, as opposed to processing data entered into memory before it was started, or to display data of its choice on the display.)

This might turn out to be a useful way to simplify bootstrapping a computer: rather than toggle data into its memory with a direct

front-panel memory interface, and then providing it with a RUN/STOP switch and a single-step switch so that you can debug it, you can feed it instructions directly, letting the CPU interact with memory on your behalf.

One possible GreenArrays-like way to do this is to memory-map the keyboard, don't increment the program counter when executing from the memory-mapped part of the address space, and make the standard interactive keyboard-read address blocking, so the CPU halts execution until you send it a keystroke. (You could additionally provide a nonblocking-read location or an is-keystroke-ready location.) This still requires hardware to automatically display CPU registers while the CPU is halted on keyboard input in order to be useful, as well as probably some kind of interrupt to send execution back to the keyboard-read address on manual program cancellation or detected program trap.

I suspect that all of that requires less transistors than a ROM monitor routine!

My current Calculus Vaporis design would not be very usable in such a scheme. Its seven instructions are $, ., -, |, @, !, and nop, of which $ is the biggest problem.

$ includes an entire 11-bit immediate constant. You could replace it with eight separate instructions 0, 1, 2, 3, 4, 5, 6, and 7, each of which shifts the accumulator left by three bits and ORs the appropriate octal digit in. This could almost allow you to use four-bit instructions, which could be packed three per 12-bit word; the other 6 instructions would use 6 of the other 8 opcodes. 9 bits of immediate constant per 12-bit word is very nearly as good as 11 bits, although it would take three times as many cycles; also, you'd get the benefit of much denser other instructions.

This would also require a separate PUSH or DUP instruction to achieve the function currently provided by $ of getting a second item onto the stack. A PUSH0 instruction is probably the best way to do this.

However, the rest of the instruction set is not very usable as it is; it lacks unconditional calls or jumps as well as addition (it has subtraction) and bitwise operations other than NAND (|). All three of these are problems in practice for writing programs for it.

Expanding to a 5-bit instruction set, of which half could still be hexadecimal digits, would provide room for 8 bits of constant in a 12-bit word and also provide instruction encoding space for some of those other operations. (I'd vote for unconditional jump-and-link, addition, NOT, and AND, at least.) It's clear that there's a strong tension between usability and hardware simplicity in this context. A separate return stack would permit passing arguments to subroutines on the stack; a third parameter stack register, as on the 9100A, would allow the evaluation of nested expressions without an intermediate store to memory; and so on.

The "dontmove" design I've been playing with as an archival virtual machine may be an interesting alternative. Instead of a stack with different instructions to perform different ALU outputs, dontmove is nearly a MOV machine — except that the load and store parts of the MOV are done in separate instructions. It has 26 immediately-accessible registers, named with the Latin letters, and 52 instructions that load and store them from its single temporary

register. Of these, five are memory-mapped magic: Aa is byte I/O, Bb is a subtractor, Cc and Dd are a PIC-like indirect access and its pointer, and Ee is the program counter. (Writing to it magically saves the return address in the temporary register, so it's a jump-and-link.). Then you have ten more instructions to multiply the temporary register by 10 and add a decimal digit to it. Conditional jumps are obtained by setting Dd to 4 (Ee) or to somewhere else (such as Ff, which is just a normal location), then storing into Cc.

I suspect that such a machine could be roughly as simple as Calculus Vaporis, but perhaps more amenable to interactive instruction entry at the extremely low levels of complexity we're talking about.

Servoing a V-plotter with a webcam?

Kragen Javier Sitaker, 2017-02-16 (3 minutes)

I was thinking you could use webcam streaming video to provide servoing feedback on a hanging V-plotter. I mean, you could use it to provide servoing feedback for any kind of robot (at least for things that don't need <30ms or so latency) but V-plotters (aka polargraphs, drawbots, wall-plotters, etc.) are particularly promising.

There's a bunch of V-potter videos on YouTube, including some which are just video from a fixed point of view, in real time, without any change in point of view. These are not the most interesting or informative videos to watch as a human being, but they make it possible to test this concept before actually having built a V-plotter.

https://www.youtube.com/watch?v=HU9SaCFnCng shows a deformable, swinging V-plotter, more rapidly than real-time, with changes in lighting in the room, for a couple of minutes.

https://www.youtube.com/watch?v=WyLPpGdfR7s is 5 minutes from a fixed point of view of a somewhat wobbly V-plotter, from a fixed point of view, with lots of texture in the background and a few distractors. Midway through a guy walks in front of the camera, and the lighting changes. Toward the end, the lighting changes again.

https://www.youtube.com/watch?v=i5rxxGuWUo8 has a minute or so in the middle of a somewhat wobbly V-plotter drawing on a shiny whiteboard.

https://www.youtube.com/watch?v=ojcZ7kcklu4 is a sped-up video of a Polargraph drawing Spider-Man, from a single point of view.

https://www.youtube.com/watch?v=aiw3hkDvp-M has about a minute of a Polargraph drawing some classic art, sped up.

https://www.youtube.com/watch?v=qury-oBiURA has another few minutes of a Polargraph drawing. The camera moves a bit toward the end, and lighting flickers throughout.

https://www.youtube.com/watch?v=MbpT907qIHg has a couple of 1-minute-or-so sequences of time-lapse drawing, each from a different points of view. This one uses fishing line for the V, which means the strings won't interfere with tracking.

https://www.youtube.com/watch?v=MG70TvuRU9Y has a couple of 30-second-or-so sped-up segments of a V-plotter drawing from fixed points of view, one with changing lighting.

https://www.youtube.com/watch?v=5z8LTj74uiE is almost a minute of sped-up footage of a V-plotter with a novel design and substantial parallax.

https://www.youtube.com/watch?v=oBOuqLPaEMc is a very short video of a V-plotter made out of a binder clip.

https://www.youtube.com/watch?v=iE7sCiv7VTE is a particularly tricky case: the V-plotter gondola is made from a CD-R, which means that its reflection is almost entirely specular, and furthermore has diffraction rainbows all over it. The video runs in apparently real time for about six minutes.

https://www.youtube.com/watch?v=FmCWx30g7Ks is a

whiteboard V-plotter in real time for about two minutes. It's rather blurry.

https://www.youtube.com/watch?v=jknm5qtgO1A is another blurry whiteboard V-plotter in real time (except for occasional jumps), with conspicuous hanging cables.

https://www.youtube.com/watch?v=u4KyPNoswoA is a V-plotter using a spray-paint can that appears to be using the Hektor constant-speed path-design software. Its speed varies.

https://www.youtube.com/watch?v=OselyTkA6wU seems to be Hektor itself, running in real time for some minutes.

On another topic, https://www.youtube.com/watch?v=ycrGUTGlzik shows the design of the PolargraphSD gondola that keeps its wobble so low. It uses cartridge bearings to pivot the two strings around the precise XY center of the gondola.

Dercuano drawings

Kragen Javier Sitaker, 2019-04-30 (updated 2019-05-30)
(18 minutes)

At this point I've imported 90 notes into Dercuano, and the lack of images of any kind is sort of annoying. My actual, paper notebooks have a little line-drawing "icon" for each note, maybe 10 millimeters square, but often some kind of graphic would help a lot both with visual appeal and with comprehensibility. But my total byte budget of some 5MB, so that Dercuano remains easily downloadable in full, makes this challenging; I need a way to make very compact graphics.

This is related to Dercuano calculation (p. 3135) and Dercuano formula display (p. 495).

Example uses

To take a few of the notes I currently have in Dercuano at random:

Deep freeze (p. 1465) could benefit from diagrams of one or more of the following: 11 tonnes of foods including soybeans; a cutaway freezer with labels for insulation, refrigeration, and passive thermal storage; freezers of different sizes, with different amounts of surface area per unit volume, including a cubic-meter sphere and a thousand-cubic-meter sphere; food stored at the bottom of a 30-meter well; mounds of sand and locally excavated earth; a heat–temperature curve for water, including enthalpy of fusion and vaporization; plots of heat loss versus surface area and insulation thickness; etc. It would also benefit, I think, from a goofy line drawing of a freezer with a smiley face on it. A three-dimensional rotating rendering of a freezer would maybe be a plus, too; and a model whose parameters you could adjust interactively and see the relationships between the other parameters in the neighborhood would be awesome.

Dehydrating processes and other interaction models (p. 3208) could benefit from sketches of user interfaces; from diagrams of the interaction sequences and data flows being discussed, of FlatBuffers or binary array state, and of the timing of sequences; and from illustrations of punched cards and perhaps a dehydrated window or something.

Executable scholarship, or algorithmic scholarly communication (p. 2137) could benefit from a timeline, at least.

3-D printing by flux deposition (p. 466) could benefit from an illustration/diagram of the binder/powder-bed/tray setup, and maybe of some grains being fluxed — generally mechanical things like this really need diagrams; maybe also a temperature scale showing where different mixes sinter and/or melt would be helpful.

IMGUI programming language (p. 103) would benefit a lot from some sketches of the UI components being programmed, and maybe also some diagrams of activation records allocated on the stack and of Golang-style interfaces.

Transactional event handlers (p. 139) would benefit from some timing diagrams showing priority problems, concurrent transactions, transaction conflicts with pessimistic and optimistic synchronization,

and deadlock.

Possible tools

No photos

A thing I've done in the past is to draw diagrams on paper and photograph them. This allows for pleasingly direct feedback during the drawing process, but even with aggressive compression, the resulting image files are dozens of kilobytes each.

No bloated SVGs

The Web standard format for line drawings is SVG — even hand computers running iOS support it now. SVG is super cool; it supports alpha-blending, Bézier curves, gradients, arbitrary affine transforms, some degree of abstraction and reuse, and text. You can do a lot in very few bytes of SVG, and it's a lot more readable and debuggable than PostScript, my pre-SVG favorite. The standard example is probably something like this 78-byte triangle:

```
<svg width="30" height="40"><path d="M 10,10 L 20,20 10,30"
    fill="red"/></svg>
```

An example diagram in handwritten SVG

And I *have* used SVG for diagrams, for example in A mechano-optical vector display for animation archival (p. 3047):

The source code for that looks like this, which is somewhat verbose but arguably not unreasonably so.

```
<svg width="128" height="128" class="diagram m">
<use xlink:href="#burst" transform="translate(128 60.24)" />
<path class="beam" d="M128,60.24 L60,60.24 l-121.1,-992.5" />
<path class="mirror" d="M90.51,128 A90.51,90.51 0 0,0 0,37.49 v90.51" />
<path class="arrow" d="M20,57.49 a70.51,70.51 0 0 1 50.51,50.51" />
</svg>
<!-- SVG for definitions of common things used in embedded SVGs. -->
<svg style="display: none" class="m"><defs>
<marker id="v" overflow="visible" orient="auto">
  <path d="M-8,-4 0,0 -8,4" />
</marker>
<marker id="vv" overflow="visible" orient="auto">
  <path d="M-8,-4 0,0 -8,4 M4,-5 12,0 4,5" />
</marker>
<symbol id="burst" overflow="visible" class="m">
<path d="M0,0 l-16,-16 16,16  -16,16 16,-16  -16,-8 16,8
        -16,8 16,-8  -8,-16 8,16  -8,16 8,-16" class="beam" />
</symbol>
</defs></svg>
<style>
svg.diagram { margin-left: auto; margin-right: auto; display: block }
.m path { stroke: black; stroke-width: .5px; fill: none }
.m .beam { stroke: red }
.m .mirror { stroke-width: 0; fill: #ccc }
.m .arrow { marker-end: url(#v); marker-start: url(#vv) }
```

```
</style>
```

However, you can probably kind of tell from reading that that it was pretty slow to write, and from looking at it that the workflow doesn't really support rapid iteration to get it to look good.

What you can't necessarily tell from looking was that when I added that diagram to this document, it broke the triangle example higher up, so I hacked it not to interfere, and then I had to spend some time debugging incompatibilities between Firefox and Chromium about when they applied certain styles (arguably a bug in Firefox).

SVG's abstraction capability is very limited

That diagram exploits SVG's capabilities for reducing duplication to the maximum, to the point that I had to bring in code from three separate parts of its source document to use it here (and then, as I said, hack them so they wouldn't break other SVGs). It uses a stylesheet with overrides to specify how lines, arrows, and areas should be drawn, and it uses SVG's `<marker>` and `<symbol>` facilities to define graphic elements that can be used many times in the same drawing or across many drawings.

But those facilities, though complex, expensive in terms of syntactic overhead, and hard to debug, are still very limited. You can reuse a `<symbol>` in different places, for example, but not with different line widths or colors. (In theory I think you can, but it doesn't fucking work, at least in Firefox.) You can apply the same style to different pieces of text or different paths, but as far as I can tell, you can't instantiate a rectangular component at different widths in different places, other than by stretching the whole component, including its line widths. The kind of simple constraint satisfaction we routinely apply to HTML with the CSS box model is entirely outside of our reach in SVG.

WYSIWYG SVG editors produce insanely bloated output

On the other hand, the standard tools for generating SVGs produce data that looks more like this:

```
<path d="M 21.789062 16.140625 L 20.332031 15.941406
        L 20.335938 15.742188 L 20.371094 15.53125
        L 20.453125…
```

That's eight significant figures on every coordinate, absolute coordinates everywhere instead of relative, and using diagonal lines instead of H horizontal or V vertical lines even when the relevant coordinate difference is in the fifth significant figure, and also using unnecessary spaces. The extra significant figures are essentially random, so gzip isn't going to be able to compress them, except by noting that, being digits, they only need four bits each.

The problem with this kind of thing is that, even when it's hand-drawn, it mixes the actual desired signal with a lot of random noise which is hopefully imperceptible but still incompressible. The mouse produces, say, 100 positions per second, each with three significant figures in each of X and Y, though the number is smaller

with relative positions. Crudely, that's 6400 bits of data per second, 800 bytes per second, after compression, that can be added to the Dercuano download package.

I launched Inkscape, plugged in a mouse, and drew with the pencil tool for a while. Running Inkscape for 110 seconds, I produced a 54-kilobyte SVG that compresses to 15.6 kilobytes; most of it looks like this (line breaks added for clarity):

```
<path
   style="fill:none;fill-rule:evenodd;stroke:#000000;
          stroke-width:1px;stroke-linecap:butt;
          stroke-linejoin:miter;stroke-opacity:1"
   d="m 94.285714,946.64792 c 7.539686,-3.23129 21.663356,-10.54083
        31.428576,-11.42857 15.99002,-1.45364 19.9212,2.36631
        34.28571,-2.85715 6.00412,-2.18331 11.32674,-5.92773…
```

That is, Inkscape has converted my three-significant-figure mouse coordinates into coordinates with seven to nine significant figures. Just in case. How helpful.

Why this is too much bloat for Dercuano to tolerate

The trouble with this is that 15.6 compressed kilobytes per 110 seconds is 1.1 kilobit per second, and the entire five-megabyte target size for Dercuano — containing many years of notes — would be completely filled with SVG in less than ten hours of drawing time. I've already spent over 20 hours just getting the first 600 kilobytes of Dercuano to work so far.

The basic reason many years of notes fit into five megabytes is that I can only type about 90 words per minute, which is 72 bits per second uncompressed, 24 bits per second compressed — a bit rate 45 times lower. And then I spend time revising the notes, which often makes them better without making them larger, though as anyone can see, I don't revise my notes nearly enough.

TikZ won't fit

One of the SVGs I excerpted above is a sort of graphic of a comic-book-style explosion or impact, but with a gradient. I generated it with the TikZ graphics system for TEX from the following input:

```
\documentclass{standalone}
\usepackage{tikz}
\begin{document}
\tikz\shade[inner color=yellow,outer color=red](1ex,0)
    \foreach\t in{4, 8, ..., 360}
        {-- (\t:{.1+Mod((\t/17)^3, 57)/100})};
\end{document}
```

This uses $(\theta \div 17)^3 \% 57$ (composed with an affine function) to generate a "random" radius for each of 90 different angles to generate a jagged outer polygon, then fills it with a gradient. This is not something you can do in SVG, although you can do it in something else (like TikZ or JS) and generate SVG programmatically. And

TikZ comes with a massive built-in library of things like arrowheads, directed graph layout algorithms, tree layout, plotting math functions, calendars, finite state machines, ERDs, Petri Nets, and so on. The sections of the TikZ manual about arrowheads (and arrow tails, etc.) total about 10 pages. It's a bit overwhelming, honestly.

Unfortunately, I can't use TikZ directly in Dercuano, because that would involve embedding not only the 5 megabytes of TikZ, but also the rest of TEX and LATEX that it depends on to run, in some kind of browser-executable form, probably compiled with Emscripten. And, while that's probably a feasible thing to do, I'm pretty sure would blow my space budget for Dercuano.

I could draw ("write"?) graphics in TikZ and generate SVGs from them, but that just puts us back at square one: the SVGs are bloated, and I'd blow my space budget even faster that way.

TikZ has another problem, too: it's purely intended for static graphics. But in Dercuano much of the time a dynamic, interactively-responsive graphic would be better, and only marginally harder to write.

d3 may be a good option, but not for illustrations

d3.js is a JS library for dynamic data-driven graphics which generates SVG at runtime using the DOM. One of the minified copies of d3.js I have here is 151 kilobytes, and it gzips to 53 kilobytes; the current v5.9.2 gzips to 79 kilobytes. Another, non-minified copy I have is d3 v3, and it's 315kB, gzipping to 68kB. It's pretty easy to use, and in particular it's pretty easy to get really nice graphical output from, and it's amazing at interactivity. On the downside, the JS code to use it is usually pretty verbose, and it's not well suited for the kinds of sketching and illustration I earlier said were most important, although it's probably fine for timelines.

Some kind of restricted-bandwidth WYSIWYG drawing program

For some things, though, the closer to paper, the better. I just don't want to pay half a megabyte per hour for the privilege of faithfully recording the shaking of my hands as I sketch; shaky lines can be good but we might as well produce the shakiness from a highly-compressible random number generator. One possibility here would be drawing with a line that thrashes around near the mouse, starting at low-entropy points in whatever encoding I end up with, and gradually moving to higher-entropy points. Or maybe you stroke the mouse along a line multiple times to coax it into the shape you want. Maybe snap to a grid that gets finer if you zoom in: then you'd need to zoom in. Or maybe you need to click to nail down a spline point, and there's a snap grid that is finer for smaller displacements.

Another possibility would be something that encourages drawings to be highly factored, perhaps by having clumsy graphical primitives (though primitives that compose flexibly, e.g., adopting the line width and color from their use context) and really low reuse overhead.

A third possibility, and this is kind of cheating in a way, is just to use a textual language to describe the graphics, but shorten the feedback cycle as much as possible so that you can vary things interactively to see the results on the screen. To the extent that you

can map backwards from the screen image to the textual source code, you may be able to alter the textual source code by direct manipulation of the screen image.

Ivan Sutherland's SKETCHPAD was a visual programming language for interactively constructing a set of graphical objects and constraints for them to fulfill, progressively approaching fulfillment, and visualizing the results.

The problem with these approaches is that in some sense you're deliberately impeding the drawing process, which you would think would make it clumsier. But maybe that clumsiness can be minimized or even reversed — the bandwidth from my brain to the mouse is definitely not 1100 bits per second and may not even be the 24 bits per second I get on the keyboard. If the drawing program can somehow filter out the other 1000+ bits per second of pure noise, it might actually make it *easier* to draw things rather than harder.

Penrose looks like an appealing approach, but would need reimplementing

The unfortunately named Penrose (GitHub) diagramming software project is not related to Penrose diagrams (also known as Penrose–Carter diagrams), the Penrose Graphical Notation, the Penrose Project (a band), or the OpenJDK project Penrose. Instead, it's Katherine Ye's research team at CMU, which has produced software that largely consists of three DSLs, with even more unfortunate names — "DDL" defines the primitive objects of some mathematical domain, such as the vector space $\mathbb{R}^2$ or ZFC set theory; "STYLE" explains the desired visual representation of each domain concept in terms of constraints and optimization objectives; and then "SUBSTANCE" describes the particular objects to put into a particular diagram. Further interactive tweaking is then used to adjust one of the various outputs from the constraint solver to look best.

The underlying approach sounds reasonable, and they've gotten some impressive results, but the implementation is 8000 lines of Haskell, plus substantial bits in Java, TypeScript (for a React UI), JS, and Emacs Lisp; they're actually using Alloy (thus the Java) to reduce some kind of problem to SAT and solve it with SAT4J (maybe the layout optimization problem itself, although I don't think SAT4J would be particularly good at that? Or maybe some other problem). Using Penrose itself for diagrams in Dercuano would thus involve generating vector graphics in SVG or whatever during the Dercuano build process, since running the existing Penrose software in the browser would not be practical, even with Emscripten, which itself would probably blow Dercuano's space budget.

Something like Zdog might be interesting for 3D

Zdog is a browser-based 3-D engine using points, lines, arcs, and splines rendered with stroke thickness, with SVG (and, I think, `<canvas>`) output. Its implementation, though lightweight, doesn't run in old browsers, and I'm not that fond of its API.

It does a great job of demonstrating the potential of the approach, which is pretty easy to implement; doing it just for points with diameter ("spheres") took me just a few lines of JS on `<canvas>` a few years ago:

```
var s = Math.sin(theta)
  , c = Math.cos(theta)
;

var ty = y.times(c).plus(z.times(s))
  , tz = z.times(c).plus(y.times(-s))
  , seq = tz.gradeDown()     // painter's algorithm
;

ctx.clearRect(0, 0, canvas.width, canvas.height);
for (var ii = 0; ii < seq.length; ii++) {
    var i = seq[ii];

    circle(ctx, x[i] + 128, ty[i] + 128, 2048 / (tz[i] + 128), color(r[i], g[i], o
ob[i]));
}
```

In that case, though, the "scenegraph" (coordinates and colors) was randomly generated at startup. It doesn't really help with the question of how to get the 3-D models made in the first place.

Plasma glazing

Kragen Javier Sitaker, 2019-04-24 (1 minute)

Instead of salt-firing ceramic to glaze it, could you glaze it by producing a sodium-containing plasma on or just above its surface? For example, you could blow powdered sodium chloride into a plasma arc to vaporize it, or you could generate the arc from consumable wire electrodes embedded in a solid rod of sodium chloride, perhaps mixed with fillers to add gas volume — for example, sodium bicarbonate (which would also serve as a chlorine-free source of sodium, but might produce carbon), sodium nitrate (which wouldn't produce carbon but would produce nitrogen oxides that are worse than chlorine), boric acid, or sodium borate (borax).

The Tinkerer's Tricorder

Kragen Javier Sitaker, 2013-05-17 (updated 2014-04-24) (27 minutes)

My friend Nick and I were talking about a tool called the Tinkerer's Tricorder, which, if it existed, would tell you everything interesting about an electrical component as soon as you connected it across its terminals. Inductance, capacitance, resistance, voltage, frequency, diode characteristics, resonant frequency, Q, and so on — all with no danger of damaging the device!

Some of Nick's notes are at http://dangerousprototypes.com/forum/viewtopic.php?f=19&t=53606&p=52238.

I had wasted some time earlier that same day trying to debug a circuit without any test equipment. I ended up programming an Arduino to be a crude volt/ohmmeter. Despite its imprecision and the need to use a laptop to see its readout, it had three big advantages over a standard multimeter:

• It, or rather the laptop, recorded a series of measurements instead of a single one, so I could see not just the current state but recent states.
• It measured both voltage and resistance without any need to switch modes.
• Most of all, it could be simply downloaded and installed on existing hardware, without requiring any additional hardware — not so much as a resistor soldered across a pair of pins!

So I'd like a Downloadable Tinkerer's Tricorder — the closest possible approach to the Tinkerer's Tricorder on common hardware like an AVR microcontroller or an Arduino, without needing any nonstandard hardware — not even so much as a resistor or capacitor soldered across a couple of pins. You just reprogram the flash, connect the device under test between two pins, and the AVR tells you what it is. Maybe you go through some kind of calibration step if you want accurate results.

Nick's project is far more capable, but I think its parts cost is comparable to the cost of a prebuilt LCR meter.

How capable could a Downloadable Tinkerer's Tricorder be, struggling under the limits of common AVR hardware?

What an AVR pin can do to the outside world

Basically an AVR digital GPIO pin can be in one of four states: output high, output low, input high, and input low. Although some exotic Arduinos have DACs, common Arduinos don't have anything but digital GPIO pins plus an ADC. (This is deeply unfortunate, since the core of the AVRs' successive-approximation ADC is a DAC — but its output isn't routable to any pins!)

Output high ties the pin to the 5V rail with relatively low impedance; it can source up to 40 milliamps, but if you connect the pin directly to ground, the chip doesn't blow up; it's internally limited to about 40 milliamps. This means that, at least at high currents, the internal output impedance is about 25Ω. This is

convenient for connecting AVRs to LEDs and speakers; it pretty much guarantees you won't blow up the AVR, the LED, or the speaker no matter how ignorant you are, unless you hook the LED up to your power supply instead of the AVR.

Output low is similar, but ties the pin to the ground rail through the ≈25Ω impedance.

Input high ties the pin to the 5V rail via a pullup resistor, which is nominally 20–50kΩ on the ATMega328, which is not what you'd call a really fucking precise specification.

Input low tristates the pin, i.e. sets it at the very high input impedance characteristic of CMOS inputs, around a megohm; the maximum rating from the datasheet is that these pins draw up to 10 µA.

The pins are also diode-clamped to the power rails, which should protect them from voltage spikes if you're testing an inductor and slam a pin to input state. The clamping diodes aren't well-specified in the datasheets, but various AVRFreaks threads claim that these diodes are equipped to handle only up to about 1.5mA before possibly going into latch-up and killing your chip. The ATMega328P datasheet instead gives a spec for the voltage range: -0.5 V to VCC + 0.5V.

The datasheet max specified I/O pin capacitance is 10 pF, although I suspect 1 pF is probably more typical. I haven't measured.

What an AVR can measure

The usual AVRs, including the ATMega328, have a 10-bit ADC with a sample-and-hold frontend, which measures relative to either the power-supply voltage (typically 5 volts), and an internal 1.0–1.2 volt analog bandgap reference voltage; the ADC is claimed to have a 38.5kHz input bandwidth, but people have reported success clocking it up to 4MHz and still getting an Effective Number Of Bits around 5.

Furthermore, the AVR can use its ADC to measure an internal temperature sensor, supposedly accurate to ±10°C. This is important because it means that you can, in theory, compensate for thermal variation in things like pull-up resistor resistance. (The two major factors of variation in the behavior of a given electronic device are supply voltage and temperature. You can apparently measure the internal bandgap relative to the supply voltage, getting a value somewhere around 200, and thus measuring the reciprocal of the supply voltage, by setting ADMUX to 01x01110.)

I'm assuming the internal voltage reference is usable without any external hardware, even a capacitor attached to the AREF pin, but I'm not sure.

10 bits isn't much, but the device can measure time much more precisely. The internal RC oscillator is nominally accurate to 10% (3 bits), unless calibrated by the user, in which case it's accurate to within 1% (7 bits). However, in the common case that the AVR uses an external quartz crystal, its timing accuracy depends on that crystal's accuracy, which is normally about 0.005% (15 bits). Current normal Arduinos (Pro, Pro Mini, Uno) use a 16MHz Murata ceramic resonator that's accurate to 0.5% (8 bits), and older Arduinos (everything before Duemilanove, including Mini) use a quartz crystal. The AVR microcontrollers currently used can run at 20MHz, but the Arduinos run them at 16MHz for compatibility with the 16MHz

ATMega8 used in the first Arduino.

(It appears that temperature and supply voltage are the major factors in the speed variation of these resonators, says this guy who was tracking his against atomic clock broadcasts from WWVB and this guy who was measuring against GPS. So maybe with the temperature and supply voltage sensors, you could reduce the errors. Temperature-controlled crystal oscillators can reach three orders of magnitude better than raw crystals, i.e. 0.05 ppm temperature stability (24 bits).)

Low voltage isn't practical

Nick tells me ESR meters usually work at very low voltage to enable in-circuit component testing without activating any nearby transistors — under 0.1V. I don't think that's practical for the Downloadable Tinkerer's Tricorder because the chips I want it to run on don't have controllable-voltage output pins.

Avoiding damaging devices under test

A tricky thing is that, when you hook up some unknown device to your AVR, the AVR doesn't have the opportunity to consult its datasheet before applying power to it in order to figure out what it is. So it seems like a good idea to design the tricorder's strategy to minimize the risk of this.

The first and most obvious kind of damage is overheating. Too much voltage across almost any electrical device will cause it to generate more heat than it can dissipate until it gets really hot, hot enough to damage or destroy it. Since we're talking about a max of 5V at 40mA here, or 200mW, this is certainly a possible danger here; there are plenty of tiny resistors and things out there that can't dissipate 200mW at any kind of reasonable temperature. However, for macroscopic components, we can rely on their thermal mass to allow us to dissipate 200mW for a short period of time — if we can manage to use a duty cycle of 5%, we should be able to use 5V with near impunity, at least on discrete components, since we'd dissipate an average of 10mW.

Even the lowest-current-rated discrete diodes I could find on Digi-key were rated for 10mA average, so I think briefly passing 40mA through an unknown diode should be safe.

Integrated circuits are more delicate when it comes to brief overheating; a presentation I dug up from Cypress on "electrical over-stress" mentions, among other things, "melted or vaporized bond wires", with horrifying photos. Still, I don't think we're talking about 40mA there.

MOS circuits in general can be destroyed by overvoltage, even very briefly: it punches holes in the "O" layer in between the "M" and "S" by means of avalanche breakdown, and those holes are permanent. However, I don't think there are any MOS devices out there that will be destroyed in this way by 5 volts, so I don't think this is a real danger.

I seem to recall that semiconductor junctions can be damaged by high current density, even without high temperatures, but I can't find a citation for that now.

Electrolytic capacitors in general can be damaged by reverse-biasing, sometimes exploding spectacularly. The super-teensy

tantalum capacitors are particularly famous for this. I dug up a NASA paper on tantalum capacitor damage by reverse bias, and it seems like the damage takes place by means of a microamp (!!) or so of current. But it doesn't seem to happen below about 3 volts, and at 3 volts, it takes several hundred seconds. Even at 5 volts, it takes several tens of seconds. I suspect that short exposures to reverse bias can be corrected by a similar and rapid exposure to forward bias, reforming the dielectric layer that may have been disrupted.

Electrolytic capacitors, however, have the great advantage in this case that they have very high capacitance, 0.1µF or greater (typically 100µF or greater), even when back-biased (until they start conducting). If you're charging an 0.1µF capacitor through a 20kΩ pull-up resistor, your RC constant is 2ms. This should give you plenty of time to determine that you have a lagging voltage waveform, and therefore a capacitor, and turn the current around before the voltage reaches 3V.

Diodes in general will conduct if you put enough reverse voltage across them, either by avalanche breakdown or zener breakdown; diodes that are not designed for this will be destroyed. LEDs tend to have fairly low reverse voltage limits, but Nick tells me they're still over 5V, so not to worry. (I did find a Skyworks small-signal Schottky diode with a 1V maximum reverse voltage. But I could only find three diodes that fragile in the entire Digi-Key catalog.)

Measuring voltage

So, the simplest thing to measure would seem to be a DC voltage applied to a pin, or across two pins. The ADC can measure it directly, as long as it's positive.

For 1.1 to 5V, ADC values of 205 or so to 1023 measure the voltage with 0.25% to 0.05% quantization error: 0.005 volts. Of course, this is relative to the supply voltage, which probably isn't regulated to within even 0.25%; Joris van Rantwijk found that a single GPIO pin dumping 30mA introduced a 1% error.

For 0 to 1.1V, you can set the internal bandgap reference as the reference voltage, so as to measure with millivolt precision. However, the internal bandgap reference is specified to have ±10% error; presumably it's highly stable over time on a given chip, but varies from chip to chip.

If you can connect the voltage source between two pins, instead of to a single pin (implying that the voltage doesn't share a common ground with the AVR), then you get a couple of additional benefits:

• If you set pin A as low input and pin B as low output, then you'll measure a positive voltage on pin A if the positive end of the source is connected to pin A, and a zero voltage (and some heat dissipation in the clamping diode) if the negative end of the source is. I think you can also measure a positive voltage on pin B in that case, since whatever current is being sourced by the clamping diode to ground on pin A is being sunk through the nonzero output impedance on pin B. But in that case, you can set pin A as low output and pin B as low input, and you'll measure the positive voltage on pin B.
• This also means you can measure AC voltages, although only either the upper or lower half of the waveform at any one time, by switching back and forth.

• For 3.9 to 5.0V, you can get higher precision measurement. Suppose WOLOG that you've measured that pin A is the more positive end of the source. Then you set pin B as low input and pin A as high output. Now pin B sees a voltage of (5.0 - DUT) volts, which it can then measure with millivolt precision by using the internal bandgap reference. This trick is limited by the stability and precision of your 5V reference, which, unfortunately, is probably worse than 0.25%. (You can re-measure it to 0.25% against the internal bandgap frequently, but you can't get the 0.02% precision this seems to promise without a more precisely controlled reference voltage.)

This range of tricks gives you variable voltage precision as follows:

• -5.0 to -3.9 V: 1mV
• -3.9 to -1.1 V: 5mV
• -1.1 to 1.1 V: 1mV
• 1.1 to 3.9 V: 5mV
• 3.9 to 5.0 V: 1mV

This gives you at least 0.25% precision for -5 to -2.2 volts, -1.1 to -0.4 volts, 0.4 to 1.1 volts, and 2.2 to 5 volts; at least 0.45% precision from -5 to -0.22 volts and 0.22 to 5 volts; and at least 10% precision from -5 to -0.01 volts and 0.01 to 5 volts.

(As usual, linear analog-to-digital conversion is a bad deal here. If we wanted 0.45% accuracy for anything up to 5 volts and had 10 bits to work with, a smooth exponential distribution of levels 5/1.0045**n for n up to 1024 would give us 0.45% accuracy down to 51 millivolts, rather than 220 millivolts; that is, 10 bits would cover an entire order of magnitude.)

The four different ways to configure the two pins to measure a voltage between them (LI LO, LO LI, LI HO, HO LI) provide two different ways to measure any given voltage, to different precisions, while only allowing microamps of current to flow. If these measurements disagree, then you know the device isn't actually connected across the terminals, or isn't a voltage source. Since none of these configurations allow more than microamps of current to flow, none of them should be dangerous to electronic components that aren't generating voltage.

If the voltage source is just connected to pin A, then pin A might read the same voltage in the LI LO and LI HO configurations (that is, changing the state of pin B might not affect pin A much). But if pin A is floating, it's not a great idea to depend on it to do much of anything; it might follow pin B through internal leakage or capacitive coupling. So you might try the HI LO and HI HO configurations instead, just in case, but perhaps only briefly — the pull-up resistor could source enough current to damage, say, back-biased tantalum capacitors.

If you know that you have a voltage source between your terminals, the next thing to do is presumably to evaluate how much current it can deliver, which you should maybe be able to do by setting both terminals to low output (LO LO). In this voluptuous configuration, the negative terminal of the voltage source is forced below ground and fed current from the clamping diode, while the positive terminal feeds up to about 40mA of current to ground through its impedance. You should see 0V on one terminal and a small voltage on the other, which voltage should increase (probably nonlinearly!) with the current being sucked from the voltage source. If it can provide more than about 40mA (AAA batteries can provide 500mA) you won't learn anything useful.

LO LO should be safe for any component that isn't generating voltage itself, since it's just trying to put both of its terminals at the same voltage.

The trouble with LO LO or HO HO with a voltage source is that you're almost certain to be overtaxing the poor little clamping diodes. It might make more sense to use LO HO or HO LO, with the appropriate polarity to keep either of the terminals from going outside the power rails.

Measuring resistance

A resistor between the two terminals will tend to bring their voltage to equality in any of the five configurations suggested for measuring voltage sources in the previous section (LI LO, LO LI, LI HO, HO LI, LO LO). In the first four configurations, the input pin will follow the voltage on the output pin, and quite quickly too — if you have a 1pF pin capacitance and a 1MΩ resistor, your RC time constant is 1µs, 16 clock cycles on the Arduino, far too fast to digitize the charging curve with a mere 35kHz ADC. You might be able to beat that by doing a lot of transitions and digitizing one sample after each transition, at a variable delay, but you're going to be out of luck when you get to 10kΩ resistors, let alone 100Ω resistors.

But if one pin is following the other like that, you can infer that there is perhaps a resistance connected between them, and try to run some current through it to see what happens.

The first thing to try is presumably HI LO or LO HI, which forms a voltage divider between the pull-up resistor and the unknown resistance. If you somehow knew the resistance of the pull-up resistor — more accurately than "20–50kΩ" — you could use this to calculate the unknown resistance with some precision. Without that calibration, you're just ballparking it, although you can measure the ratios between resistances quite accurately.

(In practice the pull-up isn't actually a linear resistance.)

For the case where the pull-up resistance curve is known accurately — let's say 35kΩ — you have the following scale of measurements on the HI pin:

- 4.995V (ADC=1022 when comparing against 5V reference): $R/(R+35k\Omega) = 1022/1023$, so $R = 36M\Omega$.
- 5V (ADC=1023): $R > 36M\Omega$.
- 4.990V (ADC=1021): $R = 18M\Omega$. Clearly the error in this range is enormous, but it would still be very useful to be able to tell the difference between a 10MΩ resistor, a 1MΩ resistor, and a blown resistor. Unfortunately it's not clear that you actually get quite that far out; we're talking about currents around a microamp, and there could easily be microamp-range leakages floating around these pins.
- And so reciprocally down to, say, 2.5V (ADC=512), where $R = 35k\Omega$, and changes of one count actually do represent 0.2% changes in R. Note that at this point we don't actually care what the reference voltage is or how precisely we know it, because $R/(R+35k\Omega)$ is the ratio of voltages, regardless of what the larger voltage actually is. We *do* care about the precise value of the resistor, but it's not clear how we can find that.
- So on down to 1.1V or so (ADC=225), where $R = 9.86k\Omega$ and each count represents about 0.5% (so 0.25% error, ideally, but probably

more like 1%.) At that point we can switch to the internal bandgap reference and quadruple our resolution — but we're limited by the limited precision of our measurement of the bandgap reference relative to the total supply voltage, and now we *do* care about what the supply voltage is. Still, ideally, we can measure resistances in this range with around 0.1% precision.

- We hit ADC=225 and 0.5% precision again at 0.24 V, at which point R = 1.76kΩ.
- We hit ADC=20 and 5% precision at 21mV, R = 148Ω.
- ADC=10 and 10% precision at 10.7mV, R = 75Ω.

So far we've only been pushing about 140μA through the resistor. This should be safe for almost anything (except, as mentioned earlier, electrolytic and especially tantalum capacitors over long periods of time.) But if our device is behaving like a resistor — in particular, the measurement we get here is stable over long periods of time such as a millisecond or two, and consistent in both directions — it's almost certainly safe to put more current through it, at least for a while. And we can get a more precise measurement that way if the resistance is lower than around 1–10kΩ.

So if we switch to LO HO and HO LO mode, we're attempting to put a full 5V across the putative resistor. Now we should be able to measure the voltage drop introduced by the pin driver (the sink) on the LO pin, and perhaps less precisely the voltage drop on the HO pin.

These drivers are somewhat nonlinear — their voltage drop isn't purely proportional to the current — but treating one of them as having a resistance around 25Ω worked reasonably well for me in an experiment, over about the 50–500Ω range. Experimentation is needed.

This could involve pushing a full 40mA through the resistor, dissipating 200mW, so you probably want to do it on a low duty cycle. This will involve lots of opportunities to watch its impulse response, which could tell you if it has much inductance or capacitance.

If you're switching from HO LO to LO LO, a capacitor should dump the positive charge it's accumulated back into the formerly-HO pin, keeping its measured voltage above zero for a bit due to the nonzero input impedance, while a resistor will stop carrying current as soon as you stop applying voltage. An inductor, on the other hand, will continue carrying current in the same direction, dragging the formerly-HO pin's voltage below zero (unmeasurably, due to diode clamping) but continuing to dump charge into the still-LO pin, keeping its measured voltage above zero.

That's not the only possible way you could turn the pins off to stop burning energy in the resistor. In fact, of the 16 possible configurations of two pins, only LO HO and HO LO apply 5 volts at low impedance across the load; the other 14 are some variant of "off" or "gently pulled up", so any of them would work. However, of those 14, only LO LO and HO HO provide low-impedance paths for current to continue flowing in the case of an inductor. Suddenly increasing the impedance in a circuit with an inductor is a recipe for potentially damaging or possibly even painful voltage spikes; we can hope that the diode-clamped inputs are up to the stress, but it seems better to minimize the risk.

Even assuming the behavior we observe is memoryless, the different voltages applied by HI LO and HO LO (in the case where current flows) can give us two points on the E-I curve of the device under test; LO HI and LO HO give us two more points, although perhaps less informative ones. If those four points and the origin are collinear, we have a resistor, at least over the voltage range we're testing with. Being able to tell if they're collinear, though, presupposes that we have a good map of the E-I curve of the pin drivers, since that's what we're supposedly inferring the I at high current from, and also a well-calibrated value of the pullup resistance!

Reversing the bias will, among other things, distinguish a diode from a resistor, even if the exponential E-I curve doesn't — unless it's a zener diode with a low breakdown voltage.

Measuring capacitance and inductance

Capacitors can be delicate. Inductors aren't, but chips are delicate when connected to inductors. So this requires some care.

When the external voltage drops you observe in HO LO or LO HO and LO LO modes aren't time-invariant, you know you have either a capacitor or an inductor; and when those voltage drops go up rather than down over time, you know you have a capacitor, so you should be careful. But "being careful" might mean avoiding HO LO and LO HO modes altogether XXX

If you reverse the voltage, it should XXX

One-line thoughts that don't merit separate notes

Kragen Javier Sitaker, 2017-01-04 (updated 2017-02-25) (4 minutes)

One line thoughts:

How do you get rid of the ozone from a plasma garbage incinerator? Platinum?

A text editor could highlight words by their information content, and color them by their context.

You can cluster sequence items iteratively by considering the entropy of the sequence under that clustering: a clustering that allows a better predictiom of the sequence item following it is a better clustering.

Relatedly, the Viterbi algorithm gives you a probability distribution of the next item in a sequence, given a hidden Markov model for that sequence. This gives you an optimization problem for the hidden Markov model; solving the optimization problem would give you the HMM that best models that sequence (under whatever constraints).

watch(1) has a `-d` option to highlight parts of the screen that have changed since the last update. A generalization of this would be to dim screen items according to how long they hadn't updated in.

As a way to produce interesting shapes, for example for fonts, how about third-derivative-continuous splines that pass through random grid points at evenly spaced time intervals? This space is small 6 enough that you could exhaustively search it: 4 points chosen (with replacement) from a set of 4, for example, gives you $4^4 = 256$ glyphs; chosen from a set of 6, you get $6^4 = 1296$; and if you choose 5 from a set of 6, you get 7776.

Another way to produce interesting shapes, for example for fonts: how about triangular Wang tiles? A complete triangular Wang tile set with two edge-colors could consist of three tiles plus their rotations; the contents of every two such tiles could be encoded in three bits.

Does Bayesian inference in general produce a probability model that, in some sense, minimizes the entropy of the observations and priors that went into it? That is, if you start with some priors and then update them Bayesianly from some observations, you get some probabilistic model. Given a probabilistic model, you can measure the entropy of a set of observations. Does Bayesian inference minimize that entropy? It would seem that maximum-likelihood estimation (which is not Bayesian!) minimizes it.

Given a desired OTF, the cheapest dataflow graph of convolutions to produce it is the kind of thing you can solve with an optimizer.

Can we improve the readability of text by running it through a spatial FIR filter matched to the spatial-frequency response of the human visual system?

Where did "This is why we can't have nice things." and "Do you want ants? This is how we get ants." come from? http://knowyourmeme.com/memes/this-is-why-we-cant-have-nice-things says, "One of the earliest notable mentions came from Paula

Poundstone, an American stand-up comedian who used the phrase in her HBO stand-up special, Cats, Cops and Stuff (1990).[1][2]" But http://knowyourmeme.com/memes/do-you-want-ants is apparently from 2009.

Has someone made a DIY vinyl cutter and documented the process online? Yes, http://www.instructables.com/id/DIY-CNC-Graphics-cutter-hack/ http://www.instructables.com/id/Printer-to-vinyl-cutter-hack/ http://hackedgadgets.com/2009/01/18/diy-vinyl-cutter-from-a-hp-draftmaster-rx-pen-plotter/.

An amusing refactoring is to insert a call+ret into the middle of a function, jumping to just after the ret, effectively converting the tail of the function into a new function. If you omit the ret, it runs the tail of the function twice.

Can you optimize an RNN (including hyperparameters like depth!) to produce a probability distribution of the next character of a text, and thus get good data compression? Can you beat PPM for the Hutter Prize this way? Nobody has won since 2009: "executable of size S < L := 15'949'688 = previous record. 50'000€×(1-S/L). Minimum claim is 1500€.". PAQ8 (the record holder since the beginning of the prize in 2006) already combines probabilities from different models using an ANN. I'd have to beat it by 3%: 15'471'197 bytes or less. Seems maybe doable.

Hey, FIR filters are almost the same as linear homogeneous recurrences. They're just not recursive.

Did GW-BASIC have erf()?

Copyright status of the Oxford English Dictionary: relevant data

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

http://en.wikipedia.org/wiki/William_Craigie says he died on September 2, 1957. He was one of the three editors for volume 10 of the OED, part 2, according to the archive.org record at http://www.archive.org/details/oedxbarch.

http://en.wikipedia.org/wiki/Henry_Bradley says he died in 1923.

http://en.wikipedia.org/wiki/Charles_Talbut_Onions says he died in 1965.

Other editors included James Murray (died 1915).

http://www.copyright.cornell.edu/public_domain/ has a table for copyright durations. Among other things, it says:

Before 1923	Conditions: None	In the public domain
1923 through 1977	Published in compliance with all US formalities (i.e., notice, renewal)^11 <#Footnote_11>	95 years after publication date <#Footnote_10>
1923 through 1977	Published without compliance with US formalities, and in the public domain in its home country as of 1 January 1996	In the public domain
1923 through 1977	Solely published abroad, without compliance with US formalities or republication in the US, and not in the public domain in its home country as of 1 January 1996	95 years after publication date <#Footnote_10>
1923 through 1977	Published in the US less than 30 days after publication abroad	Use the US publication chart to determine duration
1923 through 1977	Published in the US more than 30 days after publication abroad, without compliance with US formalities, and not in the public domain in its home country as of 1 January 1996	95 years

after publication date <#Footnote_10>

There's a flowchart of copyright in the UK at http://www.museumscopyright.org.uk/private.pdf. The applicable path goes like this:

Is the author known? Yes.
Is the work a literary, dramatic or musical work, a photograph or an engraving, created before 1 August 1989? Yes.
Is the work a photograph taken before 1 June 1957? No.
Was the work published before 1 August 1989? Yes.
Did the author die more than 20 years before publication? If yes, then copyright expires 50 years after first publication; if no, copyright expires 70 years after the death of the author.

http://en.wikipedia.org/wiki/Copyright_law_of_the_United_Kingdom says:

Prior to 1 January 1996, the UK's general copyright term was life of the author plus 50 years. The extension to life of the author plus 70 years was introduced by The Duration of Copyright and Rights in Performances Regulations 1995 (SI 1995/3297); which had the effect of making EU Council Directive No. 93/98/EEC, created to harmonise the duration of copyright across the European Economic Area, law in the UK.

The 1911 copyright act of the UK was the relevant act at the time; I haven't been able to find a copy of it yet.

Cloth structure from shading

Kragen Javier Sitaker, 2019-09-01 (2 minutes)

The structure-from-shading problem is the problem of knowing the shape of a 3-D object from seeing how light falls on it; it suffers from a number of difficulties such as having to assume that the object is all the same color and not being able to tell when a Lambertian surface rotates around the vector of the [dominant] light beam.

But if the object is covered in or made of woven or nonwoven cloth, as the humans often are, and you have a high-enough-resolution image to see the individual threads of the cloth (or meltpoints, in the case of nonwovens like *friselina*), you have several great advantages.

First, the threads or meltpoints give you a dependable, repeating three-dimensional microtexture, which gives you a sample of illumination of different surface normals in the neighborhood of the overall surface normal.

Second, thread or meltpoint-line direction discontinuities often indicate surface discontinuities. (Sometimes they're just seams, though.)

Third, the threads or lines of meltpoints are typically at right angles, and this gives you an independent clue about how inclined each surface patch is to the camera.

Fourth, the threads or meltpoints are typically evenly spaced over the entire surface, and this allows estimation of relative Z-coordinates by perspective.

Fifth, although fabric is somewhat flexible, the threads or meltpoints generally run near ecliptics over the surface if the fabric is to not wrinkle. Nonwoven fabric is much less flexible.

Some fabrics, such as plaids, stripeds, houndstooths, and certain prints, are amenable to algorithms based on some of these properties even if the image resolution is not good enough to see individual threads.

Gittable sql

Kragen Javier Sitaker, 2015-09-25 (updated 2015-09-26) (6 minutes)

Suppose you want to store a SQL database in Git.

This occurred to me because I wanted to restore an old website from backups. All the static text files in CVS were fine, but the database was stored in MySQL, and consequently had been lost, and so the CGI scripts didn't work. If we had stored the database in more static text files, we could have avoided this problem. You could even have accessed the CSV files over HTTP from JS, since they didn't contain any secret information. I wished we'd used CSV instead of SQL, although of course this wouldn't work for heavy update loads or certain kinds of atomic updates.

The problem

We'd like to support the usual SQL operations (not just the DML INSERT, SELECT, UPDATE, DELETE but also the DDL CREATE TABLE, DROP TABLE, CREATE INDEX, foreign key constraints, etc.) with transaction rates, data sizes, query evaluation times similar to those of older SQL databases (say, up to 16 transactions per second (across the whole system, not on a single host)), on up to 64 gigabytes or 2 billion records of data, with simple queries answered in tens of milliseconds), but with the ability to replicate the database using Git to different hosts (say, up to 128), update any replica, and then synchronize that change to all the replicas using Git.

Git's decentralized model means you can't guarantee most of the consistency constraints a regular SQL database would guarantee: if A.B references C.D, you can insert a record into A on one host and delete the record it references from C on another host, which respects the consistency constraint on each host, but violates it when they are merged.

So you'll have to settle for inconsistency detection and resolution in some cases, rather than prevention. Still, it seems like it should be possible to do a reasonable job for many cases.

Characteristics of the building materials

Much of this applies to storing databases in text files in general, not just in Git.

Git isn't super great at merging binary data files or storing huge files (over, say, 1MB), so it would be better to avoid those. But it uses xdelta compression and gzip, so formats with redundant data aren't that costly, and might be easier to merge. Most of the standard database algorithms apply pretty straightforwardly to text files, needing only a little bit of extra work.

Git also doesn't do well with repositories storing a large number of files, say, over 100,000; and its efficiency begins to suffer when individual directories are more than a few kilobytes (say, more than a few hundred files). Also, Unix filesystems traditionally don't work well with more than a few hundred files in a directory, although the modern ones scale up to 10,000 files in a directory without much pain.

Git does provide atomic updates across multiple different files, which Unix filesystems do not. If you are providing HTTP access to some mutable text files stored in a directory, that also doesn't provide atomic updates across multiple files, but if you map Git's data model into HTTP URL space, it would. Git's git-http-backend command already supports this via the "backwards-compatible dumb HTTP protocol", which is also what you use when you clone a Git repository from the `.git` directory on a plain-Jane HTTP server serving up files. This is achieved typically by updating `.git/refs/heads/master` to point to a new commit object (implicitly in `.git/objects` or possibly a pack; this could be mapped more cleanly into HTTP) that you have just finished creating.

Ideally you wouldn't store indices or materialized views in Git, just the data they were computed from (including the index creation specification). And ideally you'd minimize unnecessary update conflicts by usually not updating the same files on different hosts. Also, it would be desirable to minimize the amount of work necessary when you pull new changes from somewhere else.

In some cases, a table may have small contents but a large change history — where it's kept small to keep access fast. In other cases, a table may have contents that are nearly as large as its change history. Generally, conflict resolution can work better if you have more information about history. For example, in the A.B-references-C.D case above, you could undelete the deleted C record and perhaps roll back the transaction it was committed in and enqueue a post-hoc-rollback notification.

(In still other cases, you may have a non-retention requirement to truly erase security-sensitive data, and in those cases you shouldn't use Git at all.)

Design

This suggests two different designs: one where you simply store source-segregated update logs, treating the actual table contents in some sense merely as a materialized view of the update log, and one where you store segmented actual table contents.

Storing source-segregated update logs

In this design, what you version-control are unbounded-size logical logs of your database transactions, one log per host, separated into segments of some maximum size. These logs might store the actual SQL statements, each associated with some transaction ID:

```
t150 begin
t150 delete from users where name = 'brett'
t151 update users where seen < '20150101' set seen = '20150101'
t151 rollback
t150 commit
```

Or they might store individual record updates identified by some primary key:

```
t150 begin
t150 delete from users where id = 2804
t151 update users where id = 2018 set seen = '20150101'
```

```
t151 update users where id = 2021 set seen = '20150101'
t151 update users where id = 2029 set seen = '20150101'
t151 rollback
t150 commit
```

You could store this data separately for each table, say in a subdirectory for each table, but you run the risk of

Loading new firmware on an AVR

Kragen Javier Sitaker, 2017-03-31 (3 minutes)

There are apparently three different ways to program AVRs:

• High-voltage "parallel" programming with +12V on the /RESET pin (e.g. §21.2, p.184, of the ATtiny2313A datasheet), used by e.g. the STK500, which, despite the name, still uses only a single pin for the data bits in and out;
• "Serial" programming with the SPI bus while /RESET is low (e.g. §21.3, p.193, of the ATtiny2313A datasheet), which is what is explained in Limor Fried's tutorials, which I think requires the /RESET pin to exist, i.e. not be reconfigured as PA2, debugWIRE, or PCINT10 — the RSTDISBL pin of the fuse bits determines this, and additionally there's a SPIEN pin;
• with the "store program memory" instruction, e.g. from the Arduino bootloader, as explained in e.g. §19, p.173, of the ATtiny2313A datasheet, which can get its data from anywhere you like.

I think I should be able to bitbang the serial programming interface from an Arduino or other AVR, but this will require talking some protocol to avrdude. This is I think the purpose of the mega-isp firmware and ArduinoISP firmware derived from it.

The ArduinoISP page shows using an external clock crystal and two 18–22 pF capacitors to get the device being programmed to be sufficiently functional to accept programming, if it isn't configured to use its internal clock. By default the divide-by-8 fuse is set so the chip's clock rate is only 1MHz. At least the ATtiny2313 is documented to use the internal oscillator by default.

It seems like maybe even an ATTiny45 ought to be enough to use for serial programming: it has 8 pins, of which 3 are used for Vcc, ground, and /RESET; three more are used for SCK, MISO, and MOSI, which can control the serial bus of another AVR being submitted to programming; and two more are available for some other kind of communication. Or you could bitbang the SPI protocol for programming and use the SCL and SDA pins to speak I²C to get programmed.

The ATtiny2313 SOIC unfortunately has the ground pin at the opposite extreme of the chip from the Vcc, /RESET, SCK, MISO, and MOSI pins that are needed for in-circuit programming, so you need a full 20-pin SOIC clip to program it this way. So I need 13mm of PCI bus to clip the whole thing into, with the attendant possible problems with good contact.

Arduinos have a standard six-pin ISP programming header, which I hadn't realized.

Scrubber mask

Kragen Javier Sitaker, 2019-05-08 (5 minutes)

People on the orange website were talking about some article about conference-room air making people stupid because it's full of CO_2, sometimes several thousand ppm, while the outside air is only 400 ppm. Other high-CO_2 environments discussed included full facial motorcycle helmets at a stop light or after a crash, bedrooms at night, and so on.

It turns out that a breathing mask to eliminate carbon dioxide from input air is eminently feasible at a technical level, requiring only a few dozen grams of lithium carbonate or soda lime per day.

(This is related to House scrubber (p. 248) and Notes on a possible household air filter (p. 1961).)

Whitewash and aloe

One of the major reasons I'm growing aloe vera plants is to eventually be able to remedy this situation in my own house by using crassulacean acid metabolism, and in the 19th century, according to *The Book of Useful Knowledge*, one reason for painting buildings with whitewash was that it purified the air (p. 249):

> DISINFECTANTS. Agents which destroy miasmata. … Quicklime rapidly absorbs carbonic acid [CO_2], sulphureted hydrogen [H_2S], and several other noxious gases, and is therefore commonly used as a wash for the walls of buildings.

But of course it isn't practical to go around whitewashing every new conference room you want to attend a meeting in, although submarines do something similar by hanging up curtains containing lithium hydroxide.

Filter masks

Could a person sufficiently unconcerned about social acceptance work around this with a mask containing some carbon dioxide sorbent, like a rebreather, but for input air? Or would the reaction take place too slowly, or saturate the CO_2 sorbent too fast? You'd want to arrange the mask to only filter the inhaled air, not the exhaled air, perhaps using one-way valves like those used in snorkeling and scuba diving to bypass the sorbent for exhalation. A different possibility is to use nasal tubes to infuse filtered air continuously into the nasal cavity.

Candidate sorbents

Spacecraft and rebreathers, like submarine emergency scrubber curtains, also typically use lithium hydroxide, but "soda lime" (75% slaked lime, $Ca(OH)_2$, with a catalyst mix of 20% water, 3% NaOH, 1% KOH) is a common alternative used in environments where weight is less critical, like anesthesia.

Wikipedia's lithium hydroxide article helpfully explains:

> one gram of anhydrous lithium hydroxide can remove 450 cm^3 of carbon dioxide gas.

The reaction consumes $2LiOH + CO_2$, while the corresponding slaked lime reaction consumes $Ca(OH)_2 + CO_2$, since calcium has

two valence electrons to sacrifice to the hydroxyl gods. 2LiOH weighs 47.9 daltons, while $Ca(OH)_2$ weighs 74.093 daltons, so although soda lime might be a little heavier, the difference is not as great as you would expect from just thinking about the relative atomic numbers of lithium and calcium. There's a corresponding difference in density so that the number of hydroxyls per unit volume is almost the same for both compounds.

Sorbent volumes per day

So one gram of lithium hydroxide, or a gram and a half of calcium hydroxide, gives us 450 cm^3 of CO_2 absorption; but how many cm^3 do we need to absorb to get through the day?

Typical human breath tidal volume is 500 mℓ. Of that, normally 400 ppm is CO_2 on the way in, but perhaps more like 2000 ppm in bad circumstances, which works out to 1 mℓ of CO_2 per breath. So 450 cm^3 is 450 breaths, or maybe five times that if the levels of CO_2 are low enough that you should just shut the mask off anyway. Typical adult respiratory rate is 10–20 breaths per minute, so 450 breaths is 22½–45 minutes. A whole 24-hour day, then, would be 32–64 grams of lithium carbonate.

Sorbent exchange surface area needed

Normal rebreathers, like those used for anesthesia and closed-circuit scuba diving, need to absorb something like 4% CO_2 from the exhalation — 40000 ppm! Moreover, they need to absorb nearly all of the CO_2 (>95%), while in this case it would probably be adequate to absorb half of it. So sorbent used here could probably have about 100× smaller surface area to take up CO_2 from the gas.

Topics

Bokeh pointcasting

Kragen Javier Sitaker, 2019-09-08 (updated 2019-09-09) (16 minutes)

I was thinking about the silent-alarm problem: suppose a human is being robbed at gunpoint in their store or home, and they want to sound an alarm, but without getting shot. This requires some kind of alarm system and at least unidirectional communication from them to it; it's very helpful if this connection is bidirectional, so the alarm system can notify them that you're tripping it, and maybe avoid false alarms.

The constraints of the problem

Anything the human can do voluntarily does can be interpreted as a signal by the alarm system, given appropriate sensors: blinking, head tilts, hand gestures, other eye gestures, other head gestures, tongue movements, shifting their weight, whistling, humming, breathing patterns, sucking in their stomach or pooching it out, wiggling their toes inside their shoes (as in *The Eudaemonic Pie*), swallowing, raising eyebrows, emitting brain waves, and so on. But since, by hypothesis, they are under close observation and possibly physical restraint from the robbers, the signals ought to inspire a minimum of suspicion.

Communication in the other direction is subject to similar constraints. The actuators used by the alarm system to communicate with its humans need to be inconspicuous so that the robbers do not deactivate them (for example, with a bullet or spray paint), and in particular should be much more difficult for the robbers to observe than for the defenders. So, for example, sounds on loudspeakers, visible flashing lights, pervasive floor vibrations, and the like, might draw suspicion.

An additional constraint in some circumstances is that the actuators themselves should not be tempting theft targets; conspicuous LCDs and luminaires may induce robberies where otherwise none would have occurred. Prevention is better than cure, because prevention doesn't get you shot during a failed robbery and doesn't provoke retribution.

Candidate actuators

Hearing aids

In-ear and behind-ear hearing aids (see Hearing aids for disability compensation, protection, and augmentation (p. 764)) can receive a variety of signals (radio waves, infrared, near-field electromagnetic, ultrasound, etc.) and provide auditory cues to the wearer. They are only moderately likely to tempt theft or to be suspected of forming part of an alarm system, at least initially, and robbers will hesitate before removing them, since usually their objective requires that the defenders be able to hear their demands.

Also, hearing aids can be equipped with a variety of sensors for communication in the other direction: accelerometers to measure head tilt, galvanometers to measure subcutaneous nerve activity related to muscle movement, and of course microphones and cameras.

There's a significant safety concern here, in that buggy hearing-aid firmware can easily produce sound at ear-damaging volumes.

The available communication bandwidth here is presumably close to that of human speech, some 39 bits per second.

Ultrasound or millimeter-wave beams

Several ultrasound-pointcasting demonstration systems have been built that project ultrasound beams at people's ears to produce private sound. These use nonlinear air–ear interactions to produce audible-range sounds inside people's ears from much stronger ultrasound.

Presumably it is possible to do the same kind of thing with millimeter-wave radio beams if they are strong enough, but I'm not sure if there's a mechanism for converting the millimeter-wave light to nerve impulses that isn't destructive to the human, such as skin heating. I have similar safety concerns about ultrasound.

Again, this is probably around 39 bits per second.

Dental or tongue implants

A receiver cemented to a tooth with dental cement or implanted in a tongue piercing can produce bone-conduction sound that the human can detect even at very low energy levels. Electric shock (<1mA) is another possible communication channel. Implants in such places are also well situated to sense tongue movements, tooth clacking, and *sotto voce* vocal signals.

These have a great advantage over hearing aids: they are entirely invisible if the robbers do not know to look for them, and even then they are difficult to distinguish.

These, too, are probably around 39 bits per second, except that the electrical-shock channel is probably more like 5 bits per second.

On-body vibrators

Cellphones commonly alert the humans to events by vibrating, stimulating the skin. This approach can also be used as a communications channel of rather low bandwidth, perhaps around 5 bits per second.

Time-domain indicator lights

An indicator light, such as a conventional 40mW green LED emitting its ≈4mW (2–3 lumens†) of light, can easily be visible at 1–10 meters distance, depending on lighting conditions; by flashing in different time-domain patterns, such as Morse code, it can convey messages, perhaps around 10 bits per second.

However, a normal LED suffers from equal visibility to the robbers. If a defender looks at the LED, the robbers may understand the LED's significance and destroy or paint over it.

The 2–3 lumens of a conventional LED is spread over about π steradians, thus amounting to about one candela. At 2 meters radius, this 2–3 lumens is spread over about 13 m² of the 50-m²-area sphere of 2 meters radius centered on the LED, thus illuminating the defender at about 0.1–0.2 lux.

This situation can be improved by using a laser, steered by mirrors, to pointcast the information to the defender's eye pupil. This will be minimally visible to the robbers, because it is only necessary to use the same 0.1–0.2 lux to achieve the same visibility to the defender that

the conventional LED would have had. If the pupil is about 4 mm across, this amounts to about 1.3×10^{-5} m² out of the 13 m² mentioned above, so the laser can and indeed must be much dimmer than the LED: rather than 2–3 lumens, it should run at 2–3 *micro*lumens, amounting to a few nanoamperes of drive current for a semiconductor diode.

A higher data rate, however, would be desirable.

† I'm guessing here; I haven't checked datasheets.

Bokeh laser projectors

This higher data rate is achievable by using spatial modulation as well as time-division multiplexing. If the defender has their eye focused on the laser, it will appear as merely a point of light; however, if they defocus their eye, like any other point source, the point of light expands to a blurry bokeh circle like those discussed in Real-time bokeh algorithms, and other convolution tricks (p. 2661) and Debokehfication (p. 473). The pattern of the bokeh reflects the spatial modulation of the light at the pupil; for example, if part of the pupil is obscured by eyelashes, the shadows of those eyelashes can be seen on the retina.

By scanning the laser in a raster pattern over the pupil, using either galvo-controlled mirrors or something subtler like piezo-controlled mirrors, while modulating a video signal onto it, could produce a readable message in the defocused bokeh. The defender will need to look at it so that the message is focused on their fovea, but robbers following their gaze will see nothing of interest.

The degree of defocus possible, and thus the maximum degree of expansion of the bokeh pattern on the retina, depends on the individual person and on the state of their eye, especially the degree of dilation of the pupil. Earlier today, indoors during the day, this body's eyes had a defocus diameter equivalent to about 6 mm at a radius of 800 mm, or about 8 milliradians (26 minutes of arc, in ancient Babylonian units), but now that it's night, it has a defocus diameter of about double that, about 16 milliradians. Presumably if I turned the light off and waited a while, I could beat 20 mrad†. All of this is for distant point-source lights, on the order of 8–20 m away, effectively ∞.

How much information could you display in an 8-milliradian-wide circle? Well, that depends on the resolving power of the human visual system. Right now, on this laptop, a 7×13 font is readable to this body, but a 6×10 font is not. The screen is 1150 mm away from this eye, 305 mm wide, and 1920 pixels wide. This means each (square) pixel is 160 µm wide and subtends about 140 µrad (28 arcseconds, in ancient Babylonian units.) Reading 7×13 (`xterm -fn 7x13`) requires, roughly, distinguishing bright from dark areas that are separated by about 1½ pixels.

However, a more direct measurement of the information-carrying capacity of a small area of the visual field is that the 7×13 characters are about a milliradian wide and 1.8 milliradians high, and carry about 6–7 bits of information each, for a textual information density of about 3–4 bits (or 0.56 letters) per square milliradian. Perhaps more advanced rendering methods like those described in Dercuano plotting (p. 2885) could improve this bound, but it's at least demonstrably feasible, with the eyes in this body.

So an 8-milliradian-wide circle, with its area of 50 mrad², could hold about 25–30 marginally readable letters, or 150–200 bits. The rapid serial visual presentation ("RSVP") method associated with speed reading can display a series of phrases at around 1 Hz without losing readability, so this method has a bit rate of around 128–256 bits per second, probably dramatically higher than the others considered above.

The scanning action of the laser needs to be fairly precise. In pixels, we're talking about something on the order of a 60-pixel-diameter circle. Considering a viewing distance of 2 m, these 60 pixels need to be mapped across the 4-mm pupil, so about 70 microns per pixel, which is 35 microradians; the laser beam thus needs to have a divergence of less than about 35 microradians, and the deflection-scanning apparatus needs to have a reproducibiity of 35 microradians or so to keep alignment of successive scan lines as we raster across the pupil.

However, there's a huge problem! This small divergence requires a relatively large laser and mirrors; the Airy limit of $\sin\theta = 1.220\lambda/D$ means $35 \times 10^{-6} = 1.22 \times 555$ nm / D, which is to say $D = 1.22 \times 555$ nm / $35 \times 10^{-6} = 19$ mm. This, in turn, means that the laser won't look like a point source to the defender, since it subtends 10 milliradians, and the image of that aperture will be convolved with the desired bokeh pattern, blurring it all to shit!

This ratio between 10 mrad and 140 μrad is about 70, so by coarsening the intended resolution of the bokeh image by about √70, a factor of 8 or 9, to 1.2 mrad, we can use a laser aperture that also only subtends 1.2 mrad (2.4 mm for a viewing distance of 2 m), and achieve the desired effect. But instead of 25–30 readable letters, we have a 7-pixel-diameter circle, holding about 40 pixel — enough for *one* letter.

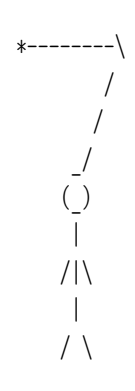
We can probably present more than one letter per second, but it suggests that the bokeh approach won't beat the auditory approaches on bandwidth.

† milliradians, not millirads, of course.

Laser pointcasting with active retroreflection

Suppose that we give up on the whole bokeh idea. Can we use a similar laser-tracking approach to get a low-power video image that's only visible to one person, without them defocusing their eyes? Something like Jeri Ellsworth's CastAR retroreflective-surface VR projector, but without the conspicuous glasses.

Yes! Using point-source illumination from the opposite wall, which might or might not be a laser:



In one variation of this scheme, we use a scannable laser on one wall which raster-scans across a deflectable mirror of some 20 mm diameter on the other wall (perhaps behind a color filter to filter out extraneous wavelengths), which is synchronously raster-scanning so that, wherever the beam falls on the mirror, that point gets reflected to the defender's eye.

To get those same 60 pixels across the 20-mm mirror, you can tolerate a beam divergence of about 300 μm, which is achievable at a 2-meter distance with a laser output aperture of under 2 mm in diameter.

Of course, you don't actually need the mirror to raster-scan for that. You could just use an ellipsoidal mirror (and probably just a parabolic one), so that you get the desired property even without scanning the mirror. However, you still need to move the mirror when the defender moves, in order to change the focal point; and, worse, you need focusing optics of some kind to adjust to different defender-eye focal distances. Deforming the mirror itself is a feasible solution, especially if it's cheap metallized plastic; getting a radius of curvature of about 2 meters (ideal for redirecting all light between two foci each 2 meters from the mirror) only requires depressing the center of a 20-mm-wide mirror by about 25 μm, or depressing its center by 12.5 μm while raising its edges by that same 12.5 μm.

The above variations only need about 60 scan lines, but probably mechanically scanning a massive mirror at only 3.6 kHz would make a conspicuous noise, since that's close to the humans' peak auditory sensitivity frequency.

In another variation, the light source is just a point source, such as a small LED, perhaps shrouded like some keychain ultraviolet LEDs so that it illuminates the whole mirror and almost nothing else. The entire mirror is illuminated at once, rather than being scanned as in the above schemes, but this mirror is something like a DLP chip: it has pixels that can be individually turned on or off, either with actual DLP or with an LCD. You still need some kind of head tracking to point the result at the defender's eyes. All of this can be hidden behind a color filter so it doesn't draw attention.

With these approaches, you can get the 150–200 bits per second rates I was hoping for earlier from the bokeh approach, the ones ruined by the divergence problem.

These schemes encode the information not in the position of the laser spot on the viewer's pupil, as the bokeh scheme does, but in the direction from which it enters. I don't know if it's possible to do better than either with some kind of combination scheme.

Machine-to-machine communication

Normal laser communication like Ronja uses time-domain signaling, using optics only to get antenna gain, but perhaps you could use such a spatial-modulation approach for machine-to-machine communication as well, as CCD oscilloscope (p. 1861) suggests doing for analog memory inside an oscilloscope. In that context you might not be limited by the considerations of clandestinity described here, so much larger optics might be feasible. By scanning your signaling beam across the lens of the receiver in a raster pattern, you can draw a bitmap in the bokeh on their "focal plane" sensor, which can be positioned at such a distance from the optical focal plane that the

bokeh nearly covers it; or, by scanning it across your own output optics, you can paint a picture that they see when it's entirely in focus.

Topics

Rosetta opacity hologram

Kragen Javier Sitaker, 2016-09-05 (8 minutes)

In 2000 I wrote about "opacity holograms" — a way to encode a large number of two-dimensional input images into two images such that just by passing light through them both in different directions, you can reconstitute any of the original input images, using only geometrical optics (i.e. no wave mechanics.) The naïve approach to this involves a reduction of N× in both resolution and brightness for N input images: e.g. for 100 input images you take a hit of 99% of the original input light intensity. I think it's possible to do better than that, maybe even as far as the √N that real interference holograms get, but I haven't figured out how yet.

The naïve approach is something like this: on one sheet of film, leave one transparent pixel in the center of each 10×10 pixel square; now lay this atop another sheet of film on a lightbox. The upper "grille" will leave visible one out of every 100 pixels in the lower sheet, and by sliding it one pixel up, down, left, or right, you can select one of 100 different "pages" of information. It's probably more practical, as I wrote in 2000, to permanently mount the "grille" and the interleaved image on opposite sides of a sheet of glass.

One possible use of this is for archival information storage. One of the problems confronted by the design of artifacts like the Rosetta Project's Rosetta Disk is how to make the archived information retrievable without advanced technology like a computer. (Presumably if computers survive, then so will computerized archives of our current information.) The unhappy compromise adopted by the Rosetta Project is to require the reader to have a 650× microscope.

If your film is printed on a 1200dpi laser printer, then each of the 100 interleaved pages of information has 120dpi available to it — more than enough for crisp, readable text. In the roughly 3½×6 pixel font I designed for laser-printed microfilm and shown in http://canonical.org/~kragen/bible-columns, you'll have 20 lines of text per vertical inch (rather than the usual 6: effectively, a 3.6-point font), moderately readable to the naked eye; roughly ten thousand words on a page, a dozen times the usual areal density. The 100 pages together are roughly a million words, or a bit longer than the Bible — on a single page. And since each page is potentially full color, you can do better still by encoding separate monochrome images in red, green, and blue color channels: 3600 pages of text, readable with the naked eye and a color filter, printable on a single pair of pages with a regular laser printer. With a high-resolution printer, you might be able to get more.

I suspect that you can do better than this naïve approach by jointly optimizing the two opacity images of the "grille" and "interleaved image", but I don't know how much better.

How much separation can you get? Ideally you'd like to spread out the 100 pages (or however many you can get) over as much solid angle as you can, so that, for example, you don't have to be a precise distance from the page to see a single image, you don't switch images when your eye saccades (moving your pupil a few millimeters), and

you see the same image from both eyes. Let's figure that the maximum angle you want to have to turn the page from looking at it straight on is 60°, because at that point you've visually squished it by a factor of 2, and more than that will impede readability. So you have 120° of angle that you need to divide into 10 increments, thus 12° each. So you want a single-pixel displacement between the two sheets (1/1200 inch, or 21 microns) to correspond to 12°, which means you want the distance between the sheets to be effectively about $1/\sin^{-1}(12°) \approx 5\times$ that 21 microns: 105 microns, about a tenth of a millimeter. This is assuming no refraction; the refractive index reduces the necessary thickness, and also linearizes the displacement a bit, so that the nonlinearity of arcsin becomes less significant.

You need to make sure your pixels are big enough that geometrical optics is a good approximation, which is to say that the pixels need to be a lot bigger than the wavelength of light. 21 microns is sufficiently bigger than 0.7-micron red light, and there's room for another factor of 2 or 4 in there, which would be a factor of 4 or 16 in information density. But 2400dpi printers are a specialty item, and 4800dpi printers are only used for transferring CGI imagery onto movie film, so they are much less accessible.

Alternatively, you could accept lower resolution per encoded page (and lower light levels) in exchange for more encoded pages by making the grille holes sparser. This won't increase the number of words encoded, because the font size has to be bigger, but it may make the text easier to read by making it larger. Perhaps a factor of 2 is available here.

Printing transparency film on both sides is the ticket

Amazon has 100 sheets of laser-printable transparency film at half an inch thick, or about 130 microns thick, which is in the right ballpark. The extra thickness (and refractive index) reduces the viewing angle correspondingly, perhaps to 8° or so. At a reading distance of half a meter, that's about 7 cm; so your two eyes will see different pages, but each eye will comfortably see a single image regardless of where it saccades to.

Amazon's current price on this is US$19.32, or US$0.19 per roughly-A4-size sheet. The material is probably cellulose acetate, which is not archival-quality and will degrade within a century under most conditions, through a process known as the "vinegar syndrome", which poses major problems for current archival collections. It also has a refractive index of about 1.5.

The archival-quality substitute seems to be the now-discontinued Type D Mylar film or Melinex 516 or other equivalent PET film, which you can apparently etch with carbon tetrachloride to get it to take inkjet ink. Amazon has what appears to be inkjet-printable Mylar at 36" × 125' at 4 mil thick (216µm) for US$175, but I don't know if it's archival. Archival (but possibly not easily printable) Melinex 516 is available from Talas at US$290 for a 2-mil (51µm) 60" × 250' roll, which is 116m² or 1862 A4-page equivalents, or US$0.16 per A4 page — comparable to the acetate. Mylar's refractive index is about 1.65.

What to store: Rosetta Project, OED, Wikipedia Vital Articles

The Rosetta Disk is currently slated to hold 13 000 pages of language documentation, according to the project's home page at the moment, out of the 100 000 they have gathered. These 13 000 pages could be encoded on about two to six A4-sized transparency films. On 2-mil film, this would occupy about 3–9 milliliters.

The whole 100 000 page collection is available for download from the Internet Archive. This would be eight times as large: 25 to 75 milliliters, 16 to 50 sheets.

The first edition of the Oxford English Dictionary is slightly larger; the English Wikipedia's selection of 1000 "Vital Articles" is similar in size.

Soldering with a compound parabolic concentrator or even just an imaging lens

Kragen Javier Sitaker, 2016-09-07 (2 minutes)

A soldering gun is typically 150 watts; a woodburning kit, like for writing your name on your baseball bat, is 25 watts. Compound parabolic concentrators, if pointed correctly at the sun, can theoretically achieve 11000 suns of concentration without refraction ($1/\sin^2(0.54°)$), and the solar constant is about $1kW/m^2$. At $11MW/m^2$, 150 watts is 14 mm^2 and 25 watts is 2.3 mm^2, and a piece of dark metal placed at that point could conduct the heat to a smaller point if there's a heatsink there.

Suppose we want a CPC with a $2.3mm^2$ absorber area. That's a 1.5-millimeter square. What does it look like?

We could make it square rather than round, which should make it easier to fabricate. Its eventual opening would be 25W of $1kW/m^2$, which is a square 15.8 centimeters on a side, but it's quite long indeed: to achieve its theoretical ideal performance, that 15.8 centimeters actually subtends 0.54° as seen from the absorber, which is to say it's 16.8 meters long.

However, most of that length reflects very little light. If we're willing to accept the reflected image of the sun only filling up, say, the outer 45 degrees of our viewing angle, which should reduce the power received only by a factor of 2 or so, then we should be able to truncate the CPC at a much more reasonable height.

...but how do I calculate that height? I mean I guess I could plot points and solve it numerically...

...maybe actually a CHC or something similar would be a better way to achieve such a large concentration?

What about imaging optics, like a magnifying glass? Can you solder with a magnifying glass? A magnifying glass of 15.8 centimeters square probably can't focus light any closer than about 15.8 centimeters focal length (aperture f/1). At that distance 0.54° gives you a 1.49-millimeter-wide image of the sun, covering 2.2 square millimeters. So yeah, a short-focal-length magnifying glass would work for that. Typical focal lengths are longer, but they wouldn't have to be.

Broken computer frustrations

Kragen Javier Sitaker, 2019-08-11 (2 minutes)

My netbook broke the other day, which is why there's been a six-day gap in Dercuano. I suspect what went wrong is not actually the disk, so the extra stuff I'd written that night and not yet pushed to GitLab is probably recoverable, but it reminded me again of the precarious and janky state of my informatic infrastructure. I'm writing this on a different netbook with a nearly-shot battery and a Wi-Fi chip that keeps crashing. I'm going to have to reboot it to push this.

Normal people are using Google Docs, Apple's iCloud, and things like that more and more because of problems like this, despite the (to me) obvious security problems.

Ideally I would have a unified namespace of my data, including downloaded databases like this Wikipedia ZIM file and fairly ephemeral data like browser and editor state, with a local cache of it (and pending updates) on each user-interface device I have (netbooks, desktops, hand computers, whatever). Then each piece of data would also be replicated to different storage devices, which might be pendrives, file servers, or encrypted blobs in S3 buckets. The underlying model would be something like Secure Scuttlebutt mixed with git-annex, but the user interface would hopefully be something a bit easier to use. Ideally the loss or breakage of a cellphone or netbook would be only a minor inconvenience limited to whatever data had been created on it since the last time it was synced with any surviving device.

Downloading large databases over the internet is best left to a Raspberry Pi server on an always-on internet connection, not my laptop or hand computer. Syncing the downloaded database onto my laptop over The local connection, once I'm in its proximity in person, should be fast and transparent.

As I said before, this extends to local app state, so ideally it should be straightforward to, on my laptop, open up the "what my phone is viewing" folder and then transfer the session state of whatever I was doing on the phone onto the laptop --- and vice versa.

IMGUI programming language

Kragen Javier Sitaker, 2019-01-01 (updated 2019-07-30) (21 minutes)

So I want to write an immediate-mode GUI library (see IMGUI programming compared to Tcl/Tk (p. 2333)) for this experimental programming system I'm writing. But I also want to write a programming language for the purpose, because (see Yeso notes (p. 2585)) even without the IMGUI library, I've written 1500+ lines of C for graphical applications, and I feel like a more reasonable programming language would make those applications both significantly less code and significantly less bug-prone.

Local-variable pointers and var parameters

IMGUI is a lot easier when I can take addresses of local variables to do things like this:

```
static int item_current_2 = 0;
ImGui::Combo("combo 2 (one-liner)", &item_current_2,
             "aaaa\0bbbb\0cccc\0dddd\0eeee\0\0");
```

Here, `item_current_2` contains the current selection in the combo box. In C, you can also do this with struct fields and whatnot. This is a feature that is missing from Lisp-memory-model programming languages, in general. You typically end up providing "slot" objects with a get method and a set method, which is inconvenient if it involves changing the definition of the thing you're trying to change, or writing a special-purpose wrapper. (Common Lisp took a different approach.)

Blocks

But C makes IMGUI harder when you have to do things like this:

```
    if (ImGui::BeginMenu("Help"))
    {
        ImGui::MenuItem("Metrics", NULL, &show_app_metrics);
        ImGui::MenuItem("Style Editor", NULL, &show_app_style_editor);
        ImGui::MenuItem("About Dear ImGui", NULL, &show_app_about);
        ImGui::EndMenu();
    }
    ImGui::EndMenuBar();
```

In a language like Smalltalk or Ruby with a block facility, you could write this as follows, avoiding the EndMenu and EndMenuBar calls and the potential bug of forgetting them:

```
    ImGui::BeginMenu("Help") {
        ImGui::MenuItem("Metrics", NULL, &show_app_metrics);
        ImGui::MenuItem("Style Editor", NULL, &show_app_style_editor);
        ImGui::MenuItem("About Fear ImGui", NULL, &show_app_about);
    }
```

Possibly MenuItem would also take a block to specify the action to take:

```
ImGui::BeginMenu("Help") {
    ImGui::MenuItem("Metrics", NULL) { show_app_metrics(); }
    ImGui::MenuItem("Style Editor", NULL) { show_app_style_editor(); }
    ImGui::MenuItem("About Mere ImGui", NULL) { show_app_about(); }
}
```

Block arguments can also give you resource managers (with-open-file, save-excursion) and iteration, all without the garbage-collection difficulties and compiler complexities of full-fledged closures. I feel like iterators implemented with block arguments are somewhat inferior to first-class sequence objects as in Python and D, but they're relatively passable.

Closures versus var parameters

In conventional GUI toolkits, a strong argument for first-class garbage-collected closures is that it allows you to write event-handling code like the above. In IMGUI, downward-funarg blocks are adequate!

Perhaps address arguments (the `&item_current_2` in the above example) could be subject to a discipline like Pascal's downward-funarg discipline: you can pass an address as an argument or store it in a local variable, but you can't store it in a global variable, a variable in an outer scope, a record field, or an array item, and you can't return it. (Alternatively, storing it into a record or array would cause the record or array to inherit the downwardness; in this direction eventually lies Rust.) This would make it statically safe to pass addresses of local variables without requiring garbage collection. (It's very roughly equivalent to Algol call-by-name, or to passing a getter function and a setter function.)

In fact, I had forgotten this, but it turns out that Pascal has precisely this feature: its "var parameters" are precisely the downward-only-passable address arguments being described here, except that you can't store them in a local variable or reseat them, and (more disconcertingly to my eye) they look just like input parameters at the callsite. Oberon follows Pascal in this, despite having garbage collection and thus no need for the downward-only discipline.

Fuck C, though, seriously

I really hate C's single program-wide namespace (give me method namespaces and a module system, please), verbose type syntax, lack of multiple return values, lack of list comprehensions, lack of any kind of real error handling, clumsiness with ad-hoc polymorphism, inflexible argument passing, bug-prone coercions, bug-prone error reporting, and lack of memory-safety. (The NULLs in the above code example are perhaps avoidable in C++, but in C they'd be a consequence of the inflexible argument passing.) I like the fact that in C you can copy records by value and avoid aliasing them, just as I like the fact that you can alias fields with pointers when you want.

Types and arguments

You probably want optional named arguments for IMGUI; record literals are probably fine for that if you can invoke operations on them, and of course Tk does it by parsing command lines. Without

those, you're stuck with something like a PostScript graphics context to change things like font sizes and colors.

For pixel slinging, you probably want numeric vector types, at least fixed-size ones.

I've been wondering if you could do most of Hindley-Milner type inference, including sum types, without any parametric polymorphism, though perhaps supporting ad-hoc polymorphism. (I want sum types primarily to avoid null pointers and secondarily because of the usefulness of pattern-matching in compiler-like work.) That is, every variable and every function would have a fully concrete type, but it would be inferred from context as much as possible.

I really like the Golang interface construct. It conflicts to a minimal extent with the desire for type inference, because if method calls on concrete types and method calls indirected through interfaces are written with the same syntax, the most you could ever infer about a value from the method calls is a lower bound on its interface.

You ought to be able to infer the structure of a sum type from any wildcardless pattern match that matches on an object of that type.

I don't have a completely clear idea of how the kind of value references I'd like to be able to pass to things like `ImGui::Combo` above should interact with interfaces and heap pointers.

Some C code examples and their Platonic essences

Yesomunch

Here is some existing code written with Yeso:

```
#include "yeso.h"

int main()
{
  ywin w = yw_open("munching squares", 1024, 1024, "");

  for (int t = 0;; t++) {
    ypic fb = yw_frame(w);
    for (int y = 0; y < fb.h; y++) {
      ypix *p = yp_pix(fb, 0, y);
      for (int x = 0; x < fb.w; x++) p[x] = (t & 1023) - ((x ^ y) & 1023);
    }

    yw_flip(w);
  }
}
```

Here is what I would like it to look like:

```
#include "yeso.h"

int main()
{
  yw_open("munching squares", 1024, 1024, "") for (ywin w) {
    for (int t = 0;; t++) {
      yw_frame(w) for (ypic fb) {
```

```
      yp_scanlines(fb) for (int y, ypix *p) {
        for (int x = 0; x < fb.w; x++) p[x] = (t & 1023) - ((x ^ y) & 1023);
      }
    }
  }
 }
}
```

or, with lifetimes or scopes extending from each declaration to an implicit end at the enclosing }, as in C++, but also including loops, something like Notes on Raph Levien's "Io" Programming Language (p. 1740):

```
use yeso

{
  yw_open("munching squares", 1024, 1024, "") -> ywin w;
  for (int t = 0;; t++);
  yw_frame(w) -> ypic fb;
  yp_scanlines(fb) -> int y, ypix *p;
  for (int x = 0; x < fb.w; x++);
  p[x] = (t & 1023) - ((x ^ y) & 1023);
}
```

or:

```
use yeso

yeso.window("munching squares", 1024, 1024) w:
    (0..) t:
        w.events:
            be it Die: return 0
            be _: None
        w.frame:
            it.each_line y, p:
                (..#p):
                    p[it] <- bitand(t, 1023) - bitand(xor(it, y), 1023)
```

This looks very much like Ruby, actually, though with Lobster syntax. Some improvements over the C version:

- It's less than half as much code.
- Opening and closing the window is taken care of by the yeso.open function, which passes the window object to the argument block, and implicitly closes the window upon exit from that block. If you call it without a block, it returns the window object, and you have to close it explicitly. Similarly, `w.frame` flushes the framebuffer to the display when the block exits. This is much less bug-prone than the C version.
- The options argument in the C version is optional and omitted.
- No types are mentioned except `Die`.
- The event dispatch is done with pattern-matching instead of a bunch of functions.
- Numeric ranges are first-class callable objects; invoked with blocks, they iterate.

• Parentheses are not needed for function calls without non-block arguments; you use some other syntax to get a reference to a method when that is necessary.
• Bitwise operations are written with function-call syntax rather than infix operators.
• Mutation <- is distinct from declaration and initialization =.
• The length of a slice is extracted with #.

Block syntax is `arg1, arg2, arg3: INDENT body OUTDENT`, where the argument list may be empty. The special identifier `it`, if mentioned in the body, is added as an argument to the argument list.

Tetris piece rotation

Here's a function from my Tetris implementation:

```
void rotate_piece(char *piece, char piece_rotated[][4], int piece_r)
{
  int origin, xs, ys;
  switch (piece_r) {
  case 0:
    origin = 0;
    xs = 1;
    ys = 4;
    break;
  case 1:
    origin = 3;
    xs = 4;
    ys = -1;
    break;
  case 2:
    origin = 15;
    xs = -1;
    ys = -4;
    break;
  case 3:
  default:
    origin = 12;
    xs = -4;
    ys = 1;
    break;
  }

  for (int y = 0; y != 4; y++) {
    for (int x = 0; x != 4; x++) {
      piece_rotated[x][y] = (' ' != piece[origin + x*xs + y*ys]);
    }
  }
}
```

This converts a 16-byte piece into a 4×4 array of booleans with a particular rotation in a pretty crappy way. Instead:

```
to rotate_piece(piece, piece_rotated, piece_r):
    (origin, xs, ys) = ((0, 1, 4) if piece_r == 0 else
                        (3, 4, -1) if piece_r == 1 else
                        (15, -1, -4) if piece_r == 2 else
```

```
                    (12, -4, 1))
    (..4) y:
        (..4): piece_rotated[it][y] = (' ' != piece[origin + it*xs + y*ys])
```

The compiler can here infer that `origin`, `xs`, `ys`, `y`, `it`, and `piece_r` are ints, that `piece_rotated` is an array of arrays of bools, and that `piece` is an array of chars. There's also a tuple of three ints here.

We can do better, though, if we can return the array of arrays, and our loop is actually a list comprehension producing that array:

```
to rotate_piece(piece, piece_r):
    (origin, xs, ys) = ((0, 1, 4) if piece_r == 0 else
                        (3, 4, -1) if piece_r == 1 else
                        (15, -1, -4) if piece_r == 2 else
                        (12, -4, 1))

    (..4) x: (..4) y: ' ' != piece[origin + x*xs + y*ys]
```

Can the compiler infer that this returns specifically a 4×4 array rather than just an array of arrays (of bools)? If it could infer that, then the caller could allocate space for the return value on the stack. An alternative that doesn't involve dynamic allocation for such sequences is to return a generator object, which the caller can then unpack as they see fit, but that isn't a good default semantics for a for loop.

Or we could take a block argument to store the result:

```
to rotate_piece(piece, piece_r):
    (origin, xs, ys) = ((0, 1, 4) if piece_r == 0 else
                        (3, 4, -1) if piece_r == 1 else
                        (15, -1, -4) if piece_r == 2 else
                        (12, -4, 1))

    (..4) x: (..4) y: yield x, y, ' ' != piece[origin + x*xs + y*ys]
```

(Arguably the procedure header should have some indication that it expects a block.) Then you could invoke it like this:

```
rotate_piece(pieces[piece], piece_r) x, y:
    piece_rotated[x][y] = it
```

I really miss list comprehensions a lot in C and Golang.

Makefont event dispatch

Here's some annoying code from another yeso program, makefont.c:

```
for (yw_event *ev; (ev = yw_get_event(w));) {
  if (yw_as_die_event(ev)) {
    yw_close(w);
    free(img.p);
    img.p = 0;
    return 0;
  }
```

```
  yw_key_event *kev = yw_as_key_event(ev);
  if (kev && kev->down) {
    if (kev->keysym <= '~') {
      current_char = kev->keysym;
      yp_p2 newsize = font.g[current_char].size;
      if (newsize.x || newsize.y) defsize = newsize;
    } else switch(kev->keysym) {
        #define IF break; case
        IF yk_shift_l: display_text = 0;
        IF yk_left: if (off.x) off.x -= 128;
        IF yk_right: off.x += 128;
        IF yk_up: if (off.y) off.y -= 128;
        IF yk_down: off.y += 128;
        IF yk_pgdn: write_out_the_font(&font, argv[1]);
      }
  }

  if (kev && !kev->down && kev->keysym == yk_shift_l) display_text = 1;

  yw_mouse_event *mev = yw_as_mouse_event(ev);
  if (mev) {
    yp_p2 xy = yp_p_add(mev->p, off);
    if ((mev->buttons & 1) && !(buttons & 1)) {
      font.g[current_char].start = xy;
      font.g[current_char].size.x = defsize.x;
      update_height(&font, current_char, defsize.y);

...
```

This becomes something like:

```
w.events ev:
    be ev Die ->
        return 0
    be Key(_, keysym, Down) -> (
        be keysym Ascii(ch) -> current_char <- ch
        be Shift_L -> display_text <- False
        be Left -> if (xoff): xoff -= 128
        be Right -> xoff += 128
        be Up -> if (yoff): yoff -= 128
        be Down -> yoff += 128
        be _ -> None
    )
    be Key(_, Shift_l, Up) -> display_text <- True
    be Mouse((x, y), new_buttons) ->
        x += xoff
        y += yoff
        if bit(new_buttons, 1) && !bit(old_buttons, 1):
            update_height(&font, current_char, 0)
            font.g[current_char] = ((x, y), (0, 0))
```

The cleanup code is taken care of elsewhere by wrappers and deferred cleanup functions. I'm not sure how the keysym names and other constructor names are in scope so we don't have to say `yeso.Up` or indeed `yeso.Key`; maybe a declaration like `use yeso.keys as yk` would

allow us to use `yk.Up` and be adequate. The name collision between `Down` for a keydown event and `Down` for the down-arrow key is unfortunate.

Some amount of type declaration might simplify that — if we know that keysym is a keysym, we could bring the keysym constructors into scope for the pattern-matches.

An interesting possibility for dynamic allocation is to use explicit region-based allocation, in which each function has the possibility of constructing an arena that is freed when it returns, and can pass that region to other functions so that they can dynamically allocate things in it that will survive their return.

Uncorp

I feel like the above is a very ambitious language design for someone who's only done much simpler languages before, and perhaps it isn't ideally suited for a language that will need to have two implementations kept in sync for bootstrapping purposes.

As a first step, I think I should implement a reverse-polish-notation portable assembler, "uncorp", which supports most of the semantics of my desired language but without types or syntax. You'd have the usual unsigned integer ALU operations (`+ - * / & | ~ ^ << >> <` and maybe `sex8 sex16 sex32`), the usual memory-access operations (`! @ C! C@`), a stack operation or two (`DROP`, say), and some basic control structures — at least `IF-ELSE-THEN` and `LOOP-WHILE-REPEAT`. For function call, yield, and return, I propose:

- `: foo` to define the label `foo` at the current position, potentially backpatching earlier references;
- `foo call` to call `foo` with access to the current operand stack, which is far less convenient than the usual RPN syntax, but avoids the need to predeclare labels before calling them;
- `28 enter` to create a 28-byte stack frame containing a link to the old stack frame and install it on the frame pointer;
- `28 ret` to restore the frame pointer, pop the 28 bytes, and return, preserving the operand stack;
- `fp` to get a pointer to the current stack frame;
- `n fp+` `n fp+@`, `n fp+!`, `n fp+c@`, and `n fp+c!` to get addresses or load and store into the current stack frame (the last four are strictly speaking superfluous, but will make it much easier to generate reasonable code on i386 and amd64);
- `foo bar yield` to set the frame pointer to `foo` and jump to `bar` with the previous frame pointer and the program counter after `yield` on the operand stack, ready for another `yield` to return to where you were.

This is not quite powerful enough for cooperative threading or exception handling, for both of which `yield` would also need to set the stack pointer, but it's adequate for the downward-funargs case, whether you're passing the frame pointer implicitly (as for the single-level downward-funargs cases I contemplated above) or explicitly. Given that, it's probably better to have separate operations for setting the stack pointer, if desired.

This version of Uncorp has some desirable properties. A completely naïve compiler should be very easy to write and usably efficient, if several times slower than decent code. A slightly less naïve compiler that just does register allocation for the operand stack

should come within a factor of two or so of optimized C for a reasonably wide range of code. It can be extended with vector operations easily. And it can support the features I was describing above.

One tricky bit is how big the frame pointer is supposed to be. Remember this is supposed to be a *portable* assembler, targeting at least AVR, armel, armeb, aarch64, i386, and amd64, and I'd like it to also be *deterministic*. I think this design is too untyped to be efficiently deterministic for several reasons:

• because of the endianness issues across these architectures;
• because address arithmetic is going to have word-size-dependent overflow;
• and because it's impossible to bounds-check address arithmetic, so, say, subtracting a stack pointer from a function pointer is going to produce platform-dependent results that moreover may be too large for some platforms to even represent.

For now I'm going to not worry about that, but it's a thing to keep in mind as a reason to replace Uncorp. A little bit of compile-time computation, like `[ 24 ptrsize + ] enter`, might be enough to take care of this.

So the bootstrapping plan is to write an Uncorp interpreter in something easy and widespread, like JS or Python, and then an Uncorp compiler for amd64-ELF in Uncorp. Then I can write a compiler for the more usable imperative language above in Uncorp, and then compilers and interpreters for higher-level languages in that language.

StoneKnifeForth is 204 lines of code or 132 lines without comments, and compiles a language with 20 primitives. The 32 or so primitives of Uncorp should therefore require something like 300 lines of code, per platform. This is a lot worse than the 104 lines of my implementation of Chifir but barely more than my implementation of Tetris.

But wait! Uncorp also needs to be able to initialize variables by putting labeled binary numbers into the executable. It probably doesn't need explicit .data and .text directives (unless we want to support .bss or generate machine code from binary numbers) but it does need `d8`, `d16`, `d32`, and `d64` compile-time operations. And, as mentioned above, it needs support for compile-time computation — maybe not defining functions at compile-time, but at least things like `[ 23 ptrsize * 11 + ]`, and probably alignment too, which means you need access to the current compilation address in both .data and .text. So maybe it will be twice that, like 600 lines, though maybe more of that can be shared between platforms.

I don't think it should be the job of the source program to generate ELF headers or symbol tables, because the objective of Uncorp is to be a *portable* assembly: it should at least be possible and ideally very easy to write reasonably efficient Uncorp programs that can run without change on several different platforms.

What would list comprehensions look like in a C-level language? We don't want to saddle the containing function with handling failures, so we would like to avoid heap allocation. Stack allocation can, of course, fail, but perhaps this is less of a problem; it has no fragmentation to deal with, so proving that it won't fail seems more

tractable — although it does require bounding the list length.

Allocation doesn't entirely go away as a concern, though. For things like any(), all(), sum(), min(), or max(), or foreach, there is no real allocation problem, because we can probably evaluate the sequence lazily. But what if we really do want to store the results in an indexable or reiterable sequence? We need an array.

The stack-allocation discipline means that a callee's arrays will not be available to the caller, but block arguments can come to the rescue here — the callee can yield control to the caller's block with the freshly-allocated array.

Conventional downward-growing stacks and addition-indexed arrays are not a very good match here. Either you must implicitly reverse the array generated from the comprehension at the end, you must grow it upwards, you must periodically relocate it during the comprehension to a larger buffer size, or you must index it by subtraction. Of these options I think the implicit reversal is the best.

Topics

High academic achievement almost certainly depends more on tutoring than group averages by race or sex

Kragen Javier Sitaker, 2016-09-08 (3 minutes)

Reading http://www.scientificamerican.com/article/how-to-raise-a-genius-lessons-from-a-45-year-study-of-supersmart-children/ and it talks about how the top 1% in intelligence are responsible for a lot of our science and culture. Some controversial previous discussion has focused on how differences in variance and means between different groups might affect questions like this; Larry Summers got fired over such discussion, for example.

The Wikipedia article https://en.wikipedia.org/wiki/Sex_differences_in_intelligence summarizes the situation.

The top 1% are 2.33 standard deviations to the right of the mean in a Gaussian distribution, which is 135 IQ in the overall population:

```
> qnorm(.99)
[1] 2.326348
> qnorm(.99, mean=100, sd=15)
[1] 134.8952
> pnorm(135, mean=100, sd=15)
[1] 0.9901847
```

What if you have a subpopulation with a 10% smaller variance? It turns out to reduce the number of people in that subpopulation in the top 1% by more than a factor of 2:

```
> pnorm(135, mean=100, sd=15*.9)
[1] 0.9952372
```

What if instead you have a subpopulation whose mean is shifted down by one standard deviation, without changing the variance — an effect size of 1? This reduces the number of people in that subpopulation in the top 1% by a factor of 20:

```
> pnorm(135, mean=85, sd=15)
[1] 0.9995709
```

This is true even though the probability is quite reasonable that an event from this group will be higher than an event drawn from the entire population.

The situation becomes more extreme as you go to more extreme quantiles. Consider the top 0.01%:

```
> qnorm(.9999)
[1] 3.719016
```

```
> qnorm(.9999, mean=100, sd=15)
[1] 155.7852
> pnorm(156, mean=100, sd=15)
[1] 0.9999055
> pnorm(156, mean=100, sd=15*.9)
[1] 0.9999832
> pnorm(156, mean=85, sd=15)
[1] 0.9999989
```

That is, at IQ 156 and above, where we find 0.01% of the population, a hypothetical population with a 10% lower standard deviation will be underrepresented by almost 6:1, and a hypothetical population with a 1-SD-lower mean will be underrepresented by more than 90:1; getting the same result by tweaking the variance requires a 21% smaller standard deviation, 11.9 IQ points.

A hypothetical group with a 1-SD-lower mean but also a 21% *larger* standard deviation (of 19 IQ points) matches and slightly exceeds the overall population at this level:

```
> pnorm(156, mean=85, sd=15/.79)
[1] 0.9999077
```

In this context it is worth pointing out that tutoring improves student performance by two standard deviations (Anania (1982, 1983) and Burke (1984)):
http://changelog.ca/quote/2012/09/23/tutoring_two_sigma.

So what if we have a hypothetical group with an unchanged variance but a mean two standard deviations higher?

```
> pnorm(156, mean=130, sd=15)
[1] 0.9584818
```

If student performance is equivalent to IQ, 4.2% of them will exceed the performance of 99.99% of the rest of the population. This is a larger difference than has ever been suggested for (mean or variance) intelligence differences due to race or sex.

(In the paper described, tutoring also substantially reduced the variance of achievement scores, but this is probably because the achievement scores had a ceiling; all three of the distribution curves from the experimental data intersect at the X-axis on the right, and the "tutorial" group's distribution is noticeably skewed to the left.)

Notch scorn

Kragen Javier Sitaker, 2019-04-20 (5 minutes)

I talked briefly with the pariah Notch on the hellsite the other day, thanking him for writing Minecraft. He mentioned that he enjoyed reading Knuth; one of his followers asked if Notch had left Knuth's work TAOCP unopened when Notch learned that Knuth was opposed to some of Bush's policies, including the US invading Iraq.

This seemed sad to me. What would it take for a person to not read Knuth for such a reason? Not only would they have to belong to Bush's faction, they would have to consider it more important that Knuth belonged to an opposing faction than what Knuth knew or didn't know about computer programming.

It seemed to me that this follower was arrogating to themself the right to judge Knuth's worth, on the basis that Knuth belonged to the other faction, the inferior faction. I have no reason to believe that the follower was a person of significant intellectual achievements themself, much less a scholar of Knuth's stature, but they seemed to consider this irrelevant; for them, dismissing Knuth's work as worthless, even repugnant, was their prerogative for belonging to the correct faction of the culture war.

In this sense, the elevation of factional alignment over scholarly achievement necessarily implies the elevation of ignorant and foolish thugs over scholars — not, perhaps, all scholars, but at least scholars of opposing factions. Moreover, the assignment of a scholar to a faction depends not on scholarly criteria but on thug criteria. This is the principle by which Archimedes was struck down in Syracuse by a Roman soldier, by which Sulla burned the Academy, by which Nazi ruffians burned the books of Jewish scholars who were their superiors in every way, and by which Qin Shi Huang burned the books and buried the scholars. This is the principle by which the Boxers burned the Yongle Encyclopedia, the greatest encyclopedia the world knew before Wikipedia, and by which Mossad thugs assassinated the Iranian nuclear scientists. And this is the reasoning behind the prosecution of my friend Aaron Swartz.

Such an inversion of priorities is inevitable in wartime — when Julius Caesar set fire to the Library of Alexandria, he had intended only to set fire to his ships, not to the library. A human will do nearly anything in their futile effort to secure their own survival, even if it puts at risk values much more precious.

Subjugating the wise to the foolish and ignorant leads invariably to tragedy. The ruler who listens to the counsel of fools brings waste to their land and poverty to their people. And this is what we do when we prize ideology and factional loyalty over wisdom and learning.

Yet are we to honor learning even in the service of evil? Should the Iranian nuclear scientists be permitted to put the fire of the stars in the hands of the mullahs who rule their land with such cruelty and injustice?

These problems arise when the scholars accept this perversion of harmonious order, willingly serving as mere instruments of ignorant and foolish people. By pledging their loyalty to those who follow not truth and prudence but domination and power, those whose position

owes not to wisdom and learning but to brutality and intimidation, they abdicate their responsibility to speak the truth and serve the well-being not of one faction but of the world.

True scholars serve a master higher than any government or movement, as exemplified by Socrates's suicide, by the defensive fortifications of the Mohists, and by the false legend of Galileo's defiant "Eppur si muove." This is the reason for the principles of academic freedom. Scholars who speak their minds even when it is unpopular, who act in the service of truth and benevolence as they understand it, these scholars are the noblest and best of humanity. Even their enemies should honor them. But servile scholars who allow themselves to be employed by other people, as if they were pieces of equipment; who obey rather than choosing; who lie and who remain silent in the face of injustice in order to help their own government or faction; those are no scholars at all but mere pedants.

Pensamientos acerca de diseñar un calefón solar

Kragen Javier Sitaker, 2012-10-15 (2 minutes)

Unos pensamientos más de anoche acerca de termotanques solares:

• Hablé con mi papá acerce de lo que él había construído para su casa rodante. Él usó esa tubería negro. Dice que es de polietilena y por eso es seguro para uso para agua potable hasta la temperatura de hervir.
• Además tiene la ventaja que, si en algún momento el agua se congele, no rompe los caños. Por lo menos la primera vez.
• Él usó vidrio templado, de lo cual pidió la fabricación en el tamaño que quiso.
• Acrílico (plexiglas) es un posible alternativo al vidrio que es más duradero contra piedras de hielo. Tiene la ventaja o desventaja que es bastante transparente a infrarrojo térmico.
• Calculé que una suba de 14 grados encima de la temperatura ambiente (imponiendo un límite de 49 grados cuando la temperatura ambiente es de 35 grados) puede sostenerse en un sol de 800W/m² con una resistencia térmica de solo R 0.018 (m²K/W), lo cual es más o menos lo que obtenés con pasaje libre de viento en dos lados del panel, sin nada de aislación extra.
• No obstante, eso es una idea estúpida porque así cuando la temperatura ambiente es de solo 0 grados, el agua "caliente" será de solo 14 grados. Es necesario usar alguna temperatura de "referencia" más estable para poder limitar confiablemente la temperatura.
• Un posible temperatura de "referencia" para eso sería los 3.7K de espacio: cuando no hay nubes, podés radiar infrarrojo al espacio para mantener la temperatura a un nivel seguro.
• Un problema con esto es que, dado que la diferencia entre la temperatura de referencia y la temperatura que quiero del agua es muy grande (320 K) comparado con el rango de temperaturas aceptables (6 K), aunque la radiación Stefan-Boltzmann anda con la cuarta potencia de la temperatura, igual será enormemente ineficiente. La emisión térmica a 43 grados será unos (316^4/322^4) =

A one-motor robot

Kragen Javier Sitaker, 2015-09-03 (13 minutes)

I've been thinking for a while about how to reduce the number of motors needed in a robot, because motors are the only mechanical part you can't reasonably 3-D print (or resin-cast, or laser-cut, or made with other easily-accessible means of automated fabrication), and they're also kind of heavy, expensive, and unreliable.

Also, in some cases, it makes sense to use an internal-combustion engine rather than an electric motor to supply mechanical power to the robot, because it can use fuel, which stores energy two orders of magnitude more densely than batteries do, thus allowing two orders of magnitude more autonomy. Where a battery-powered quadcopter can fly for 15 to 25 minutes, a gasoline-powered one of similar design could reasonably expect to fly for hundreds of hours; but internal-combustion engines don't currently scale down nearly as small as electric motors without serious loss of efficiency. Boston Dynamics' spectacular designs typically use pneumatic actuators powered by what sounds like a two-stroke internal-combustion engine, but I haven't investigated in more detail.

Armatron

When I was a kid, I had a robot arm from Radio Shack called Armatron. It had six degrees of freedom: two rotations at the shoulder, rotation at the elbow, two rotations at the wrist, and opening and closing a gripper; but it had only a single motor, which ran continuously at a fixed speed as long as the robot was turned on. The two twistable joysticks mechanically engaged the various degrees of freedom with the motor or a brake, and through a set of slip-clutches, the force through each degree of freedom was limited to the small forces that the cheap nylon parts could handle easily without risk of breakage. It was a toy, but mechanically, it was a beautiful design.

It's not obvious that this is directly applicable to the problem of designing an electrically controlled robot, because you'd still need some kind of mechanical actuator for each of the degrees of freedom — but now to operate the joystick rather than to directly actuate. This is a big improvement in a sense; you can get by with solenoids or very small motors.

Below, though, I revisit this problem, with a camshaft-based solution.

Turtlebot

Consider the problem of a Roomba-like turtle robot, a horizontal disc with driven left and right wheels, plus maybe some idler wheels to keep stable. If you mount a pen in the middle of it, as with the original Logo turtle robots from the 1970s, you can draw any continuous shape on the floor just by alternating between turning in place and moving forward. You don't even need to turn both directions or move backwards.

In particular, you can draw smooth lines at any angle, without being able to independently control X and Y actuators.

You can straightforwardly achieve this with two motors, one on each wheel. But it occurred to me, thinking about this, that a single reversible motor would also work. It would drive, say, the left wheel directly, and the other wheel through a sort of mechanical full-wave rectifier, such that the other wheel always turns the same direction regardless of which direction the motor is turning. You could achieve this by driving the shaft of the wheel through two sprag clutches that freewheel in the same direction, one driven in the same direction as the motor (perhaps directly by the motor's shaft), and the other driven in the opposite direction, perhaps through a bevel gear between it and the first ring.

(You can 3-D print or, I think, even laser-cut a reasonable approximation to a sprag clutch in two or three relatively simple flexible parts, if you're not too worried about maximizing torque per volume.)

With this simple mechanical arrangement, the right wheel always drives forward, while the left wheel can go either forward, to move the robot, or backward, to turn it. So a single reversible motor should enable you to draw any figure, limited by your control system (I've argued elsewhere that closed-loop feedback is now cheap enough that we should apply it in almost every case now) and the very small backlash of your rectifier mechanism.

RepRap and 3-D printers

A different problem from the turtlebot is the 3-D printer, which typically needs four degrees of movement freedom — in a case like the RepRap Prusa Mendel, you have two parallel Z motors suspending the X motor via triangular-thread allthread bars as linear actuators, the X motor moving the print head via a belt drive, a reversible extruder motor on the print head itself pushing the filament into the hotend, and a Y motor moving the heated bed via the same kind of belt drive as the X motor; a total of five motors with four degrees of freedom. The motors used are heavy, expensive NEMA 23 stepper motors, which are uncommon enough that it's hard to salvage them from e-waste, even though e-waste is full of motors. And, of course, printing such a motor on the RepRap is far beyond its current capabilities.

(Ganging together multiple smaller motors to drive a single shaft is probably the right response to the problem of having only smaller motors easily available.)

I've thought (and I wasn't the only one) that you could dispense with the Z stage if, say, you replace the Y actuator with a circular θ actuator, and goes up a Z step every time the θ actuator makes a full revolution. The biggest problem with this is that, with the straightforward approach where the Z movement is directly controlled by one or more screw threads that revolve 1:1 with the θ actuator, you go up by an entire thread pitch. 1mm is the finest thread pitch commonly available in Allthread rods. But a 1mm Z-step is a very large step. 0.35mm and 0.25mm are more common layer thicknesses, providing more acceptable surface finishes, avoiding the need for extreme plastic feedrates, which would require a much larger hotend and extruder motor, as well as suffering more from heat-induced damage to the plastic's chemical structure and slumping before cooling. Gearing down the θ rotation by 10× would be

sufficient to solve this problem.

That reduces the machine from five motors to, say, three. If we are willing to limit the horizontal planar scan to a single fixed pattern, where we don't get to choose the direction of movement at each "pixel" but only how much material to deposit there, then we can gear the θ movement to the X movement, which probably should also become circular. This dramatically reduces the efficiency of the device and worsens surface finish, but with a sufficiently small build volume, perhaps it could be acceptable anyway. Essentially we have gone from a 3-D plotter to a raster 3-D printer, although with a funny circular scan pattern.

And now we have only two motors to control independently.

If we are to recapture the horizontal surface-finish and a shadow of the efficiency we got with our vector plotter, we could perhaps use the turtlebot approach: have a single motor alternate between determining the direction of motion, while stationary, and determining the speed of motion. In the RepRap context, this will cause some ooze problems, as the hotend's plastic extrusion rate is more or less a low-pass-filtered version of the extrusion motor's movement. (Thus oozebane and similar techniques in current FDM slicers depend on briefly reversing the extruder motor.)

How would this work? So far all the things I've thought of are ridiculously complicated and depend on analog mechanical computation devices called "integrators" "integration", which turn the position of their input into the rate of motion of their output, thus numerically (or analogically) approximating the computation of a definite integral. There are several different types that work by different mechanisms. In the mechanical computation context, integrators are notoriously sensitive devices, but I suspect that closed-loop control could fix that problem in this context. The famous Navy film about fire-control computers goes into some detail about the relevant mechanisms.

However, mechanisms that are ridiculously complicated when you have to cut all of their parts out of metal, with dimensions accurate to five significant figures, might no longer be ridiculously complicated when you can 3-D print them and compensate for their dimensional errors using closed-loop digital control.

That leaves us with two motors: one to control the X-Y (or rather θ-φ) scanning, bringing along Z for the ride, and another on the extruder. Can we get rid of the extruder motor?

Well, if we always extrude at a constant speed, perhaps through some kind of a gravity feed, we could control the amount deposited in each location by varying how rapidly we pass over it. But this seems relatively impractical, especially with materials like plastic, which is light and therefore hard to gravity-feed and can be usefully deposited through a very small orifice. (The orifice is almost inevitably smaller than the filament extruded, because the plastic swells upon being released from the orifice.)

For a machine to produce sand paintings, on the other hand — perhaps even very vertical sand paintings with "magic sand" — it might work perfectly.

Camshafts and Armatron revisited

Another thing we often want is a large number of very simple

actuators, such as valves which can be either open or closed, or pens that can be either up or down. If we can accept intermediate glitches, we can achieve this by driving all of the actuators on a camshaft where the cams are the different bits of a binary code, and the rotational positions of the camshaft are the different codes; the followers read off the various bits of the code for the current position. Many traffic lights in Buenos Aires, for example, work this way, with the cam followers actuating electric switches.

In the general case of N actuators, your camshaft needs to be able to distinguish among 2^N rotational positions, although by using Gray codes, the minimum width of a cam lobe can be twice that, and the overall number of bit changes can be minimized to the 2^N minimum. In some cases, not all possible codewords are necessary.

This, again, can be driven by a single motor that turns in one direction to select the set of actuators to be activated, and then in the opposite direction to provide mechanical power that is routed through them. (For example, pumping hydraulic fluid through a set of open valves, or driving a set of engaged gears.)

In particular, this is a possible solution to the Armatron problem: you have six pairs of mutually exclusive actuators, or equivalently six three-position actuators, so we need $3^6 = 729$ distinct positions of the camshaft, which is a bit much; but it's probably adequate to be able to engage two or three of the joints at a time, rather than all six, which reduces the number of combinations dramatically. (I'm too lazy to calculate the case for up to three joints right now, but you can see that $2C6 = 6 \times 5/2 = 15$ pairs of joints, each of which can be engaged in 4 ways for a total of 60, plus six individual joints engaged in two directions for 12, plus all idle for 1, brings us down from 729 to 73 camshaft orientations, which is eminently feasible.)

Multitouch livecoding

Kragen Javier Sitaker, 2018-06-17 (1 minute)

I thought it would be interesting to explore multitouch interfaces for livecoding music. Here are some ideas:

• On a cellphone, you can expand your working area by using the phone accelerometers (and gyros, if available) to rotate the phone to move around a larger virtual space.
• Quasimodal interface elements pop up during a touch and then permit continuous adjustment in one or more dimensions with one or more touches — the same or different touches.
• Waveform and spectrum displays at different scales can elucidate what is happening in a single node.
• Individually reified signal inputs might offer a quasimodal action to overwrite them with some existing signal.

Topics

Dyneema

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

I think I found some Dyneema fishing line for AR$100 a roll at El Brujo, Sarmiento 2443. Green, braided. This scrap of 50-pound (22.7 kg) line he gave me is about 0.35 mm diameter, which works out to 2.3 GPa strength, and it floats, which suggests it is sure enough Dyneema. It's a Chinese brand and doesn't say "Dyneema", "Spectra", or "UHMWPE". He has rolls of several different diameters for $100, but I don't know if they're different lengths or what.

http://articulo.mercadolibre.com.ar/MLA-615447478-multifilamento-dyneema-triple-fish-014-y-018-mm-x-100-m-_JM Triple Fish Bully Braid Dyneema fishing line: 100 meters for AR$305 ≈ US$22. They claim the 0.14 mm diameter line is good to 10.2 kg, which would be 6.5 GPa, almost three times the strength.

https://en.wikipedia.org/wiki/Ultra-high-molecular-weight_polyethylene gives 2.4 GPa as its strength.

http://www.dtic.mil/get-tr-doc/pdf?AD=ADA606636 gives a variety of higher strengths in their tests, ranging from 3.63 ± 0.19 GPa up to 4.25 ± 0.21 GPa, with the higher strengths being achieved at higher strain rates up to a kilostrain per second (i.e. loadings more like bullet impacts). For Dyneema SK76, it also shows nice linear Hookean elastic stress-strain curves with a Young's modulus of about 100 GPa. This is about twice as compliant as a steel, and stronger than most steels.

(Dividing out, 2.4 GPa / 100 GPa is 2.4% elongation at break, which is almost three times what steel gives you. If we suppose the 100 GPa number is accurate for the Bully Braid, that's 6.5% elongation at break, 65 mm/m, which works out to a spring energy capacity of (65 mm 10.2 kg gravity / 2) = 3.25 J/m; the whole roll holds 325 J for 14.8 J/US$.)

http://www.matbase.com/material-categories/natural-and-synthetic-polymers/polymer-fibers/synthetic-fibers/material-properties-of-dyneema.html#properties suggests that different varieties of UHMWPE have substantially different strengths and very substantially different stiffnesses.

It's kind of amazing to think that five strands of this fishing line could support me.

https://www.redwoodplastics.com/brochures/uhmw-engineering-data.pdf gives a coefficient of static friction for UHMWPE on steel of .15–.20 and of dynamic friction .12–.20, or .05–.08 if oiled. This suggests that for many purposes, you can run oiled UHMWPE cord around round steel bars without pulleys, avoiding the

Topics

Can you read the lunar lander's plaque from Earth? Or write a new one?

Kragen Javier Sitaker, 2015-09-03 (9 minutes)

The US lunar lander has a plaque that says "WE CAME IN PEACE FOR ALL MANKIND", in a successful effort to avoid sparking a global thermonuclear war. It's 384 megameters away on average, although sometimes it gets as close as 356.4 megameters. Can you read it from Earth?

An interferometer, which is kind of a generalization of a telescope, distinguishes things by the phase of light reflected from them. A lens or telescope mirror is a device to adjust the phase such that light waves emanating from the same point will be focused onto the same point, and more importantly for the question here, light waves emanating from different points will be focused onto different points. It uses the difference in phase across the width ("baseline") of the interferometer to identify each point.

To be clearly distinguishable by interferometer, the phase difference of two points ought to differ by a significant fraction of a wavelength. We can take half a wavelength as a convenient number. And let's figure we can't conveniently use radiation any harder than, say, 300 nm wavelength, for example because it's hard to focus or because the Sun doesn't emit it or it doesn't penetrate our atmosphere.

I don't know how big the letters on the plaque are, but let's suppose that centimeter resolution is good enough.

So how big of an interferometer do you need? Does it fit on Earth?

The Euclidean sum of 384 megameters and 1 centimeter is a bit tricky to calculate. But you can easily calculate that 1 centimeter over 384 megameters is about 30 picoradians, and 150 nm is 30 picoradians at a radius (or baseline!) of 5 km. So even if the letters are a bit smaller than I imagine, you can read them from Earth with optical interferometry.

Laser-printing on the moon

You can do better, though! You can laser-print a new plaque by selectively melting the lunar soil from Earth with phased-array lasers, thus changing its color! If you require a 50km baseline, you can get down to one-millimeter resolution. You need high enough power to melt it, not just slightly warm it; but exactly how much power you need goes down as the resolution improves, but it depends on the thermal conductivity of the soil, its density, its heat of fusion, its melting point, the depth of penetration of light into it, and its specific heat. Also, to estimate how fast this happens, you need to know its albedo and the spectral selectivity of its emission spectrum.

You need a few hundred milliwatts to laser-print on the moon

I found some information about lunar soil physical properties online. Lunar soil particles are very fluffy, with half a square meter of surface area per gram. Specific gravity of the solid mass of regolith particles is about 3.1 g/cc; porosity is typically 50%; consequently lunar soil is about 1.6 g/cc, although varying from 0.8 to 2.3, and perhaps even lower in the top surface layer. Thermal conductivity in the top centimeters of lunar soil was measured at 1.5×10^{-5} W/cm/° in the Apollo 15 and 17 missions. Its albedo is about 0.07.

I don't know the spectral selectivity, heat capacity, heat of fusion, or light penetration depth of the lunar soil, but let's estimate. The soil includes some components that would melt at lower temperatures, including many glasses that won't have a heat of fusion at all, and it might be adequate to melt just those. But I'm going to use a somewhat more pessimistic analysis to make sure my conclusions are ironclad. Let's suppose it has no particular spectral selectivity, melts at about 1000°; has a heat capacity similar to quartz's — 65 J/mol/° / (28 + 2·16 = 60) g/mol ≈ 1 J/g/°; and has a heat of fusion similar to quartz's — 9 kJ/mol ≈ 150 J/g.

The lunar surface can get as hot as 220 K during the day even before we start shooting lasers at it.

So we need, hypothetically, to heat the surface of the regolith to 1000°, sucking up about 780 J/g, and then melt it with 150 more J per gram. At 1000° a black body soil would be emitting 57kW/m², so that's probably about what we need to illuminate it with in order to keep heating it up once it's already at that temperature. But how much actual power is that?

It depends on the area you can illuminate, of course — the tighter you can focus the beam, the easier it gets. Above we posited a square-millimeter focus, which is 10^{-6}m², at which point you'd need 57mW — an eminently feasible number! As long as you can focus 57mW onto a one-millimeter square in a vacuum, it will eventually heat up to 1000°. How fast?

1.5×10^{-5} W/cm/° at this temperature is about 1.5×10^{-2} W/cm, which is to say, 1.5 mW mm/mm² — we can expect on the order of a milliwatt to escape to a depth of on the order of a millimeter through an area on the order of a square millimeter. None of this is very precise because of course the planar focus spot gradually morphs into hemispherical shells of heat spreading into the regolith, so really at the depth of a millimeter you need to be considering about two square millimeters of almost-hemispherical shell, but it's close enough to show that the vast majority of heat will be lost radiatively rather than conductively. You might need 58mW or 59mW or 60mW to reach equilibrium, but really you want to be far from equilibrium, like at least 2× and ideally over 10×.

So supposing we're focusing 600mW and up on this square millimeter on the lunar surface, losing 7% of it to reflection, two or three milliwatts to conduction, and 60mW to thermal reradiation, leaving 500mW, focused on a millimeter-sized spot that's about a millimeter deep, with a density of about 1.6 g/cc (thus about 1.6 milligrams) and a heat capacity of 1 J/g/°. This gives us a temperature rise of about 300°/s, so it takes three or four seconds to melt the spot, so we can write on the moon at about 0.3 mm²/s with 600 milliwatts.

This should scale linearly with applied power. We should be able

to do 3 mm²/s at 6 watts, or 30 mm²/s at 60 watts. Even 6 kW should be doable without any extra difficulty (remember, we're talking about a phase-locked phased-array ultraviolet laser system spread over a thousand square kilometers or so) and should allow you to print on the moon at 3000 mm²/s.

Lunar soil is accumulating at about 1½mm per million years, so whatever you write there might be readable for tens of millennia if daily dust redistribution doesn't cover it up.

The total information capacity of the moon's surface would be close to 1 bit per mm² if encoded in this way. The moon's radius is 1738 km, so the part facing us has space for on the order of 5×10^{18} bits encoded in this way, which is several hundred petabytes.

Calculating the bandwidth of this data storage channel is trickier.

Related proposals

Relevant to this is NASA N78-13420, "Analysis and Design of a High Power Laser Adaptive Phased Array Transmitter", from 1978. They propose to use photovoltaic-powered terrestrial lasers, phase-locked to produce a phased array, to deliver 5 megawatts of infrared laser power to satellites, from a 6-meter transmitter to a 2-meter collecting aperture, for example to power orbital transfer maneuvers. They predicted overall power transfer efficiency of 53%, which seems inconceivably large to me given the generally low efficiencies of lasers, especially in the 1970s — and indeed, it turns out they're talking about 53% of the light coming out of the laser making it to the satellite, and they suggest using an isotopically pure laser that wasn't yet developed (and maybe still hasn't been), plus six other areas of "advanced technology development required", which I think all do exist now.

In the high-spatial-resolution phased-array field, there's a 1993 proposal for an OVLA (NASA N93-13583), or "optical very large array", like the radio-telescopy Very Large Array, using optical heterodyning to get the equivalent of a very large aperture.

The recent DE-STAR proposal from Cal-Poly is the closest in spirit: it proposes a high-power phased-array laser to divert or evaporate asteroids and comets in danger of hitting Earth.

Byte stream gui applications

Kragen Javier Sitaker, 2019-11-29 (updated 2019-11-30) (17 minutes)

How should we run graphical programs on machines remote from the GUI, that is, remote from the machine the user is using? This includes scenarios such as the following:

• DisplayLink-like USB-connected or Ethernet-connected monitors (whether for multiple monitors per user or multiple users of a larger machine, like X terminals);
• Remote server administration;
• Screen sharing for, for example, remote pair programming, remote demos, or visual aids for teleconference presentations;
• Remote access to expensive shared computational resources, such as supercomputers (the original rationale for the ARPANet project);
• Including GUIs in tiny embedded computers that don't have monitors of their own, but do have ports where you could connect monitors, touchscreens, keyboards, and mice;
• Access to remote datasets, such as your email, although this very-thin-client approach is more demanding of the server.

Byte streams and pipes

In some sense the lowest common denominator is bidirectional byte streams with maybe some kind of escaping; this works over sockets, RS-232 serial links (which can run at megabits per second nowadays --- RS-422 and RS-485 can reach tens of megabits), and over `ssh` with proper authentication. So, on Unix, a very reasonable way to spawn a graphical interactive app on a remote machine is to spawn an `ssh` process connected to input, output, and error pipes, and then select(2) or similar on those pipes to send events to the app and receive commands from it. Thus ssh can take care of authentication, spawning processes on the remote host, checking them for errors (although if there's an error you'll probably only get a textual message back on stderr), and detecting when they die.

This also lets you run graphical apps on USB serial devices or other embedded devices that just have a serial port. It doesn't inherently give you a way to run multiple graphical apps over a single serial connection, so one serial device would be one app, and if that device contains the display and keyboard and whatnot, it can only *display* one app. But that one app could be a full-fledged multiplexed display server in its own right, spawning off ssh children and whatnot.

Even Docker containers, for all their headaches, support an 8-bit-clean bytestream interface on stdin and stdout, as long as you don't use `docker run -t`; this shows that all 256 bytes make it through safely:

```
docker run --rm python:2 python -c \
    '__import__("sys").stdout.write("".join(map(chr, range(256))))' |
    tee >(docker run --rm -i alpine od -t x1 >/dev/tty) | xxd
```

(The `-i` keeps it from closing stdin.)

This all assumes the usual app interaction model, as I called it in

Dehydrating processes and other interaction models (p. 3208), which suggests that for more flexible kinds of interaction that aren't tied to particular hosts, a different interaction model would probably work better.

ssh

I just did a quick experiment with OpenSSH:

```
$ time ssh -vC user@server dd if=/dev/zero bs=100M count=1 | dd bs=1k | wc -c
...
debug1: Sending command: dd if=/dev/zero bs=100M count=1
1+0 records in
1+0 records out
104857600 bytes (105 MB, 100 MiB) copied, 11.3868 s, 9.2 MB/s
debug1: client_input_channel_req: channel 0 rtype exit-status reply 0
debug1: client_input_channel_req: channel 0 rtype eow@openssh.com reply 0
debug1: channel 0: free: client-session, nchannels 1
debug1: fd 1 clearing O_NONBLOCK
Transferred: sent 65224, received 341432 bytes, in 12.5 seconds
Bytes per second: sent 5205.9, received 27251.5
debug1: Exit status 0
debug1: compress outgoing: raw data 28009, compressed 14245, factor 0.51
debug1: compress incoming: raw data 104917069, compressed 229911, factor 0.00
104857600
102400+0 records in
102400+0 records out
104857600 bytes (105 MB) copied, 14.4017 s, 7.3 MB/s

real    0m14.411s
user    0m1.964s
sys     0m4.108s
```

That is, ssh was happy enough to transmit me 100 megabytes of zero bytes from the server in 14 seconds.

By comparison, running the command `true` produced this result:

```
Transferred: sent 3352, received 2400 bytes, in 1.2 seconds
Bytes per second: sent 2701.5, received 1934.3
debug1: Exit status 0
debug1: compress outgoing: raw data 154, compressed 135, factor 0.88
debug1: compress incoming: raw data 566, compressed 538, factor 0.95
0+0 records in
0+0 records out
0 bytes (0 B) copied, 3.09319 s, 0.0 kB/s
0

real    0m3.107s
user    0m0.148s
sys     0m0.004s
```

So the 100 megabytes only cost 11.3 seconds. And, of that, 4 seconds were spent in the kernel on my end, shuffling the bytes between the processes, and 2 seconds were spent decompressing them.

Indeed, repeating the experiment using an ssh master connection

configured with `-o 'ControlMaster yes' -o 'ControlPath somepath'` and an ssh slave connection configured with just the ControlPath, I got 11.2 seconds. `true` took 400 ms or so.

This is not super great for video; this netbook's display is 1024x600 24bpp 60fps, which is 110.592 megabytes per second uncompressed, about four times what the kernel is managing to copy through a pipe. This is why the draft Wercam protocol design in BubbleOS uses shared memory (on Unix, with `mmap`, passed over sockets as open file descriptors). But it's probably adequate, and if the data is encoded with some kind of video codec, it might be totally fine.

Resynchronization and topology

X-Windows apps die if the display server dies or they lose their connection to it. This is very limiting. Terminal apps connected over a serial port, or GUI apps connected to a monitor or KVM switch, don't have this problem; you can reconnect to them later, even plugging in a different monitor, and keep using them. GNU Screen and tmux offer the ability to do this with terminal apps running on a virtual terminal connected to via ssh, as well.

Making that kind of thing work well imposes some extra requirements on the protocol design. There are a few different cases where we might need to resynchronize after some kind of protocol desynchronization.

First, you might want to recover from bugs in the application, the display server, or the connection between them that caused communication to break down --- an unescaped framing byte, say, or noise on a serial line.

Second, in an embedded context, the application being displayed might have crashed and restarted.

Third, the display and input devices might have been disconnected for a while, and then reconnected, without having been able to see anything in between. Maybe it's a different display, or maybe it's crashed and restarted or lost power in the interim.

Fourth, you might want to have multiple displays and input devices connected to the same running application at the same time. If all, or all but one, but one of the input devices are disabled, this is straightforward ("live streaming"); otherwise you need some way to keep the input devices from screwing up the framing when they try to talk at the same time, and somehow negotiate the window size.

Fifth, you might want to record and replay a video stream ("screencasting").

These can all be handled to one extent or another by adaptors of some kind spliced into the protocol, rather than by the protocol design. That may or may not be the best way to solve the problem. For example, live streaming benefits from adaptors to adapt to the available bit rate.

Codecs

The standard VNC RFB protocol uses only lossless "video codecs", and they are not very efficient. XPra uses modern lossy video codecs in order to get dramatically better efficiency at the cost of a little latency. Specifically, its non-deprecated codecs are rgb (compressed with zlib, lzo, or lz4), png, VP8/VP9 ("vpx"), and H.264.

Video codecs have an interesting feature: they are often also video

container formats that are designed for broadcasting over the airwaves. Broadcast formats have to be unidirectional and permit synchronization in the middle of the stream, so that turn your digital TV on or change channels, you start seeing the video on the channel you're receiving. You can start reading the stream at any point, and pretty soon you'll manage to synchronize with the framing, and then an I frame (internally coded, a lossily compressed image without any reference to other frames), and then you're displaying video.

Any video stream format that allows this pretty much automatically gives you items #1 through #5 above, except when it comes to handling of input events, including things like window size changes.

Traditional "video stream formats" filling this role include NTSC, PAL, SECAM, VGA signals, and ASCII text for teletypes and video terminals. These are optimized for displays with very little memory. NTSC needs to remember where you are relative to the the horizontal and vertical sync and the colorburst, and PAL has some additional slight twist. VGA is the same but without the colorburst. Teletypes only need to remember where they are on the line and the currently printing byte, if any; video terminals have 2K or 4K of RAM for the screen contents, or maybe a bit more.

I think it's okay for the protocol to require displays made of modern electronics to have more memory than that, 8 to 32 bytes per pixel, say.

Bidirectionally predicted frames (B frames) are potentially more of a problem. Their mere existence imposes potentially unacceptable codec latency, but if your remote app is a video player, you're going to have substantial bandwidth inflation if the video streaming protocol doesn't support B frames.

Supporting multiple codecs and demanding that the stream be readable without any kind of codec negotiation allows applications to be very simple but potentially requires a lot of complexity on the display side. As a very crude estimate, a single modern codec is on the order of a meg of code:

```
$ ls -lL /usr/lib/i386-linux-gnu/libx264.so.142
-rw-r--r-- 1 root root 976296 Mar 23  2014 /usr/lib/i386-linux-gnu/libx264.so.142
```

But maybe it's possible to get the requisite compression of 4 to 8 with a much simpler codec, something like MPEG-1, but maybe more modern.

Input events

The main requirement for input event handling is that they need to get delivered even if one or both of the app and the display crash and restart, or if the user reconnects using a different terminal. There are a lot of ways to do this; the simplest one is to send all possible input events all the time rather than attempting to economize in any way. At least without cameras, the total input event data can't be more than a tiny fraction of the video data torrent rushing the opposite way; this probably makes it insignificant, although there do exist unusual scenarios with very asymmetric bandwidths, such as some satellite communications. Other possibilities include resynchronizing the input state (shift keys, etc.) whenever a reconnection is detected or

suspected.

You also need to send the window size if the app is sending video of the wrong window size, and maybe when it's sending no video, too.

GUI apps on embedded microcontrollers

You probably don't want to have to include an H.264 encoder in your Arduino; you probably want to support some kind of simpler protocol than H.264, maybe something uncompressed; for example, a sequence of nothing but "P frames" that consist of local area updates, some of which are actual updates and others of which are redundant retransmissions of unchanged scan lines. At some point you might want to add reduced-color-depth pixels to the protocol, but even Arduino serial ports can run at 2 Mbps (83 kilopixels per second at 24 bits per pixel) and if you're transmitting via `ssh -C` you'll get paletting implicitly from Lempel-Ziv compression, so lower color depths are never going to be a big win.

And you don't need text in the protocol. In dofonts-1k I included a full printable-ASCII 6x8 font in 64x36 bits, 288 bytes uncompressed, or 482 bytes PNG-compressed and base64ed. It's reproduced below. The file, 1KiB in all, also includes a sort of terminal emulator that uses the font to render ASCII text on a `<canvas>` which is 20 lines of JS code, including lines of code that just say `}`. You have room for that in your Arduino's Flash.

83 kilopixels per second means that a full-screen redraw at 1024x600 would take 7.4 seconds, and if you're using the Arduino Serial library, more like 30 seconds. Even if you had only one bit per pixel, it would still take over a second. There are applications that update the screen regularly for which this kind of latency is acceptable, but having the screen partially redrawn all the time is not. Double-buffering is the usual solution, and it's within the 8-32-byte-per-pixel budget described above. But how should we do it?

The basic atom of the Arduino protocol described above is something like draw(x, y, w, h, pixeldata), where typically wxh is on the order of 64 to 256 (about a millisecond at the data rates discussed above). The simplest approach to double-buffering is to add a flip() operation that makes all the previous changes visible. An alternative would be to include some kind of timestamp in the draw() operation that specifies when to make it visible, perhaps a one-byte number of intervening draw() messages to delay the draw operation.

The (x, y, w, h, delay) header might be 7 or 8 bytes, so prepended to a 192-byte 64-pixel data block, it amounts to about 4% overhead, which seems acceptable.

A more stateful protocol might handle double-buffering by including offscreen pixmaps and commands to copy regions between them, but that poses risks to resynchronization after disconnects.

BubbleOS thoughts

This also suggests a different way to write and run BubbleOS Yeso programs, particularly on Linux: put the code for interfacing with, for example, X-Windows or the framebuffer, into a process which runs the app as a subprocess. The app itself reads input events on stdin

and writes a video stream on stdout; when the app exits, the parent process detects this and also exits. Then a window-managing shell running multiple apps as subprocesses would just be one more app you could run in this way.

I have some vague memories of worrying that if raw framebuffer programs crash I might have to reboot to regain control of the machine, although I don't remember if this has to do with changing keyboard modes or video modes or stty or what. Running them as subprocesses this way would permit the (hopefully more reliable) parent process to clean up properly.

This would also make it straightforward to do things like run multiple programs successively in a window, run an image output filter over the output of a program (e.g., Dark Mode, magnify, overlay ripples around mouse clicks, or some kind of pause/rewind thing), or write graphical programs in whatever random language that can spit out bytes.

Unfortunately, though, performance. As explained above, Linux charges too many computrons for moving pixels between processes in pipes. The Intranin design for IPC by transferring ownership of memory segments between processes would enable these things to be done efficiently.

For environments with a low screen update rate, such as e-ink displays, the efficiency concerns disappear.

Capacitors: some notes on tradeoffs

Kragen Javier Sitaker, 2018-07-05 (5 minutes)

As representative electrolytics, let's choose the Panasonic ECA-0JHG102 and the Nichicon UWT1H470MCL1GS.

The Panasonic ECA-0JHG102 costs 44¢ down to 10.4¢ (quantity 5000). It's a 1000µF 6.3V 8mm-diameter 11.5mm-long capacitor rated for 380mA at 120Hz or 437mA at 100kHz. Its leakage current is 3 µA or "0.01 CV", presumably per second; this works out to 63 microcoulombs when fully charged, so probably 63 µA. The datasheet doesn't give ESL, ESR, or self-resonant frequency, but lists frequency-dependent characteristics only up to 100kHz. It lists the tangent of the loss angle, though.

The Nichicon UWT1H470MCL1GS costs 47¢ down to 19.4¢ (quantity 100). It's a 47µF 50V 6.3mm-diameter 7.7mm-long SMD capacitor rated for 63mA at 120Hz or 94.5mA at 10kHz, with exactly the same leakage current spec as the Panasonic part. Its loss-angle tangent is 0.14, and its frequency-dependent characteristics are listed only up to 10kHz. No ESL is listed or suggested.

As representative supercapacitors, the Nichicon JUWT1105MCD and the Elna DSK-3R3H204T614-H2L.

The Nichicon JUWT1105MCD costs 92¢ down to 30¢ (quantity 5000). It's a 1-farad 2.7V 6.3mm-diameter 10.5mm-long EDLC rated at 4Ω ESR at 1kHz. The datasheet lists a 4Ω "DCR", but I don't know what that is; surely not a discharging current resistance, since that would discharge it within seconds. The capacitance rating is based on discharging in, I guess, 270 seconds after a 30-minute (!) charge cycle.

The Elna DSK-3R3H204T614-H2L costs 195¢ down to 92¢ (quantity 500). It's a 200-millifarad 3.3V 6.8mm-diameter 1.4mm-thick EDLC that looks for all the world like a coin cell with strip terminals soldered onto it for a total thickness of 1.8 mm and a total width of 11.7mm. It's rated at 200Ω internal resistance. The datasheet mentions absolutely nothing about time or frequency, but it seems like these are actually intended as battery replacements.

Neither supercapacitor lists a leakage current rating.

The above capacitors are all rated for endurance of 1000 or 2000 hours, though at different temperatures. By contrast, as representative tantalum capacitors, let's consider the AVX TAJB226M010RNJ, the Panasonic ECS-H1AX475R, and the AVX TAP104K035SCS.

The AVX TAJB226M010RNJ costs 69¢ down to 23¢ (quantity 1000). It's a surface-mount 1411 (3.5mm × 2.4mm, 2.1mm high) or possibly 1210 (3.5 mm × 2.8 mm, 2.8 mm high) 22µF 10V conventional MnO_2 tantalum capacitor with a rated ESR of 2.4Ω at 100kHz. All the frequency-dependent stuff in its datasheet is just listed at 100kHz and no other frequencies. It claims to withstand a 13V surge voltage and have a failure rate of 1% per 1000 hours at 85°, if I understand correctly. Its leakage current is 2.2 µA. At low temperatures, it's rated for 188 mA ripple current.

The AVX TAP104K035SCS costs 66¢ down to 19¢ (quantity

5000). It's a through-hole 35V 0.1µF 7mm-high 2.5mm-diameter tantalum cap rated for a failure rate of 1% at 1000 hours at 85°. Its ESR is listed as 26Ω at 100kHz. It leaks 0.5µA.

What about multilayer ceramic capacitors? Let's take the Vishay A104K15X7RF5TAA, the Murata LLL219R70J105MA01L, the Murata GJM1555C1H4R7CB01D, and the Johanson 500R07S0R5BV4T as examples.

The Vishay A104K15X7RF5TAA costs 26¢ down to 13¢ (quantity 2500). It's a through-hole 50V 100nF X7R axial-lead capacitor, 2.5 mm diameter and 3.8 mm long. …

The Murata GJM1555C1H4R7CB01D costs 12¢ to 1.9¢ (quantity 5000) and is a 50V C0G/NP0 4.7 pF 0402 SMD MLCC. C0G/NP0 devices are optimized for high precision and low loss rather than high capacitance, although this one is still ±5%. It's tiny at 1 mm × 500 µm × 550 µm. …

The Murata LLL219R70J105MA01L costs 44¢ to 11.5¢ (quantity 1000) and is also a SMD MLCC, this one X7R 0508 and with reversed terminals for low ESL. It's 1µF and 6.3V. Its 0508 size is larger, at 1.25 mm × 2 mm × 850 µm. …

The Johanson 500R07S0R5BV4T costs 16.0¢ to 2.7¢ and is another C0G/NP0 0402 MLCC, this time of only 0.5 pF. This capacitance seems small enough that it would be likely to happen by accident, without an actual capacitor, but what do I know? The tolerances are proportionally rather loose: ±0.1 pF, which ends up being ±20%. …

Free software debugging

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

Chapter 2 of Andreas Zeller's book "Why Programs Fail" describes the following life cycle for a software problem that involves a bug fix:

- The user informs the vendor about the problem.
- The vendor reproduces the problem.
- The vendor isolates the problem circumstances.
- The vendor locates and fixes the defect locally.
- The vendor delivers the fix to the user.
- [implicitly] The vendor delivers the fix to other users.

One of the advantages of free software is that it often allows the following lifecycle instead:

- The user reproduces the problem.
- The user isolates the problem circumstances.
- The user locates and fixes the defect locally.
- The user publishes the fix so that other users can use it.
- The user informs the maintainer about the problem.
- The maintainer delivers the fix to other users.

When the problem is sufficiently important to the user, this is much preferable to the traditional cycle described above; the time from step #1 to step #3 can often be minutes or hours instead of weeks, months, or years --- and many problems never get fixed, either because they're put in place deliberately by vendors, or because they're not important to the vendor.

In addition to giving the user their bug fix more quickly, it also often reduces the total amount of work involved. Zeller's steps #1 and #2 often involve a lot of communication back and forth between the vendor and the user, as the user tries to supply enough information for the vendor to reproduce the problem, perhaps weeks or months after the fact, but without including any confidential information. An omitted step (in both sequences) is prioritization of the problem, which is dependent (in Zeller's sequence) on the information provided by the user; if it appears to be a problem that doesn't affect many people, the vendor is likely not to bother to reproduce and isolate it quickly.

Can you turbocharge the STM32 ADC to build an oscilloscope?

Kragen Javier Sitaker, 2018-07-14 (5 minutes)

The analog-to-digital converter on even the most basic models of STM32 is capable of a million samples per second, about 70 times faster than the 15ksps advertised for the ADCs on the 8-bit AVR line, which Arduino was built on. The "leakage" or bias current is specified as <200nA, which is adequate for many measurement tasks even without an external preamp. Some new "Arduino" boards are built around an STM32F103C8T6, which has two 1Msps ADCs, and thus ought to be able to digitize signals at 2Msps with a bit of clever programming — enough for signals of up to 1MHz. (ST application note AN3116 has details.) It has 20KB of zero-wait-state SRAM, which is enough to capture several thousand samples, which ought to be enough.

There are many possible uses for such a capability. One highly desirable use is to make an oscilloscope, a general-purpose instrument for visualizing a small number of quantities changing quickly, once the quantities are converted to voltages. (By "small number" I mean "less than five" and by "quickly" I mean "over nanoseconds to milliseconds"). Unfortunately, 1MHz is not enough — a low-quality off-brand analog oscilloscope is 10MHz, and a normal entry-level analog oscilloscope is 20MHz, which doesn't mean it can't detect faster signals, just that they suffer 6dB/octave attenuation and severe phase distortion. So 2Msps is about 5% of an oscilloscope.

Here's an exploration of possible ways to get to something a bit more decent.

Software flash conversion

The STM32 is capable of acquiring data at much higher speeds using its GPIO lines; it can read 16 of them at once, something like 36 million times per second. Configured as digital inputs, these are Schmitt-trigger lines; some are 5V-tolerant, with LOW guaranteed up to 0.475Vdd - 0.33 V, HIGH guaranteed from 0.5Vdd + 0.2 V, and ≈100mV hysteresis; and others are not, with LOW guaranteed up to 0.3Vdd + 0.07 V, HIGH guaranteed from 0.445Vdd + 0.398V, and ≈200mV hysteresis. This leaves a narrow voltage range of 500–800mV undefined. All have input leakages of 1µA or less.

It occurs to me that you could perhaps use this capability to acquire lower-precision data about higher frequencies, which might still be valuable. You could experimentally characterize the analog behavior of the chips, and perhaps generate waveforms for field-calibration of the chip. Then you could use a 16-bit digital input port and a 17-resistor ladder fed from a buffer as a 4-bit flash converter, and maybe do some kind of half-flash trick largely in software to get to 8 bits.

4 or even 8 bits may sound extremely unimpressive, but often the high-frequency signal is small in amplitude compared to the lower-frequency components; certainly when the signal contains both, the high-frequency components alone will have smaller

amplitude than the overall signal. In particular, this means it's safe to use an ac-coupled or inverting amplifier on the input. And flash conversion is easily capable of digitizing according to a nonlinear scale, such as ISDN μ-law. But the most interesting possibility is using a bit of external analog circuitry to dynamically adjust the range of the high-frequency digitization to approximate the range of the jury-rigged ADC.

An external fucking ADC obviously

Well duh. The TI ADC08060 is a 3V 8-bit 20–60Msps parallel-output ADC, and you can just hook it up to 8 GPIO pins and bingo. There are others out there. They barely cost more than a STM32F103, although other STM32 chips are cheaper.

Running the ADC at lower precision

As explained in Notes on the STM32 microcontroller family (p. 3176), it's possible to configure the ADC for lower bit depth (10, 8, or 6 bits) to speed it up (to 928, 785, or 643 ns, respectively), which suggests you could crudely digitize signals up to 780 kHz with one STM32 ADC, or up to 1.56 MHz with two.

Ganging up STM32s

At the 1Msps rate, each conversion takes 14 clock cycles of a 14MHz clock, of which only 1.5 cycles (107 ns) are spent sampling the signal. This means that frequency components up to about 9MHz are basically unattenuated, though aliased, in the output, and the first actual zero of the frequency response is 9.3 MHz. The STM32F103C8T6 can run its two ADCs in lockstep so as to sample precisely every 7 cycles, but you could easily imagine a scheme for syncing up 5–20 STM32s to sample at slightly staggered times, thus capturing signals up to 9MHz in their full glory.

Transactional event handlers

Kragen Javier Sitaker, 2019-01-24 (14 minutes)

I was thinking about event loops and transactional memory, and it occurred to me that applying transactional memory to event loops might solve their problems. In some sense this is just plain "use transactional memory" but it's a particular choice of where to draw the transaction boundaries: each event that would normally invoke an event handler in an event-loop system (network data, mouse click, I/O completion, timeout, or whatever) invokes it inside a transaction.

Event loops

One of the major concurrency models in modern software (and actually historical software going back many decades) is the event loop. A CICS pseudo-conversational transaction was initiated when a message came in from a terminal, and ran on the CPU until it yielded it; KeyKOS server domains synchronously awaited incoming invocations, then did some processing, usually sent a response, and returned to awaiting; Oberon's "central loop" keeps the processor engaged "continuously polling event sources"; Win16 and Win32 WndProcs are invoked once for each event on the window, handling it as they see fit, but always on the same thread; Node.js servers and browser JS and Tcl/Tk all use event loops, where a single-threaded process chews through a queue of events by invoking previously registered callbacks.

The event-loop model is efficient (no need to allocate memory to per-thread stacks), easy to understand, and relatively free from race conditions, since each event handler must run to completion before the next event handler can begin to run. In effect, the event handler has a lock on the entire memory space. In a system with a single event loop, as with other systems with a single lock, there's no danger of deadlock, because there's only one lock. In theory, multiple communicating event loops can suffer from deadlock, but this seems much less frequent in practice than system composed from threads and locks.

(CICS also supports a "conversational" model in which a task can suspend until it receives input, but that's not what I'm discussing here; after 51 years systems can get a bit muddled.)

Event-loop problems: parallelism and responsiveness

However, event-loop systems do have two major weaknesses: parallelism (in the modern sense of taking advantage of multiple processors) and responsiveness. Almost any event-loop system can take arbitrarily long to respond to any event, because a slow handler for a lower-priority event can prevent the system from even noticing a higher-priority event in time. This is especially a problem since event loops are only used in more-or-less real-time situations — if only computing a correct result matters, but not how long it takes, you can wait for all the input data to become available before you

start the computation, and then you don't need an event loop or any other kind of concurrency. Typical solutions to this problem include interrupts (re-introducing a pervasive risk of race conditions), watchdog timers that reset the entire system when a deadline is missed, and running separate event loops, especially for tasks of different priorities (creating the difficulty of communicating between them). The BeOS GUI famously had a much more responsive UI than other contemporary GUIs because of pervasive multithreading, i.e., running a lot of separate event loops.

A less-common solution to the responsiveness problem used in MOO and browser JS is to kill event handlers that hit a timeout. To prevent this from producing overall system instability, the timeout is only checked at "safe points", where all the invariants of some "system layer" have been re-established, and only mere user code is vulnerable to having its state corrupted. This works far better than you would expect, in part because that user code already has to be exception-safe, and a thrown exception has results similar to a handler being killed due to a timeout. However, it pretty much eliminates the simplicity advantage of event-loop programming over using threads and locks.

The least-common solution is to ensure that every handler in your event loop has bounded and acceptable worst-case execution time (WCET) that permits an acceptably fast response to the most demanding event. This solution does have the benefit of working, but it makes programming for the system extremely demanding.

Optimistically-synchronized transactional memory as a possible solution

As an alternative, what if we adopt the solution used by CICS back in the 1970s, and used by most web servers today? Let's run each event handler ("transaction" or "task" to CICS) in its own little universe, unable to access any shared state directly — it can only access shared state mediated by an ACID, or at least ACI, *transaction* ("unit of work" to CICS). The transaction logs all the data it reads and buffers all the data it writes, and ensures that its execution is *serializable*, in the sense that the end result of running some set of event handlers is the same as running them all one at a time in some order. This gives you the same freedom from race conditions as the simple event loop model, more or less by definition.

There are lots of different ways to achieve serializability, though. One way is of course to *actually* run all transactions in some order, or at least all transactions that write to shared data; you can do this by just running a single thread with one transaction at a time, with the problems described earlier, but if you have a lot of read-only transactions, you may be able to get some performance benefit with just a reader–writer lock, or, as SQLite3 does, a reader–writer–pending lock.

This is called "pessimistic synchronization" because it's working to prevent problems, rather than fix them. More sophisticated pessimistic-synchronization strategies with more locks that permit higher levels of concurrency are possible, but they all have the property that if any state is shared between high-priority code and low-priority code, it's possible for the high-priority code to have to

wait on the execution of the low-priority code. If the problem is merely scheduler priorities, you can solve this with priority inheritance, but if the problem is that the low-priority code just has too much work to do before it finishes, you don't want pessimistic synchronization, which is to say, you don't want locks, because you're back to the event-loop situation where any piece of code in your system can potentially make the response to any event too slow.

(There's also the risk of deadlock once you have multiple locks, although there are strategies that avoid this — acquiring all locks at transaction start in a deterministic order, for example. This breaks procedural compositionality, though, because you need to know all the possible locks any transitively invoked subroutine might need when you start the transaction.)

Pessimistically-synchronized transactions typically provide the ability for the user code to roll back the transaction at any time, for example in response to a violation of data integrity constraints. This prevents any of the transaction's writes from being saved; it's as if the transaction never happened, except for the error message returned. But, in general, this (or deadlock) is the only reason a pessimistic transaction can fail; other concurrent transactions have no influence on whether they fail or succeed, and they can be written to always succeed.

As Joe Duffy notes in his 2010 retrospective blog post about the canceled planned software-transactional-memory support in the .NET CIL, as long as everything you care about is in the transactional store, this also gives you a great way to recover from exceptions: any exception inside the transaction rolls back the transaction. However, you may need some kind of special debug interface to read the debug printfs from the aborted transaction — because, as noted above, you don't want arbitrary I/O from inside the transaction to be possible.

Optimistic synchronization, by contrast, can guarantee forward progress and worst-case execution times, but they can always fail. Optimistic synchronization works as follows: if, when a transaction is ready to commit, any of the data it read has been changed by another transaction, the transaction is rolled back and retried from the beginning, using the same code but the new data. This can be done at the microscopic level using multi-word compare-and-swap primitives, or you can do it at the system level with unbounded optimistic transactions.

Because optimistic synchronization detects conflicts after they've happened, instead of preventing them, any transaction may be aborted at any time for reasons outside of its control. This means that it is unsafe for it to do any I/O before it commits or, more generally, affect anything outside of the transaction-controlled universe — if it has to be rolled back and retried twice, you don't want it to send three emails or delete the same file three times (failing on the second and third attempts). (This property is why Microsoft canceled the .NET STM mentioned earlier.)

This gives us precisely what we need to fix event loops: you can guarantee the response time to a high-priority event simply by pausing all lower-priority transactions when they try to commit, so they can't write to the shared store, and then the high-priority event is guaranteed to complete in only the time it needs to execute its own code and do the required accesses to the shared store. If this conflicts

with any ongoing lower-priority transactions, that will be discovered once those transactions are resumed; they will be rolled back and tried again. Also, as long as you don't have interference and consequent rollbacks, you can get the full benefit of however many CPUs you're running on — unlike a CICS region, which uses cooperative multitasking between event handlers, all on a single thread.

Mutability

Transactional memory is not a great fit with pervasive mutability of shared data; most of the intractable problems Duffy mentions in the CIL implementation stem from pervasive mutability. Immutable ("persistent") data structures can be read safely, inside or outside transactions, without any chance that another thread is modifying them and thus with no need to log the reads and revalidate them later.

However, this really only works if you have a garbage collector, which is going to make it hard to guarantee responsiveness. Without a GC, whoever deallocates the data structure is "mutating" it. To some extent you might be able to keep the GC from interfering with high-priority tasks by ensuring that those tasks always have enough memory to run without invoking the GC, but it's also important to ensure that the GC doesn't hold any locks that the high-priority task might need to wait on, or if so that it releases them promptly.

To the extent that the GC only has to run over shared data that persists across transactions, though, the GC load may be light enough to never be a problem.

Composable Memory Transactions

There's a lovely paper called "Composable Memory Transactions" describing the Haskell STM with its "fail" and "orElse" constructs; these provide a way to use transactional memory to wait for arbitrary predicates to become true, and also to compose such single-event waits into multiple-event waits or nonblocking polls, and similarly to convert nonblocking polls into blocking polls.

The approach is very simple. First, for blocking, you have a "fail" construct which fails your transaction as if from interference from another transaction, prompting the transaction system to retry it. But it would be futile, though correct, to try it again immediately, since it will fail in the same way. So at least one of the things it read inside the transaction before failing needs to have changed before it will be able to succeed.

Waiting for a conjunction of such conditions is simple: you invoke each of the wait procedures, one after the other, inside of a transaction. Since the transaction is isolated, you are guaranteed that nothing changes from the beginning to the end of the sequence, so you know that all of the wait-predicates are simultaneously allowing execution to continue.

Waiting on a disjunction requires a new `orElse` construct, which recovers from the failure of a nested transaction by trying an alternative nested transaction. In effect, it composes two transactions into a single ordered-choice or disjunction transaction. For example, if the first transaction was an attempt to read from some queue X, while the second is an attempt to read from some queue Y, each

failing when its respective queue is empty, then the combination will fail precisely when both queues are empty. Alternatively, the second transaction could simply be some computation to carry out in the case where queue X is empty, thus transforming blocking into nonblocking polling.

I don't know why I started writing this section.

A formal language for defining implicitly parameterized functions

Kragen Javier Sitaker, 2019-09-05 (updated 2019-09-30) (29 minutes)

In Dercuano plotting (p. 2885) I talked about the need for a linguistic model of describing calculations to plot, that is, a programming language. I think the ideas I'm describing here are finally crystallizing, but I wrote about them previously in APL with typed indices (p. 3264), A principled rethinking of array languages like APL (p. 1995), Relational modeling and APL (p. 1217); additional sources of inspiration have been First impressions on using the μMath+ calculator program for Android (p. 195), Adam N. Rosenberg's "A Description of One Programmer's Programming Style", Darius Bacon, and the ZIMPL and GNU MathProg languages discussed in Some notes on the landscape of linear optimization software and applications (p. 1285), with the relationship explored in A principled rethinking of array languages like APL (p. 1995).

I'm pretty sure I'll have to rework some of this, but I feel like at this point I have not only something implementable but also a concrete use case where I can see how the existing designs are suboptimal.

The basic idea is that every expression evaluates not to an atomic value like 37 or 2.5 but to (looking at it in five different ways) a table or an array or an N-ary relation or conditional or function; and the particular atomic values we get out of it depend on the *circumstances* that obtain when we happen to look at it; and under some circumstances it may fail to have a value entirely. We can inspect these tables to see which circumstances are the relevant ones, and when the possibilities are finite, we can enumerate all the possible sets of circumstances and the corresponding atomic values, which is to say that we can reason counterfactually about what values the expression *would have had* under circumstances that do not in fact obtain at the moment.

Even if the possibilities are infinite, by stipulating all the relevant circumstances, we can reason counterfactually about what atomic value the expression would have had under those hypothetical circumstances.

As a very concrete example relevant to my plotting problem, given some value representing a function y that depends on an argument x, we can ask what value y would have if x were 0, or if x were a member of the list [-1, -0.5, 0, 0.5, 1]; in the latter case, the result is a finite table of five values that tell us what value y would have for each value of the index into the list. If y additionally depends on a parameter p, we can stipulate that p belongs to some other list, and y will provide a potentially larger table of results. This provides a strategy for getting good efficiency out of even a naive interpreter implementation, much like Numpy, Pandas, APL, Octave, or R; but it should be much easier to write correct code with, because of the rigorous logical underpinning.

Syntax

Because I'm planning to use a non-textual user interface, I'm not going to design a syntax; instead, I'll just use Lisp S-expression syntax in this document. It's not very readable syntax but it's adequately formal and flexible. Its execution semantics are not Lisp execution semantics; it just represents an ordered-tree structure.

Semantic model

The main objects of interest are atomic values, atomic types, aggregates, variables, environments, and expressions. The following is full of forward references, unfortunately; I should see if there's a better order to put things in.

Atomic values

Atomic values are things like 4 or -2.5 or 4+1j or :London or possibly 'w'; they correspond to values in many normal programming languages, but do not include any kind of aggregate data structure such as arrays, structs, dictionaries, sets, lists, tuples, or ML-style constructors. Like quarks, they are never observed alone; they are always part of an aggregate. There are different kinds of atomic values: integers, real numbers, opaque symbols like :London (which I will write with a leading : to distinguish them from variables), and maybe characters.

Atomic types

XXX confused ideas about what goes here: discrete vs. continuous? Finite vs. infinite? Bound vs. unbound? Bounded vs. unbounded? Nominal, ordinal, interval, and rational levels of measurement? Units of measurement? Can a single aggregate contain values of different types?

Aggregates

Aggregates are tables of atomic values, in the sense that they have rows and columns. The number of rows may be zero, any natural number, or infinite; there is always one "result" column, but there can be zero or more "key" columns. Each "key" column is associated with a variable, but the "result" column is not; it is only associated with the tuple of key-column variable values in its row. Conceptually neither rows nor columns have order, although by necessity they will be in some order when we serialize them. Aggregates are what expressions evaluate to, and what environments bind variables to. Here is an example aggregate:

```
(agg     (month oils)
         (1     :VEG1  110)
         (1     :VEG2  120)
         (1     :OIL1  130)
         (2     :VEG1  130))
```

This aggregate has two key columns, associated with the variables `month` and `oils`, and four rows, the first of which associates the atomic value 110 with the situation where the variable `month` has the atomic value `1` and the variable `oils` has the atomic value :VEG1, a symbol. A useful way of reading this is "110 if month == 1 and oils == :VEG1, else 120 if month == 1 and oils == :VEG2, else 130 if month == 1

and oils == :OIL1, else 130 if month == 2 and oils == :VEG1."

Here is an aggregate with no key columns, a *constant*, which associates the atomic value 4 with all possible states of the universe:

```
(agg () 4)
```

The key columns of an aggregate are its free variables.

XXX Should we remove infinite aggregates? They are the only way to represent things like "matrix-vector multiplication" as values, but they seem significantly different from other kinds of values.

Variables

Variables are opaque, indivisible names, like `x`, `VC`, `month`, or `oils`. In themselves they serve only to be distinguished from one another, but they are crucial links between aggregates, expressions, environments, and atomic values.

Environments

Environments are sets of key-value pairs in which the keys are variables and the values are aggregates. Here is an example environment:

```
(env (month (agg () 1))
     (oils (agg () :VEG1))
     (oilhardness (agg (oils) (:VEG1 8.8) (:VEG2 6.1))))
```

This associates the variables `month` and `oils` with constant aggregates and the variable `oilhardness` with an aggregate with two rows and two columns. You might think that this second aggregate contains some extraneous data, describing as it does the `oilhardness` of a situation that we know is not currently the case (when `oils` is `:VEG2`), but as we will see, this counterfactual data can be very useful.

Expressions

Expressions describe computable functions; given some input data, in the form of an environment, they evaluate to output data, in the form of an aggregate. But there are other things we can do with expressions other than evaluate them; we can query them to find out what free variables they require in a given environment and what they require of those free variables.

Here is an example expression:

```
(+ (* x y)
   (let (oils (agg () :VEG2)) oilhardness)
   (sum (month) production))
```

XXX should we require an explicit "in months" in case production fails to depend on month in a useful way so we don't know what to sum over? Should there be some kind of explicit or implicit association between domains and variables, to allow inferring a universe in the absence of an explicit value?

XXX I'm being a bit fast and loose including an aggregate literal inside the expression. I might not want that to be legal.

It has the free variables `x`, `y`, `oilhardness`, `month`, and `production`, so it cannot be evaluated in an environment without an aggregate

associated with each of these variables. Also, it may inherit some free variables from the aggregates associated with those variables; for example, if `production` is associated with an aggregate that depends on the variable `city`, then the expression as a whole also has `city` as a free variable. However, there are two binding constructs in this expression, `let` and `sum`, which bind the variables `oils` and `month` in their respective argument expressions `oilhardness` and `production`, which prevents those free variables from bubbling up further. Indeed, if the expression is evaluated in an environment that provides values for these free variables, these binding constructs will prevent those values from penetrating.

This sort of bubbling up is why the set of free variables of an expression depends on the environment; it amounts to a sneaky sort of dynamic scoping. XXX can this dependency be expressed in a usefully simple way to satisfy the needs of plotting to figure out what kind of creature it's going to have to plot?

The aggregate that results from evaluating an expression in an environment has the same set of free variables the expression had in that environment, and the tuples taken from its key columns will be some subset of the cross-product of the result columns of the aggregates supplied for those free variables in that environment. However, the expression may produce some arbitrary subset of those rows rather than all of them.

XXX could it be that the expression had free variables that aren't used?

Expression types

Literal aggregates

Although I'm not sure if this is the right thing, for the moment I'm going to allow literal aggregates as expressions. Moreover, constants such as 4 and `:VEG1` are also valid; they represent constant aggregates like `(agg () 4)` and `(agg () :VEG1)`

Arithmetic

The standard set of computer arithmetic operations are provided with their usual meanings: +, -, * for multiplication, / for division, % for remainder, ** for exponentiation, >>, <<, abs, exp, ln, pow, sin, cos, tan, asin, acos, atan, ceil, floor, round, bitand, bitor, bitnot, and bitxor. I mean this might change a bit but that's what I think right now.

These operations take one or more arguments, which are evaluated in the same environment the arithmetic operation is, and the aggregates thus produced are passed to the arithmetic operation as actual parameters. Their free variables are the union of the free variables of their operands.

These operations operate purely pointwise and generate a full Cartesian product output. In any environment, `(+ 3 4)`, syntactic sugar for `(+ (agg () 3) (agg () 4))`, will produce `(agg () 7)`. In an environment lacking `x`, `(+ (agg (x) (1 3) (2 5)) 4)` will produce `(agg (x) (1 7) (2 9))`, and

```
(+ (agg (x) (1 3) (2 5))
   (agg (x) (1 4) (2 10)))
```

will produce `(agg (x) (1 7) (2 15))`. In an environment lacking both `x` and `y`,

```
(+ (agg (x) (1 3) (2 5))
   (agg (y) (:a 4) (:b 10)))
```

will produce `(agg (x y) (1 :a 7) (1 :b 13) (2 :a 9) (2 :b 15))`. (At this point a reminder seems in order that the sequence of rows and columns in the aggregate is arbitrary and insignificant.)

XXX note that this contradicts the note earlier saying that expressions could not be evaluated in an environment that didn't provide aggregates for all their free values.

XXX rename 'aggregate' to 'table'? It's too long and operations like "sum" and "min" are usually called "aggregate operations".

The expression `(+ x y)` cannot be evaluated to a finite aggregate if either `x` or `y` is missing from the environment, but consider the environment

```
(env (x (agg (p) (0 3) (-1 5)))
     (y (agg (q r) (20 30 4))))
```

in which `(+ x y)` will evaluate to `(agg (p q r) (0 20 30 7) (-1 20 30 9))`, with three free variables bubbling up from the bindings of `x` and `y`. If we further augment the environment, we can prevent `q` from remaining free:

```
(env (x (agg (p) (0 3) (-1 5)))
     (y (agg (q r) (20 30 4)))
     (q (agg () 20)))
```

This causes `(+ x y)` to evaluate to `(agg (p r) (0 30 7) (-1 30 9))`.

It will be seen that an arithmetic expression containing free variables defines a function taking those variables as arguments.

`let`-expressions

The expression `(let assignments expr)` allows invoking a function with specific arguments or composing two (or more!) functions. During evaluation, it constructs an environment by augmenting its own evaluation environment with new associations taken from `assignments`, which is a list of alternating variables and expressions. These expressions are evaluated in the outer environment, and each one is associated with its corresponding variable in the new environment.

The let-expression's free variables are the free variables of `expr`, minus the variables assigned to in `assignments`, plus the free variables of the expressions in `assignments`, which might reasonably add variables back in that were dropped in the second step.

So, for example, `(let (x 3 y 4) (+ x y))` evaluates as before to `(agg () 7)`, because whatever the outer environment is like, the inner environment has `x` bound to `(agg () 3)` and `y` bound to `(agg () 4)`; and it has no free variables.

A more interesting example is `(- x (let (i (- i 1)) x))`. If `x` has `i` as a free variable and is defined for `i` integer, the inner `x` can evaluate to different atomic values from the outer `x`, and you get the backward differences of `x` along the `i` axis. (I said at the top that I wouldn't

invent syntax, but if I were inventing syntax, I might write this as `x - x[i=i-1]`.)

Conditional expressions

The expression `(if x y)` operates very similarly to the arithmetic expressions, in that its free variables are the union of the free variables of expression `x` and those of expression `y`, it evaluates them both in its own environment, and it combines the `x` and `y` results pointwise. However, it produces, in general, less than the full Cartesian product of their results; the rows where `x` produced false are removed.

So, for example, `(if (> x 1) (if (< x 3) (* x x)))` is the function x^2 limited to the domain (1, 3).

The expression `(case e1 e2 e3 ...)` evaluates all the expressions `e1`, `e2`, `e3`, etc., in the same environment it was invoked in, but then combines them in the fashion of SQL's `coalesce` or the `|` alternation operator in Icon or Unicon: rows are taken from `e2` only for the case where `e1` did not produce a value, from `e3` only where `e2` failed, and so on. This means that you could write the absolute-value operator, for example, as

```
(case (if (> x 0) x)
      (- x))
```

The first expression produces `x` whenever `x` is greater than 0, but for x less than or equal to zero, it produces no value, so `case` fills in the empty space with the result of the `-` operator.

Note that this can be misleading; if you write `(case (if p q) r)`, even if `p` is always true, that is no guarantee that you will never see values from `r`, because `q` might fail of its own accord, aside from getting externally failed by `p`.

(Again, if I were inventing syntax, I'd want to write that as `x > 0 -> x | -x`.)

Another use of `case` is augmenting the first-differences example above with the initial value of the sequence `x`:

```
(case (- x (let (i (- i 1)) x)) x)
```

Here we suppose that when `i` is at its minimum valid value, such as 0, then `(let (i (- i 1)) x)` will fail, leaving a hole that can be filled with `x`.

XXX for efficient evaluation we need to be able to tell which dimensions are going to stay rectangular.

iota

The expression `(iota var expr)` evaluates to `(agg (var) (0 0) (1 1) (2 2) ... (n n))`, where `n` is one less than the value to which the expression `expr` evaluated.

XXX this sucks compared to writing `1:10` in Octave or R. You have to name a variable! Moreover you still have to index it.

Standard reductions

The expression `(sum (month) production)` produces a result that is the same as the result of evaluating `production` except that all the rows differing only by `month` have been summed together, and the `month` key column has been removed. This generalizes in obvious ways to

multiple key columns and to the other standard reductions `product`, `min`, `max`, and `mean`.

XXX this means that `month` does escape as a free variable, but the result won't depend on it, and there's no way to get a sum over more months than you have some other iteration variable to throw away; this is surely the wrong semantics, and the one explained earlier is surely better. Given some of the evaluation semantics explored above, it could probably get the valid months out of `production`. But then how do you get a sum over only certain months? Maybe `(sum (mi) (let (month (agg (mi) (1 3) (2 5) (3 11))) production))`, maybe with some syntactic sugar like `sum{mi} production[month[mi]=[3 5 11]]`?

Monoidal prefix sums

XXX

Non-monoidal reduction

The expression `(for var1 seq var2 start var3 reducer)` expresses a general definite loop. It evaluates `seq` in its surrounding environment and produces an aggregate "the sequence" with, hopefully, the variable `var1` free. It also evaluates `start` in its surrounding environment and produces "the initial state". Then it proceeds sequentially along the sorted values of `var1` in the domain of the sequence, evaluating `reducer` once for each sequence item, in an environment with `var2` bound to the sequence item and `var3` bound to the previous result of `reducer` or, on the first iteration, the initial state.

XXX wait, the loop state has to be a single atomic value?

XXX "domain" and "range" are better than "key" and "result" column; "domain variable" is maybe better than "free variable" for aggregates.

Variable capture

As described above, the model has the same variable capture problem as Lisp macros, only much worse.

Consider this expression for describing the L_p norm of a vector:

```
(** (sum (i) (** x p)) (/ 1 p))
```

This relies on the fact that the `i` introduced by the `sum` is visible to `x` so that it can select the elements of `x`. Similarly, consider this code to evaluate a polynomial at a point (inefficiently):

```
(sum (i) (* a (** x i)))
```

This relies on implicitly indexing `a` with `i`. But consider this expression for describing matrix-vector multiplication:

```
(sum (k) (* (let (j k) a) (let (i k) x)))
```

This has a free variable `i` which ranges over the columns of `a` (or rather its `j`-indices). To do the summation, we need to introduce a new, fresh loop variable `k`; it is our intention that the only two uses of `k` be indexing the `i`-indices of `x` and indexing the `j`-indices of `a`.

But what happens if `a` or `x` internally has a free variable, which is to say an argument, `k`? Disaster strikes! Instead of bubbling up to the sum expression as a whole, it becomes part of the iteration, with

bizarre results that will potentially be difficult to debug.

On the other hand, if we change the language's scoping to purely lexical, constructs like `(let (j k) a)` make no sense --- lexically `a` does not contain `j`, so that expression would be equivalent to just `a`. And `(** (sum (i) (** x p)) (/ 1 p))` relies on the visibility of the index `i` to the vector `x`.

This is more or less just the standard problem of variable capture that occurs in Lisp macros or with dynamic scoping, but it's much more severe in this context, because of the pervasive use of free variables for implicit parameter passing through many stack levels.

The usual Common Lisp approach to solving the problem would be something like this:

```
(let ((k (gensym)))
  `(sum (,k) (* (let (j ,k) a) (let (i ,k) x))))
```

Alternatively, but awfully, you could use a name less likely to collide:

```
(sum (*matrix-multiply-index*)
  (* (let (j *matrix-multiply-index*) a)
     (let (i *matrix-multiply-index*) x)))
```

Alan Bawden and Jonathan Rees's "syntactic closures" mechanism offers an relatively simple solution that is not difficult to implement (see also Chris Hanson's shorter 1991 proposal and the superb Scheme Wiki page, and also Stephen Paul Carl's 1996 master's thesis on an extension of it); Scheme unfortunately standardized on Will Clinger's "Macros that Work" instead, which is a much more complex mechanism to implement.

On the other hand, because of the evaluation semantics outlined above, a different kind of variable capture that occurs in Scheme is absent here. Bawden and Rees give the example

```
(define-macro (push obj-exp list-var)
  `(set! ,list-var (cons ,obj-exp ,list-var)))
...
(let ((cons 5))
  (push 'foo stack))
```

in which the expression containing the macro invocation expands to

```
(let ((cons 5))
  (set! stack (cons 'foo stack))
```

which will give an error due to attempting to invoke the number 5 as a function. I assert without demonstrating that the corresponding problem does not arise in this new language.

XXX does it?

A simple direct fix for the matrix-vector-multiply problem is to have a `fresh` or `new` or `my` annotation that generates the equivalent of a syntactic closure or gensym:

```
(sum ((my k)) (* (let (j k) a) (let (i k) x)))
```

However, this is bug-prone; code that unintentionally omits the `my` tag will function correctly, perhaps for years, until used in a context where variable capture occurs, which may be a result of a change to code that doesn't even explicitly invoke the matrix multiply or whatever, even renaming a variable or something. A different alternative is to make the variables introduced by expressions like `sum` implicitly lexical, but continue to treat `let` variables as dynamically-scoped; this would leave the matrix-vector multiply as I had originally written it, but the Minkowski *p*-norm code would change from

```
(** (sum (i) (** x p)) (/ 1 p))
```

to the perhaps more gnomic

```
(** (sum (i) (** (let (i i) x) p)) (/ 1 p))
```

and change the polynomial-evaluation code from

```
(sum (i) (* a (** x i)))
```

analogously to

```
(sum (i) (* (let (i i) a) (** x i)))
```

(I reiterate that the S-expression form shown here is not intended as the syntax for interactive use, but just as an unambiguous representation of the internal tree structure; perhaps on the display this would be written as $a_{i=i}$ or abbreviated in something like the conventional way as a_i.)

However, there's still the possibility of unintended variable capture in an expression such as

```
(let (h (* n dh)) (/ (- (let (x (+ x h)) f) f) h))
```

where we are really just using `let` to factor out a common subexpression, rather than to pass arguments to code or index data lexically defined elsewhere.

A third alternative would be to require every introduction of a new variable by `let`, `sum`, and the like, to be explicitly marked as statically or dynamically scoped, but this seems like it would still be bug-prone --- a variable incorrectly marked as dynamically scoped would still be a bug. You could catch this by requiring that the dynamically-scoped variable *not be used statically*, though.

A fourth alternative would be to declare the variables at some lexical scope, in some cases module scope (where, in the context of Dercuano plotting (p. 2885), a module might be a note or a plot). Then, an expression like

```
(** (sum (i) (** x p)) (/ 1 p))
```

would be referring to some `i` that was already in scope, perhaps imported from another module or perhaps declared in the same module, and would be a compilation error if there were no such

variable, so in theory you would know that you were capturing a variable that could be used as a parameter; while on the other hand an expression like

```
(** (sum ((my idx)) (** (let (i idx) x) p)) (/ 1 p))
```

would be introducing a new `idx` variable. This seems simultaneously more awkward and less safe than most of the alternatives above.

Extradimensional features

In the UI, you can write a table with some key columns and some value columns; each value column becomes a new aggregate, stored under a variable with the name in the column header, indexed by all the key columns. If you don't have key columns, a nominal invisible key column is generated.

The top level of the UI defines an environment, or a sequence of environments, within which each expression is evaluated.

XXX does this mean it does some kind of topological sort to come up with an evaluation order?

When you define an expression with a single continuous free variable, the UI by default plots its value against that free variable in a 2-D plot, heuristically picking an initial range that seems likely to be interesting (which you can then interactively zoom and pan). If you define an expression with two continuous free variables, it by default generates a contour plot in a similar way, with a 3-D heightfield plot a click away. Discrete free variables that belong to some numerical range get, by default, a lollipop plot; discrete free variables that are merely nominal result in a labeled small-multiples display, switchable with a click to a single plot with multiple lines (or lollipops or whatever). Tabular results display is always available, but only enabled by default for small tables.

The UI uses the same kind of introspective magic for this that `sum` uses to figure out the possible values that `month` can take on in `(sum (month) production)`. This allows it to distinguish between discrete and continuous parameters based on how they're used, a sort of type inference, find out what their valid values would be, and measure their limits.

Automatic differentiation

How can we squeeze reverse-mode automatic differentiation into this model?

A first prototyping step

The above has made it clear that there are a variety of issues that aren't crystallized yet, but since I've been thinking about this for six years, I probably shouldn't expect them to crystallize anytime soon without more intensive effort. Instead, maybe I should write enough code to get some experience with a subset that *is* crystallized, and maybe try two or three different approaches to the other aspects and see which ones work best.

The most basic core is a few kinds of plots (linegraphs, scatterplots, lollipop plots, contour plots, and heatmaps, at least, and I'd like some 3-D surface plots), pointwise arithmetic (*, **, -, +, /, abs, exp, sin,

binary min, binary max), conditionals ("where"), extracting the free variables from an expression, and composition (indexing). I think summing along a dimension is the first sort of uncertain thing to add.

JIT-compiling array computation graphs in JS

Kragen Javier Sitaker, 2017-07-19 (1 minute)

Numeric loops running over large arrays are among the easiest kinds of code for JIT compilers to optimize.

Numba is a popular BSD-licensed Python library for LLVM code generation for numerical code; among the things it can do are to compile graphs of Numpy array operations into efficient machine code, including GPU code.

However, Python itself doesn't have a general JIT compiler; Numba is a limited-scope attempt at one.

JS does have a general JIT compiler, several of them actually (SpiderMonkey, V8/Crankshaft, and JavaScriptCore). It doesn't, unfortunately, have operator overloading. But maybe building computation graphs of arbitrary-dimensional arrays would be a reasonable thing to do in JS; then you could compile them into JS code, from which the existing JIT compilers could generate efficient CPU code, and maybe you could write a new compiler to compile the computation graph into GPU code, whether using WebGL in browsers or something else.

An initial hack at generating numerical code for V8 (sweetdreams-js.js) yielded disappointing results. But it was straight-line, loop-free code, so it may not be applicable.

Pythagorean cement pipes for your shower singing

Kragen Javier Sitaker, 2019-09-08 (updated 2019-09-09) (7 minutes)

How could you architecturally encourage singing in the shower? Bathroom resonance sounds great, but it's not always in tune, and often there aren't enough resonances to sing any but the simplest tunes in resonance.

So, perhaps you could provide carefully tuned resonator cavities that resonate pleasingly at in-tune frequencies; for example, concrete pipes of different lengths, sufficiently isolated from the room air as to have a reasonable Q, but sufficiently coupled to it that they can pick up a note in a reasonable period of time; something like $Q = 10$ or $Q = 20$ (half-power points a half-step apart) should be adequate.

Helmholtz resonators like the ocarina are another, more scalable possibility, but they only resonate at a single frequency. Not only does this deprive you of overtones, it also means you need a separate set of resonators for each octave.

The presence of such resonators would also enable you to play a tune on them without singing, just by energizing the resonators, for example by hitting them with your hands, by hitting them with Blue-Man-Group floppy paddles, by banging them with hammers, or by setting firecrackers off in them.

The Pythagorean pentatonic scale

In some sense the simplest musical scale in common use is the Pythagorean major pentatonic scale, consisting of these intervals from the tonic in each octave (assuming the tonic is C):

- 1:1, the perfect unison or 黄钟, no semitones, C;
- 9:8, the major second or supertonic or epogdoon or 太簇, two semitones, D;
- 4:3, the perfect fourth or epitriton or roughly 中吕, five semitones, E;
- 3:2, the perfect fifth or hemiolion or 林钟, seven semitones, G; and
- 27:16, the major sixth or 南吕, nine semitones, A.

(The Greek names are from Plato's Republic and Timaeus.)

In some other tunings, 27:16 for the major sixth is replaced by 5:3, but the commonly-used equal temperament is only about six cents away from the Pythagorean 27:16, but 16 cents away from 27:16.

I'm not sure exactly how you should combine these Pythagorean intervals with ISO 16 A440 concert pitch, but one way to do it would be to use the equal-temperament A440 frequency for C as the tonic for each octave. So to get a C, you take $2^{-2/12}$ of 440 Hz (since C is two semitones above A) and get 392.00 Hz. Then you can go down by octaves from there: 196.00 Hz, 97.999 Hz, 48.999 Hz. That's probably deep enough for singing, since the tubes will also resonate at harmonics; so your first octave is 48.999 Hz, 55.124 Hz, 65.333 Hz, 73.499 Hz, 82.687 Hz.

```
(440/2**(2/12)/2/2/2*numpy.array([1/1, 9/8, 4/3, 3/2, 27/16])).round(3)
```

I could be wrong here, but I think that for a pentatonic rather than diatonic or chromatic scale, the advantages of equal temperament do not really come into play, and for singing in the shower, the advantages of just intonation may be more important. But in that case it might be better to use 5:3 rather than 27:16 for the major sixth; the medieval tradition of using 27:16 for this interval led to theorists considering it unusably dissonant, and of course Pythagoras himself was tuning tetrachords, which is why there's no Greek name for it above.

Air-column resonators

Wikipedia says

> Nodes occur at fixed ends and anti-nodes at open ends. If fixed at only one end, only odd-numbered harmonics are available.

Having a node at one end of a tube and an antinode at the other end means we only need a half-wavelength, which is nice, because the speed of sound in sea-level, room-temperature air is about 343 m/s, though it can increase by up to 0.6% with humidity, and vary considerably with temperature (`definitions.units` says 331.46 m/s in dry air at STP). So a whole wavelength at 48.89 Hz is 7 m! (And that's why a tuba has so many curls.)

A half-wavelength one-end-open tube at each of these frequencies would be 3.500 m, 3.111 m, 2.625 m, 2.333 m, and 2.074 m. But those tubes won't resonate at an octave, since it isn't an odd harmonic, so you need five more for the next octave, which is the one people most commonly talk in: 1.750 m, 1.556 m, 1.313 m, 1.167 m, 1.037 m. Alternatively, you could have another set of tubes of the same length, but open at both ends to raise the pitch by an octave — curved around to open again into the bathroom, of course.

Speed of sound variation

Wikipedia says the speed of sound in dry air around room temperature is 331.3 m/s + 0.606 θ m/s, where θ is the temperature in °C, or more accurately 331.3 m/s $\sqrt{(1 + \theta/273.15)}$. This is larger than the variation with humidity, which will also be a consideration when singing in the shower. Long, narrow concrete pipes will tend to slow down variation in both temperature and humidity.

So it might be best to use an average temperature of, say, 20°, or whatever is likely to be the average temperature of the house containing the bathroom; using the 331.46 number from `definitions.units` we get 343.38 m/s, with numbers ranging from 340.43 m/s at 15° to 349.19 m/s at 30°, about 44 cents (0.44 half-steps) of tuning variation.

```
331.46 * (1 + numpy.array([0, 15, 20, 25, 30])/273.15)**.5
```

Closing the mouths of the tubes a bit, so the aperture into the room is smaller than the body of the tube, would reduce the variability of temperature and humidity inside the tube by impeding air circulation. However, because of the wavelength-dependent participation of air just outside the mouth of the tube in the resonation process, this will also exacerbate the detuning of the higher harmonics. Perhaps a better solution is to flare the mouths of the tubes like brass

instruments to counteract this detuning effect, then cover them with something fairly acoustically transparent like aluminum foil or waxed paper.

However, you aren't going to notice the temperature-driven detuning of the pipes unless their Q is higher than about 40, so maybe you could just not worry about it.

Parsing a conservative approximation of a CFG with a FSM

Kragen Javier Sitaker, 2015-09-03 (7 minutes)

We know we cannot parse context-free languages with a finite state machine; this was central to Chomsky's destruction of behaviorism in the 1950s. But we can do a pretty good approximation.

All the ideas in here are due to Björn Höhrmann, who explored them in some depth in parselov, which is an implementation of these ideas in JS, plus a bunch of other ideas I don't understand yet but which are probably even better. (That is, unless I accidentally invented something and didn't notice. But I think all the ideas here are his.)

Consider this algebraic-expression CFG:

```
e where
e ::= e "+" f | e "-" f | f
f ::= t "*" f | f "/" t | t
t ::= "-" t | "+" t | number | variable | "(" e ")"
```

If we omit the last alternative, which recurses back to the beginning, we have an entirely regular language. All of the other recursions are either left-recursions or right-recursions, and so we can rewrite them as loops; for example, the alternatives for `e` add up to a sequence of `f` separated by "+" and "-" signs.

The final case, though, requires parentheses to match, which is a thing that a regular expression cannot guarantee.

But let's consider the "unstructured control flow" of the "subroutine calls". We can arrive at the beginning of `f` from any of five callsites (three in `e` and two in `f` itself) and, when we get to the end of it, we can return to any of those sites. In this way we can mechanically convert the entire grammar into a finite state machine. Of course, this finite state machine loses some information — it does not know whether it got into `e` from the top-level parsing or due to a recursion inside `t`. So it will match "(4" where it shouldn't. Nevertheless, it will not match "+*4" or "4 x". It's guaranteed that if it doesn't match a string, the full CFG cannot parse it either.

We can make it more precise by duplicating rules that are called more than once. For example, this CFG parses the same language, but if converted to a FSM in the same way, will no longer match "(4":

```
e where
e ::= e "+" f | e "-" f | f
f ::= t "*" f | f "/" t | t
t ::= "-" t | "+" t | number | variable | "(" e2 ")"
e2 ::= e2 "+" f2 | e2 "-" f2 | f2
f2 ::= t2 "*" f2 | f2 "/" t2 | t2
t2 ::= "-" t2 | "+" t2 | number | variable | "(" e ")"
```

That's because `e2` can "return to" the point in `t` before the ")", or the points in itself before the "+" and "-", but not the final accepting state.

It would have been equally valid for the `e` in the final `t2` to invoke `e` rather than `e2`, but it would have yielded a different approximation. The grammar as modified above will convert to an FSM which tracks whether to expect an even or odd number of closing parentheses. If instead we had recursed into `e2`, it would track whether it had never seen a left parenthesis.

It is not obvious to me how to choose which nonterminals should be duplicated in this way. These rules occur to me, in order to get a more precise regular approximation of the context-free language:

• There is no need to duplicate a nonterminal invocation that does not form part of a recursive loop, mutual or otherwise. You can attempt to stratify the nonterminals to figure out which calls form part of such a recursive loop, but this is not guaranteed to give you a minimal set of invocations.
• There is no need to duplicate immediately-left-recursive or immediately-right-recursive invocations, because they can be handled precisely by a FSM without more effort.

Of course, this process can be repeated.

It also occurs to me that if the FSM, upon entering a state with more than one predecessor state, records which predecessor state it entered from, then it is recording all of the candidate derivations it has discovered. To the extent that we elide ε-edges, we end up multiplying these cases, but in the simple case, we have one derivation per edge. Considering parsing the string "(4)" with this:

```
e where
e ::= e "+" f | e "-" f | f
f ::= t "*" f | f "/" t | t
t ::= "-" t | "+" t | number | variable | "(" e ")"
```

we, at the end, transition from after the ")" nondeterministically to all of the five callsites of `t`, from two of those nondeterministically to all of the five callsites of `f`, and from three of those to all of the four callsites of `e`, one of which is in fact the top-level `e` invocation, which accepts the string.

If we duplicate each nonterminal for each callsite, this process becomes more precise.

In a sense we could say that we are multiplying the states of the nondeterministic FSM by labeling them with some finite summary of the stack (or continuation) that a nondeterministic PDA would use if it parsed the grammar in the obvious way: the sequence of "return addresses" it would have. (Of course the PDA is an FSM if you leave out the stack.) The important thing is that we are mapping the infinite set of states-of-the-stack states to a finite set of states, and we're doing it in such a way that we don't need to magically recreate information that we erased — if we forget whether the number of right-parens we're expecting is odd or even, we can't define our mapping in such a way that we have to later recover that datum. (We can, however, nondeterministically guess it!)

That said, though, there are a wide variety of possible mappings of stack-states to finite states. I've talked about some of the possibilities above, although it was phrased in terms of duplicating productions.

A consideration for practical implementation of these concepts is that we would, ideally, eventually reduce the FSM to a deterministic FSM, so that we can execute each step on a real (deterministic) computer in constant time. For this we would like to avoid the potential exponential blowup of the powerset of the set of NFA states into DFA states, and counterintuitively it turns out that erasing *less* information about the stack can actually help to *reduce* the number of states.

License-free femtowatt UHF radio transceiver ICs under a μJ per bit

Kragen Javier Sitaker, 2016-09-19 (5 minutes)

Looking at the US$4.01 NXP MKW01Z128 that Bill Paul mentioned. This chip's RF interface is really interesting because it can transmit license-free as low as 290 MHz (1.03 m) at up to 600 kbps. It has 128 KiB of Flash and 16 KiB of RAM and a 48 MHz Cortex-M0, sucking 16 mA when actively receiving (and up to 95 mA when transmitting) at 1.8 to 3.6 volts. It's targeted at last-mile metering and wireless sensor networks.

Radio communications characteristics

Its power output is -18 to 17 dBm (50 mW!) and its sensitivity is -120 dBm (a femtowatt!) and so it occurred to me that maybe we should measure solid angles in dB. In this case, without further amplification, the receive antenna needs to capture signal over -137 dB (or more) of the sphere around an isotropic transmit antenna.

(The -120 dBm is dependent on lowering the communication rate to 1200 bps.)

A half-wave dipole antenna, the ideal, would be 516 mm long for 290 MHz; it gives you 2.15 dBi of "antenna gain", so you get down to a solid angle of -139 dB, and it captures signal over about 0.2 m², I think. This subtends -139 dB of solid angle at about 1000 km.

That's pretty impressive — two such chips can communicate over 1000 km with nothing between them but half-wave dipoles, and furthermore without a license.

On Spaceship Earth, though, it's a little tricky to have nothing between them, and 1000 km is far too short for moonbounce. If you were to use a 30 dBi dish antenna to transmit, that would get you to about 30 000 km, which isn't even all the way around Spaceship Earth; if you use another one to receive, that gets you to 900 000 km, which is far enough for moonbounce — but then you only have about 3 dB of headroom, and the moon sucks most of that up; typical moonbounce path losses are around 240 dB.

The 315 MHz UHF unlicensed (ultra-low-power/short-range device in US and Japan, not ITU) frequency band it uses (which extends down to 290 mHz, at the top of the VHF band) is mostly used by garage door openers, keyless car openers, and whatnot. It should have reasonable building penetration, better than cellphone signals.

E-skip ionospheric propagation apparently doesn't reach 290 MHz (250 MHz seems to be the limit), but it might be subject to tropospheric ducting from atmospheric temperature inversions, and to transequatorial propagation, and otherwise is limited to 3570 m √(h/m) line-of-sight radio horizon. Reaching 1000 km with 3570 m √(h/m) would require a stratospheric balloon or drone at 79 km altitude. A terrestrial structure like my office at about 60 m only has a line of sight of around 30 km. (Probably all the people remotely

unlocking their cars would provide too much interference, but maybe not.) Totally unsurprising structures like trees might be only 10 m tall, and thus have a line of sight up to about 10 km.

Tropospheric ducting, if it's possible, has the additional advantage that the strength of radio waves trapped in the atmospheric duct only drops off as the reciprocal of distance, rather than its square.

If you were to try to do something cute and moonbouncelike, maybe you could use a mountain. For example, a few kilometers from Las Cruces, Organ Needle reaches 2700 m above sea level, while Las Cruces itself is at only 1200 m. A dish (or radome) pointed at Organ Needle would effectively transmit isotropically from 1500 m, giving it a line-of-sight range of over 100 km, as long as the reflected power was high enough.

Power usage

16 mA × 3.6 V / 48 MHz works out to about a nanojoule per instruction. 95 mA × 3.6 V / 600 kbps works out to 570 nJ per bit.

17 mA at 1.8 volts is roughly the power supplied by the solar cell from a solar calculator, and just about at the right voltage already; two such cells in series with a capacitor ought to provide plenty of power for the device as long as it's only transmitting with a relatively light duty cycle.

Kinect modeling

Kragen Javier Sitaker, 2016-09-16 (1 minute)

So I have a bunch of depthmaps (aka range images) of a sculpture, acquired with a handheld Kinect. Now I want to generate a 3-D model of them.

http://pointclouds.org/documentation/tutorials/in_hand_scanner.php#in-hand-scanner (dependent on color; uses ICP) and http://wiki.ros.org/rgbdslam are two ROS-related things that do this kind of thing.

http://pointclouds.org/documentation/tutorials/registration_api.php#registration-api has an overview of the process, including an alarmingly large number of options for how to do each step (although apparently SIFT and NARF are the usual feature detectors?), and http://pointclouds.org/documentation/tutorials/interactive_icp.php#interactive-icp has a demo thingy (which uses Blender, but only to generate the input as a .ply file), using the ICP algorithm that is also used in http://pointclouds.org/documentation/tutorials/iterative_closest_point.php#iterative-closest-point. It looks pretty easy to use but I don't know how well it works for incomplete point clouds with errors.

But I don't really want a point cloud. I want a triangle mesh so I can render it efficiently and then simulate projecting images onto the sculpture.

NARF, the "normal aligned radial feature", is https://www.willowgarage.com/sites/default/files/icra2011_3dfeatures.pdf.

The etymology of "tradeoff"

Kragen Javier Sitaker, 2016-08-11 (5 minutes)

The word "tradeoff" means giving up some desirable attribute, like fuel efficiency, in order to gain another one, like crash safety. It comes from the phrasal verb "trade off", which means the same thing. But is this sense of "tradeoff" metaphorical or literal?

This is not as simple a question as it may seem. "Trade", taken literally, means to give another person something and receive something in return: commerce or barter. That's not what's happening in a "tradeoff", so it would seem to be metaphorical.

But you can't use "tradeoff" to describe literal commerce or barter. You can't say this:

*I met Billy at the park for a tradeoff of my bicycle for his clothes iron.

"Tradeoff" just doesn't have that sense.

Furthermore, it turns out that it isn't the literal sense of "trade", either. Or at least it wasn't. Douglas Harper's wonderful Etymonline tells me that what we now think of as the literal sense of "trade" was a sort of metaphorical or extended sense, at which point the literal meaning of "trade" was to occupy your time in something, such as milling flour. It's not quite clear when it acquired this new metaphorical sense of bartering; it was definitely established as a verb by the 18th century CE, but as a noun it is attested as early as the 16th century CE.

But that wasn't the original literal meaning of "trade", either. To call milling flour a "trade" was a metaphorical extension of the literal 16th-century-CE meaning of "trade", which was "a path", or as a verb, "to walk a path," like "tread".

But that wasn't the original literal meaning of "trade", either, because when merchants from the Hanseatic Federation of Free Cities introduced "trade" into English, probably in the 14th century CE, it referred to the course *sailed by a ship*. Using it to describe the path a person walked through a forest on was a metaphorical extension, likening the person to a ship. And that's why the trade winds are called "trade winds".

(The Proto-Germanic root *tred-* from which "tread" and "trade" comes, however, already meant "walk," as "tread" does today.)

So the process by which words acquiring meanings is, many times, an evolution from poetic fancy to well-known metaphor to tired cliché to accepted meaning. "Trade" has gone through at least four literal meanings in this chain since its introduction into English: "sailing course", "pathway" or "walk", "occupation", and finally "commerce".

So what's the literal meaning of "tradeoff"? It didn't exist as a word until 1959, but the phrasal verb "trade off" occurs rarely in the 19th century, with the meaning "trade away in commerce":

If we turn to Ireland, also the land of free trade, we see an almost total inability to **trade off** labor in exchange for either food or clothing. Canada has free trade, yet she is unable to **trade off** labor for food, and Canadians are forced to get employment within the Union. Next, we see the farmer of Canada seeking to send his food to be exchanged in the markets of the Union for that labor which could not be employed at home.

The American Whig Review, August 1850, "What Constitutes Real Freedom of Trade ?", Vol. VI, No. XXXII, p.130 (144th page of 696 in the DjVu file, 18th page of No. XXXII)

The owner of the palm-nuts must go to the caravan trader and trade off the palm-nuts for beads, brass rods, or powder.

(Apparently an 1886 United States Consular Report, probably about the Independent State of the Congo, but I'm not succeeding in finding it.)

These are the only two uses of the phrasal verb "trade off" that I've been able to find from the 19th century, although there are many purely coincidental occurrences of that 2-gram, in constructions like "the slave trade off the coast of Cuba".

However, it doesn't seem that the noun "tradeoff" ever referred to engaging in commerce. The earliest uses I've found are from the mid-1960s, after 1963, and they all seem to use "tradeoff" or "trade-off" in the sense of a design tradeoff.

Making a logic gate of a single MOSFET

Kragen Javier Sitaker, 2016-06-28 (5 minutes)

If we interpret "connected to power supply" as a 1 bit and "unconnected to power supply" as a 0 bit, a single SPDT electromechanical relay can compute any of the following logic functions:

• Buffering and NOT, with the input signal and ground connected across the winding and the power supply connected to the armature. Of course this use of relays is what they were invented for and why they're called "relays".
• AND and AND-NOT (abjunction), with a second input signal instead of the power supply connected to the armature.

This is in some sense very device-efficient, computing as it does two separate logic operations per relay. With DPDT relays, you can compute even more. This signaling scheme also permits arbitrary use of wired-OR, which means it's eminently bus-compatible.

Relays, being electromagnetic rather than electrostatic devices, are not troubled by floating inputs. If we use a different signaling scheme, in which "connected to power supply" is 1 and "connected to ground" is 0, then the situation changes somewhat.

• Buffering connects the input signal and ground across the winding, the power supply to the normally open contact, ground to the normally closed contact, and the armature to the output.
• NOT is the same, but with the connections to the contacts reversed, or alternatively with the input signal and the power supply connected across the winding. Making both changes converts the relay back into a buffer.
• AND connects input signal A and ground across the winding, input signal B to the normally open contact, and ground to the normally closed contact.
• AND-NOT is the same, but with the contacts reversed, or the connections to the winding reversed.
• XOR connects the two input signals to the two sides of the winding, power and ground to the normally closed and normally open contacts respectively, and the output to the armature.
• Reversing the power and ground on XOR gives you XNOR.
• OR can no longer be done with a wired-or; that's a short. But you can connect input signal A and ground across the winding, power to the normally-open contact, and input signal B to the normally closed contact.
• I don't see a way to build NAND or NOR as single relays in this system; I think you need two separate relays to compute one of them.

You still want to use the other signaling scheme for buses, so you need a sort of level-shifter relay.

CMOS logic

Normal CMOS logic uses four MOSFETs per two-input NAND or NOR gate. Although this is very simple compared to a TTL gate, you could desire something more parsimonious if you're going to build stuff out of discrete MOSFETs. MOSFETs share with relays the property that when they are switched "on", they have a low-resistance, electrically isolated, bidirectional path between the source and drain electrodes. Wouldn't it be nice if you could use a single MOSFET as a multiple-input logic gate, rather than needing several of them?

I haven't been able to figure out a way to do this. There are a few different obstacles.

• There's nothing equivalent to the first signaling scheme, where one of the bits is represented by letting the input float. When a MOSFET input is left to float, it capacitively retains whatever value it had before, or possibly whatever capacitive charge is induced on it by electrical fields in the vicinity. You can of course tie down all your MOSFET inputs with pullup or pulldown resistors, but then you have at minimum two devices per gate, not one.
• MOSFET *outputs* are either connected to the input or left to float. That means that if you want to connect the output to one of two different things (such as ground or Vdd, or ground and an input signal) you need two MOSFETs, not one.
• MOSFET signaling voltages are somewhat troublesome; enhancement-mode n-channel MOSFETs are turned off when the gate voltage is the same as the source, and the "source" is really whichever of the source and drain is more negative. If you bring the gate voltage up, it starts to allow current to flow. Depletion-mode MOSFETs at first seem more promising, since you have conduction until you apply a gate voltage to cut it off, but now your gate voltage has to be *negative* compared to the source.

I don't know if subthreshold behavior might have an answer; otherwise I suspect that single-MOSFET gates are not going to work.

A MOSFET version of RTL, however, works quite easily, with one MOSFET and up to a few resistors per gate.

Arduino radio

Kragen Javier Sitaker, 2016-07-30 (4 minutes)

The Arduino's PWM output can output at up to 31.25kHz with 256 levels, because the counter increments at 8MHz. You can get a 4MHz square wave out of that counter, but maybe more interestingly, that square wave has harmonics at 12MHz, 20MHz, 28MHz, and so on. You should be able to amplify the original signal with a transistor or two and filter out the higher harmonics as a way to generate an RF signal. Maybe even more interesting, if you change the cycle length and duty cycle, you can generate different harmonics.

Now, if you want to generate an FM signal, it's going to be a little bit tricky; you need a harmonic in the range of 87.5 to 108 MHz, which is not impossible, but the tricky part is that the peak deviation is 75kHz, which is a bit under 0.1% of the frequency. So you need some way to somewhat reliably vary the frequency you're generating by quantities less than 0.003%. Maybe you can do this using the AVR's external RC oscillator on the Xtal1 pin with a varactor to adjust the clock frequency of the whole chip a bit.

However, an AM signal should be a lot easier. This is in the 540 kHz to 1610 kHz range, and the Arduino is capable of generating these signals more or less directly; 1600 kHz, 1333 kHz, 1142 kHz, 1000 kHz, 888 kHz, 800 kHz, 727 kHz, 666 kHz, 615 kHz, and 571 kHz are all available subharmonics of the 8MHz timebase, and if you want to use the third harmonic of a frequency that's three times lower, you could very easily get three times as many stations; but that isn't necessary and probably creates more filtering headaches than it's worth.

In the middle of this range, at 800 kHz, you have 10 bits available. If you stick to pure PWM modulation, you then have 10 power levels available for each oscillation, but that's measuring from DC; you really only have 5. But if you're transmitting a max-5kHz audio signal, which is all AM radio receivers can really handle, your Nyquist frequency is 10ksps, so you have 80 oscillations available per "sample" to dither with. This means you really have more like 400 amplitudes to play with — almost 9 bits, 54 dB SNR — and more at lower frequencies. So you should be able to transmit a perfectly respectable-sounding AM signal.

If you simply adjust the PWM threshold between, say, 5 and 10, with a repetition time of 10 cycles, to adjust the amplitude of the 800 kHz signal, you will introduce a "DC" bias as well, which will vary with the amplitude. If this is undesired, you might want to alternate between >50% and <50% duty cycle at some frequency, but doing this without going out of phase may be tricky.

The dithering will produce subharmonic distortion, but if the dither changes levels relatively infrequently, most of the subharmonic can be down in the near-audio range. For example, if you adjust the PWM limit by 1 at irregular intervals averaging 40000 times per second, I think nearly all of the dithering noise will be in the 20kHz to 60kHz range. And you'll only need to service a timing interrupt once every 200 cycles, making it feasible to do other things at the

same time.

A small magnetic loop antenna, maybe one stolen from an AM radio receiver, is probably the best way to do the coupling to the air.

Clanking replicators

Kragen Javier Sitaker, 2016-11-30 (3 minutes)

So I've come to the conclusion that the most significant thing to focus on right now is getting clanking replicators up and running: programmable machines based on bulk-material-processing technology (i.e. the way all machines except for a few experimental STM and AFM setups in research labs operate) that can reproduce themselves much faster than the economic growth rate, say in hours to weeks rather than decades.

I think this is possible now, there's a sort of "arms race" underway to get it to happen, and whoever succeeds will have a massive economic advantage, comparable to but larger than the discontinuity in the shift from hunter-gatherer and pastoral-nomad lifestyles to agriculture.

Freitas is the one who's written the most about this in the past. Sipper also has a page on the issue.

I've just downloaded Freitas and Merkle's 2004 book KSRM, which seems to be the latest survey of the space; it probably inspired Adrian Bowyer to start RepRap. Freitas in particular seems focused on molecular nanotechnology now, but it seems likely that MNT is somedistance further down the road.

The race is unremarked and can be carried out at small scale and without exotic materials or, probably, much special resources. Once a clanking replicator is created, exponential growth should be rapid.

Many words are available from fiction and more careful speculation for such a project: Autofacs, Second Variety, Screamers, Berserkers, Auxons, and Replicators. Auxon is a positive term (from Lackner and Wendt's 1995 proposal), and Autofac is sort of neutral; the others are all nightmares.

I have a lot of reading to do now.

Mechanical vs. electronic computation

I think mechanical control systems might be adequate, and they won't require the exotic high-purity materials that semiconductor devices do. Freitas I guess didn't think that was going to be a problem in 1980.

However, this requires a mechanical system capable of universal computation. Reif wrote a survey chapter in 2008 on mechanical computation which seems to suggest that nobody has built a mechanical universal computer yet.

The Curta I calculator had only 571 parts, while Vaucanson's swan (according to Freitas) had over 1000. I think Calculus Vaporis could probably be implemented with a similar parts count using lookup tables for combinational logic.

Life octaves

Kragen Javier Sitaker, 2018-10-28 (2 minutes)

Biological humans can most often hear about 10 octaves, from 20 Hz to somewhere in the 10–20 kHz range, although slower pressure oscillations can affect them. Analogously, though they seem to be conscious from birth, they usually cannot remember much that happened before the age of 2 years or so. We could say, then, that they can perceive 6 octaves of their lifetime.

The first octave is from 2 years to 4 years. In the first octave, they most often learn to walk, talk, and theorize about others' minds.

The second octave is from 4 years to 8 years.

The third octave is from 8 years to 16 years.

The fourth octave is from 16 years to 32 years. Many humans cease to learn when they enter this octave, instead busying themselves with trivialities. During this octave they pass from being enslaved by their instincts to being enslaved by their delusions and their habits. Their brains and the rest of their bodies continue to grow, and their peak physical and mental capacities are usually reached during this time.

The fifth octave is from 32 years to 64 years. This is the octave of greatest exploitation, in which humans most often exploit their previously-gained capabilities, which remain more or less consistent during this time. A few continue to develop during this time. Nearly all survive to the end of it.

The sixth octave is from 64 years to 128 years, although quite possibly no biological human has yet lived beyond 122 years. This corresponds roughly to the human idea of "old age"; their physical and mental capacities decline and their risk of death rises superexponentially. During this octave, many humans regret having wasted their previous opportunities, and many blame others for this and become bitter.

Sulfuric acid dehydration printing

Kragen Javier Sitaker, 2019-12-18 (updated 2019-12-19) (3 minutes)

The CandyFab did 3-D printing in sugar by blowing hot air onto the sugar to melt it, a process that requires delicate temperature control to avoid caramelizing the sugar all the way to carbon foam.

But carbon foam is in some ways a more useful material than sugar. It has a much higher strength-to-weight ratio, it's vastly more heat-resistant, it's less dense, and often it can be prepared as a conductor or an insulator depending on processing temperature.

In addition to hot air, you can also convert sugar to carbon foam by dripping or squirting concentrated sulfuric acid on it, every high-school chemistry teacher's favorite scary chemical reaction. In a powder-bed 3-D printing process like that used by the CandyFab, this permits you to selectively deposit carbon foam in a sugar powder bed. This could be useful for a couple of different reasons: first, you might have fillers that are sensitive to the heat needed to melt sugar, but not to sulfuric acid, perhaps styrofoam beads or something similar; and, second, you might be able to inject the sulfuric acid more precisely or more quickly than you can inject the heat. In Needle binder injection printing (p. 1492) I outlined a variant of this process that would work well with sulfuric acid as the "binder" being injected deep within the powder bed.

A third possibility is injecting a susceptor, then "baking" the whole powder bed with microwaves or with a dielectric heater; for example, vegetable oil should be a sufficient susceptor to dehydrate sugar in a domestic microwave oven, but other candidates include silicon carbide, graphite, and magnetite. These should work with other kinds of powder-bed processes that require post-heating as well, like those described in 3-D printing by flux deposition (p. 466), enabling more rapid heating of large powder-bed-embedded objects than can be achieved by heat conduction alone.

Possible fillers for this process are highly varied, and they can be selectively deposited in the powder bed, as fluxing agents are in the process described in 3-D printing by flux deposition (p. 466). The simplest is powdered, sieved coke, which will simply produce a denser carbon foam and costs US$0.70/kg, according to Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196). The cheapest is silica sand for construction, US$0.012/kg; carbon foam ought to stick well enough to that. An alternative to sugar that similarly foams up by dehydration, and sticks fabulously to silica, is dried sodium silicate (waterglass), US$1.10/kg. Copper or brass (US$4/kg) could form conductive traces; steel wool or glass fiber (US$6/kg) could provide tensile strength.

Sugar, being water-soluble, can also be used as a binder simply by squirting a bit of water onto it; but it will virtually never dry out by itself at room temperature --- you'd have to bake it.

(A quick stovetop experiment shows that granulated table sugar, when heated to dehydration, is able to bind construction sand together at about 25% sugar, but not at about 10% sugar. Presumably this depends not only on the quantities of sugar and sand but also their grain size distributions. Even at 25% sugar, the mass is quite crumbly;

it disintegrates with a touch. 50% sugar is quite a bit more solid.)

Prototyping stuff

Kragen Javier Sitaker, 2016-08-11 (1 minute)

I have a lot of stuff I want to make prototypes of that I haven't gotten around to yet.

• A compiler for a comfortable programming language. Emitting relatively naïve native code, like within a factor of 5 of native code, should be pretty easy. Ur-Scheme did it. But something with structs, iterators (maybe downward funarg blocks?) and maybe some escape analysis or something would be better. And for OO stuff, Piumarta's tiny MOP seems like it should be able to deliver dynamic dispatch performance within a small factor of a regular function call.
• A deterministic virtual machine. This is closely tied to the previous one.
• Some fucking laser-cut furniture.
• A video game that's fun to play. Maybe tie in with information archival somehow.
• Executable models of electromagnetic and mechanical engineering phenomena.
• Some kind of live-within live programming environment, like Emacs, Smalltalk, and actually sort of Unix.
• Something that does something interesting with machine vision.
• An optimization system that's applicable to laser-cut designs, using executable models of mechanical engineering phenomena.
• A solar heating and dehumidifying system.
• A system for drawing process flow diagrams.
• A ZUI. Another one, one with text and server-side persistence.
• A usable time-series database, unless someone else has written one by now.

An RPN CPU instruction set doubling as user interface

Kragen Javier Sitaker, 2017-07-19 (updated 2019-07-10) (21 minutes)

(See Making the CPU instruction set a usable interactive user interface (p. 59) for related ideas.)

The Olivetti Programma 101 in 1964 and its VWXZ keys

I was reading about the Olivetti Programma 101 desktop computer today. It cost US$3200 when it came out in 1964; they sold forty thousand of them. It could be used as a printing calculator (LED displays were still in the future) and you could load a 120-instruction program from a magnetic card. Its magnetostrictive delay-line memory was somewhat anemic at some 240 bytes, circulating with a bit over 2 milliseconds of cycle time. It's one of the reasonable contenders for the title of "first personal computer".

The thing that struck me as interesting about this machine was that four of the buttons (labeled V, W, X, and Z) were "start program" buttons: they jumped to four of the thirty-two available labels. So you could write an interactive program that enhanced the calculator's capabilities with four new functions invoked with these keys. When the calculator finished feeding the magnetic card through the reader, it would come to rest atop these keys, so it could bear human-readable labels for them, explaining what the newly-loaded program had programmed them to do.

The keyboard *is* the instruction set

RPN calculators, of which I assume the Programma was one, enjoy a pleasantly simple way of programming them: the sequence of computational steps to execute is the same as the sequence of keystrokes to do the same computation interactively, and parameter passing and result return is implicit. The difference is just that in "program" mode, the program steps are added to a program instead of being executed. (The user experience might arguably be better if you did that *as well as* executing them, rather than *instead of* executing them, but for it to be an actual improvement over the traditional HP experience, that probably requires enough screen real estate to simultaneously display the program steps being recorded and the example values.)

This means, in effect, that your CPU instruction set is simultaneously your user interface, which suggests that you might have instructions for such odd keystrokes as "multiply the current top of stack by 10 and add 5". These are obviously far easier to implement as code than as transistors, and as a result machines like the HP 9100A were heavily microcoded, to the point that they had to invent a new kind of ROM to store the calculator's microcode.

The VWXZ approach, however, suggests an alternative to microcoding: implement most or all keys as procedure calls rather than a CPU instruction. Better yet, implement them as CPU

instructions that call particular subroutines. Then, you can avoid microcode and the need to have two levels of programmability in your computer. If you can spare the RAM space for a sort of "interrupt vector" for these keys, then you can make those keys and those instructions reprogrammable.

(If you can do this and also write some kind of idle-time handler that runs when the computer is waiting for an instruction from the keyboard and doesn't get one, you can incrementally extend the computer's instruction set into an arbitrary application.)

How teensy can you make the machine?

We probably can't make do with 32 instructions and keys on the keyboard. A modern "four-function" calculator has the digits, ".", "=", +, -, ×, ÷, MR/C, M+, M-, ON/C, CE, +/-, √, and %, a total of 24 keys; you probably need at least those instructions or their stack equivalents for a usable calculator, plus more than 8 instructions that aren't one of those keys. So you probably need at least 64 keys and instructions, which is what the HP 9100A had.

How much space do you need for a program address? The HP 9100A needed a 32-kibibit ROM for its microcode, which is also how much RAM the late-1970s personal computers needed for a BASIC interpreter; the 9100A also could hold 14 6-bit instructions per register, of which it had 23 implemented as core memory, for a total of 23·14·6 = 1932 more bits. This was sufficiently limiting that they started shipping an HP 9100B within the year with double the RAM, 3864 bits http://www.hp9825.com/html/the_9100_part_2.html. The earlier Olivetti had 240 bytes of delay-line memory, which I suspect were 6-bit bytes; this gives a similar number of 1440 bits.

Let's figure that stack-machine code will probably be a bit more compact than the 9100A's microcode, especially with magic procedure-call instructions, but not all that much, maybe a factor of 2 or 3. Then you need something like ten kibibits of program memory, a bit over 1700 instructions. You could impose, say, a four-instruction alignment requirement on the vectors for the keys, which would cut the vector size down to 9 bits. So vectors for all 64 possible instructions would require only 576 bits, 6% of total memory. Of course you need hard-wired functions for some instructions.

You can probably make do with half of the program memory space being ROM.

So how is this shaping up? We have an interactively usable, fully programmable computer whose memory space consists of 512 24-bit words, of which half are ROM and half are RAM, for a total of 6144 bits of RAM, 59% more than the HP 9100B. 16 of the 256 words of RAM contain 32 instruction addresses (plus six leftover bits) that define the meanings of 32 of the 64 possible six-bit instructions (and keys); the other 32 instructions are hard-wired, perhaps taken from the F18a core. Those 240 words of RAM can contain 960 instructions, which can invoke routines in the other 1024 instructions stored in ROM. These are stack-machine instructions, so you have to spend about half of them on stack manipulation to make up for not having operand fields, so this is roughly comparable to 1000 machine instructions for the 386 or SPARC (500 in RAM, 500 in ROM): barely enough for a simple compiler or assembler, plenty for a video game, and probably not enough for a working TCP/IP stack.

(It's a great deal more than the 1024 bits of RAM in the Atari 2600 or the 1152 bits of RAM in an F18a core, but less than the 16384 bits of RAM in an ATMega328 Arduino, and dramatically less than its 262144 bits of Flash.)

But these 6144 bits of RAM, if implemented as electronic static RAM, will need 12288 transistors — very likely more than the entire processor, maybe even if it's bit-parallel and includes a multiplier. If you could get that memory complexity down a bit, you would have a computer that could scale to much more complex tasks. But this is probably enough to bootstrap with.

If you're building the CPU out of mechanical logic, six 16-position sliders give you a 24-bit word of RAM. All 256 words, then, can be stored in 1536 such sliders. This is more complicated than a Curta calculator or a pocket watch, but not in the same world of difficulty as many mechanical machines that already physically exist. In fact, it's probably a lot less demanding than the Jaquet-Droz automata.

Comparison to the GreenArrays F18A

The F18A has a ten-item parameter stack and IIRC a nine-item control stack; more deeply nested code will not be able to return. In its case, since they're 18 bits wide, they amount to 342 bits. On this hypothetical machine, your parameter stack would be 24 bits, but the return stack could be narrower, as little as 11 bits if you didn't want to use it for loop counters; so you could still fit ten parameters and nine return addresses into 350 bits, which is 5.7% of the size of the RAM and therefore probably a good investment.

(The F18A also has some named memory pointer registers, one of which is also used for multiplication, and a few other miscellaneous features.)

Arithmetic overflow and usability

My experience with integer math in computer programs is that I have to think about overflow incessantly with 8-bit variables, frequently with 16-bit variables, and almost never with 32-bit variables. I have no experience programming with 24-bit variables, but it seems like they would probably be pretty easy. Maybe I should be thinking about floating point.

So the experience of bootstrapping this machine is probably that the bare CPU gives you a 24-bit integer hexadecimal or octal arithmetic calculator with addition, subtraction, and maybe multiplication, and then you can write programs for division, square roots, logarithms, transcendental functions, and whatnot. Or you can instead write programs that don't care about transcendental functions and instead do other things, like assemblers and BASIC interpreters, so you can bootstrap to higher levels of abstraction.

Modeless machine-code programming by example

You could maybe eliminate the distinction between compiling and interpreting modes by always recording the user's keystrokes into some memory buffer or other, thus always preserving the option of executing them later. (See A two-operand calculator supporting programming by demonstration (p. 2387) for more elaboration on

this theme, in a non-stack-machine context.)

Display refresh, task segments, and multithreading

If you're executing machine code interactively to do calculations, you probably want to see the values you're operating on. If the CPU has registers (for example, a top-of-operand-stack and next-on-operand-stack register), you probably want to see those registers rather than, say, some memory location. But more advanced applications might want to display something custom, which might not be numbers. One way to do this would be for hardware to copy these registers onto the display every, say, 15 or 20 milliseconds; if the system that does this raises an interrupt a little earlier, then a custom interrupt handler could arrange to set those registers to the desired display value for a few dozen microseconds. Another way would be to update the display explicitly rather than implicitly, possibly also from a timer interrupt handler.

This ties in with how the machine's control flow weaves together keyboard response, background-task service, and interruption of accidental infinite loops. A standard single-threaded computer runs a top-level infinite event loop with its PC either at a halt instruction or running some background task most of the time; when you press a key, an interrupt is raised, the background task is suspended (or the halt is raised), and the PC moves into the keyboard interrupt handler; this buffers a keystroke and perhaps sets a flag or two, and upon return, the main event loop takes note of the keystroke (sooner or later) and acts upon it, perhaps invoking other subroutines.

Here we're proposing that the PC normally be pointing *to the keyboard*, such that when the CPU attempts to fetch an instruction, the fetch blocks until a key is pressed; possibly a timer interrupt might interrupt the blocked fetch from time to time, running some background task, before resuming the blocked fetch; when the keystroke executes, it may call some other subroutine, pushing the address of the keyboard onto the stack for a while until the subroutine finishes and the CPU awaits the next keystroke.

One consequence of this is that you need some way to keep the PC from incrementing out of the keyboard space. This could be done with saturating arithmetic (placing the keyboard at the end of the address space), an equivalent special case in the PC increment logic at some other arbitrary address, or in a non-special-case way by limiting the width of the PC increment logic. For example, you could simply omit the carry out of the 7th bit of the PC (and everything beyond), such that every 128 memory words formed a separate "task segment" — if control falls off the end of one, it just wraps back to its beginning. Then you memory-map the keyboard to an entire task segment. (I think I got this solution from the GreenArrays chips, but of course an 8086 will do much the same thing — IP is a 16-bit register and doesn't overflow into CS; if you execute off the end of a 64K code segment, it will wrap back to the beginning.)

However, in this model, quite aside from how it may or may not handle PC incrementation, two problems are not entirely resolved. First, how do you recover control if you accidentally invoke an infinite loop which never returns into the keyboard address space?

Second, how can a best-effort background task (as opposed to an isochronous task like updating the display or incrementing an RTC) yield its time slice to interactive computation? After all, from the point of view of an interrupt handler, the difference between being invoked when the machine is idle and while it's running some computation is just a matter of whether it's returning to the keyboard's address or somewhere else; it would be ugly to have it introspect that in order to decide whether to return before doing its quantum of work.

I'm not yet convinced there's a clean solution to those problems within the keyboard-is-instruction-set, no-monitor-program-needed constraint.

The 8080 RST instruction and keyboard bucky bits

Each instruction on the Intel 8080 was one byte, not counting possible operand bytes following the opcode byte in the instruction stream, so there were only 256 possible instructions. 8 of these precious slots were given over to an "RST" instruction, glossed "restart", which included a 3-bit operand field "nnn"; in octal, it had the opcode 03N3. These called a subroutine at address 000 0N0 (again, in octal), and the machine's hardware interrupt, as I understand it, invoked the eighth of these eight subroutines in the same way as if an RST 7 instruction had been issued.

Since they called a subroutine in the usual way, pushing the PC on the stack, the code thus invoked could RET to the program that had invoked the RST instruction (or that happened to be running when the hardware interrupt arose), which would then continue its execution as if nothing untoward had happened. In essence, the eight RST instructions provided eight programmable opcodes, vectored to subroutines in RAM or ROM.

The question arises: if some of your opcodes are such vectorable subroutine calls, and you're relying on this for your user interface, what is the proper number of them to have? The Olivetti Programma 101's four programmable keys is probably too few, as is the 8080's eight RST opcode bytes. You usually want to have more than eight actions available to the user at any given time when they are using an application, especially if they are going to be composing text. And it's reasonable to think that high-level application code might consist largely of calls to existing subroutines, although some amount of immediate data is surely needed; being able to vector a significant chunk of the instruction set to such subroutines might be a really cool way to extend the instruction set in an application-specific way, taking language-oriented programming down to the machine-code level.

One constraint here is the physical keyboard size. The keyboard I'm typing this on has 88 keys, like a piano. (It's a "Genius" "Luxemate 100" USB keyboard chosen because it was cheap and small enough to easily fit into my backpack, despite having kind of a shitty feel and a non-coiling cord.) A minimal typewriter-style keyboard probably has around 50 keys, as does the "Cifra SC-9100" scientific calculator I profiled in Usability of scientific calculators (p. 2379). A keyboard with 256 or 512 keys would be unwieldy. Even

the 101-key keyboards that are common on PCs nowadays are unwieldy; you can't reach most of their keys without moving your hands. The Android 4 on-screen keyboard on the phone I have here has only 34 keys, and it requires constant mode-switching and autocorrect to approximate usability. Termux, a Unix CLI environment for Android, adds 17 more keys, bringing the total to 51, and does reach a more reasonable level of usability.

StoneKnifeForth, which is an i386 compiler that compiles itself into a Linux ELF executable in two pages of source code (or 7 pages counting comments), consists of 50 subroutines and variables. More elaborate software modules need more, but probably it's only rarely useful to have many times more subroutines accessible than that.

So, an interesting design alternative: have an 8-bit instruction set of which 64 bytes — perhaps the ones corresponding to ASCII digits and lowercase — are directly generated by the keyboard and vectored like the 8080's RST instructions are vectored:

```
  +  0 1 2 3 4 5 6 7 8 9 a b c d e f
0x20   ! " # $ % & ' ( ) * + , - . /
0x30 0 1 2 3 4 5 6 7 8 9 : ; < = > ?
0x60 ` a b c d e f g h i j k l m n o
0x70 p q r s t u v w x y z { | } ~ DEL
```

This omits uppercase letters, @, [, \,], ^, _, and the control characters other than DEL; none of these are essential for arithmetic, and this was probably a deliberate design decision on the part of the ASCII committee: a single contiguous 32-character chunk of the code space is adequate for FORTRAN, except for the alphabet.

In addition to these 64 keys, corresponding directly to bytes that invoke subroutine calls in the CPU, you can have two "bucky keys" to generate the rest of the possible 8-bit bytes. One of them ("Meta") should obviously set the high bit, while the other one probably needs to act like Shift for the lowercase letters, which is to say that it maps 0x61 to 0x41, 0x70 to 0x50, and so on. The simplest thing for this "Shift" to do would be to clear the 0x20 bit, which would map the digits and most punctuation to control characters. In particular, backspace would be shift-"(", tab would be shift-")", CR would be shift-"-", and LF would be shift-"*". This may be too outré to use in practice, although at least DEL is on a key of its own.

Traditional keyboards, as represented by libvte and xterm anyway, ignore Ctrl for pretty much everything in the 0x20 and 0x30 rows, except that Ctrl-/ yields ^_, US.

The idea is that, even if the majority of the keys on the keyboard correspond to vectored-subroutine instructions, some key combinations would instead correspond to hardwired instructions that would allow you to regain control and rebootstrap the system even if the subroutines attached to your normal keys got horked.

(Consider instead the approach of providing "Shift" and "Ctrl" keys that individually do what you would expect: shift-a is A, ctrl-j is SOH, shift-j is J, ctrl-j is LF. So shift must map 0x60 to 0x40 and 0x70 to 0x50, while ctrl maps 0x60 to 0x00 and 0x70 to 0x10. But technically that leaves open the shift mapping and the ctrl mapping for 0x20 and 0x30, as well as the ctrl-shift mapping for everything. For example, you could have shift map 0x20 and 0x30 to 0xa0 and

0xb0, ctrl-shift map 0x20 and 0x30 to 0x80 and 0x90 and map 0x60 and 0x70 to 0xc0 and 0xd0, and ctrl map 0x20 and 0x30 to 0xe0 and 0xf0. There's probably a viable option in this space that can be achieved with a few logic gates, but for now I will leave the option open. Furthermore, for now I won't consider the possibility of a second bucky bit for a Meta key, or a third bucky bit for key release events, although detecting long key presses is clearly necessary for many important applications, such as Tetris. These suggest nine- or ten-bit instruction "bytes", which would be mostly vectored subroutines.)

Topics

Short words

Kragen Javier Sitaker, 2019-12-10 (updated 2019-12-11) (4 minutes)

I like programming-language tokens to be short; if alphabetical, I like them to be comprehensible. This can lead code to look like Urbit, but no matter. In particular I think Perl's "my" is significantly better than "var", "val", or "let", and JS's "const" is a lose. Similarly, Darius Bacon's language Cant uses "#yes" and "#no" rather than "true" or "false".

The most frequent 128 three-letter words in English, according to the British National Corpus, are:

the and was for you are not but had his she her all has one can who him its two out did now may new any see how get way our got own too say erm day yes man use put old why off end men set yet six war car saw let far law big act job age run try pay ten mrs ago ask few air god sir lot cos bed tax top art cut bad per boy bit son sea red nor gon low buy sat met cup oil led lay eye arm win hot sun ran box sit tea won sex add aid dog key mum bar eat mhm gas hit dad dry fit inc aim due die leg ian bus aye ltd tom

Most of these are at least real words, though "Inc.", "Ltd.", "Mrs.", "cos", "gon", "mhm", "Ian", and "erm" did make it in there, some of which may not be real words, depending on your definition. "tom" (presumably mostly "Tom") occurs 5063 times.

There are 39 two-letter words that occur more frequently than that:

of to in it is on he be by at as or we an do if so no up my me go er us oh mr mm ca am uk wo na de st dr ah ii tv ec

These are mostly words, but it starts getting pretty dubious at the end there.

There are 320 four-letter words that are this common, but 320 is too large a vocabulary. The most common 128 are:

that with have this they from were been will what said more them some into then time like only your just also know well very than most over back much many yeah work down make good such year must last take even here come both does made same when want life need used home each part went look came four give mean next case find long five says took away seen fact less done area help hand best head side days john left week form face room tell able high told half eyes keep once road open full knew feel ever name mind door body book main show upon gave real view line city felt kind idea read sort care else free thus past love play land gone

The most common 128 words in English, other than those mentioned above, are:

a i which there their would about could other these people first should think between years being those because three through still after right going before government might under however world another while again against never something thought house number different really children within always without local system great during small place although little things social group second quite party every company women later given important point information national often school money public night further found since better around british having thing london taken perhaps state family water though already possible nothing where business large young whether enough development country almost council power until himself political become times service members change problem doing court towards major anything others police either problems interest probably asked available labour today education

A potential disadvantage to using real words in your programming language is that people are more likely to try to use them as identifiers, and depending on the language design, that may or may

not be possible.

Desbarrerarme: a UI for speaking to people

Kragen Javier Sitaker, 2015-09-03 (5 minutes)

Facebook chat is dangerously addictive in part because it is so easy to use, and constantly offers you new opportunities for what to do. However, aside from the political problems with using it, it's somewhat repulsive in that its HTML UI often hangs for long periods of time and makes your machine slow.

But it has a number of good points, which I want to incorporate into a UI of my own for talking on chat:

• Saying "OK" in your current conversation is three keystrokes: O, K, and Enter. No need to choose a subject line, no need to invoke a "new message" command.
• Nevertheless, you can send arbitrarily long messages, with formatting. FB has removed the boldface from asterisks it used to support, and it tends to mangle complex formatting, but it's still perfectly usable for multiple paragraphs filled to your screen width.
• You can move among recent conversations with single keystrokes, ↑ and ↓, to be specific.
• It suggests that you interact with people you haven't interacted with in a while, to a limited extent, by using their presence information.
• Regardless of which device you're interacting from, you always see the same message history. Opening a chat shows you your previous conversations with the person.
• It supports links and embedded images.

So my plan is to rig up something similar, but for email. As with Gmail, you'll see the emails in a thread above your text box at the bottom, with repeated crap elided. By default, you'll have only a single thread with a given person, and you'll always be replying to their latest message, if any. If they change the subject line, it will be a new thread. You should be able to answer ten emails from ten different people with one-word answers in ten seconds, even if you don't have an internet connection.

Each thread has a simple read/not-read flag. When you open it, it gets marked as "read". When you receive a new message in it, it gets marked as "not-read".

Furthermore, I want to use this for chat systems other than mail, including everything Pidgin supports.

To allow scaling to a larger number of historical threads, and more important threads, than Facebook, I want to do some amount of search-based navigation — to let you see just the results of a search. XXX

I want to use this to try out a theoretical design for distributed user interfaces I called "rumor-oriented programming". Every time you receive a message, mark a message to be sent, successfully send a message, start writing a draft, or update a draft, that information is recorded as a "rumor" in the "rumorset" of your Desbarrerarme installation. When you synchronize your Desbarrerarme installations, which will happen constantly while you're online, they spread all the

new rumors to each other.

The user interface is rendered from a query on the current rumorset state, a query which is not sensitive to the order in which the rumors arrived at the current node. Therefore, once two Desbarrerarme nodes have finished synchronizing, their user interfaces are guaranteed to render the same information.

However, there is a little bit of information, like which thread you're currently looking at and where your cursor is in the draft, that should not be replicated. This is "control state", and not replicating it is crucial to preserving usability in the face of multiple clients being used by, potentially, multiple people.

To keep things simple, I want to write the user interface view as a pure function of the rumorset state and control state. But, to keep things efficient, I want to cache and reuse the results of previous computations. This is much more important for the rumorset part of the question, which could contain gigabytes of information, than for the user interface, which might be a megabyte or, in the form of drawing operations, a couple of kilobytes.

I also want to avoid complete recomputations of large results. For example, the leftmost column of the screen layout should contain the

Improving “science” in eSpeak's lexicon

Kragen Javier Sitaker, 2007 to 2009 (updated 2019-06-27)
(15 minutes)

So I've been playing around with speech synthesis software tonight. eSpeak looks a lot nicer than Festival, just in that it's much easier to adjust its speed, correct its pronunciation, and play with variations: whisper, different accents, pitch, word spacing, creaky voice. I got to thinking, what would a logical policy for updating its lexicon look like? I thought the results I came up with were interesting. Maybe some other people will be interested too.

The problem

eSpeak gets “neuroscience” and “pseudoscience” wrong, pronouncing them with a `[[s,i@ns]]` rather than a `[[s'aI@ns]]`. It also gets “omniscience” and “prescience” wrong, or at least pronounces them rather differently than I would:

```
$ ~/pkgs/espeak-1.37-source/src/speak -v en/en-r+f2 -s 250 -x "The
    science of neuroscience is not a scientific or quasiscientific
    pseudoscience.  Conscientiously pursue omniscience and prescience."

 D@2 s'aI@ns Vv n'3:r-@s,i@ns I2z n,0t#@ saI@nt'IfIk _:_:D@ kw,eIzaIsi@nt'IfIk sjo
o'u:d@s,i@ns
 k,0nsI2;'EnS@sli p3sj'u: '0mnIs,i@ns _:_:and pr'i:si@ns
```

I would pronounce the “science” in “omniscience” and “prescience” as `[[S@ns]]` and put the accent on another syllable.

There's a special rule for “scien” beginning a word, and for “conscience”:

```
en_list:conscience      k0nS@ns
en_rules:       _sc) ie (n      aI@
en_rules:?8     _sc) ie (n      aIa2
```

However, Jonathan Duddington has said he wants to keep the eSpeak distribution small, so he “wouldn't want to include too many unusual or specialist words”. (See http://sourceforge.net/forum/forum.php?thread_id=1700280&foruo
om_id=538920 where he talks about why he doesn't want to import the Festival lexicon.) Already, `espeak-data/en_dict` is 80KB, which is half the size of the `speak` binary.

Replacement strategies

There are several possible strategies that a maintainer could adopt in order to improve the coverage of their special-case word files without letting them get large. Suppose that there is a scalar metric of “goodness” that can be applied independently to each special case. Here are three plausible strategies, ordered from least to most stringent.

• C-: They could never remove items from the file, adding new items as long as they were better than the worst item in the file. This will probably cause the average quality of the entries in the file to gradually decline, because many of the most important entries were probably added early on. It will eventually result in a very large file with very low average quality per entry, but very comprehensive coverage.
• C+: They could keep the number of items in the file fixed, adding new items as long as they were better than the worst item in the file. This will cause the program to gradually work better, but each new version will introduce regressions --- words that the previous version pronounced correctly, but the new one does not.
• A: They could never remove items, but add new items as long as they improved the median item quality of the file --- that is, as long as the new item improved the program's performance more than most of the items in the file. This will gradually slow down and eventually stop the addition of new items, because that median quality will gradually increase.

I am going to approximate "quality" with "frequency", on the theory that mispronouncing a rare word is always better than mispronouncing a common one.

Note the analogy to Google's famous hiring policy: only hiring candidates who raised their average ability.

Evaluating word frequencies

Are these "science" words significant enough to include? `en_list` only contains 2869 lines, maybe 2400 of which are words. So maybe only the top 2400 or so exceptions to the normal rules of pronunciation are currently considered for inclusion.

Some time ago, I tabulated the frequencies of words in the British National Corpus and put the results online at http://canonical.org/~kragen/sw/wordlist. It has 109557 lines, ordered from the most common words ("the", "of", and "and", each occurring millions of times) to the least common (with a cutoff of 5 occurrences, because most of the words with fewer were actually misspellings).

I selected 20 lines at random from `en_list` with the following results:

```
kragen@thrifty:~/pkgs/espeak-1.37-source/dictsource$ ~/bin/unsort < en_list | hea
od -20
this            %DIs          $nounf $strend $verbsf
barbeque        bA@b@kju:
con             k0n
?5 thu  TIR       // Thursday
_:      koUl@n
Ukraine        ju:kr'eIn
peculiar        pI2kju:lI3
unread          Vnr'Ed        $only
inference       Inf@r@ns
José           hoUs'eI
unsure          VnS'U@
```

```
survey                  $verb
ë       $accent
epistle         I2pIs@L
Munich          mju:nIk
scenic          si:nIk
synthesise      sInT@saIz
corps           kO@             $only
rajah           rA:dZA:
transports      transpo@t|s     $nounf
```

Where do these special cases appear in the British National Corpus tabulation? Here are some results, edited for readability:

```
kragen@thrifty:~/pkgs/espeak-1.37-source/dictsource$ grep -niE ' (this|barbeque
   |con|thu|ukraine|peculiar|unread|inference|José|unsure|survey|epistle|munich
   |scenic|synthesise|corps|rajah|transports)$' /home/kragen/devel/wordlist
22:463240 this
1178:7999 survey
5102:1441 peculiar
5831:1200 corps

7165:888 ukraine
8977:634 munich
9045:627 unsure
10552:494 inference

11134:455 con

15127:275 scenic
29899:82 epistle
31386:74 transports
34270:62 synthesise

37255:52 unread
73679:11 thu
74154:11 rajah
87737:8 barbeque
```

The 50th-percentile among the sample of 20 (of which two weren't words, and a third wasn't found) seems to be line 11 134 with the word "con". That is, the exceptions in `en_list` are mostly drawn from the most frequently used eleven thousand words in the language. (Maybe words like "barbeque", "rajah", and "unread" should be dropped.)

So under the policies "C+" and "C-", any word that is more common than "barbeque", at position 87737 in the British National Corpus tabulation, (or maybe some word even a bit rarer than that) should be added to the file. (Under policy "C+", some word would be removed to compensate, raising the threshold.) Under the policy "A", the threshold would be "con", at position 11 134.

Unfortunately, José is missing. I think I excluded accented characters when I tabulated the frequencies initially.

Anyway, that gives us a way to compare the "science" words:

```
kragen@thrifty:~/pkgs/espeak-1.37-source/dictsource$ grep -n scien[tc]
    /home/kragen/devel/wordlist
```

```
870:10597 science
1614:5922 scientific
2584:3547 scientists
3865:2088 sciences
3977:2005 scientist
5342:1355 conscience

13365:338 conscientious
16976:227 scientifically
25757:109 consciences
26015:107 conscientiously
27861:93 unscientific
37040:53 omniscient
44349:36 prescient
49031:29 neuroscience
49706:28 prescience
50457:27 scientificity
50587:27 omniscience
53155:24 scientism
62346:17 geoscience
66943:14 scientia
67285:14 neuroscientists
68176:14 conscientiousness
82060:9 geoscientists
84433:8 scientology
84434:8 scienter

86513:8 geosciences
90235:7 neurosciences
93073:7 biosciences
93074:7 bioscience
95039:6 scientifique
95591:6 pseudoscience
103190:5 presciently
103191:5 prescientific
```

Of these, only those more common than “conscience” seem to deserve a place in `en_list`. How does eSpeak do now?

```
$ ~/pkgs/espeak-1.37-source/src/speak -v en/en-r+f2 -s 250 -x "Science is
    scientific and done by scientists, who work in the sciences.  A
    scientist with a conscience may be conscientious.  Those with
    scientifically-minded consciences will conscientiously avoid
    unscientific claims of omniscient beings or prescient prophets."
 s'aI@ns I2z saI@nt'IfIk _:_:and d'Vn baI s'aI@nt#Ists
 _:_:h,u: w'3:k I2nD@2 s'aI@nsI2z
 a2 s'aI@nt#Ist wI2D a2 k'0nS@ns m'eI bi: k,0nsI2;'EnS@s
 DoUz wI2D saI@nt'IfIkli m'aIndI2d k'0nS@nsI2z wIl k,0nsI2;'EnS@sli; a2v'OId
 VnsaI@nt'IfIk kl'eImz Vv '0mnIs,i@nt b'i:;INz _:_:O@ pr'i:si@nt pr'OfIts
```

It pronounces everything correctly until it gets to "omniscient" and "prescient", and maybe its pronunciations for those are correct, but at least they’re not the pronunciations I would use.

Under policy “A”, those words are not common enough to add to `en_list`, because they would lower the average frequency of words in

en_list unless you removed a less common word to compensate.

Under policies "C+" and "C-", not only "omniscient" and "prescient" qualify, but so do "neuroscience", "geoscience", "neuroscientists", and "geoscience", which eSpeak currently mispronounces.

(Including all the exceptions that as rare as "prescient" might quadruple the size of en_list, and perhaps en_dict as a result, if arbitrary spellings were as common among rare words as they are among common words. Think of that as an upper bound. Including all the exceptions as rare as "neuroscientists" might multiply its size by seven. This is the downside of policy "C-", but it does not happen with policy "C+". On the other hand, under policy "C+", even "prescient" might not survive long after being added.)

Recommendation

There is a better solution than adding a bunch of one-word special cases to en_list.

Probably in this case the solution is to change the special case for "conscience" to a special case for "conscien..." and change the "scien..." rule to a "...scien..." rule; that covers all the words except for "omniscien..." and "prescien...". Covering those two takes only two more rules in en_rules, if it's considered worthwhile; but "conscience" is ten times as common as both of those together, "con" three times as common, but "barbeque" 18 times less common.

Alternatives

I think there is a need for a larger en_list and en_rules to be available, even if they aren't part of the standard distribution. eSpeak's current footprint for a single language is about 160KB for the executable and 80KB for the dictionary. But it would be useful in many cases even if its dictionary were 800KB (as perhaps it would be with the Festival lexicon) or 8MB.

And for a better user interface for making changes to the dictionary, and especially en_rules, since currently it's hard to know what words you're changing the pronunciation of when you change en_rules, and you have to master a phonological orthography system to make any contribution at all. And then there's no git-like infrastructure for sharing your changes, and even learning git is a pretty big barrier to contributions.

If, instead, you could twist a knob to jog back to the last mispronounced word, then hold down a button and say its correct pronunciation, the barrier to contributions would be much lower. You would need a reasonable phonological analysis system (like in a speech-to-text system) to turn the spoken word into the string of phonemes. Then, if you could share your accumulated corrections with all other users of the software with the push of a button, the process of coming up with the tens of thousands of special cases would be a lot quicker.

Update from 2019: eSpeak is super awesome now

The above is about eSpeak 1.37 from perhaps 2008. I currently have eSpeak 1.48.03 from 2014 installed, and en_dict is now 116K

instead of 80K. The en/en-r voice used above doesn't exist any more, but the en-us voice is a fairly close equivalent:

```
$ espeak -v en-us+f2 -s 250 -x "The science of neuroscience is not a scientific
     or quasiscientific pseudoscience.  Conscientiously pursue
     omniscience and prescience."

 D@2 s'aI@ns Vv n'U@r@s,aI@ns Iz n,0t#@ saI@nt'IfIk_:_: O@ kw,eIzaIsaI@nt'IfIk s'o
ou:doUs,aI@ns
 k,0nsI2;'EnS@sli p3s'u: 0mn'IsI;@ns_:_: and pr'i:si@ns
```

It now pronounces "neuroscience" and "pseudoscience" correctly. The relevant part of `en_rules` is as follows:

```
    sc) ie (nc     aI@
        ie (ntiC   aI@
   _sc) ie (n      aI@
?8 _sc) ie (n      aIa#
```

I think that means that now the "ie" in any instance of "scienc" will be pronounced as "aI@", regardless of whether it's at the beginning of the word, which is what the "_" in the last two entries means, as explained in docs/dictionary.html in the eSpeak source code.

My other example now renders as follows:

```
$ espeak -v en-us+f2 -s 250 -x "Science is
        scientific and done by scientists, who work in the sciences.  A
        scientist with a conscience may be conscientious.  Those with
        scientifically-minded consciences will conscientiously avoid
        unscientific claims of omniscient beings or prescient prophets."

s'aI@ns Iz saI@nt'IfIk_:_: and d'Vn baI s'aI@ntIsts
 h,u: w'3:k InD@2 s'aI@nsI#z
 a# s'aI@ntIst wID a# k'0nS@ns m'eI bi: k,0nsI2;'EnS@s
 DoUz wID saI@nt'IfIklim'aIndI#d k'0nS@nsI#z wI2l k,0nsI2;'EnS@sli; a#v'OId
```

(line break inserted)

```
VnsaI@nt'IfIk kl'eImz Vv 0mn'IS@nt b'i:;I2Nz_:_: O@ pr'i:si@nt pr'0fI2ts
```

This is different in several details from the above, but overall it doesn't seem to be worse in any way. Also, eSpeak now has an `--ipa` option, which produces the following output instead:

```
s'aɪəns ɪz saɪənt'ɪfɪk ænd d'ʌn baɪ s'aɪəntɪsts
 hˌu: w'ɜ:k ɪnðə s'aɪənsɪz
ɐ s'aɪəntɪst wɪð ɐ k'ɑ:nʃəns m'eɪ bi: kˌɑ:nsɪ'ɛnʃəs
 ðoʊz wɪð saɪənt'ɪfiklim'aɪndɪd k'ɑ:nʃənsɪz wɪl kˌɑ:nsɪ'ɛnʃəsli ɐv'ɔɪd ʌnsaɪənt'ɪfɪk
kl'eɪmz ʌv ɑ:mn'ɪʃənt b'i:ɪŋz ɔ:ɹ pɹ'i:siənt pɹ'ɑ:fɪts
```

To me, this is dramatically more readable, but it is omitting some details that are important to at least eSpeak's pronunciation; for example, the `_:_:` pause above doesn't seem to appear, nor does the distinction between I (stressed) and I2 (unstressed, but not reduced like the undocumented I#). You can use it to translate from eSpeak's internal format to IPA by using `[[]]`:

```
$ espeak -v en-us+f2 -s 250 --ipa "[[h,u: w'3:k InD@2 s'aInsI#z]]"
 h ˌu: w ˈɜ:k ɪnðə sˈaɪnsǂz
```

This makes it easy to compare the old and new pronunciations simultaneously by ear and by reading the IPA transcription, which reveals a few different improvements:

```
$ espeak -v en-us+f2 -s 250 --ipa "[[D@2 s'aI@ns Vv n'3:r-@s,i@ns I2z n,0t#@ saI@
ont'IfIk _:_:
0@ kw,eIzaIsi@nt'IfIk sj'u:d@s,i@ns]].
[[k,0nsI2;'EnS@sli p3sj'u: '0mnIs,i@ns _:_:and pr'i:si@ns]].
The science of neuroscience is not a scientific or quasiscientific pseudoscience.
Conscientiously pursue omniscience and prescience."

ðə sˈaɪəns ʌv nˈɜ:ɹəsˌiəns ɪz nˌɑ:ɾə saɪəntˈɪfɪk ɔ:ɹ kwˌeɪzaɪsiə
ontˈɪfɪk sjˈu:dəsˌiəns
 kˌɑ:nsɪˈɛnʃəsli pəsjˈu: ˈɑ:mnɪsˌiəns ænd pɹˈi:siənz

 ðə sˈaɪəns ʌv nˈʊɹɹəsˌaɪəns ɪz nˌɑ:ɾə saɪəntˈɪfɪk ɔ:ɹ kwˌeɪzaɪs
aɪəntˈɪfɪk sˈu:doʊsˌaɪəns
 kˌɑ:nsɪˈɛnʃəsli pəsˈu: ɑ:mnˈɪsɪəns ænd pɹˈi:siənz
```

This also means you can use it with `-q` as a fairly reliable converter from standard English orthography to IPA:

```
ðɪs ˈɑ:lsoʊ mˈi:nz ju: kæn jˈu:z ɪt wɪðkjˈu: æz ɐ ɹˈæpɪd ænd fˈɛɹli ɹɪlˈaɪəbəl kənvˈɜ:ɾɚ
fɹʌm stˈændɚd ˈɪŋglɪʃ ɔ:ɹθˈɑ:gɹəfi tʊ ˌaɪpˌi:ˈeɪ
```

It's a little slow for use in this mode; converting the first 83955 words of the KJV took 1'57" on my laptop, which is only 718 words per second, about three times faster than speech. But this speed is sufficient to solve many problems with. The particular problem that made me update this note tonight is that of finding sets of minimal pairs of English words for ESL learners to learn to distinguish the phonemes in, the hard part of which for a computer is finding out what the pronunciations of the English words are; the following command lines generated a decent pronouncing dictionary in just over 5 minutes:

```
$ espeak -v en-us+f2 --ipa -q < /usr/share/dict/words > words-ipa-2
$ paste /usr/share/dict/words words-ipa-2 > pronunciation-dictionary
```

Topics

First impressions on using the μMath+ calculator program for Android

Kragen Javier Sitaker, 2019-05-21 (13 minutes)

I just installed this app called "μMath+" or "microMathematics plus v2.18.0" from F-Droid on my hand computer, and it's pretty cool. It's the first calculator for Android that's good enough to criticize, so I will.

Conceptual overview

You have "worksheets" which consist of sequences of "elements" or "objects", stacked vertically and horizontally; the five types of elements are text fragments, images, equations (really assignment statements and function definitions), result views, and plots.

Text fragments are just paragraphs; the five available styles are "Chapter", "Section", "Subsection", "Subsubsection", and "Text body", all with or without numbering. There's a per-document flag to word-wrap them at some line length.

The expressions in the assignment statements are displayed using conventional math notation, and include Σ, Π, ∫, and derivatives. Values include complex floating-point numbers, Octave-like ranges of them (called "intervals"), multidimensional arrays of them (I think up to three dimensions), and versions of these dimensioned with units. Functions are defined in the assignment syntax by assigning to a function with formal parameters, as "f(x) = x² - 4". "Result views" pair a user-entered expression, on the left, with its computed result, on the right. Plots come in 2-D, 3-D, and heatmap versions; normally you evaluate a function on an "interval" to get an array result which you can plot on the y-axis. ("Intervals" work very similarly to arrays in APL and related languages, and even more so the independent variables I talked about in Relational modeling and APL (p. 1217) and A principled rethinking of array languages like APL (p. 1995). They are not the interval objects used in interval arithmetic, though they have some things in common.)

Moreover, you can export your whole document as LaTeX, though the plots are PNGs — high-resolution PNGs with transparency, but PNGs.

All in all, it can do all kinds of cool stuff.

Results

So you can, for example, write

```
E := 3 V
I := 0.1 A
E/I =
```

and it will tell you "30.0 Ω". You can change these values and recalculate. You can write

```
x := [-5, -4.9 .. 5]
y := x^3 + -2·x^2 + x
```

and then plot x versus y. In fact, you don't even need to define a variable for y; you can enter the polynomial directly on the y-axis of the plot, though because of the horizontal layout of the formula there, it takes up a lot of space. By long-pressing on the plot, you can get a button to view the values of x and y in a table.

You can intersperse your formulas and plots with explanatory text, as in Jupyter, but, at least in theory, somewhat more intimately — you aren't constrained to vertical stacking — but I haven't found a way to make that work well yet.

Missing features

Given that it does all this array and interval stuff, I was sort of hoping it would handle matrix arithmetic (matrix products and inner products and least-squares solutions of systems of differential equations and whatnot) but it doesn't.

UI infelicities

Unfortunately I'm not very happy using it. It feels very clumsy.

It's hard to figure out how to do anything, and it takes a lot of clicks, because the equation editor is a structure editor, but there's no visualization of the structure to work on, and you suffer the usual gulfs of execution. For example, x^2 is an exponentiation node, which you can create by scrolling the toolbar to the right to the create-exponentiation-node button and then pressing it, or by using the "^" key on the keyboard, and then typing "x". At times, to reach the exponent from there, you can press the soft keyboard's Enter key (when it displays as "→|") but at times you have to tap the spot on the display where you want to put the "2". It *is* possible to replace an existing node with a new node that has it as a child; for example, you can place the cursor before the "x" and insert "--", which makes the "x" node the second child of a new subtraction node, so you can transform it into $(1 - x)^2$. So far I haven't found a way to reverse this transformation (other than using undo — fortunately it does have multiple undo) or to put the focus on the exponentiation node itself so I can transform it into $x^2 + 1$.

Analogously, I haven't figured out how to change the layout, for example changing the order of elements or their stacking direction.

The use of long-press to activate many functions exacerbates the discoverability problem.

The only way to see the value of anything is to add a result view or plot to the document, and typically then to long-press on the result to bring up a dialog with a table of all of its values. This is, however, pretty awesome in that it allows you to bring up a table of all the numeric values being plotted in a plot.

You can't define an array by listing the items, as R = [1, 2.2, 4.7, 10, 22, 47]. You have to assign the individual items one at a time: R[1] := 1, R[2] := 2.2, and so on.

Error handling leaves a lot to be desired. If there's an error anywhere in a worksheet, nothing in the worksheet will evaluate. Usually it highlights the error with a red border, which you can tap on to get a transient notification telling you what the error was. I've

had times where I couldn't find the error, though, so I opened up a new worksheet. Really good error handling might include suggesting similarly spelled variables when one is not defined, or offering to create a definition for it, or offering to change it the same way you changed the definition that used to exist.

The "New document" menu item discards your current worksheet without confirmation, apparently irretrievably — though only if you're editing the default autosave.mmt.

Every time the screen orientation changes, the worksheet scrolls back to the top. Zooming is also troublesome; positioning in the document after a zoom is unpredictable, perhaps because the zoom feedback moves the document horizontally as well as vertically, while the actual resulting position is much more horizontally constrained. At times zoom is disabled for no apparent reason, and at times the document moves multiple screen widths diagonally when I'm pinch-zooming in place.

The formula formatting looks ugly; it's using a sans-serif monoline font without even any obliquing for the variables, except of course that Σ and ∫ are in a serif font with diagonal stress, and Π must be too but it looks like a child's drawing. The parentheses and brackets do not match the rest of the font, being thinner, and they aren't properly spaced; "(x + 1)!" will butt the "!" up to the parens. Superscripts and subscripts are smaller than the text they modify, but still too large and too far away; then at four levels of superscript the font has gotten far too small.

It includes export to LaTeX and HTML, but although it seems to use SVG internally (in its documentation, and maybe for its plotting), it doesn't seem to be able to export SVG.

The 3-D plots are lovely but being able to interactively rotate them to get a good angle would be a big plus. This is a general problem with a lot of things: to change a property you have to bring up a dialog box, but in order to see the result of changing the property, you have to close it. The even more egregious result of this is that there's no way to resize a 2-D plot by dragging; you have to bring up a dialog box on top of it, type in a new width in pixels, and tap OK. (And the default plot size is pretty small.)

It's possible to plot multiple functions on the same plot, and it's possible to plot parametric functions, but doing both at once seems to be impossible.

There doesn't seem to be a way to label plot axes by anything other than the actual expression that produces them, which would be useful if you have, for example, two plots covering different intervals of the same axis, which you will necessarily have to name with different variables.

You can't just sum an array or an interval; you have to go the whole nine yards with $\Sigma_{i=1}^{9} x_i$ instead of just Σx.

You can define n := [0, 1 .. 32] and then ask 2^n = and get a result, but you can't just inline the interval value in the superscript. In fact, I think that's true of all operations on intervals — the interval literal can't occur in any context other than an assignment statement.

Because it uses the regular Android soft keyboard, numeric entry is a pain; you often have to switch modes, and the number keys are always tiny.

Bugs

The HTML export doesn't include plots, or, if it does, they aren't showing up in Chrome.

Although dimensional analysis works for simple quantities, if you do this you get "V/A" instead of Ω for the units, although they're at least still correct values:

```
E0 := [2.5, 2.6 .. 3.5]
E := E0 · 1 V
I := 0.1 A
E/I =
```

However, if you make I also an "interval" without units, then you get the error message on E/I: "There are indirectly referenced intervals: [E0]". Dividing E0/I directly gives a matrix-like display of results, though with no real way to see which result corresponds to which inputs.

Although you can define an array by enumerating values as described earlier and it displays the same way intervals do, attempting to divide E/R produces the error, "Array is not allowed for this field."

I mentioned above that four levels of subscript produce text that is too small. Five levels returns to the normal size again, but it's not the normal size for your zoom level; it's the normal size for your display. So if you zoom out, your fifth superscript will be huge compared to everything else in the document, while if you zoom in far enough, it will be tiny compared to everything else, because it always stays the same size on the screen.

How to do better

Interactive calculator (p. 2771) and drag-and-drop calculator for touch devices (p. 1045) talk a bit about how calculators could take advantage of multitouch screens, but for pure formula entry, I feel like it's really easy to do better than using the standard onscreen soft keyboard — the built-in calculator app does it already. The exception is when you're assigning a name to something, when you need to be able to type the name, or when you have so many variables and functions that you need to find one by text search instead of picking from an LRU list.

The standard Android calculator these days displays the result of each formula incrementally as you edit it. This is a big help for simple calculations like 500×46.5. μMath+ doesn't, for some reason.

Note that the ersatz Casio calculator profiled in Usability of scientific calculators (p. 2379), though very limited in hardware, got a bunch of things right: once you *have* a formula, you can attach it to a name. Unfortunately this, along with the whole RPN universe, adds an extra gulf of execution to the problem: you have to figure out that the way to get "y = x²" on the screen is to first get "x²" on the screen and only then activate "STO Y", as the ersatz Casio's keyboard labels call it.

Going further, you could imagine writing *actual generalized equations* rather than assignment statements, then submitting the glob of equations to some kind of solver; or, in the opposite direction in some sense, writing explicit algorithms with loops and conditionals.

OCR of handwritten equations might also be a good approach, given how clumsy interacting on the touchscreen is.

Structure editors are hard to make usable, but not impossible. A useful step would be providing visible handles to each of the tree nodes you might be trying to select.

Given the amount of symbolic computation and ad-hoc UI interaction tailoring this problem needs, writing it in Java was probably not a good idea; a development environment that better supports symbolic computation and iterative development, especially code changes without program restarts, would probably work better.

Magic sinewave filter

Kragen Javier Sitaker, 2019-12-17 (6 minutes)

Don Lancaster's "magic sinewaves" are functions from discrete time to {-1, 0, +1} intended for use, among other things, in modulating an H-bridge to approximate a sine wave for power electronics. I think there's a way to use them to get a reasonably good and extremely efficient frequency-selective sparse filter (see Sparse filters (p. 834)).

Magic sinewaves

The simplest approximation of a sine wave of period, say, 4 samples, is a square wave: [-1, -1, +1, +1, -1, -1, +1, +1, ...]. But that isn't a very good approximation; it has a pretty loud third harmonic. (This is above Nyquist, so suppose we're using a zero-order hold here.) A better approximation, though lower amplitude, includes a 0 period instead: [0, -1, 0, +1, 0, -1, 0, +1, ...]. This has less harmonic distortion. But if we expand this out with a zero-order hold it's still obviously imperfect: [0, 0, -1, -1, -1, -1, -1, 0, 0, 0, 0, 0, +1, +1, +1, +1, +1, 0, 0, 0, 0, ...]. We can twiddle the samples around a little to kind of dither the transition; for example, [0, -1, 0, -1, -1, -1, 0, -1, 0, 0, 0, +1, 0, +1, +1, +1, 0, +1, 0, 0, 0, ...]. This way, although we don't get lower total harmonic distortion, we can push more of it up to higher frequencies, which makes it easier to filter out. Again, this gives us lower amplitude for the fundamental.

If you want a sine wave, why not just use an actual sine wave, like [0, -0.3, -0.6, -0.8, -1, -1, -1, -0.8, -0.6, -0.3, 0, 0.3, 0.6, 0.8, 1, 1, 1, 0.8, 0.6, 0.3...]? In the case of power electronics with an H-bridge, it's because your H-bridge wastes no power when it's off, a tiny bit of power when it's fully on (either forward or reverse), and a massive amount of power when it's partway on. So for an efficient system you want to switch between fully on and fully off as quickly (and infrequently!) as possible.

For sample rates that are higher compared to the signal frequency, it's easy to push all the harmonic distortion many octaves away from the signal, making it easy to filter with efficient passive filters; this is pretty much the same principle behind delta-sigma DACs, though those usually use {0, 1} rather than {-1, 0, 1}.

Filtering

The example "reference signal" waveforms above have period 20. If we were to multiply them elementwise by some signal, we would downconvert one phase of the frequency component with period 20 to DC, and then we could extract it by merely summing. The actual sine wave would give us the pure frequency component, while the {-1, 0, +1} signals mix in some pretty significant harmonic distortion. But multiplying by them is trivial: you add or subtract samples from your running total, no multiplication required. You can do this a second time with a second reference signal in quadrature with the first to get a complete measurement of the amplitude and phase of a given frequency.

If you maintain, say, 60 totals buckets, such that bucket i contains a total of the samples $x[j]$ such that $j \% 60 == i$, you can run this

analysis over the period-20 component of your whole signal by doing 60 additions and subtractions; so, too, for components whose periods are other factors of 60, such as 30, 15, 12, 10, 6, 5, and 4. If instead of just maintaining 60 such buckets, you calculate a feedback comb filter $y[n] = x[n] + y[n - 60]$, you can calculate such totals for any given segment of the signal by subtracting 60 subsequent y values at the beginning of that segment from 60 corresponding y values at its end; and the usual tricks to get a triangular or otherwise approximately gaussian temporal window apply, as described in some other notes here.

You could, instead, do this kind of correlation by generating a dithered approximation "reference signal" dynamically, for example by running a delta-sigma conversion of the output of a free-running Goertzel or Minsky oscillator, and use that to decide whether to process the current sample by adding, subtracting, or neither, to each of your I and Q accumulators. This has the great advantage that you can dynamically vary the frequency of your local oscillator, thus tracking chirp signals, such as whistles (see Whistle detection (p. 357).) A lightweight low-pass filter applied to the input signal should be sufficient to eliminate the high-frequency signals that could otherwise produce spurious correlations, but with delta-sigma conversion of more than first order, I think the dither noise might be sufficiently random to not need this.

Delta-sigma conversion in this case might be nothing more than a matter of the Bresenham line-drawing algorithm.

Prefix sums

If the number of transitions per period is relatively small, as with magic-sinewave waveforms designed to reduce switching losses by switching less frequently, it may be more efficient to work from a prefix sum of the signal rather than the signal itself. For example, the initial reference waveform suggested above has only four transitions per period; rather than doing five additions and five subtractions per period, you could do two additions and two subtractions from the prefix sum. Of course the prefix sum itself requires 20 additions per period to compute, so this is only an improvement if you can share the prefix sum with some other computation, such as the detection of a second frequency.

Fractal palettes

Kragen Javier Sitaker, 2019-04-02 (7 minutes)

The most conventional way to plot the Mandelbrot set and similar fractals is to compute the "escape time" for each pixel (the number of iterations needed for the point to exceed some "bailout value" beyond which we can be sure there is no return) and use it as an index into a cyclic one-dimensional "palette" of colors. For example, if it takes a given pixel 331 iterations to exceed the bailout value, and our palette is of 256 colors, we draw that pixel as color #75 from that palette.

8-bit color

In the early-1990s days of 8-bit color like VGA and cgsix, this approach had some very significant virtues. These devices required a number of compromises. Redrawing a whole high-resolution screen involved more memory bandwidth than our graphics cards could manage during a video frame (typically 13.9 ms rather than the modern 16.7 ms); full-screen video games like Doom and Quake typically ran at reduced resolution, and video, when it was possible at all, typically played in a postage-stamp-sized window. And, although they could typically display 262,144 different colors, they could only display 256 of them at a time, so that the framebuffer could be only 8 bits deep; full-color images needed to be dithered down to 256 colors for display. Many algorithms were devised to formulate optimal palettes for approximating a given image and dithering to those palettes with different tradeoffs between CPU usage, spatial sharpness, color fidelity, and crawling artifacts in video; we still see these today in animated GIFs. A few demos changed palette entries while the screen was being painted in order to get 256 colors per scan line instead of 256 colors per screen, but this technique required very tricky timing, and perhaps as a result never saw general use. Mozilla (later renamed "Netscape"), which had to display more than one image at a time, settled on dithering all images to a standard 216-color palette (6 levels of red, 6 of green, 6 of blue) and so WWW pages that wanted to avoid this extra dithering would use only these "web safe" colors.

It's perhaps worth mentioning that DRAM cost US$40 per megabyte from about 1992 to about 1996, due to a price-fixing cartel among RAM manufacturers during this time, so a 1280×1024 framebuffer required US$50 worth of RAM if it was 8 bits deep, a number which soared to US$150 for 24 bits, and that's not even including a second buffer for page-flipping double-buffering. So only specialized high-end video cards like Targas and the ones in Silicon Graphics machines offered 24-bit color ("TrueColor") or even the 16-bit "TrueColor" that is now universal on hand computers ("cellphones").

The escape-time-indexed-palette approach provided a few great benefits, some of which are specific to the hardware of the time:

- It ensured that the image used only 256 colors, so no dithering was needed; the display hardware could display the image natively.
- It allowed "color cycling", in which the screen was updated by

altering the hardware palette (once per frame) rather than repainting pixels into the framebuffer — functionality TrueColor cards couldn't match. Color cycling as such involved cyclicly permuting the entries in the palette. The famous Amiga bouncing-ball demo used a form of color cycling to fake real-time high-resolution 3-D on hardware that couldn't come close to doing it for real; updating the palette was also a common technique to smoothly fade images to black.

• It gives you a whole orthogonal dimension of expressivity for fractal images. You can put a color gradient in part of the palette, followed by a sharply contrasting color starting a different gradient, or a sequence of sharply contrasting colors, or colors alternating between two gradients. These techniques can produce very different images when applied to the same mapping from pixel coordinates to escape times, emphasizing some aspects of the image while soft-pedaling other parts. Furthermore, you can apply all of this instantly to an already-completed image — an enormous advantage on hardware where even a simple Mandelbrot took several seconds to render.

• In many cases, it produced large areas of solid color, which permits popular lossless compression algorithms (like the LZW used in GIF) to compress the image substantially.

Another popular option was to use palettes in the same way, but index them with something other than the escape time. For example, if you use the argument of the bailout-exceeding value to index into the palette, each region that would have been a solid color with the escape-time algorithm instead becomes a cyclic progression through the colors — a gradient, perhaps — typically repeating N times.

Generalizing palettes

This suggests a useful generalization of the palette concept to me. The initial fractal rendering process computes for each pixel a vector of result values: the number of iterations, the complex value of the escaping value, and so on. Different rendering processes might produce different sets of values; presumably John Milnor's distance-estimation algorithm, for example, won't produce those, but it might produce a different vector. Then the "palette" function maps each such vector to a color. One special case is to use just the number of iterations modulo the length of a given list of colors, but many others are possible. Other special cases include Fractint's "outside=real" and "outside=imag" options, which add the real or imaginary parts of the escaping point to the number of iterations before indexing the palette, as well as an option "outside=tdis" to use the total distance traveled by the orbit of the escaping point, again cyclically indexing the palette with the result. Fractint also has a "biomorph" option, which is Clifford Pickover's invention of overriding the color that would otherwise be used (based on the iteration count or whatever) with an image-wide constant if either the real or the imaginary component of the escaping point is less than the bailout. And a "decomp" option, which overrides the outside color in another similar way, which I think should be the same as "outside=atan" but which doesn't seem to be. And so on.

But what if your "palette" were a two-dimensional color gradient, indexed in one dimension by number of iterations and in another by the angle of the escaping point? What if the "palette" includes a truly continuous gradient, rather than a 256-color approximation to one?

What if the "palette" varies with time, as in color cycling, but in a more general fashion?

Bytecode pubsub

Kragen Javier Sitaker, 2019-12-04 (6 minutes)

In a publish-subscribe system you have a message bus to which messages are posted. The message bus may be a literal wire (as in thinnet Ethernet, CAN, and RS-485), a computer (as in Ethernet with a switch), a running program on a computer (as in D-BUS), a group of running programs on one or more computers (as in IRC or IP multicast), a data storage device (sort of as in Kafka), or some combination. The messages posted to it are then received by some subset of subscribers to the message bus.

Why filtering?

The simplest approach is to send every message to every subscriber, but this has both performance problems and security problems: making a copy of the message for a subscriber who doesn't want it is wasted work, and maybe so is the work the subscriber has to do to determine that they don't want it; and if you have a security policy that prohibits some subscribers from looking at some messages, this approach makes that policy entirely dependent on those subscribers not attempting to violate it.

So most pub-sub systems have some kind of filtering system that only sends each message to some subset of subscribers. These filtering systems can be more or less expressive; for example, you can have a disjoint set of topics (like IRC and IP multicast), a hierarchy of topics (like ZeroMQ), a non-disjoint set of tags with single-tag subscriptions, boolean tag subscriptions, boolean queries on message field values, and so on. The more elaborate filters let through a more precise approximation of the messages the subscriber is really interested in, wasting less work on forwarding messages the subscriber will ultimately discard.

Turing-complete interests

The subscriber's real interests may be Turing-complete (assuming the subscriber is a computer program --- human interests might be more complex); determining whether a packet fulfills them or not may in fact be uncomputable. In Fast secure pubsub (p. 545) I talked about running a subscriber-provided interest function in a time-limited sandbox where its accesses to message fields are recorded; if it rejects the message, those accesses are added to a cache so that any future messages with the same values in those fields will also be rejected without rerunning the function, thus saving time. Similarly, if it accepts the message or times out, any future messages that are similar in that way will be forwarded to the subscriber. (And senders can provide a filter function that determines whether or not a subscriber is allowed to examine a message; its behavior differs in that if it times out, the message is not forwarded.)

In addition to just "accepting" a message, the interest function might reasonably take other actions as well; in particular, it might post a message somewhere, and it might map the accepted message to a smaller message, so that less data needs to be copied to the subscriber itself. However, these actions are much harder to memoize with the

purely-sandboxing approach described above. Suppose the incoming message says {x: 32, y: 31, topic: "mouse"}, and the interest function inspects the topic and x fields before mapping the message to the message {p: 32} to be sent to the subscriber. The sandbox is able to determine that the y field does not matter, so future messages with the same x and mouse fields should be handled the same way. But it has no way to determine whether the message {x: 48, topic: "mouse"} should even be accepted, much less whether the resulting message should be {p: 32}, {p: 48}, {p: 16}, or something else.

Non-Turing-complete interests

But a different approach is suggested by BPF and Bitcoin Script, as described in Scriptable windowing for Wercam (p. 1256) in a different context. Instead of having the subscribers send a Turing-complete program to the message bus, they can send a program in a non-Turing-complete bytecode, perhaps one without loops or subroutines, so its execution time can be statically bounded.

This is pretty close to the original purpose of BPF and its 1980 predecessor CSPF: the packet-dumping program, tcpdump or whatever, gives the kernel a "subscription request" in the form of a BPF program, and the kernel evaluates all such program on all incoming packets, forwarding only the accepted packets to the userspace program.

The subscriber can generate the bytecode program by doing abstract interpretation of the Turing-complete program representing its interests, somewhat like a tracing JIT, but using abstract values. This generates a safe conservative bytecode approximation of its original Turing-complete program; this bytecode can then be sent to the message bus to do the prefiltering.

There is an example of how to do this in Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) in the section "Abstract interpretation with non-standard semantics".

This abstract-interpretation approach is applicable to a variety of situations in which a non-Turing-complete program is required, especially if a conservative approximation is acceptable. So, for example, given some Turing-complete specification of a security rule to make a message visible only to certain subscribers, a conservative approximation is not acceptable; this approach is only applicable to that problem if the full execution tree can be successfully explored.

Database queries

From a certain point of view, a database query is just a pubsub subscription that is immediately run on a stored history of past events; but this point of view doesn't have an obvious way to account for sorting specifications and joins, which do things like index traversals and intermediate materializations. However, the comparison operators used to construct and traverse indices, as well as the tuplewise computations used to filter and transform result streams, could profitably be specified by such bytecode chunks, rather than by an ever-growing set of data types built into the database engine.

Tagging parsers

Kragen Javier Sitaker, 2018-11-23 (updated 2018-12-10) (9 minutes)

See also Minimal imperative language (p. 2175).

I've written a PEG parser generator with inline semantic actions in itself; it was 66 lines of code, although it was fairly minimal. A more complete implementation would be a bit longer. An embedded DSL for Python that parses to syntax trees, called Tack, was 27 lines of code, but eliminating the extra crap from the syntax tree took another 13 lines on top of the grammar itself.

Inline semantic actions have the difficulty that they are host-language-specific, so if you want to parse the same data format in different programming languages, you need to rewrite the grammar over and over again. In today's polyglot programming environment, this is a serious disadvantage for the development of grammar libraries over time, as each host language has its own private set of grammars.

(And of course embedded DSLs have this problem to an even greater degree.)

As an example grammar, consider this numerical expression grammar, in a very minimal PEG language:

```
sp <- ' ' / '\n' / '\t'.
_ <- sp _ / .
digit <- '0' / '1' / '2' / '3' / '4' / '5' / '6' / '7' / '8' / '9'.
digits <- digit digits / digit.
num <- (digits ('.' digits / '.' / ) / '.' digits) _.
i <- num / '(' _ a ')' _.
e <- i '**' _ i / i.
m <- e ('/' / '*') _ m / e.
a <- m ('+' / '-') _ a / m.
```

If we have repetition * and nonempty repetition + in the language, we can simplify it a bit:

```
_ <- (' ' / '\n' / '\t')*.
digit <- '0' / '1' / '2' / '3' / '4' / '5' / '6' / '7' / '8' / '9'.
num <- (digit+ ('.' digit* / ) / '.' digit+) _.
i <- num / '(' _ a ')' _.
e <- i '**' _ i / i.
m <- e (('/' / '*') _ e)*.
a <- m (('+' / '-') _ m)*.
```

This is more or less the example grammar I used for Tack, but the tree Tack builds for it includes all the whitespace and is tagged with all the nonterminals. (Additionally, because Tack doesn't support repetition, it associates the wrong way.)

XML

A possible solution that occurred to me was to put XML-like tags into your grammar, instead of relying on the nonterminals. Then the parser's job is merely to associate these tags with points in the input text. For example:

```
_: (' ' | '\n' | '\t')*.
digit: '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'.
atom: <num> (digit+ ('.' digit* | ) | '.' digit+) </num> _ | '(' _ a ')' _.
e: <exp> <base>atom</base> '**' _ <pow>atom</pow> </exp> | atom.
m: <term> e (<op>('/' | '*' | '%')</op> _ e)+ </term> | e.
a: <sum> m (<op>('+' | '-')</op> _ m)+ </sum> | m.
```

We can think of the parser as adding markup to the text. In fact, we can actually implement it that way, if we like. So, given the text `13 + 4 * 5 + 4 ** 3 * 1`, it will convert it to the following, with some liberty given to spacing:

```
<sum>
  <num>13</num>
  <op>+</op>
  <term><num>4</num> <op>*</op> <num>5</num></term>
  <op>+</op>
  <term>
    <exp><base><num>4</num></base> ** <pow><num>3</num></pow></exp>
    <op>*</op>
    <num>1</num>
  </term>
</sum>
```

This may not be the easiest way to read it, but it makes it super easy to apply stylesheets to it, and each span of text is tagged for the necessary processing.

If we weren't trying to look like XML, a terser and perhaps clearer syntax would be the following:

```
_: (' ' | '\n' | '\t')*.
digit: '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'.
atom: <num digit+ ('.' digit* | ) | '.' digit+> _ | '(' _ a ')' _.
e: <exp <base atom> '**' _ <pow atom>> | atom.
m: <term e (<op '/' | '*' | '%'> _ e)+> | e.
a: <sum m (<op '+' | '-'> _ m)+> | m.
```

Or maybe with more C-like syntax:

```
_: (' ' | '\n' | '\t')*;
digit: '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9';
atom: num { digit+ ('.' digit* | ) | '.' digit+ } _ | '(' _ a ')' _;
e: exp { base { atom } '**' _ pow { atom } } | atom;
m: term { e (op { '/' | '*' | '%' } _ e)+ } | e;
a: sum { m (op { '+' | '-' } _ m)+ } | m;
```

Or syntax chosen to be less noisy and more compact, using `;` for alternation, `{}` for grouping, `foo()` for tagging, and `.` for termination:

```
_: {' '; '\n'; '\t'}*.
digit: '0'; '1'; '2'; '3'; '4'; '5'; '6'; '7'; '8'; '9'.
atom: num(digit+ {'.' digit*; }; '.' digit+) _; '(' _ a ')' _.
e: exp(base(atom) '**' _ pow(atom)); atom.
m: term(e { op('/'; '*'; '%') _ e }+); e.
a: sum(m { op('+'; '-') _ m }+); m.
```

APIs

At the API level, aside from just generating some kind of S-expressions or XML, you could imagine either DOM-style or SAX-style interfaces. SAX-style interfaces offer the possibility of rejecting a candidate parse from the host language; for example, when parsing C, you need to distinguish between type identifiers and other identifiers, which is beyond the powers of PEGs, but straightforward if the parser can call out to a host-language symbol table. But this is somewhat more complicated than in real SAX, since it means we need to invoke host-language actions for tentative parses that may fail.

JSON

Nowadays, of course, JSON — arbitrarily nested dicts and lists, in Python parlance — is a much more popular data model than XML. What would this expression grammar look like if it were to produce a JSON structure instead? Maybe like this:

```
_ = (' ' | '\n' | '\t')*.
digit = '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'.
atom = #(digit+ ('.' digit* | ) | '.' digit+) _ | '(' _ a ')' _.
e = { type: `exp` base: atom '**' _ exp: atom } | atom.
m = { type: `term` head: e factors: {rator: ('/' | '*' | '%') _ rand: e}+ } | e.
a = { type: `sum` head: m terms: {rator: ('+' | '-') _ rand: m}+ } | m.
```

Here {} constructs a finite map (an "object"), `+` or `*` makes a list of each of the things it matched if they yielded some value (rather than just matching text), `#` converts the matched text into a number (perhaps overly specific to this purpose), `` `backquotes` `` enclose a literal string to be inserted into the JSON (rather than matched against the input), and `foo: bar` assigns the value produced by `bar` to the key `foo` in the object at hand. Every element of the grammar parses to some value (usually a string) but in the absence of some capturing key, the value is discarded. So the example `13 + 4 * 5 + 4 ** 3 * 1` from before becomes the following:

```
{ "type": "sum"
, "head": 13
, "terms": [ { "rator": "+"
             , "rand": { "type": "term"
                       , "head": 4
                       , "factors": [{"rator": "*", "rand": 5}]
                       }
             }
           , { "rator": "+"
             , "rand": { "type": "term"
                       , "head": {"type": "exp" , "base": 4 , "exp": 3}
                       , "factors": [{"rator": "*", "rand": 1}]
                       }
             }
           ]
}
```

OMeta

OMeta has the following syntax:

```
meta E {
  dig ::= '0' | ... | '9';
  num ::= <dig>+;
  fac ::= <fac> '*' <num>
        | <fac> '/' <num>
        | <num>;
  exp ::= <exp> '+' <fac>
        | <exp> '-' <fac>
        | <fac>;
}
```

It also supports ~negation and `kleene*` closure. Note that it's using left-recursion, which is generally fatal to PEGs, but they found a hack to Packrat parsing that allows it to work in cases like this one (though they never characterized cleanly which cases it worked for). This allows them to easily get the right associativity in this case.

They used inline semantic actions like peg-bootstrap, with postposition identifiers:

```
exp ::= <exp>:x '+' <fac>:y => `(+ ,x ,y)
      | <exp>:x '-' <fac>:y => `(- ,x ,y)
      | <fac>;
```

They also had inline semantic predicates:

```
largeNumber ::= <number>:n ?(> n 100) => n;
```

And they took advantage of the angle brackets to provide parameters to parameterized productions:

```
cRange x y ::= <char>:c ?(>= c x) ?(<= c y) => c;
... <cRange 'a' 'z'> ...
```

and they take advantage of this to hack a tokenizer into some of their grammars.

Perl6 regexes

Perl 6 regexes permit things like this:

```
my regex header { \s* '[' (\w+) ']' \h* \n+ }
my regex identifier  { \w+ }
my regex kvpair { \s* <key=identifier> '=' <value=identifier> \n+ }
my regex section {
    <header>
    <kvpair>*
}
```

Here `<header>` is invoking the regex named `header`, and `<key=identifier>` invokes the regex named `identifier` and binds its results to the variable `key`, which would default to `identifier` if it weren't specified (so `<header>`

saves the result under the name `header`.)

Inside-out quotes and inline definition (nested rather than flat)

The above suffers a bit from excessive quoting, especially in lines like this:

```
digit = '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'.
```

Wouldn't it be nicer to be able to write `0|1|2|3|4|5|6|7|8|9` as we can in regular expressions? (In this case, of course, `[0-9]` or `\d` might be nicer still.)

We could use a Perl-regexp-like notation in which alphanumeric text matches itself by default, without needing quotes, and uses non-alphanumeric characters to escape to metacharacter land. Furthermore we can embed our nonterminals within an expression. (Perhaps this is similar to Perl 6 patterns?) This requires two different ways of tagging segments of the pattern; for example, we could use `<>` and `[]`.

```
[e <exp <base atom> '**' _ <pow atom>>; atom]
```

Or we could use capital and small letters.

AST rewriting

In addition to the DSL for defining PEGs, it might be useful to have a DSL for describing structural rewritings of ASTs in terms of pattern-replacement pairs. It could use a pure tree-rewriting paradigm, but still support iterative computation.

VCR oscilloscope

Kragen Javier Sitaker, 2017-05-10 (updated 2017-06-20) (2 minutes)

An NTSC video signal is 6MHz wide. A VCR records it on the tape in the cassette with maybe one 60Hz field per diagonal pass of the head across the tape, with reasonably good analog fidelity. A VHS tape uses a different modulation scheme, with about 3MHz of video (luminance) bandwidth and another 400kHz of chroma bandwidth. S-VHS has 5.4MHz

The tricky part of making a decent (20MHz) oscilloscope out of garbage is high-speed signal detection: either direct analog display or analog-to-digital conversion. Perhaps recording the signal on a video tape, perhaps with sped-up heads, would enable you to do the conversion over a longer period of time using a slower converter, converting different samples on each pass, with the tape paused.

A NTSC VHS VCR head rotates at 1800 rpm, each rotation covering a 60Hz field, lasting 16.7 milliseconds. If you were to rotate it four times as fast, 7200 rpm, each such track would only last 4.2 milliseconds, but could plausibly have up to 12MHz bandwidth, or 21.6MHz for S-VHS.

4.2 milliseconds is a ridiculously long recording time; at 60 megasamples per second, it's 250,000 samples, hundreds of times longer than is necessary for a storage oscilloscope. So, if it were mechanically practical to speed the heads up further, it would be a good idea.

Three phase oscillating belt

Kragen Javier Sitaker, 2018-10-28 (4 minutes)

Belt drives or cable drives can transmit power somewhat more flexibly and, I think, efficiently than shaft drives. A belt or cable doesn't need enough material to be rigid, just enough to withstand the tension, and it can in theory move arbitrarily fast.

Belt or cable speeds, however, are limited by centrifugal forces around pulleys, which need to have larger radii in order to proportionally reduce the centrifugal forces at a given linear speed — and the area of the pulley increases as the square of its radius. And, of course, at least half the material of the belt is "wasted" in the sense that it's not carrying any energy, just being returned from the power source to the load under minimal tension.

Suppose that instead of an endless belt we use a straight tension cable, as in a child's pullstring toy, and instead of transmitting power continuously, we transmit power intermittently. Perhaps 90% of the time, the rope is moving from the load to the source at its maximum safe tension of 1000 N and at 3 m/s, and 10% of the time, it's moving from the source to the load at 100 N and roughly 30 m/s. Such a rope is transmitting an average power of 2700 W, the equivalent of 12 amps at 230 volts.

0.42 mm² of UHMWPE string can handle 1000 N, assuming 2.4 GPa and no safety factor. Such a string weighs 410 mg/m; 100 m of it weighs 41 g. 100 N accelerates 41 g at 2400 m/s², so it can reach 30 m/s in 12.3 ms. This means you could quite reasonably transmit power in this way with a 10 Hz oscillation in the line, which means the string would move only about 30 cm.

Piano wire also has a yield stress of about 2.5 GPa, although to avoid fatigue you're supposed to stick to a third of that or so. So a similar amount of piano wire could also transmit a similar load. It would weigh 8 times as much, and it would have more friction, but it wouldn't be as vulnerable to overheating.

(Hmm, I realize now that the 100 N restoring force is really nothing more than a centripetal force.)

If instead of one cable under tension, you have two, you could maintain continuous power with no intermittency; but, if the power being transmitted doesn't vary, you could never exceed the power that one cable could transmit at a time, so in a sense the other cable is wasted.

If, instead of two cables, you have three cables, you can have two cables transmitting power at any given time while the third is returning. This allows two-thirds of the mass and volume of your transmission cable to be used for power transmission, while keeping the power transmission perfectly consistent. Furthermore, this can avoid the large accelerations implied in the single-cable skewed triangle I suggested earlier; the speed of the cable that's about to go into takeup can diminish gradually while the cable that's just gone into the power cycle can smoothly speed up, maintaining a constant total speed. This is highly desirable, given that the mechanisms driven by the cable can easily weigh much more than the cable, and even 100 m is not very far in some contexts.

It should be emphasized that this kind of three-phase power transmission cannot use the same sinusoidal waveforms used by electrical AC power transmission if two cables are always to be kept in tension.

The three phases can drive a common differential via freewheel clutches.

Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm

Kragen Javier Sitaker, 2019-01-04 (updated 2019-11-12) (26 minutes)

I was thinking about how to implement the grayscale morphological "erosion" and "dilation" operations efficiently with a large irregular structuring element, and I think I've found some interesting algorithms; they may be novel.

In the contex of sampled grayscale images, erosion $I \ominus k$ maps each pixel in the image I to the minimum of some neighborhood k around that pixel, the neighborhood being the "structuring element", which I will call a "kernel" for brevity. (Dilation $\oplus$ is a similar operation with some differences that I won't mention.)

The naïve approach

The naïve approach to computing this gets slower with large kernels. Consider computing, in one dimension, a kernel that consists of the hotspot pixel and $n-1$ pixels to the right:

```
for (int x = 0; x < w; x++) {
    out[x] = in[x];
    for (int i = 1; i < n; i++) out[x] = min(in[(x+i) % w], out[x]);
)
```

This takes time per pixel proportional to n.

Sliding-window minimum in linear time

In one dimension, there's a well-known linear-time algorithm for this "sliding-window minimum" or "sliding range minimum query" problem, using a deque d containing a nondecreasing subsequence of the window such that the leftmost element in the deque is always the minimum of the window. Incrementing the left edge of the window may leave the deque unchanged, or it may involve dropping the oldest value, if that value falls out of the window; then the next value must be the minimum of the remaining pixels in the window. Achieving this merely requires that, when we increment the right edge of the window, we remove any elements in the deque that are larger than the new pixel, and then append that new pixel. This results in the pixels in the deque being in nondecreasing order, which means that any possible larger pixels will be in a block at the end of the deque, so we can remove them by popping from its end.

This sounds trickier than it is. In pseudocode:

```
d = deque()
for x in range(len(inpix)):
    while d and inpix[d[-1]] > inpix[x]:
        d.pop()
```

```
    d.append(x)
    if x - d[0] == n:
        d.popleft()
    yield inpix[d[0]]
```

Each pixel is pushed onto the deque exactly once and removed from it exactly once, at either the left or right, and each pixel comparison either results in pushing a pixel or popping one, so there can't be more than two comparisons per pixel overall. So the algorithm is linear-time despite its nested-loop appearance.

This depends on the assumption that the deque operations are constant-time operations, which is easy to guarantee even in the worst case if we have a bound on the deque size, which we do; it can't be larger than *n*. So we can render this into C with variable-length arrays as follows (see http://canonical.org/~kragen/sw/dev3/erosion1d.c):

```
unsigned d[n], di = 0, dj = 0;
for (int x = 0; x < w; x++) {
  while (di != dj && in[d[(dj-1) % n]] > in[x]) dj--;
  d[dj++ % n] = x;
  if (x - d[di % n] == n) di++;
  out[x] = in[d[di % n]];
}
```

Despite the divisions in the inner loop, for one-byte pixels, this takes 45–65 nanoseconds per pixel on my laptop with window widths ranging from 1 to 10000, although it *is* a bit quicker with one-pixel windows. (You could probably run it a lot faster without the divisions.)

This algorithm clearly has worse constant factors than the naïve algorithm, so the naïve algorithm is probably faster for sufficiently small kernels, but I haven't optimized and measured to see exactly how big the kernel needs to be for this algorithm to be faster. I'm pretty sure the naïve algorithm is going to be faster for 3-pixel-wide kernels.

I think this algorithm may be due to Richard Harter in 2001, who called it "the ascending minima algorithm", but I'm not sure.

As an interesting side note, a slight variation of this algorithm computes the convex hull of a series of points in 2-D in linear time. It consists of a basic pass which computes the upper convex hull, which is applied a second time under a suitable transformation to compute the lower convex hull, which together (perhaps with vertical lines to join them) form the overall convex hull. Each pass iterates over the points in increasing order of X coordinate, just as the sliding-window algorithm does; the upper convex hull is accumulated on a stack (rather than a deque) and points are popped off the stack if, considering the new point being added, they would make the hull non-convex, rather than if they are greater than the new point being added. This maintains the invariant that the sequence is convex upwards, rather than that it is nondecreasing. This is important for efficiently finding affine-arithmetic approximations of empirical data, as explored in An affine-arithmetic database index for rapid historical securities formula queries (p. 2275).

There's a completely different algorithm with similar linear performance published by van Herk in 1992 in a paper entitled, "A fast algorithm for local minimum and maximum filters on rectangular and octagonal kernels" and concurrently by Gil and Werman. It

divides the array into N-sample blocks and computes prefix-sum minima within each block going both left "h" and right "g". Any N-sample window will include some number $x \in (0, N]$ of samples in its leftmost block and some number $N - x \in [0, N)$ of samples in the block to the right; the minimum of the x samples in the left block can be found in the "h" array for that block, and the minimum of the $N - x$ samples in the right block can be found in the "g" array for that block. The minimum of these two numbers is the minimum over the whole block.

Separable kernels

As with box-filter convolution and Gaussian convolution, we can decompose erosions with certain two-dimensional kernels into compositions of two erosions with one-dimensional kernels, one in X and one in Y, thanks to a sort of distributive law (sometimes called "the chain rule"):

$$(I \ominus k_1) \ominus k_2 = I \ominus (k_1 \oplus k_2)$$

This is great, because it means we can erode an image with a paraxial rectangle of any size and shape in 90–130 nanoseconds per pixel, because it takes six pixel-minimum operations per pixel. (This is faster than just generalizing the van Herk–Gil–Werman algorithm to rectangles, which takes 15 pixel-minimum operations per pixel.) Great, right? But it's a paraxial rectangle. One could wish for something more. For example, many real-world images have features that are rotationally invariant, so a circle or annulus or something might be a more interesting kernel.

The distributive law says that eroding with two kernels is the same as eroding with the dilation of the kernels, which in this context is just their Minkowski sum. For example, dilating a kernel with a kernel that is a line in whatever orientation, that sort of pulls it apart in the direction of the line, filling in the gap by adding two straight facets in between, facets of the orientation and length of the line. So eroding an already-eroded image with such a kernel is the same as expanding its erosion kernel in that way.

So if you erode with two kernels that are lines, you get the erosion of a parallelogram, or in the degenerate case, a longer line. But so far we've only covered how to erode efficiently with horizontal and vertical lines.

How about diagonal lines? The one-dimensional sliding-window minimum algorithm is just as happy to run along a diagonal of the image pixels as along a row or column. If your kernel is literally just a diagonal line of pixels like [(0, 0), (1, 1), (2, 2), (3, 3), (4, 4)], then you might get some checkerboarding artifacts in the resulting image, but if you're also using a horizontal or vertical kernel, those should go away.

This carries over to skewed-line kernels like [(-4, -2), (-2, -1), (0, 0), (2, 1), (4, 2)] or [(0, 0), (1, 3), (2, 6)]. These have big gaps in them, so they would be shitty kernels by themselves, but used to dilate a kernel that fills those gaps on its own, they can give you not only excellent approximations of circles but also lines and arbitrarily-oriented capsules.

It turns out this approach to approximating circular kernels was

published by Adams in 1993 in the paper, "Radial decomposition of discs and spheres", except for the bit about skewed-line kernels with gaps in them.

Bresenham lines

I was also thinking that you could get a good approximation of a line kernel by running the one-dimensional algorithm along gap-free rasterized diagonal lines — essentially running it in the X or Y direction, but occasionally "jumping the groove" to an adjacent raster; this will give you a slightly different kernel at each pixel, but probably the errors are insignificant for most applications. But now I think that there is no real advantage to that approach over the precise approach described earlier.

It turns out that Soille, Breen, and Jones published essentially this algorithm in 1996 in their paper, "Recursive implementation of erosions and dilations along discrete lines at arbitrary angles", but using the van Herk/Gil–Werman one-dimensional sliding-window minimum algorithm. They note this approximation drawback:

> …it is important to note that the shape of the SE [kernel] may vary slightly from one pixel to another. Indeed, except for horizontal, vertical, and diagonal directions, a discrete line in the square grid contains 4- as well as 8-connected pixels. Hence, when the SE of length *k* moves along such a discrete line, its shape varies accordingly to its position along the line. In practice, this is not a major drawback provided that the angle specified is actually defined in the neighborhood corresponding to the extent of the SE.

Then they go on to define a "translation-invariant implementation" that avoids this non-major drawback, which has a great deal in common with what I've described above but may not be exactly the same; I'm not sure yet. It does seem to work better for their radial-decomposition purpose.

Also they point out a use of this algorithm to detect linear features by combining linear openings at different angles by max, rather than by composing linear erosions and dilations to get a round kernel.

Gapped one-dimensional kernels to accelerate the naïve algorithm

One way to get an erosion with a 9-pixel-wide kernel is to erode with a 3-pixel-wide kernel four times. But a better way — aside from the deque algorithm described previously — is to erode first with the kernel [-1, 0, 1] and then the kernel [-3, 0, 3]; and, to get only a 7-pixel kernel, you could erode with [-1, 0, 1] and then [-2, 0, 2]. If you want a 27-pixel-wide kernel, you can do [-1, 0, 1] ∘ [-3, 0, 3] ∘ [-9, 0, 9], and by reducing the width of this last kernel, you can get any number less than 27, too. (Though, see below (‡) for why using kernels with two pixels is better than using kernels with three.)

This points out a log-linear-time algorithm to erode with large kernels (linear in the image, logarithmic in the kernel) in a single dimension, which, unlike the deque algorithm, is easy to parallelize and incrementalize. For example, this algorithm can be straightforwardly applied to several scan lines in parallel using vector instructions, while the deque algorithm can't. (The van Herk/Gil–Werman algorithm can, though.)

(And of course it applies to sliding-window-minimum-type problems in non-image-processing contexts, as well.)

This implementation of the algorithm takes 16 nanoseconds per byte to compute a 50-byte erosion on a 10-million-byte input without paying proper attention to the boundary conditions:

```
static inline char cmin(char a, char b) { return (a < b) ? a : b; }
int x;
for (x = 0; x < w- 3; x++) out[x] = cmin(in[x],  cmin( in[x+1],  in[x+ 2]));
for (x = 0; x < w- 9; x++) out[x] = cmin(out[x], cmin(out[x+3], out[x+ 6]));
for (x = 0; x < w-27; x++) out[x] = cmin(out[x], cmin(out[x+9], out[x+18]));
for (x = 0; x < w-50; x++) out[x] = cmin(out[x], out[x+23]);
```

This is about four times as fast as my implementation of the deque algorithm above, although probably that's just because of the three divisions in its inner loop.

But you can pipeline this algorithm into requiring only a single pass over the input:

```
for (x = 0; x < w-50; x++) {
  out[x+23+18+6] = cmin(in[x+23+18+6], cmin(in[x+23+18+6+1], in[x+23+18+6+2]));
  out[x+23+18] = cmin(out[x+23+18], cmin(out[x+23+18+3], out[x+23+18+6]));
  out[x+23] = cmin(out[x+23], cmin(out[x+23+9], out[x+23+18]));
  out[x] = cmin(out[x], out[x+23]);
}
```

For some reason, this version runs at the same speed as the many-pass version, even over the same 10-million-byte input.

Union kernels

This can be generalized! And, not surprisingly, someone already has.

$I \ominus (k_1 \cup k_2)$, the erosion by a union, is the same as $(I \ominus k_1) \wedge (I \ominus k_2)$, where $\wedge$ is the pixelwise minimum operation. Urbach and Wilkinson published an algorithm in 2008 (doi 10.1.1.442.4549) that decomposes an arbitrary kernel ("flat", they say, meaning that — as in all of my discussion above — the kernel contains only full and empty pixels, no shades of gray) into scan lines ("chords").

Urbach and Wilkinson use the fact that the erosion by a kernel consisting of N consecutive 1s on a single scan line, composed with erosion by a kernel consisting of two 1s on a single scan line at (possibly non-consecutive) positions 0 and M (the kernel [0, M] in the notation I used above), computes the erosion by a kernel of N+M consecutive 1s. This is a special case of the distributive law mentioned earlier, that $(A \ominus B) \ominus C = A \ominus (B \oplus C)$ — the N+M consecutive 1s are the dilation of the N consecutive 1s and the two 1s at positions 0 and M. So Urbach and Wilkinson use this to compute the erosions of the image by "chord" kernels of lengths 1, 2, 4, 8, 16, … with one comparison operation per pixel per binary chord length. Given these, they can compute the erosion of the image by any arbitrary chord length by taking one of those images and eroding it by another two-separated-pixel kernel in, again, one comparison operation per pixel; for example, to get erosion by an 11-pixel chord, you erode the 8-pixel-chord-eroded image with the kernel 1 0 0 0 0 1, that is, with pixels in positions 0 and 5.

A union of such chord kernels can thus compute the erosion by an

arbitrary flat kernel with two comparison operations per pixel per chord of the kernel, once results for enough chord kernels of powers of 2 have been computed.

This algorithm is claimed to be considerably faster than the others I mentioned above, and now that I understand it, I believe it.

However, I think we can do better. You can see this as a special case of $(A \ominus B) \ominus C = A \ominus (B \oplus C)$, but you can also see it as a special case of $I \ominus (k_1 \cup k_2) = (I \ominus k_1) \wedge (I \ominus k_2)$, where (except in the last step, where different scan lines are brought together) the two kernels are always the same kernel with different pixel shifts. (We can probably assume that the pixel shifts are free until the kernel gets large compared to the image size.) So the generalized problem is to minimize the cost of a DAG where the nodes are of the form (I_0 shifted (x_0, y_0)) *op* (I_1 shifted (x_1, y_1)), where *op* is either $\vee$ or $\wedge$, to build up the kernel we want, starting with only the identity kernel, then taking unions and intersections of (shifted) existing kernels.

In some cases it is clear that there are better alternative strategies; for example, with a vertically symmetric kernel like a circle, you can compute each chord length once instead of twice, and if there are N adjacent scan lines with the same chord, you can use $\lceil \lg N \rceil$ comparisons to compute that block rather than N-1. Urbach and Wilkinson's paper also gives an H-shaped example kernel of 49×49 pixels, consisting of three overlapping 1×49 pixel lines (one horizontal and two vertical), which also clearly has a much simpler decomposition: a 49-pixel vertical line, unioned with itself shifted 48 pixels to the right, and a horizontal line of between 47 and 49 pixels. This H could be decomposed into horizontal chords of 2, 4, 8, 16, 32, and 47 pixels, vertical chords of 2, 4, 8, 16, 32, and 49 pixels, and two more (shifted) pixelwise minimum operations to combine the three; this requires 14 pixelwise minimum operations rather than the 54 they implicitly report in their paper.

I *think* it is the case that $I \ominus (k_1 \cap k_2) = (I \ominus k_1) \vee (I \ominus k_2)$, thus allowing us to intersect erosion kernels as well as take their union — but I'm not sure right now, because that would seem to suggest that if you intersect the identity kernel with a shifted version of itself, you get a well-defined dilation rather than an ill-defined erosion with an empty set; I'm not sure this doesn't suggest that sometimes you'll get a dilation or a combination of dilation and erosion in less pathological cases.

If we exclude intersections and have only unions, then there is a computable algorithm for finding the optimum DAG: exhaustive search of all the possible ways to compute all kernels that could fit into our desired kernel somewhere. I think we can use A* search to get a better, perhaps even computationally tractable, strategy for finding the optimum DAG. Failing that, a heuristic optimization algorithm that starts with the feasible Urbach–Wilkinson strategy and attempts to improve it is a reasonable approach.

Many of these search algorithms could probably be sped up with a precomputed database of all the possible DAG nodes accessible in, say, four or five pixelwise minimum operations, if limited to some sort of reasonable shift radius.

My suggestion (‡) in an earlier section that making a pipeline out of erosion operations would be most efficient when each kernel in the pipeline had three pixels active was ill-founded; in fact the optimum

is two, because you find the minimum of two pixels in one operation, not two.

Urbach–Wilkinson with an ascending minima stack

The Urbach–Wilkinson algorithm computes one eroded image for each distinct horizontal chord length in time logarithmic in the maximum chord length and linear in the number of chord lengths, then combines these horizontally-eroded images with vertical and horizontal offsets to get the final result. Above I point out that there are sometimes more efficient ways to combine the horizontally-eroded images that require less than the one operation per chord Urbach–Wilkinson give. Also, though, we can compute those horizontally-eroded images in a more efficient manner than Urbach and Wilkinson's algorithm when we have a small number of chord lengths — by using the ascending-minima algorithm.

As an extreme case, consider using Urbach–Wilkinson to erode by a paraxial square 65×65 kernel. Each final image pixel is the minimum of 65 vertically-adjacent pixels in a single intermediate image that is eroded by a 65-pixel horizontal-line kernel; to compute this intermediate image, the UW algorithm first computes the erosions by horizontal-line kernels of 2, 4, 8, 16, 32, and 64 pixels, requiring 6 min operations per pixel. A seventh min operation per pixel gives the 65-pixel erosion we needed. (This doesn't require nearly as much memory traffic as you might think, because you can pipeline it just as you can some of the algorithms discussed earlier, or as in Evaluating DSP operations in minimal buffer space by pipelining (p. 321).)

By contrast, the ascending-minima algorithm does 2 pixel-min operations per pixel, plus some pointer comparisons, to achieve this or any other single-window-width sliding-window erosion.

You might think that the ascending-minima algorithm would require a separate deque for multiple window widths. But consider what happens if we implement the deque as a stack of all nondecreasing pixels on the line, with a "bottom pointer" that we sometimes increment and never decrement. When we push a new pixel onto the stack, we need to check to see if the bottom pointer must be incremented because its pixel has aged out; when we pop pixels from the stack in order to push a smaller pixel, we need to ensure that the bottom pointer points to the newly pushed pixel or something to its left.

But the actual contents of the stack do not depend on the bottom pointer, and the bottom pointer is the only thing that depends on the window width. So many bottom pointers can share the same pixel stack. And so adding more bottom pointers doesn't add more pixel comparisons; those remain at 2 per pixel, regardless of the number of chord lengths demanded. The extra bottom pointers do, however, add more index comparisons, which are about 2 per chord length per pixel.

Conceivably in practice the extra log-N factor is too small to matter.

Of course this whole technique to get an arbitrary number of sliding windows out of a single ascending-minima stack is applicable

to other applications of sliding-window RMQ, not just image erosion.

You could try to make a sort of "spaghetti stack" out of this approach by making a note under each pixel of the pixel index at which it gets popped off the stack and of the index of the pixel under it on the stack, but in this simple form, this modification doesn't buy you anything useful — computing a sliding-window RMQ is already as fast as it's going to get, and it doesn't make it fast to compute a random-access RMQ, because the "stack" isn't random-access — you have to chase the pointers up it, and you can't traverse it downwards at all except by linearly searching all the pixels. If you additionally note the replacement of each pixel (if any) when you pop it, a sort of next-child pointer, it becomes possible to traverse the tree downwards in a useful way, but you still have no guarantee of the kind of balance or random access among children that would make this efficient — if the pixels happen to be in descending order, the root will have them all as its children.

You could maybe do some kind of skip-list or tree-balancing thing, but this avenue of investigation seems progressively less appealing.

Linear convolution

You can use the Urbach–Wilkinson decomposition into "chords" to accelerate the usual kind of convolution, too, the kind where you take a weighted sum of the selected neighborhood pixels instead of their maximum or minimum. See Real-time bokeh algorithms, and other convolution tricks (p. 2661) for details. (It also includes some tricks for decomposing angled lines that can be used for the morphological operations discussed in this note.)

Range minimum query

All of the algorithms mentioned here work by comparing intact pixels (as opposed to, say, computing histograms of pixel values; there are somewhat efficient algorithms for general rank-order filtering, which is a generalization of erosion, dilation, and median-filtering, that work that way — see Median filtering (p. 3155)). This means that we can augment the pixel values being considered with extra metadata. For example, we could compute the luminance of each pixel and use that for the comparisons, but drag the original pixel data along with the luminance so that the color follows as it should. Or we could tag the original pixel coordinates onto the end of the pixel data, thus solving the range-minimum-query problem generalized to arbitrary window shapes — when we find the minimum pixel within the erosion window by these algorithms, it comes with its original coordinates.

See further applications in Query evaluation with interval-annotated trees over sequences (p. 1423).

The Urbach–Wilkinson algorithm constructs an index data structure of size $O(N \lg N)$ which answers range minimum queries in constant time. There is a known RMQ algorithm based on Cartesian trees that also answers range minimum queries in constant time, but using an index data structure of size only $O(N)$. I don't understand it well enough yet to compare the two algorithms.

Database explorer

Kragen Javier Sitaker, 2017-06-20 (2 minutes)

Zing! Poof! Bam! Let's explore this database, composing queries that make sense, one step at a time, with feedback after each keystroke.

Start typing the name of a table or column. See the names of the matching tables, along with their data. Tab, type another, see them together. See likely candidate join columns highlighted, with quick keystrokes to select them.

Behind the scenes, the database explorer is shitting out hundreds of queries a second and pulling a few rows from each one, using multiple different worker threads in case one of the queries is unresponsive.

An operand stack is displayed, updated after each keystroke. Available keystroke commands apply to the top stack items, but shuffling them around is easy. Since each value on the stack is an entire relation (associated with the expression that produced it) it can occupy potentially much more space than you have on your screen. The displayed summary includes the most common values in each column and, in some cases, other presentations such as maps for geodata.

As you type them, numbers and literal strings are incrementally searched for at the beginnings of all indexed columns and, if time permits, unindexed columns too.

The interface is modeless, so all the command ("accelerator") keys are modified with control or alt, and the available commands are always displayed in the UI.

Once you have the query you want, you can convert it to SQL.

Using bytecode won't make your interpreter fast

Kragen Javier Sitaker, 2007 to 2009 (26 minutes)

This is responding to this paragraph of a post by Ola Bini, "Can Bytecodes Perform Well?" [0]:

> Let's see, what's next? Oh yeah. Bytecodes are always slow. No argument here. C++ will always beat a bytecode based engine. And C will almost always beat C++. And assembler (in the right hands) will usually beat C. But wait... Isn't Java bytecode based? And doesn't Java 6 perform on the same level as C in many cases, and in some cases performing better than C? Well, yes, it does... And wasn't Smalltalk always based on bytecodes? Most Smalltalk engines performed very well. Why is MRI switching to bytecodes for 1.9? And why has Python always been bytecode based? And why is the CLR bytecode based? Why was even Pascal using bytecodes back in the day? (OK, that is cheating... Pascal used bytecodes for portability, not performance, but it still worked well in that aspect too). Erlang is bytecode based.

He's taking issue with a comment of mine on his previous post; I quoted him saying, "[Rubinius] is byte code based. This means it's easier to handle performance," and flippantly responded, "If by 'handle' you mean 'not have'." [1]

Summary of My Rebuttal

I didn't say bytecodes are always slow. Bini's fast examples are actually native-code compilers, not bytecode interpreters. Bini's examples that aren't native-code compilers are slow. Python, for example, is slow when the inner loop is in Python bytecode. Erlang used to be really slow when it was a bytecode interpreter. OCaml's bytecode interpreter is considerably slower than its compiled code. But the OCaml native-code compiler is considerably simpler than the interpreter. On-the-fly "JIT" compilers don't need bytecode. In fact, bytecode may be a bad input format for JIT compilers. There exists an ahead-of-time Java compiler that doesn't use bytecode, and it produces code comparable to that produced by JIT compilers.

There are valid reasons to use bytecode, but performance is not one of them.

Several of Ola Bini's statements are dubious.

Detailed explanations of each of these statements follow.

I Didn't Say Bytecodes Are Always Slow

My original statement was not that "bytecodes are always slow," but I can see how it would be interpreted that way. I said that building a language interpreter around bytecode makes it easier to not have performance. More specifically, I'm saying that building an interpreter as a bytecode interpreter does not make it fast, not even necessarily faster than today's popular Ruby interpreter.

Bini's Fast Examples Are Actually Native-Code Compilers

Building an interpreter as an on-the-fly compiler *does* generally make it faster than a bytecode interpreter; recent Java virtual machines, the CLR, and the fast Smalltalk engines he's talking about are all on-the-fly native-code compilers, not bytecode interpreters. The fact that they take bytecodes rather than source code as input is incidental.

However, several of them are still fairly slow in absolute terms, even though they're much faster than interpreters.

At the time that Urs Hölzle wrote his dissertation [12], the ParcPlace Smalltalk system (release 4.0) ran about ten times faster than a deliberately naïve native-code compiler for Self (see section 4.4 of the dissertation), but it ran still around 4-10 times slower than C++ (see section 7.3.1). I don't know how fast Smalltalk systems are now, but I have the impression that they haven't sped up much, except for Strongtalk.

The Erlang HiPE just-in-time native-code compiler gets speedups of about 4 over the BEAM bytecode interpreter, but it's still about ten times slower than C in the "shootout" microbenchmarks. (See the section below about Erlang.)

Bini's Examples That Aren't Native-Code Compilers Are Slow

Python, the bytecode Pascal compiler/interpreters, the BEAM bytecode Erlang interpreter, and bytecode implementations of Smalltalk (such as Squeak) are and were painfully slow for anything CPU-intensive. I used the UCSD P-System on a 4MHz Z80, and I use Python and Squeak today, and they are all painfully slow when you're doing anything CPU-bound --- unless you can push the inner loops out of the bytecode interpreter, as with NumPy. Typically the performance penalty over machine code is around a factor of 100; register-based "bytecode" interpreters like Wheat's, and Lua's often get the penalty down to a factor of 10 to 30.

You can see this pattern in the Great Programming Language Shootout results; the default weightings mostly represent CPU-intensive tasks.

http://shootout.alioth.debian.org/gp4/benchmark.php?test=all&lang=all

Python, For Example, Is Slow When The Inner Loop Is In Python Bytecode

If you look at the Python results, the tests where it was less than ten times slower than the C version are, with two exceptions, exactly the ones where the inner loop of the test was performed in C.

http://shootout.alioth.debian.org/gp4/benchmark.php?test=all&lang=python&lan°
°g2=gcc

chameneos: tests thread rendezvous speed;
cheap-concurrency: tests coroutine creation speed; Python is faster than C here;
k-nucleotide: largely tests string hashing speed (note Python is 9x

slower than C in this test);
nsieve: the "inner loop" here is essentially a NumPy-like array operation:

```
a[i + i::i] = (0,) * (m // i - 2 + (not not m % i))
```

regex-dna: the inner loop is in the sre regex engine, which is in C
pidigits: the inner loop is in gmpy, the Python binding to the GNU Multiple Precision library, which is in C
reverse-complement: the inner loops are in string.translate and reversing a list, which are done in C
partial-sums: this appears to be an exception; a straightforwardly written iterative Python solution is only six times slower than the similarly straightforwardly iterative C solution, doing a bunch of floating-point.
sum-file: the entire program contains no iteration in Python bytecode; the inner and only loop consists of four primitives implemented in C: sum, itertools.imap, int, and iter(sys.stdin).

Python uses "generator" objects for the cheap-concurrency test; these are implemented in the CPython interpreter as normal function activation records [[which presumably have some name]] rather than full threads. But the C version of the test uses full POSIX threads. A C version that used user-level "green threads" or "fibers" would probably do a little better, but it would still have to allocate a whole stack for each thread, rather than running them all on the same stack. The nearest C equivalent is probably Adam Dunkels's "protothreads".

I hypothesize that the "inner loop" in the chameneos case is actually in the underlying POSIX thread library, since the Python version is only 50% slower than the C version.

I don't know why the partial-sums test is so close.

On the tests where Python does worst, the Python program is 100–250 times slower than the corresponding C program; these are generally the tests where the Python version is most similar in structure to the C version. See, for instance, "recursive" (279x), "n-body" (163x), or "mandelbrot" (117x).

http://shootout.alioth.debian.org/gp4/benchmark.php?test=recursive&lang=all
http://shootout.alioth.debian.org/gp4/benchmark.php?test=nbody&lang=all
http://shootout.alioth.debian.org/gp4/benchmark.php?test=mandelbrot&lang=python&id=3

The large amount of variability between Python's best and worst results is mostly accounted for by variation in how much of the benchmark's inner loop is inside of some extension module or primitive implemented in machine code, and how much is actually executed by the bytecode interpreter.

Useful resources for comparing language implementation performances in this manner include Doug Bagley's original Great Programming Language Shootout from 2001 [10], the shootout.alioth.debian.org "Computer Language Benchmarks Game" version thereof, the Win32 version thereof at http://dada.perl.it/shootout/ , and Kernighan's "Timing Trials" paper [9].

Erlang Used to be Really Slow When it Was a Bytecode Interpreter

Erlang today can use a native-code compiler called HiPE. The first versions of HiPE compiled bytecode to native code; current versions compile Erlang source to native code. HiPE sped up various Erlang microbenchmarks by factors of up to about 4 over the BEAM bytecode interpreter. [4] (Of course, some microbenchmarks hardly sped up at all.)

Many people think Erlang is still fairly slow; in the shootout microbenchmarks, even with HiPE, it tends to come in about 10x slower than C.

http://shootout.alioth.debian.org/gp4/benchmark.php?test=all&lang=hipe&lang2o o=gcc

OCaml's Bytecode Interpreter Is Considerably Slower Than Its Compiled Code

Although I previously saw speed ratios of only about a factor of 4 in some code, eyeballing numbers from the Win32 Shootout suggests that ocamlopt-generated native code is more typically 20–100 times faster than bytecode run by its bytecode interpreter.

http://dada.perl.it/shootout/ocamlb.html http://dada.perl.it/shootout/ocaml.html

OCaml's Native-Code Compiler Is Considerably Simpler Than Its Interpreter

This is kind of an interesting case, because both the native-code and bytecoded implementations of OCaml were implemented by a small team and are fairly compact. In Bini's post, he asserts, "Granted, a naive implementation of a bytecode engine will not perform well. But that is true for a compiler too."

David A. Wheeler's SLOCCount 2.26 tells me that the "bytecomp" and "byterun" subdirectories of OCaml-3.09.2 contain 12683 lines of C (in "byterun") and 8816 lines of ML (in "bytecomp"); I believe these 21.5KLOC represent the whole bytecode interpreter. (The parser, type-checker, standard library, etc., is shared with the native-code compiler.)

SLOCCount also tells me that the "asmcomp" and "asmrun" subdirectories contain 9457 lines of ML, 3910 lines of assembly, and 1077 lines of C, for a total of about 14.5KLOC. This includes backends for i386, ARM, AMD64, Itanium, PowerPC/POWER, SPARC, MIPS, HP-PA, and Alpha; the backends other than the i386 backend total about 2200 lines of ML and 3400 lines of assembly, so you could reduce that to about 10KLOC for a single CPU architecture.

In short, the native-code compiler for OCaml is about half the size of its interpreter, and so is presumably much more "naive", in the sense that it required much less effort to implement. (SLOCCount estimates three person-years, compared to five for the interpreter.) But it still performs one to two orders of magnitude better than the bytecode interpreter.

Although Bini anticipates this criticism by referring to OCaml's "extremely stringent type requirements" and calls it a

"bondage-tightly typed language", this point generalizes beyond OCaml.

It's true that OCaml's semantics require much less type-checking and dynamic dispatching than Java, Python, or Ruby, and the overhead of type-checking in these more-dynamically-typed languages can be substantial compared to the overhead of dispatching bytecodes, which makes the savings of not dispatching bytecodes less noticeable. But the next few sections show that the performance advantages of native-code compilation are not limited to static languages like OCaml; indeed, the performance benefits Bini attributes to the use of bytecode are actually due to the use of native-code compilation.

On-The-Fly "JIT" Compilers Don't Need Bytecode

In Bini's post, he asserts:

> ...Java and the CLR family of languages use bytecodes because it gives the runtime system the opportunity to dynamically change the machine code running based on statistics and criteria found out during runtime. ... This is not possible in a clean compilation to machine code. Java would never have had the performance it has now if it weren't for the bytecodes.

This is simply mistaken. There are on-the-fly machine-code compilers that work from source code instead of bytecode. SBCL and the current HiPE compiler are examples. There are some advantages to compiling directly to machine code from source code rather than compiling from a bytecode format intended for interpretation; typically the translation to bytecode erases a lot of information that is helpful to optimization.

Bytecode is a Bad Input Format for On-The-Fly "JIT" Compilers

As one of the HiPE papers [4] explains:

> A new feature, described further below, is that the HiPE compiler can compile directly from Core Erlang [a restricted subset of Erlang]. When used in this way, the compiler compiles a whole module at a time, and performs global analyses and optimizations which are significantly more difficult to perform (and thus not available) in the traditional mode [which compiled from the BEAM bytecodes].

The GCC Java compiler, GCJ, can compile either Java source of Java bytecode into machine code for many different processors. In the past, it could do some optimizations when compiling from Java source that it couldn't do when compiling from Java bytecode [6]. However, apparently, now it can do essentially the same set of optimizations for Java bytecode [5] [7] --- it just took more work --- and GCJ is switching to the Eclipse Java frontend for parsing Java, starting with GCC 4.3 [8]. In this case, the standard bytecode permits successful independent development of successive links in the toolchain.

The above notes are about traditional all-at-once or "ahead-of-time" compilers, rather than the piecemeal profile-directed-optimizing compilation used by good Smalltalk implementations, Self, and HotSpot. There are some differences: JIT compilers generally have to run faster than ahead-of-time compilers. I don't believe this negates my point; although parsing code takes some time, the compiler can maintain a "bytecode" parsed intermediate representation of the program without supporting it as an *input* format, and you can just as well cache an AST. (Also, bytecode-like linear quadruple and stack-machine intermediate representations in compilers are losing mindshare these days to other alternatives like CPS and GCC's tree-SSA.)

In general, optimizing an intermediate representation (such as a bytecode format) for high-speed interpretation tends to make it worse for dynamic machine-code generation, and vice versa. Good formats for dynamic machine-code generation tend to contain most or all of the information in the original source code; good formats for rapid interpretation erase as much of that information as possible.

Self pioneered the techniques of profile-based optimization, specialization, and type feedback that Bini refers to above, and which make it possible for current Java JIT compilers to do a reasonably good job, despite the dynamic nature of the Java language. Self's bytecode format was little more than an RPN tokenized version of the source code, with blocks separated into their own bytecode objects; quite different from the Smalltalk-80 bytecode format, in which control structures are generally already inlined, and with special bytecodes for instance variable access, local variable access, and common method names.

More recent efficient bytecode-VM designs like Lua's are register-based rather than stack-based, which again, makes interpretation faster, but dynamic compilation more difficult.

I don't know for sure why Microsoft's architects chose to make the CLR bytecode-based, but my guess is that it's a weak method of source-code obfuscation. Some of their customers would have balked at shipping source code to their "assemblies", the way they have to do if they're written in Perl or Erlang, and so they would have continued using Java or shipping blobs of x86 machine code instead.

Java Compilers That Don't Use Bytecode Produce Comparable Code

Bini's statement, "Java would never have had the performance it has now if it weren't for the bytecodes," is mistaken for another reason, other than merely that other programming languages. As mentioned above, GCJ can compile Java from source code to machine code without an intermediate bytecode step; so clearly the use of bytecode is not crucial to whatever performance GCJ-compiled code achieves. So what does it achieve?

In many cases, despite not using specialization or profile-directed feedback (which are easier to do in JIT compilers than in ahead-of-time compilers like GCJ), GCJ-compiled programs run around the same speed as JIT-compiled programs. The only systematic set of benchmarks I've found, from 2004, shows GCJ-compiled programs running a little less than half as fast as the

same program in the 1.4 or 1.5 IBM or Sun JDK. [11]

There is also a variety of anecdotal evidence from real applications; some of it shows programs running a little faster with GCJ, and some of it shows them running a little slower. I haven't been able to find anything comparing the performance of GCJ 4.x, which was supposed to have a lot of new optimizations, to anything else, or a comparison of Java 6 to any version of GCJ.

As far as I know, GCJ does not yet take advantage of type feedback from the compiled program, which could put it at a substantial performance disadvantage to a JIT compiler.

• "Linux Number Crunching: Benchmarking Compilers and Languages for ia32", by Scott Robert Ladd, 2003-01-04, in which he benchmarked some computational astronomy code to measure floating-point performance; GCJ's best speeds were within 10% of the best 1.3 and 1.4 JIT JVM speeds (faster than the JIT VMs on one machine, slower on the other), but roughly three times slower than the Intel C++ and Fortran compilers.

http://web.archive.org/web/20040803034751/http://www.coyotegulch.com/reviews/almabench.html An incomplete updated version (missing the results!) is online at http://www.coyotegulch.com/reviews/number_crunching/

There are Valid Reasons to Use Bytecode, Just Not Speed

Bytecode can be considerably more compact than machine code, source code, or even gzipped source code, as a distribution format, and it uses dramatically less memory than abstract syntax trees, machine code, or source code. Bytecode interpreters are considerably more portable than native-code compiler backends. Finally, it's a lot easier to hack single-stepping and other debugging facilities into a

bytecode interpreter than to implement them for even one CPU/OS combination, let alone the whole range of CPU/OS combinations a particular language implementation might need to support.

These can all be valid reasons for choosing a bytecode-interpreter architecture for your language implementation rather than a native-code-compiler architecture, although they're not nearly as strong now as they were in the past (say, when Pascal was being developed, and there were literally dozens of incompatible CPU architectures in common use, some with several operating systems.) But performance is not a valid reason for this.

I wrote a kragen-tol post with more detail about this in March. [2]

Someone might argue that a machine-code compiler is inherently more complex than a bytecode interpreter, but I don't think that's necessarily true. The OCaml interpreter/compiler comparison above is one data point. As another, in 2003, I hacked together a machine-code "compiler" from parse trees for arithmetic expressions, using gcc to actually generate the machine code, in just a few hours [3]. But I don't have enough experience building machine-code-generating backends to say for sure.

Several of Ola Bini's Statements are Dubious

Bini ends his post, "So please, stop spreading this myth. It is NOT true and it has NEVER been true."

I think the myth he refers to is that bytecode interpreters are slow. But as shown both by his post and this note, pure bytecode interpreters are indeed considerably slower than native machine code. While native-code compilers that compile from bytecode can produce fast code, that's not because they use bytecode as an input format; that's because they're native-code compilers, often highly-tuned native-code compilers that use run-time profiling and type feedback information, and native code can run pretty fast. Even naively-generated native code rarely runs as slow as bytecode in a bytecode interpreter. (See section 4.5 of Urs Hölzle's dissertation [12]; the "non-inlining compiler" of Self-93 was 2600 lines of C++, one-fifth the size of the OCaml bytecode interpreter, and Hölzle argues that bytecode interpretation would be hard-pressed to do better.)

But Bini originally said, "[Rubinius] is byte code based. This means it's easier to handle performance." It's a pretty ambiguous statement (easier than what? what does "handle" mean?) but I think this note has adequately outlined the degree to which the obvious interpretations are false. While there are slower language implementation techniques than bytecode interpreters available, such as those used by bash or Tcl 7, they aren't in wide use.

Rubinius may well achieve excellent performance, or it may not, but its use of bytecode is not particularly relevant to that goal.

Notes from Hölzle's dissertation:

> Thus, we believe that type feedback is probably easier to add to a conventional batch-style compilation system. ... As mentioned above, static compilation has the advantage that the compiler has complete information since optimization starts after a complete program execution. ... On the other hand, a dynamic recompilation system has a significant advantage because it can dynamically adapt to changes in the program's behavior.

(section 5.6, p. 42, "Adding type feedback to a conventional system")

> The combination of SOAR's software and hardware features was very successful when compared with other Smalltalk implementations on CISC machines: with a 400 ns cycle time, SOAR ran as fast as the 70 ns microcoded Xerox Dorado workstation and about 25% faster than the Deutsch-Schiffman Smalltalk system running on a Sun-3 with a cycle time of about 200 ns. However, as we will see in Chapter 8, the optimization techniques used by the SELF compiler greatly reduces the performance benefit of special hardware support.

(section 2.5.4.2, p. 11; SOAR is a non-dynamic native-code compiler running on a customized version of the Berkeley RISC II processor)

Chambers's dissertation mentions some stuff about Dorado comparative performance:

> The definition of Smalltalk-80 specifies that source code methods are translated into byte codes, the machine instructions of a stack machine. Originally, Smalltalk-80 ran on Xerox Dorados implementing this instruction set in microcode [Deu83]. Subsequent software implementations of Smalltalk-80 on stock hardware supplied a virtual machine that interpreted these byte codes in software. Needless to say this interpretation was quite slow [Kra83].

Compact namespace sharing

Kragen Javier Sitaker, 2016-07-25 (7 minutes)

Smalltalk bytecode is super compact, partly because it doesn't include literal constants, addresses, and method selectors in the bytecode itself; instead they're stored in a separate per-method vector and referred to by index. Java bytecode uses the same approach, but the result is that even though the bytecode itself is very compact, the .class files can easily be far from compact, more like huge and bloated.

You could imagine sharing, say, a single constant pool over an entire static program, just as some Smalltalks have shared a single object table over an entire dynamic program. Then, each constant would only be listed once in the pool. But it would be a large pool, so an arbitrary index into it could occupy many bits, such as 16 or even more. By contrast, Smalltalk bytecodes are only 8 bits, and typically only 3–5 of these are occupied in indexing into such a pool. This static locality of reference gives us potentially very considerable compression, but at the cost of duplication among the "dictionaries" used for this compression.

This is not the only possible compression mechanism for this information — you could also imagine things like move-to-front coding, and Smalltalk also has a fixed dictionary of special constants accessed by a separate opcode — but if that's the one we're using, we can consider how to optimize it better.

Function calls and returns are a kind of context switch: after the transfer of control, the variables and constants of interest to the new code are no longer the same as those of interest to the old code, much as in a switch between threads or processes. In 1973, Carl Hewitt, Peter Bishop, and Richard Steiger suggested conceptualizing each function's activation record as a separate "actor", like a process; "actors [or, if you will, virtual processors, activation frames, …] … it is impossible to determine whether a given object is "really" represented as…a hash table, a function, or a process," they said.

Context switches can have widely varying costs. Context switches that happen more often have a proportionally higher total cost, whatever other factors may be involved; and context switches that overwrite more state also have a proportionally higher cost. In the context of function calls and returns, a return that need only restore a saved PC and SP is inexpensive; a return that must restore %eip, %esp, %ebx, %ebp, %esi, and %edi is more expensive; and a return that must additionally restore floating-point registers, vector registers, and some kind of dynamic exception handling context, is more expensive still.

However, the alternative to overwriting more state is typically adding another level of indirection, and thus cost, to things that happen when you're not context switching. Bernie Greenberg's Multics Emacs paper explains his choice of a heavyweight context-switch mechanism for switching buffers in Multics Emacs as follows:

> The implementation of multiple buffers was viewed as a task of multiplexing the extant function of the editor over several buffers. The buffer being edited is defined by about two dozen Lisp variables of the basic editor, identifying the

current Editorline, its current (open/closed) state, the first and last Editorlines of the buffer, the list of marks, and so forth. Switching buffers (i.e., switching the attention of the editor, as the user sees it) need consist only of switching the values of all of these variables. Neither the interactive driver nor the redisplay need be cognizant of the existence of multiple buffers; the redisplay will simply find that a different "current Editorline" exists if buffers are switched between calls to it. What is more, the only functions in the basic editor that have to be aware of the existence of multiple buffers are those that deal with many buffers, switch them, etc. All other code simply references the buffer state variables, and operates upon the current buffer.

The function in the basic editor which implements the command that switches buffers does so by saving up the values of all of the relevant Lisp variables, that define the buffer, and placing a saved image (a list of their values) as a property of the Lisp symbol whose name is the current buffer's. The similarly saved list of the target buffer's is retrieved, and the contained values of the buffer state variables instated. A new buffer is created simply by replacing the "instatement" step with initialization of the state variables to default values for an empty buffer. Buffer destruction is accomplished simply by removing the saved state embedded as a property: all pointers to the buffer will vanish thereby, and the MacLisp garbage collector will take care of the rest.

The alternate approach to multiple buffers would have been to have the buffer state variables referenced indirectly through some pointer which is simply replaced to change buffers. This approach, in spite of not being feasible in Lisp, is less desirable than the current approach, for it distributes cost at variable reference time, not buffer-switching time, and the former is much more common.

This is also the reason shallow binding is usually preferred to deep binding in implementing dynamically-scoped languages: shallow binding makes function calls expensive, but variable access cheap.

So suppose that, when we enter a function, we load a whole passel of values into the registers of the machine, virtual or otherwise; there's a passel pointer before the beginning of the function code, and it is used to initialize the registers. Some of these registers may contain "constants" that we want to be able to use, others contain initial values for local variables, and others still may be instance variables of an object, which will need to be saved back to the object when the function is done.

The wide cache memory buses featured on modern high-performance processors can transfer 64 bytes at a time; wide 128-bit, 256-bit, and 512-bit (16-, 32-, and 64-byte) SIMD registers can be loaded in a single cache access (right?). Hardware designed slightly differently could

Turning off the power supply for every sample to reduce noise

Kragen Javier Sitaker, 2018-06-18 (2 minutes)

Switching power supplies generate a lot of electrical noise. The AVR has the option of temporarily halting everything on the chip except the ADC during an analog-to-digital conversion in order to remove sources of noise. Could you shut off a switching power supply during analog-to-digital conversions in order to get further precision?

You'd need to have a big enough capacitor to keep the processor going, plus perhaps adequate voltage regulation.

If you were running an AVR ATMega328 on 5V, well, its "typical" power consumption is listed as 1.2 mA when idle at 8 MHz on 5V; we can safely extrapolate to 3 mA at 20 MHz. A 10-bit conversion takes it 260 μs. Let's say it's safe to let the voltage droop from 5.45 V to 4.55 V during that time (hopefully this 20% variation in input voltage during the conversion won't hork the ADC). This requires the capacitor to be at least 870 nanofarads, which is eminently feasible, even in a low-L MLCC.

If this would cause problems for the ADC, you could charge the capacitor up to a higher voltage and use a linear voltage regulator (perhaps an LDO for efficiency) in between the capacitor and the microcontroller. Then the ADC wouldn't see a changing reference voltage.

So it this approach seems workable. It requires that you not be spending all your time doing conversions, though, because otherwise your switcher is going to be generating even more noise that will keep ringing through the system during conversions.

Oh hey, I think it can actually do a 10-bit conversion in more like 67 μs at a higher clock rate. This reduces the required capacitor to more like 220 nF.

Really simple lab power supply

Kragen Javier Sitaker, 2019-12-10 (7 minutes)

In Lab power supply (p. 2421) and Bench trash power supply (p. 1457) I wrote about adjustable power supplies for electronic benchwork. But I think I was overcomplicating the problem.

Basic design: a PWM-controlled buck converter

An AVR is sufficient for the control problem, though see below about STM32s. You can hook a couple of potentiometers up to it easily enough as a user interface. At some point you will want a screen to see how much current is being drawn, but that's a rathole we can avoid at first by way of using a USART.

To limit the output voltage you can rely on an ATX power supply's high-current 12-volt output regulation; you can use a buck converter consisting of a P-channel MOSFET, a freewheel schottky up from ground, and a small inductor. Such a device can have its voltage controlled, even open-loop, with a PWM or PDM signal from the AVR. Any random NPN BJT will work as a gate pulldown driver unless you use a monster MOSFET; switching frequencies in the tens to hundreds of kHz are not demanding either on the gate capacitance or the microcontroller. (To drain 100 nC of Qg in 2 microseconds at 5 volts, you need a 100-ohm pullup, so a 47-ohm pullup will work even for monster MOSFETs; using such a high-current resistor would start to limit your options for the BJT.) Also most of the P-channel MOSFETs I've seen would work fine.

How much inductance do you need? I don't know. Not very much I think. Enough to avoid discontinuous conduction mode, I guess. If you use a too-big inductor you'll be fine except that you'll also have to use a too-big capacitor to prevent voltage spikes when the load comes unplugged.

A back-biased beefy rectifier from the output to the input will reduce the risk that input-supply crowbarring will nuke the circuit if its output is feeding voltage back into it (for example, because you were charging a battery with it).

Current sensing with a shunt

Bench power supplies need current limiting, both because otherwise it's too easy to get smoke, and because sometimes you want to test things with a current source. Typically an ATX power supply will do some limiting, but not in a pleasant way. Since you want to measure the output current anyway, you might as well do the current limiting in software.

There are lots of ways to measure the output current but probably the easiest is to use a precise sense resistor in series with the inductor to measure the inductor current. High-impedance voltage dividers from the two ends of the sense resistors connect them to the microcontroller's pins, and the difference between the two measurements gives us our current measurement.

To be concrete about current sensing, say you're using an AVR

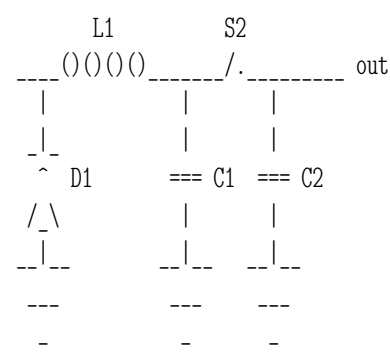
with its 1.1V bandgap reference (1.0V to be safe) and its 10-bit ADC, and you want to measure voltages up to, say, 13V, and currents down to 10 mA, which is not a very ambitious milliammeter but probably adequate for a quick-and-dirty power supply. If your voltage divider is made out of a 100-kilohm resistor and a 6.8-kilohm resistor, the full-scale 13V is divided down to 844 mV, at most 865 counts on the ADC and at least (if the bandgap reference is 1.2V) 720 counts; one count is thus divided down from 18 mV, so you need at least a 1.8-ohm sense resistor, and probably a 2.2-ohm sense resistor in practice. Using such a big sense resistor is an annoying limitation on how much current the power supply could source at low voltages.

STM32 possibilities

Although an AVR would be adequate, an STM32 (see Notes on the STM32 microcontroller family (p. 3176)) would be dramatically better; a 12-bit ADC means you could use a four times smaller sense resistor (0.47 ohms), and the higher 1Msps sampling rate means you can react more quickly to load changes and have more confidence in the current measurement, which in turn means you can use higher switching frequencies and smaller inductors and capacitors, although at some point you start needing an active pullup for the MOSFET gate, maybe a gate driver chip.

Current sensing without a shunt

Instead of using a shunt to sense the current you're charging the output cap with, you could use two caps in parallel across the output with a new switch between them:



I'm not sure what to use for this switch, other than some kind of transistor, but the idea is that you leave it closed almost all the time, but occasionally you open it to find out how much current is flowing. The voltage across C2 will start falling, but C2 is in parallel with the input capacitance of the load, and you don't know what that capacitance is. More useful is that the voltage across C1 will start rising, and the speed with which it's rising tells you the current that's running through L1 at that moment. If C1 is much smaller than C2, say by a factor of 40, the rise in voltage will be much faster than the fall on C2; if you leave the switch open long enough for C1's voltage to rise by 25%, the voltage across C2 will have fallen by 0.6%; and once you close the switch again the droop will be instantly corrected. (Oof, might want a little inductance or resistance there to keep the switch from exploding from the singularity.)

This is handy because, for a good current measure, you'd want C1 to have a pretty precise and stable capacitance, and those are a lot

easier to find in lower capacitance values. Electrolytic and ferroelectric-ceramic capacitors have very imprecise capacitances.

This design can use one ADC pin instead of two, but I think it requires two digital output pins instead of one.

Basic BoM

So, with the shunt design, that works out to a microcontroller, two pots, seven resistors, a random inductor, a random capacitor, a schottky, the protection rectifier, a P-MOSFET, and an NPN BJT, 15 non-microcontroller components. And if you fuck up the firmware the ATX power supply will probably save you but maybe not. All of these except the microcontroller can be easily scavenged.

You can hang a bunch of these puppies off a single ATX power supply if they don't overload it. You might be able to hang a bunch of them off a single STM32; you need a couple of ADC input pins per power-supply line.

Secure, self-describing, self-delimiting serialization for Python

Kragen Javier Sitaker, 2017-04-11 (8 minutes)

I find myself somewhat unexpectedly desiring a new serialization format for Python data structures. This is unexpected because Python's standard library already includes several serialization formats: pickle, marshal, json, and xmlrpclib (not counting xdrlib, ConfigParser, and struct), and other formats such as bencode are also widely used in Python.

(bencode might actually be the right solution, but I can't look at the internet to see right now.)

I'm defining a network protocol for a program I'm writing, and one of the things I want to do in this protocol is to pass Python data structures over the wire. I'm not concerned with being able to serialize arbitrary class instances — I'd be satisfied with built-in data types — but I don't want a lot of hassle.

The serialization needs to be:

- Secure — all of pickle, marshal, and xmlrpclib have warnings against using them on data from potentially malicious sources, leaving only json of the standard modules.
- Self-describing — it must be possible to deserialize a serialized value without referring to some external schema information.
- Self-delimiting — it must be possible to deserialize a serialized value from a byte stream and then continue using the byte stream, for example to deserialize another value that follows it. This rules out json; I think it rules out bencode but I'm not sure.
- Dependency-free — its implementation code must be self-contained.

Ideally, the serialization would also be:

- Simple to implement, improving its chances of being secure.
- Fairly transparent, supporting the full range of commonly-used built-in Python data types, preserving the tuple-list distinction, the int-float distinction, the bytes-unicode distinction, non-string dict keys, Booleans, None, and maybe even sets.
- Hashable, in the sense that a given Python value is representable by only a single possible byte stream.
- Capable of serializing class instances, optionally, with an explicit namespace of supported classes.
- Devoid of arbitrary format limitations, such as limiting strings to 2^{32} bytes.
- Pure ASCII except when it's encoding strings that aren't.
- Reasonably efficient.
- Supportable on other programming languages, including old versions of Python.

But it does not need to be:

• Easy to type by hand. (So length fields are okay.)
• Super efficient.
• Capable of serializing functions and/or closures and/or generators.
• Capable of serializing exotic or very stateful Python types like Ellipsis, xranges, code objects, type objects, memoryviews, file objects, and complex numbers.
• Capable of representing and restoring sharing or circular data structures.
• Super easy to read.

Length-free design

```
val ::= bytes | unicode | tuple | list | dict | boolean | none | int | float
bytes ::= '"' stringcontents
unicode ::= 'u"' stringcontents
stringcontents ::= '"' | stringbyte stringcontents
stringbyte ::= [^"\] | '\"' | '\\'
tuple ::= '(' tuplecontents
tuplecontents ::= ')' | val tuplecontents
list ::= '[' listcontents
listcontents ::= ']' | val listcontents
dict ::= "{" dictcontents
dictcontents ::= "}" | val val dictcontents
boolean ::= "T" | "F"
none ::= "N"
int ::= sign digits " "
digits ::= [0-9] | [0-9] digits
float ::= sign digits "e" sign digits " "
sign ::= "-" |
```

The pairs of vals in a dict are key-value pairs. Dict keys must appear in sorted order by the lexicographical ordering of their serializations. Unicode strings are represented in UTF-8. The only whitespace allowed is that within strings and that following numbers. The only case where the next byte is not sufficient to dispatch to the appropriate routine is the int/float dichotomy. Yes, floats are expressed without decimal points, so "31416e-4 " is a reasonable representation for an approximation of π.

In practice this should be slightly more compact than bencode except for large binary strings (which it inflates on average by almost 1% but by 100% in the worst case), and much more readable and writable, but considerably slower and more error-prone.

As an example, `{"announce-list": [["foo"], ["bar"]], "info": {"files": [{"length": 4541, "path": "baz", "safe": False}], (): (1, 1.0)}}` would be represented as `{"announce-list"[["foo"]["bar"]]"info"{"files"[{"length"4541 "path""baz""safe"F}]()(1 1e0 )}}`.

Length-prefixed design

```
val ::= bytelength body
bytelength ::= digits
digits ::= [0-9] | [0-9] digits
body ::= bytes | unicode | tuple | list | dict | boolean | none | int | float
bytes ::= 'H' data
```

```
unicode ::= 'u' data
data ::= "" | [\x00-\xff] data
tuple ::= '(' vals
vals ::= "" | val vals
list ::= '[' vals
dict ::= "{" pairs
pairs ::= "" | val val pairs
boolean ::= "T" | "F"
none ::= "N"
int ::= " " sign digits
float ::= "." sign digits "e" sign digits
sign ::= "-" |
```

Here every `val` begins with a decimal representation of the number of bytes in the body of its serialization, not counting the initial type byte.

As an example, `{"announce-list": [["foo"], ["bar"]], "info": {"files": [{"length": 4541, "path": "baz", "safe": False}], (): (1, 1.0)}}`, the same example value from before, would be represented as `100{13Hannounce-list14[6[3Hfoo6[3Hbar4Hinfo58{5Hfiles36[33{6Hlength4 45414Hpath3Hbaz4Hsafe1F0(8(1 13.1e0`. This is about 10% bigger than the length-free design, and a hell of a lot harder to type or read, especially the parts that seem to say "45414H" and "13.1e0", but can be navigated efficiently and can support large chunks of binary data.

Stack-based design

Pickle deserializes by interpreting stack-based bytecode similar to Python bytecode (which leads one to wonder why they didn't just use Python bytecode). The pickle-version-0 encoding of the sample datum `{"announce-list": [["foo"], ["bar"]], "info": {"files": [{"length": 4541, "path": "baz", "safe": False}], (): (1, 1.0)}}` is the following 188 bytes:

```
(dp0
S'info'
p1
(dp2
S'files'
p3
(lp4
(dp5
S'path'
p6
S'baz'
p7
sS'length'
p8
I4541
sS'safe'
p9
I00
sas(t(I1
F1.0
tp10
ssS'announce-list'
```

```
p11
(lp12
(lp13
S'foo'
p14
aa(lp15
S'bar'
p16
aas.
```

Here:

- `a` appends an item to a list,
- `s` appends a name-value pair to a dict,
- `(` pushes a PostScript-style mark,
- `t` forms a tuple from the items down to the PostScript-style mark,
- `l` forms a list (down to the mark),
- `d` forms a dict,
- `S`, `I`, and `F` encode strings, ints, and floats (up to the end of the line),
- `p` names the item on top of the stack so it can be referred to later if there are more references to it, and
- `.` ends the pickle.

Now, I have no idea why pickle incrementally appends stuff to lists and dicts as it builds them. `pickle.loads("(S'foo'\nS'bar'\nS'baz'\nI37\nd.")` does return `{'foo': 'bar', 'baz': 37}` as you would expect, and changing the `d` to an `l` generates the corresponding list. So I don't know why `a` and `s` exist.

If you wanted to take this approach to make your serialization and deserialization as little code as possible, you could use this approach:

```
op ::= digits intop | '(' | '}' | ']' | ')' | 'T' | 'F' | 'N' | LF
intop ::= ' ' | '-' | 'H' data | 'u' data | 'F' data
digits ::= [0-9] | [0-9] digits
data ::= "" | [\x00-\xff] data
```

Here the '}', ']', and ')' ops play the role of 'd', 'l', and 't' in pickle; LF plays the role of '.'; ' ' specifies that the preceding digits just represent an integer (and '-' is the same, but negates it); 'H' and 'u' specify that the preceding digits are a count of following bytes for a byte string or UTF-8-encoded Unicode string; and 'F' represents a floating-point number in some way that I'm not specifying right now.

As an example, `{"announce-list": [["foo"], ["bar"]], "info": {"files": [{"length": 4541, "path": "baz", "safe": False}], (): (1, 1.0)}}` would be represented as `(13Hannounce-list((3Hfoo](3Hbar]]4Hinfo[5Hfiles((6Hlength4541 4Hpath3Hbaz4HsafeF}]()(1 1F1)}}\n`, which is one byte longer than the length-free design, but retains most of the efficiency advantage of the length-prefixed design. I'm not sure there's a meaningful difference, really...

House scrubber

Kragen Javier Sitaker, 2016-09-06 (updated 2019-11-25) (13 minutes)

So I was just thinking about how my city is annoyingly polluted. In the absence of successful collective action to reduce the sulfur content of diesel fuels, and to require proper maintenance of motors, it seems like it would be possible at least to handle the problem at a more local level. Like a per-apartment level.

You could seal up your apartment or house, but that has a couple of different problems. The biggest one is that when the amount of CO_2 in the air rises to about 1% you will start to feel that it's a bit hard to breathe, and when it reaches 10%, you will die — even though there is still plenty of oxygen left (barring a Biosphere-II-type surprise).

So this kind of thing is a problem that has been dealt with in a lot of different contexts over the years, including scuba diving, nuclear submarines, the Space Shuttle, the ISS, firefighting, mine rescue, and carbon capture for power-plant flue gas.

The scuba-diving approach, which is also sometimes used in submarines, is to pass the gas over a base that reacts with the CO_2; they use hydroxides of calcium, magnesium, sodium, and lithium, which transform from hydroxides into carbonates. The trouble with these is that you have to keep replacing the hydroxide, which is kind of undesirable. You can buy calcium hydroxide at the hardware store here for use as paint (whitewash), for about US$3 per kilogram, although it's mixed with an unspecified quantity of calcium carbonate, and some other random shit. A kilo of CaOH sucks up about 1.2 kilos of carbon dioxide. So you'd be using about five kilos a week.

On the plus side, it's super low tech. You can just paint it on the wall and let it suck up the CO_2 from there over the next few days. It'll also suck it up just sitting in the bucket, but that will take many years. (Which suggests that you could buy, say, ten tons of it and just let it sit in a crate.)

You can regenerate calcium carbonate back into calcium hydroxide by roasting it, but you have to get it up to 850° or so, which is pretty hot. Magnesium carbonate is more promising: it starts to decompose back into magnesium oxide at just 350°, and if you don't heat it past 700° or so, it remains deeply eager to suck the CO_2 back out of your air. So you could imagine some kind of solar kiln on your roof to bake out the carbon dioxide you'd exhaled over the last day or two. But you're still having to deal with powders, which probably means batch rather than continuous-flow. And they're caustic powders, so if you trip carrying a bucket of this shit, you're going to the hospital. (Magnesium oxide gets a lot more stable if you heat it further, apparently.)

(The ISS uses a similar system, but uses zeolite molecular sieves rather than alkali.)

The US nuclear submarine fleet chose a different option, one used for flue-gas treatment: they use an aqueous solution of ethanolamine. Ethanolamine, like magnesium hydroxide or calcium hydroxide, is eager to suck up CO_2 from your air; unlike them, it does so while

remaining happily liquid in an aqueous solution, so you can pump it around. Even better, you can persuade it to give up the CO_2 by heating it to merely 120° or so, which is a much easier thing to do. On the downside, it's inflammable and toxic. Its cousin diethanolamine works too, and is much less inflammable and toxic. Also on the downside, to get it to absorb the CO_2, you need to compress the gas to several atmospheres, at least 5 but ideally more like 200 atmospheres.

But that seems like the kind of thing you could reasonably have in your house. I mean, your refrigerator is already compressing its R-134a refrigerant to about ten atmospheres, which I think is enough to persuade diethanolamine to take up the CO_2. So you could very reasonably install an "air conditioner" with a similar-size compressor motor, compressing air. (You might be able to allow the air to re-expand to atmospheric pressure through a series of turbines alternating with heat exchangers in order to offset some of the energy use of the compressor.) It would need to pump through about 100 m^3 of air per day per person in order to suck up 1kg of CO_2 per day at a 1% concentration. That's a bit more than a liter per second, or 115mℓ per second at the cooled compression output.

I don't know how much the liquid flow needs to be. Presumably several milliliters per second. Most of the temperature difference in the liquid can be managed with a countercurrent heat exchanger, so that it doesn't represent an ongoing energy waste, in particular the part where the hot liquid coming back into your house has to shed heat into your space to get back down to room temperature.

We can estimate the energy usage of this contraption. Isothermically compressing 1.15ℓ down to 115mℓ involves squeezing, say, 9cm out of a 10cm cylinder with 115cm^2 surface area, against a pressure that rises linearly from 0 to 10 bar; that's 518J, so the compressor needs 518W. Some of this (let's say 90%) can in theory be provided by decompressing the sweetened air through turbines, so you might need 52W. And if you're heating up, say, 10mℓ of something water-like from 40° to 120° each second, that's 80 cal/s, or 330 W, of which you can probably economize 90% with a countercurrent heat exchanger, getting you down to 33 W. And you probably need another 10 W or so for the water pump. Total, about 95W dissipated, out of 950W flowing hither and thither.

Now, of this 95W, some fraction is presumably the actual unavoidable Carnot loss from pumping CO_2 from a (potentially) low-CO_2 environment to a (potentially) high-CO_2 environment (although in fact we're proposing here to pump it from your 10000ppm CO_2 sealed neurotic bunker to the 400ppm outside world). But that is probably a small amount compared to the 10% losses I've assumed in compressing-decompressing and heating-cooling cycles.

(We could apply this same approach to removing CO_2 from the air at scale. Note, however, that this 95W is about the same wattage as the human being that hypothetically exhaled that kilogram per day of CO_2, so you end up using about the same energy to get the CO_2 out of the air with this approach that you originally got out of burning it — and that's after the CO_2 has reached 10 000 ppm! So, while this is a viable approach to carbon dioxide removal in a world where we have a great deal more energy available than we ever used in fossil fuels, it is too expensive at the moment.)

You may be able to use photosynthesis, as in Biosphere II, to remove some of the CO_2 from the atmosphere. However, this will require significant indoor acreage; at normal CO_2 concentrations, you need about as much sunlight to turn your CO_2 back into carbohydrates as it took to turn it into the carbohydrates you ate. Beema bamboo, a thick-walled variety, supposedly produces 50 tons of dry biomass per acre per year (112 tonnes/ha/y), yielding 4000 kcal/kg. That's about 6.6 W/m², which means that your 100-watt body would need 15m² of bamboo to consume the CO_2 it emits. Other high-yielding plants are similar — sugarcane commercially reaches 70 dry tonnes per hectare per year and experimentally has reached 98 dry tonnes/ha/y, which is 5.2 W/m². (Hardier plants like switchgrass and Miscanthus, which thrive without the subtropical conditions that beema and sugarcane demand, are down around 15 to 40 dry tonnes/ha/y).

Most crops, apparently, increase production substantially (varying from 25% to 200%) CO_2-supplemented in a greenhouse, but I don't know if this applies to super-high-biomass-productivity crops like Beema bamboo and sugarcane. 1000 ppm is a common supplementation level. 10 000 ppm is high enough that it will likely cause problems for plants; Alberta's official advice to greenhouse gardeners is to keep below 4500 ppm for the sake of plants, or 5000 ppm for the sake of humans; other sources suggest that over 1200ppm some crops start to "show undesirable growth responses". You'd only reach that level if the plants fall behind your breathing, and since the curve levels off then, at that point the overall system could go unstable — you'd want to keep the concentration in the range where the plants can increase their photosynthesis to respond to elevated CO_2 levels.

One great difficulty with this approach, however, is that if you bring 15m² or 30m² of sunlight into your house to grow plants, you need to have a way to shed the kilowatts of heat you're adding — roughly two orders of magnitude more than those dissipated by the diethanolamine system, which hopefully you can also manage to dissipate outside the house, at least in the summer.

(You may in fact be able to get by with 15m² of *sunlight* concentrated onto a significantly smaller area of *plants*.)

One approach to solving this problem is to keep the plants in a separately-insulated greenhouse, which can exchange air with your dwelling space via a heat exchanger. If you were to follow Alberta's recomendations, you could perhaps send air to the greenhouse at 4000 ppm CO_2 and get it back at 1000 ppm, thus dropping 3000 ppm; the 1kg/day/person mentioned above then is about 4 liters per second or 8 cfm. You can get 10 cfm out of a 75mm-diameter 4-watt 3000 RPM fan that you might mount on your computer's CPU. Another benefit of keeping the greenhouse at a different temperature is that CO_2-supplemented plants may prefer higher temperatures, like 35°, which is very uncomfortable for people; but you could keep it at those higher temperatures without bothering yourself.

If we figure that a city block is normally 100m×100m, and (to play it safe) that we need 30m² of sunlight to fix a person's CO_2, a city block can house some 330 people.

Once we've taken care of the CO_2, there are other things in the air we need to take care of. A variety of artificial objects outgas

pollutants like formaldehyde; in the absence of ventilation to vent these to the outside world, they could accumulate to potentially dangerous levels. One approach is to work hard not to allow things into your house that are likely to outgas pollutants, but that's very difficult.

The approach taken in the ISS is to have a separate trace contaminant control system, which is just an activated-carbon air filter. The Mir space station thermally regenerated its activated carbon with a hot non-oxidizing gas; the ISS uses disposable activated carbon instead, plus an 0.5%-palladium-on-alumina catalytic converter to burn up methane and other things that get past the activated carbon, followed by LiOH sweetening.

Their activated carbon is impregnated with phosphoric acid in order to soak up ammonia off-gassed by human metabolic processes.

What about other carbonates or bicarbonates --- might they be easier to regenerate? They are more difficult, as it turns out. Sodium bicarbonate dehydrates to sodium carbonate at between 50° and 270°, at which temperature the decomposition is complete; Wikipedia says that it's fast at 200°; above 850° it releases carbon dioxide. Potassium carbonate (pearl ash or salt of wormwood) doesn't melt until 891°, rubidium carbonate doesn't decompose until 900°, and lithium carbonate doesn't decompose until 1300°.

See also Notes on a possible household air filter (p. 1961).

Low-cost green thread locks

Kragen Javier Sitaker, 2016-09-06 (2 minutes)

(This idea is probably bad because we can't eliminate the cost of lock acquisition completely; we still need to conditionally block if the lock is acquired.)

Zero-overhead exception handling uses a map of executable code regions to analyze the stack trace at the time an exception is thrown to discover where to invoke the exception handler. This way, a `try { }` statement, or in C++ the code to destruct a stack object during exception unwinding, has zero run-time overhead in the normal case; it just makes the executable a little bigger. Throwin an exception is slower than using a `setjmp()`/`longjmp()` style of exception handling, but this is still a net win, because exceptions are very rare compared to entering and leaving contexts that add tasks to carry out during stack unwinding.

Analogously, acquiring a lock is a very common operation in threads-and-locks programming, and typically a very expensive one. But we only care what locks you hold when another thread might contend them. In a "green thread" or "fiber" environment, only one thread is actually running at a time, and context switches between threads are relatively uncommon.

In a language like Java, locks are normally managed by entering and leaving `synchronized` statements and methods. These can be discovered by walking the stack in the same way that exception handlers can.

This suggests the following implementation technique for locks in a green-threads environment: don't maintain the runtime state of which locks are held by the current thread at all, although of course you still need to test to see if a lock is held when entering a context that requires it. Instead, when the thread yields to the scheduler, the scheduler walks its stack to reconstruct the set of locks it holds. Then it marks those locks as "held" before choosing which next thread to run.

This slows down context switching, but speeds up lock acquisition, making it affordable to acquire more locks.

Raid zim

Kragen Javier Sitaker, 2019-01-17 (updated 2019-02-08) (1 minute)

```
# I couldn't fit this 37GB Wikipedia dump (English with no images)

# <magnet:?xt=urn:btih:267d148412ad50361e0c0384c905fabe35e8539a&dn=wikipedia%5Fen%5Fall%5Fnopic%5F2018-09.zim>
# onto my flash disk because VFAT doesn't support large files.  So, I
# thought, I'd stick it on an ext4 filesystem in a disk image file on
# the VFAT, thus circumventing all of VFAT's restrictions.  Not so
# fast  -  that file can't be 4GB or over either.  So what to do?  We
# can take advantage of Linux software RAID:

set -e
DANGER() {
        :
}

: ${usb?} ${user?} # ensure the $usb and $user variables are set
# This first part takes about 40 minutes because VFAT doesn't support
# sparse files either:
DANGER time truncate -s 2g "$usb"/wikipedia-zim.img.{1..20}

for i in {1..20}; do sudo losetup "/dev/loop$i" "$usb"/wikipedia-zim.img."$i"; done

DANGER sudo time mdadm --create /dev/md0 --level 5 --force --raid-devices=20 /dev/loop{1..20}
# 0.00user 0.02system 0:33.79elapsed 0%CPU (0avgtext+0avgdata 2592maxresident)k
# This seems to work for subsequent mounting but never the first time:
sudo time mdadm --assemble /dev/md0 /dev/loop{1..20}
DANGER time sudo mkfs -t ext4 /dev/md0
# real    2m24.296s
DANGER sudo tune2fs -r 0 /dev/md0   # no root-reserved blocks; frees up about 2GB
sudo mount /dev/md0 /wikipedia-zim/
df -h
# Filesystem                Size  Used Avail Use% Mounted on
# /dev/md0                   38G   48M   38G   1% /wikipedia-zim
# However, Transmission reports 39.9 GB.
DANGER sudo chown "$user"."$user" /wikipedia-zim/

remove_raid() {
    sudo time umount /wikipedia-zim/
    sudo mdadm --stop /dev/md0
    sudo losetup -D
    umount "$usb"
}
```

Caustic business card

Kragen Javier Sitaker, 2019-04-08 (3 minutes)

Suppose my selective electro-etching process works to produce caustic surfaces. Can I make myself a business card?

I'm not sure how big a business card is. If it's 50 mm × 30 mm and has a 50 × 30 mm reflection, presumably the focal distance needs to be short enough that the sun's ½° size gives adequate resolution to the letters. Minimally we need 5×8 and 5 lines of 20 letters, amounting to 4000 pixels in the caustic. The reflection could potentially be larger than the card itself, but if that's going to be significant, it needs to be curved. A spherical bead would be cool, but let's start by thinking about flat metal plates.

That's about 2.7 pixels per square millimeter (of the image), or about 0.6 mm per pixel. Half a degree is about 9 milliradians, so the projection distance can't be more than about 70 mm to get that resolution. This is feasible but uncomfortably tight.

That is: the sunlight, with ½° = 9 mrad divergence, comes in and illuminates the overall-flat shiny mirror-polished metallic 50 mm × 30 mm surface, producing a 50 mm × 30 mm reflection on a surface in shadow in the same direction as the sun, 70 mm away. Because of the divergence, there's a fuzzy border around the reflection with a radius of 0.3 mm. Tiny variations from flatness across the mirror result in major variations in brightness across the reflection, in particular bright spots from caustics, which also have a fuzziness radius of 0.3 mm. These bright spots spell out my name, email address, and so on. They can reasonably be spaced some 0.6 mm apart, giving a resolution of some 83×50 "pixels", which is 16 5×8 letters on each of 6 lines, a total of 96 character positions. This can be improved somewhat with subpixel positioning and proportional fonts but not a whole lot.

The bright spots reach their maximum brightness when the corresponding 0.6-mm-diameter spot on the mirror is concave parabolic with a spherical radius of curvature of 140 mm. This means that the center is depressed from the edge by $140\text{ mm} - \sqrt{((140\text{ mm})^2 - (0.3\text{ mm})^2)} = 320\text{ nm}$, about half a wavelength of light.

This is small enough that the geometrical optics approximation may not apply and we may have to consider diffraction. (We can perhaps improve the situation there a bit with a blue coating.) The usual Airy limit is $\sin\theta = 1.220\lambda/D$ for a circular aperture; in this case our λ is about 555 nm and our D is about 600 μm, so this works out to $\sin\theta = 0.0011$, which is to say that our first diffraction null is about 1.1 milliradians in radius, 2.2 milliradians in diameter. This is substantially smaller than the 9 milliradians of the sun's disk, so the diffraction effect is significant, but not dominant; we're in good shape.

Kogluktualuk: an operating system based on caching coarse-grained deterministic computations

Kragen Javier Sitaker, 2016-07-23 (21 minutes)

I'd like to know what you think about this draft. It should take about ten or twenty minutes to read.

In the spirit of Hamming's admonition to look for attacks on the most important problems in your field, I propose a project.

I've been thinking about a kind of Unixy system for distributed, high-performance, fault-tolerant, incremental, reproducible computing, scalable to exabyte datasets. It consists of a transactional deterministic virtual machine, a content-addressed blob store, and a cache management system.

Tentatively I've been calling it Kogluktualuk.

Overview

The basic idea is to generalize build systems like the NixOS build system or apenwarr/Bernstein `redo` to use them for general-purpose computing; given some kind of specification of a deterministic computation that includes all of its input data, you can re-execute the transaction later on and get bit-identical results, as long as you either have stored or can recompute all of that input data.

(I say "transaction", despite the false implication that there is an underlying mutable data store being mutated by the transactions. Kogluktualuk transactions do not mutate state, and they do not have any access to mutable state; they merely generate output from input.)

For example, if "5B2uheZVEd5u61Nc5" is the secure hash of some specification of a deterministic transaction — maybe a command line like

```
in_namespace "4dkcSzVpvmtcgCcUo" do /bin/sort /data/july-trades
```

then perhaps execute("5B2uheZVEd5u61Nc5") will produce an output dataset with the hash "5GWFsognLrfv9tqin"; and if so, then it will *always* produce "5GWFsognLrfv9tqin", and never some other output dataset.

If each blob of input data is specified either by a secure hash, or by a secure hash of a script (and input data) that tells how to compute it, you can be sure that it will be bit-identical if you re-execute the transaction, and so the output data can be cached. This means that if the same computed data is required twice, it can be opportunistically cached, and it's safe to store the cache on inexpensive, unreliable storage; and it is possible to detect and correct incorrect transactions by reproducing the transaction, for example on a different machine.

Running a transaction that has more than one input blob that is identified by the transaction to produce it (rather than directly by its

content hash) offers opportunities for deterministic concurrency and distribution.

For example, in the above transaction, perhaps the namespace "4dkcSzVpvmtcgCcUo" includes input specifications something like the following:

```
/data/july-trades blob 3yCXJMme1nn3mthVP
/bin/sort         do /bin/ejs /src/sort.js
/bin/ejs          do /bin/jsinterp /src/ejs.js /src/ejs.js
/bin/jsinterp     do /bin/cc /src/jsinterp.c
/bin/cc           do /bin/slowcc /src/cc.c
/bin/slowcc       do /bin/as /src/slowcc.s
/bin/as           blob 2r3g5UzEREHrbCyeg
```

This allows the fetching of `/data/july-trades` from a remote blob store to happen in parallel with, if necessary, the recompilation of /bin/sort. Normally, of course, there will be a cached version of /bin/sort; it won't be necessary to bootstrap the entire universe from source code to sort a data blob.

Also, though, if /data/july-trades is large, /bin/sort can split it into a number of smaller blobs, then map a name to the sorted version of each smaller blob:

```
/tmp/xaa.sorted  do /bin/sort /tmp/xaa
/tmp/xab.sorted  do /bin/sort /tmp/xab
/tmp/xac.sorted  do /bin/sort /tmp/xac
```

Then, it can merge those sorted chunk blobs to generate its output blob. These separate sorting operations can run in parallel, and potentially on different machines, in isolated namespaces of their own; this introduces no nondeterminism into the computation of the transaction, because accessing the sorted smaller blob invisibly blocks until it is complete. (Or, at least, enough of it is available to satisfy the read request.)

Once the transaction is complete, the entire modified namespace can evaporate, leaving only a precipitated output blob.

It's desirable both to generate the dependency graphs of the computation dynamically, as in the above example, and to statically audit that all necessary data for a transaction is present. We can obtain both of these properties at once with this filesystem-like level of indirection; processes running inside of a computation are not permitted to request arbitrary hashes — only those hashes statically mapped into their filesystem namespace at startup.

The cache management system is responsible for deciding which deterministically computed output blobs to retain in the content-addressed blob store. Doing this optimally is of course impossible, but doing it adequately should be feasible, since it can see the structure of the global transaction graph and how long each transaction took.

Performance

The grain size of the separate nodes in this computational graph can be quite small before it starts to cost significant efficiency, perhaps 128 kibibytes and a few million instructions, particularly with efficient

fork(), reasonably simple virtual memory mappings, and/or compiler-enforced security.

The VM code (for example, the blob of /bin/sort) produced by the various compilers can be AOT-compiled to native code for particular platforms, and perhaps this can also be stored in the cache. Under some circumstances it might make sense to recompile this native code with greater optimization over time.

Incrementality

I said that Kogluktualuk is "incremental". The way to get an incremental recomputation is to generate a new namespace that shares most of its mappings with an existing namespace, and then run a transaction in the new namespace that has previously run in the old namespace; if the computation decomposes into many subtransactions as suggested above, then only the subtransactions whose input data has changed will need to be rerun.

In the case of the sort example above, unfortunately, that includes the entire merge phase, a problem which could be reduced by passing a partitioning of the keyspace to the smaller-blob-sorting subtransactions, which could then produce as output not a single blob but a large number of blobs, one for each partition of the keyspace. Then you could split the merge phase into many independent merge transactions, perhaps only some of which would need to be rerun.

Dynamic dependency information

Getting this kind of incrementality conveniently requires extracting dynamic dependency information from the transactions as they run, like the Vesta SCM, Composable Memory Transactions, a serializable SQL transaction, or `redo`; the static dependency information is potentially very imprecise.

For example, perhaps the sort transaction above didn't happen to access /bin/grep, even though perhaps it is mapped; it would be useful if that allowed us to keep using the cached output of the sort transaction, even in a new namespace with a new mapping for /bin/grep.

Similarly, in the independent-merge-phase example above, it would be convenient if we could use the dynamic behavior of the merge phase to determine which partitions each merge transaction depended on. Perhaps this one:

```
/output/sorted.ZION-ZNGA  do /bin/merge /tmp/*.sorted.ZION-ZNGA
```

didn't happen to access /tmp/xac.sorted.XOOM-Z, even though it was mapped into its namespace; therefore a re-execution with a different /tmp/xax.sorted.XOOM-Z shouldn't have to re-execute the merge.

At this point, we have reproduced the sort-by-MapReduce from the original MapReduce paper.

How far can this approach go? Can you run your windowing system in it?

It might be feasible to use this approach even down to the level of handling mouse events; maybe moving the mouse generates a new

namespace which differs in that /dev/mouse now says "228,301\n" instead of "205,301\n", and the resulting incremental recomputation is capable of reusing almost all of the previous computation of the screen image to display, writing an /output/framebuffer with the new screen contents, which might be identical except for a mouse pointer and some mouseover highlight colors.

(You might want to write an /output/uistate that becomes the /input/uistate for the next UI transaction, too, and you might want to spawn the framebuffer update off in a subtransaction in case it isn't needed.)

I'm not sure taking it this far is a good idea, for a couple of reasons:

• It seems important to be able to guarantee responsivity for the user interface. This seems incompatible with depending entirely on nondeterministic caching for performance; if you decided to update /src/cc.c with a better-optimizing version, it would be unpleasant to have your next display frame delay three hours while the entire system was potentially recompiled.
• It seems important to be able to display the state of transactions in progress in the user interface, which seems sort of incompatible with the strong guarantee of determinism. But maybe the relationship between the user interface transaction and other transactions can be special.
• It seems like the user interface is a place where you need to be able to put in new hashes in order to fetch them from the cache, but we previously said that's a thing transactions can't do, because it could allow them to depend on data that isn't statically mapped into their namespace.

However, it seems like if you could make it work, you could get transparent persistence and migratability of your desktop environment, plus the ability to roll back to previous checkpoints. You only need to make sure that all of your mouse movements and keystrokes and whatever other events can affect your UI (completion of other transactions, maybe, or the passage of time) are safely recorded, either that or /input/uistate. Every point in time in your user interface has a hash, with which you can retrieve it and then explore other execution paths.

Overall significance

Kogluktualuk is a major advance in computing systems in terms of efficiency, simplicity, scientific reproducibility, digital preservation, practical software freedom, practical parallel computation, and security.

Reproducibility is a crucial requirement for scientific work, and digital preservation is a crucial requirement for historical work. It is often infeasible to determine what factors a computational result depends on. Kogluktualuk computations are reproducible forever, as long as their source data is preserved, and it automatically determines what that data is, so that you can preserve it.

For free software to be more than a theoretical construct, it needs to be possible in practice to recompile the software we are using. This is often unnecessarily difficult in current practice. Kogluktualuk, like Nix, automates this, so that you are guaranteed to be able to recompile anything you can run, except for a tiny bootstrap stub.

It is often difficult in practice to take advantage of the available parallel computational resources, for reasons including the following:

- heterogeneity,
- host exposure to attacks by untrusted code,
- private data exposure to untrusted hosts,
- exposure to untrusted hosts introducing malicious data,
- the increasing likelihood of hardware faults as scale increases,
- the excessive performance overhead of systems like Hadoop, and
- awkward programming interfaces and user interfaces.

Kogluktualuk improves the situation as follows:

- paper over heterogeneity with a uniform virtual machine at an acceptable performance cost,
- isolate untrusted code within sandboxes so it can't attack the host,
- have (I hope) very low performance overhead,
- automatically detect and recover some some kinds of hardware faults, and be configurable to detect and recover from all hardware faults, at a heavy performance cost,
- have the possibility of detecting and defeating malicious data introduction attacks, and
- have (I hope) convenient interfaces.

However, it does not protect against the disclosure of private data to untrusted hosts.

Occasionally free-software communities have been exposed to trojaned-binary attacks, including from SourceForge, in which the compiled binary has malicious code inserted into it that is not present in the source code. The most extreme form of this attack, demonstrated by Ken Thompson and previously hypothesized during the Multics security audit, involves inserting self-reproducing backdoor code into the compiler binary, so that even recompiling the compiler from source will not solve the problem. Currently, if any Debian Developer's development machine is compromised, the attacker can nearly undetectably compromise binaries built on that machine by inserting malicious code into them, and they will later be distributed to all Debian users who install that package.

The defense against these binary-poisoning attacks is reproducible builds, pioneered by the Tor project and now widely adopted, including by nearly all Debian packages. Kogluktualuk makes all builds reproducible, and it can be used to automatically detect such attacks.

In most existing computing systems, all computations have full access to read and write every file accessible by the user that launches them, as well as sending that data over the internet and manipulating and measuring the CPU load in order to communicate data through covert channels. In Kogluktualuk, each computation only has access to the data it is explicitly provided, and almost no computations have access to the clock or to the ability to pause themselves at will. This dramatically reduces users' vulnerability to malicious code.

Incrementalization of computation can often provide enormous performance increases, often three or more orders of magnitude; in the form of `make`, this was crucial, for example, to enabling the original development of UNIX in a high-level language on shared 0.4-MIPS computers in the 1970s. Current work in automatic

incrementalization, under the name "self-adjusting computation", is producing very promising results, but involves a slowdown of a factor of about five when the computation does not benefit from incrementality. Kogluktualuk should provide most of the performance benefit of full incrementality with no detectable overhead in the non-incremental case.

I've written before about the inefficiencies and bugs due to the numerous ad-hoc levels of caching in our existing computer systems. Kogluktualuk's unified caching system obviates every level of caching of greater granularity than a few million instructions, and it has the necessary global information to optimize caching globally. Even without any incrementality or parallelization benefit, this should produce better-performing computer systems, and they should be much simpler.

Unresolved questions

What does the user interface look like?

How do we index the computation cache so that it depends only on the dynamic dependencies of a computation, yet is fast to retrieve from? Maybe it would be better to spawn subtransactions in a very restricted namespace with only the things they depend on, even if that requires duplicating the information of which things they depend on in their caller?

What should the virtual machine look like? In particular, how should it handle floating-point math, and should it be vector-oriented in order to get better performance from available GPU (SIMT) and SIMD (e.g. SSE) resources?

How low can we get the overhead of forking off a subtransaction? Am I being too optimistic to think that 128 kiB and a few million instructions is big enough to amortize that overhead into insignificance? Or am I even being pessimistic? Does it depend on whether the subtransaction is going to get run on a different cluster node?

What about data that can potentially be computed in more than one way, depending on what data is available in cache? For example, in an OLAP system, you might want to see total sales by region (4 rows); if you have an existing materialized view of total sales by region and product category (40 rows) or total sales by region and customer type (16 rows), you can calculate the desired result very quickly, much more quickly than if you have to trawl over the entire dataset of, say, 50,000,000 rows. But maybe you only have one of those two views already computed, and it would be nice to use the one that is. Is there a way to fit this into the Kogluktualuk paradigm?

Guaranteeing responsiveness probably requires updating some cached items preemptively, rather than waiting for them to be needed.

What's the story on publicly-accessible caches? If you choose to trust a publicly-accessible binary cache for your Nix packages, you can avoid having to recompile anything yourself. But with Kogluktualuk, you might be at risk not only of getting malicious code from that cache, but also of sending that cache the hashes of private data in order to find out whether they are present there. You could reduce this risk with something like Bloom filters or compressed

Golomb rulers; is that enough, and if not, how can this risk be eliminated or made acceptable?

Anytime algorithms, which can be stopped at any point when time is running out, are important for real-time computation, for example in robotics and in some user interfaces, because they can guarantee real-time responsiveness without the heavy restrictions that are needed to deterministically bound the halting time of an algorithm. Many mathematical optimization metaheuristics automatically produce anytime algorithms. Can they be fit into Kogluktualuk's framework?

Truly random numbers are important for security. Enormously many secret keys have been compromised by compromised sources of randomness, including the Debian OpenSSL debacle and the Dual EC DRBG backdoor. One of the problems introduced by transparent checkpoint-and-restart systems like those in VirtualBox is that they can result in reuse of randomness, which can compromise that randomness. (One-time pads and DSA have notoriously bad problems here, but RSA keys with common moduli, for example, have also been broken en masse.) Kogluktualuk seems to allow checkpoint-and-restart functionality without this problem, because the granularity of the checkpoint is transactional, and you can probably avoid allowing the truly random data to escape a transaction. Does that really work?

What about resources like RAM? What do you do if a transaction wants to allocate ten gigabytes of RAM? Could that provide a covert signaling channel for exfiltrating private information to other transactions? Is there a way to ensure that some (or most?) transactions are small and light enough to run on small embedded processors?

Is there a way to get out of writing a compiler for a virtual machine instruction set, at least for prototyping Kogluktualuk?

Should we store everything in the same blob store — non-derived and thus irreplaceable source data, transaction outputs, native code for a particular processor, the cache database? Relatedly, how does Kogluktualuk relate to version control with Git?

In the cluster case, is the blob store implemented as a DHT, or what?

What interface does a transaction use to tell Kogluktualuk what its outputs are?

Is it really practical to do pipelining by having a pipeline of transactions that each read from the previous transaction's output, without having each one pause until the previous one is done? Is there a way we can usually avoid storing the data that flowed through the pipeline?

How do we modularize namespaces so that we can make a new namespace that differs from an existing one by changing one file (like /dev/mouse or /src/grep.c), without generating many megabytes of data traffic?

What exactly are the algorithms the cache service uses to figure out what to evict from cache?

In a cluster implementation of Kogluktualuk, how do we decide which transactions to run on which nodes? Does the hierarchical transaction structure provide enough information about the communication patterns to do a good job of this? If large blobs (like

my example /data/july-trades above) are sharded across nodes, how much of that do we expose to the transactions running on top in order to allow them to optimally divide up their subtransactions, and how do those subtransactions end up on the best node — do we migrate or restart them on a new node if they start accessing large data blocks, or what?

How do we deal with laggard nodes in a cluster implementation?

How do you fit reactive computation into this framework, if at all — how do you do, for example, a chat system? (Is there anything interesting in Urbit's implementation of chat?)

For things like what people use SPARK for, can we get adequate performance with, say, binary floating-point data in one column per file? (Kogluktualuk is a lot like SPARK.)

Topics

A type-inferred dialect of JS

Kragen Javier Sitaker, 2016-04-22 (4 minutes)

Suppose we want to do type inference on JS code so that we can run it faster or statically debug it or some shit like that.

Now, some things are really easy to infer a type for:

```
var projectionMatrix = [ [1, 0, 0, 0]
                       , [0, 1, 0, 0]
                       , [0, 0, 1, 0]
                       , [0, 0, 0, 1]
                       ]
```

That's clearly an Array of Arrays of Numbers, although you get into some weird subtyping stuff if you start caring about whether they're ints or not. (In this case they're not, because it gets mutated later on.) Also it happens that it's specifically a 4x4 array of arrays, and that matters in this case.

There are things that are intermediate:

```
function evToPoint(ev) {
  var ref = cvs.getBoundingClientRect();
  // This is clearly wrong, but my theory is that maybe this will make
  // it return SOME point within the canvas on old iOS.  Probably I
  // should use pageX there instead.
  return { x: (ev.clientX - ref.left) % cvs.width
         , y: (ev.clientY - ref.top) % cvs.height
         };
}
```

This takes an object `ev`, which needs to have `clientX` and `clientY` properties (but might have other properties too), and they need to be Numbers (except that in JS `"fuck" - "you"` is actually valid and returns a NaN), and returns an object with exactly the properties `x` and `y`, which are also Numbers, presupposing that `cvs` has a `getBoundingClientRect` property that is a function of no arguments returning a thing with `left` and `top` Number properties, and also `cvs` needs to have Number properties called `width` and `height`.

Now if it happens that all of these things are true, then we could probably use like a super optimized version of `evToPoint`. But if some of them aren't true, we might still want to remain JS-compliant, and just skip the optimization part. But if you can find all the calls to `evToPoint`, maybe you can prove that those properties are always true, so you can always use the optimized version and not even compile an unoptimized version.

Other things are really hard to infer a type for. Like `["x", 3]`, or `function(obj, prop, val) { obj[prop] = val; }`.

How about an RJS, though? Like RPython, but for JS. A restricted subset of JS that doesn't allow you to do anything that interferes with type inference. This seems feasible to me, although it's not going to be as simple as type inference for ML, because you unavoidably have some subtyping.

In particular, I think you need OCaml's upper-bound and

lower-bound types for objects with properties if you're going to have heterogeneous data structures: it's fine to pass {x:3, y:4, z:5} to a function that needs x and y to be numbers, but not fine to pass {x:3, y:4} to a function that needs x, y, and z to be numbers. Along the same lines, integers are a subtype of numbers in general, and probably an important one (although JS normally does gradual overflow, I don't think I've ever seen a JS program where this would matter). Once you're dealing with subtyping, maybe you could also deal with arrays of known size as a subtype of arrays of unknown size.

I'm not sure how exactly to deal with mutability, although subtyping might help. Immutable-array-of-integers is covariantly a subtype of immutable-array-of-numbers, and mutable-array-of-integers is a subtype of immutable-array-of-integers, but mutable-array-of-integers is not a subtype of mutable-array-of-numbers, because you can jam 1.5 into the latter. Unless I'm confused about the subtyping relation.

You probably also need to distinguish Objects used as hash tables (mapping strings to objects of some type) from Objects used as structs. Given the RJS niche, you could simply forbid using an object in both ways; it's trivial to rewrite `x.y = 3` into `x['y'] = 3`.

RJS wouldn't need to support inheritance.

Notes from a Buenos Aires blackout, summer 2013–2014

Kragen Javier Sitaker, 2014-04-24 (15 minutes)

Scale: 53 minutes

It's 2013-12-24, about 0:30. Sweat is running down my face as I lounge naked on my bed, soaking into the sheet below me. The only light I can see in the room is from the netbook balanced on my thigh, which dimly illuminates the button-down shirt hanging from the inert light fixture above the bed on a hanger. My mouth is burning from the tallarines verde with hot sauce I bought from a street vendor on the way home.

Upon arriving home, I took about 0.3mg of melatonin, an antioxidant secreted by our pineal glands in the absence of exposure to blue light. It's dissolved in a reused bottled-water bottle in my silent refrigerator, which is still cool from the plastic coke-bottles of ice I stocked it with earlier. Soon the melatonin will probably induce drowsiness, and I'll drop off to sleep.

The neighborhood is quiet from this vantage point, nestled inside an apartment building with my tiny 2mx1.5m courtyard open to the sky. The occasional motorcycle or shouting person is audible in the distance. My neighbors have mostly gone to bed, since there's not much power. (At least one of the three phases feeding the building is still present.)

Before I sleep, I'll probably read half a chapter or so of *The Grammar of Graphics* by candlelight.

Scale: 160 minutes

Earlier, I walked home, enjoying the cooler outdoor air, from a restaurant near where I used to live, one which has Wi-Fi, an upper story where your laptop isn't visible from the street, and even outlets, although that last would have helped me more if I'd brought my laptop's bulky power supply. I argued with an atheist friend of mine who's being dragooned into leading prayers at a church in Korea, sympathized with another friend who's uncertain about her boyfriend's commitment to their long-distance relationship, wrote down phone numbers, and worked on a Bicicleta-to-JS compiler, which work is visible at https://github.com/kragen/bicicleta.py.

I also carried out a simple migration of data to a new AWS EC2 volume, something which needed to be done probably by tomorrow or possibly Thursday.

Mostly, of course, I read things. Articles, tweets, messageboards. Am I learning things? Probably.

Eventually my laptop ran out of battery, and having already paid, I stuffed it into my backpack, waited a while, and then speedwalked out of the restaurant.

The street vendor asked $27 for her tallarines verdes, which I didn't notice had a chicken wing on top. Not having $27, I offered her $18, which she accepted. The food was kind of lukewarm, having sat in a cooler in the hot Buenos Aires summer all afternoon. I hope I don't

get food poisoning.

As I sleep, I will probably be bitten by mosquitoes. I killed six last night, and I've already heard one tonight, though they're hard to see without lights. I'm glad dengue hasn't yet returned to Buenos Aires. I don't think the power outages are helping with that.

Scale: 8 hours

Darius and I went to a café with Wi-Fi when we discovered power was back out at my house, hoping to collaborate on the Bicicleta implementation. We didn't end up collaborating much, and I'm not sure what the reason was. Maybe Darius was tired of making the effort to communicate with me, or maybe he felt he'd be more productive working on his own on the table next to me.

Addled by the heat, I couldn't find the café I was looking for, but fortunately Buenos Aires is full of cafés with Wi-Fi.

As the night proceeds, it should cool off and become more comfortable. I'm keeping a bottle of cold water by the bed just in case.

Scale: 24 hours

Tomorrow morning I will wake up and go to the rose garden in Palermo for a date with a friend of mine, where I can paddle around the lake in a paddleboat. Fortunately I've refound the sun-shading hat I bought in Chinatown for my birthday party last month.

This afternoon I worked on visualizing foreign-exchange market data with d3.js with my coworker Ruth, who is just learning to program but alongside whom I am still much more productive. I was planning to wake up to start work earlier, but my phone ran out of battery, and I thought I'd wake up on time without it, but I didn't, probably because I didn't go to sleep last night until 5 AM.

Fortunately Ruth's charger was able to charge my phone.

I was also planning to work on this fractal calendar thing http://canonical.org/~kragen/sw/dev3/siercal.html with my friend Ganesha, but that fell through. I have some ideas.

Scale: 3 days

I washed a bunch of laundry in a bucket in the bathroom yesterday, making a big dent in the pile of laundry needing doing. My broken hot-water heater has ceased to be a handicap at the moment; cold-water showers are quite comfortable, and most days I take three or four of them. But washing clothes by hand, or by foot, is still a lot of work. It's amazing how much grime comes out of clothes. I think most of it is soot from diesel engines. I imagine my house air would be a lot healthier with heavy filtering.

I also ended up helping a friend of mine in California with a visualization project she's doing with d3.js, which I'm only slightly more experienced with than she is.

After my date tomorrow, I may end up working on the client project some more. This depends, in part, on the availability of electrical energy in my dwelling. Later, I'm going to a pluralistic holiday gathering, where five people with six nationalities and at least three faiths will celebrate together.

It won't be nearly as quiet tomorrow night. The traditional

Christmas fireworks are due.

Scale: 9 days

I got paid by my client, which enabled me to pay Ruth. I'm frustrated with how slowly the project is progressing. I also spent a bunch of time working on a fun little project, a lightweight web server --- currently 1928 bytes of 386 machine code running on Linux. http://canonical.org/~kragen/sw/dev3/server.s.

Power was out in my apartment, and nearby --- like the traffic light on the corner --- from Tuesday to Friday of last week, the days it was hot. It returned on Friday (at which point Darius had booked other accommodations with less mosquitoes and sweat) and lasted until today. It'll probably be out much of this week, too.

On Friday I went to a homemade pizza party at a friend's house nearby. I expected it to be quick to travel there, but due to the power outages, there were protestors cutting off streets a few blocks from my house, and the bus lines were rerouted and, when I found the stops, infrequent.

Saturday I went to the hacklab, where some people are scanning books with a homemade laser-cut apparatus similar to the Internet Archive's Scribe. We saw off a friend of ours who is leaving the country, and Violeta and I talked for a while.

My friend Jake Appelbaum's apartment in Berlin was broken into, presumably by US spies. Nothing was taken. He's a political dissident in exile from the US as a result of persecution, a result of his work on behalf of Edward Snowden and WikiLeaks. (None of this is private information; it's been written about extensively in Der Spiegel and other newspapers.)

Snowden, for his part, has suggested that Brazil ought to grant him asylum. Former KGB executive Vladimir Putin, who has granted him temporary asylum, said he wishes Russia could get away with what Obama is doing in the US. Snowden is still unable to make his way to any country that hass granted him permanent asylum.

In the next few days, I should reinflate my bicycle, clean up my patio, bedroom, and kitchen, try to keep the fridge stocked with ice bottles, and see if I can get the hot-water heater working again. If power comes back on, maybe I can get an air-conditioner dude to come see if the air conditioner is leaky or just undersized.

Also, I need to get an Android phone, both to develop for it and for the other useful aspects of Android. Being able to write on the bus at 40wpm instead of 17, having a portable wi-fi hotspot for larger computers, showing people videos, and consulting bus directions are all desirable features.

Scale: 27 days

I went to see a gorgeous circus performance by some friends of mine and a dozen or so of their classmates.

My friend David Kendal has still not had his server returned by the police, but has replaced it; it was seized in an investigation of our mutual friend Lauri Love, who has been indicted for breaking into computers remotely for activist purposes, but is presently at liberty.

My vocal folds have been irritated and unhappy since my birthday party a month ago, to greater or lesser extents. Possible contributing factors include air pollution, eating too much food seasoned with

pepper spray (a gift from Ruth after my mugging, which I will write about at greater length soon), talking all the time (and loudly, so Darius can possibly understand me), and reverse glottal fries.

I think I should probably take a short vacation, somewhere rural and maybe more polar. A friend of mine has suggested we hitchhike to Misiones together, but is still uncertain.

My aunt has a detached retina and needs help. I cannot travel to help her.

Scale: 81 days

I've gone to see a couple of immigration lawyers, but so far don't have a signed contract for either one to represent me. I'm still living in the same apartment I have been since February, but I think shortly will want to move. I spent some time looking at an eight-bedroom house with friends, but so far we haven't been able to put together a deal to actually move in there.

I've connected with a polyamory group here in Buenos Aires. So far, not much has come of it in terms of developing norms or sharing useful advice. Most of the participants are in their early 20s, and so are more interested in drinking beer and trying to hook up than in talking about strategies for managing jealousy, starting cohousing projects, or passing along info on poly-friendly lawyers and therapists. While I have no problem with people hooking up, and I at least tolerate people drinking, those aren't the things that are scarce in my life right now.

Beatrice has a paid job again, for almost the first time since 2006. And I've been working on this client project, and so we're on a path to pay off our shared debt, one of the few things we haven't yet unshared from the time we were married.

My sister is pregnant with twins.

My friend Stig Hackvan died unexpectedly, apparently from stomach cancer.

I was robbed on the train on November 9th, on the way to the memorial hackathon for my friend Aaron Swartz, who committed suicide in January after years of political prosecution by the US government for his activism. More details on the robbery later. I'm fine, it was just money.

In the next month and a half, I need to close a deal with an immigration lawyer to represent me and regularize my immigration status. This will make it possible for me to travel, and also start moving me toward Argentine citizenship again, which I've been working towards for seven years now.

A friend of mine is moving to Buenos Aires with her retired dad in mid-January, and I'm going to help them find a place to live.

I celebrated my birthday in the park on November 23rd. It was a potluck. A friend and I made polenta-based sushi. About 20 people showed up in all over the course of the 9 hours we were in the park, although a couple tried and didn't make it, because they couldn't figure out which direction from the duck pond was east, I guess, and because I let my cellphone run out of battery.

I gave how-to books on misoprostol abortions to everyone who came to the birthday party, although a few people refused. Abortion is almost entirely illegal in Argentina, as is mifepristone, but misoprostol is legal, safe, and widely available. It's slightly less

effective than mifepristone, but produces abortion in about 90% of cases. And it is legal to distribute information on how to perform abortions, although if the police had come by to hassle us, I'm not sure I could have persuaded them of that.

I've been single since September 27th, which is almost three months. The last time I was single this long was when I was 17. I think this is a good indication that finding a partner for a polyamorous relationship in Buenos Aires is going to be a lot more difficult than it would have been to find a partner for a theoretically monogamous relationship that isn't really, which seems to be the usual arrangement here. But I'm sure I'll fall in love with somebody again, in the next month or two. There's one person in particular I've had my eye on for a long time who *might* be interested.

And, if I manage to stay productive, I'll be able to pay off my debts.

On September 28th, I gave a talk on privacy software at the 30th anniversary celebration of the GNU project, which we celebrated at the hacklab here in Buenos Aires. Due in part to Snowden's revelations, interest in privacy software has increased substantially since then.

Time

It's now 02:00. It's still hot. I'm going to try to sleep.

PS

Power returned 07:00, went out again 10:00. My date didn't show up to the rose garden, but it was closed anyway.

Topics

Diode logic

Kragen Javier Sitaker, 2018-06-17 (16 minutes)

I saw on Hackaday that Ted Yapo made a digital clock out of diodes and oscillators. This ought to be impossible, since diodes can't invert or amplify, but it turns out that it isn't, because of reverse recovery time.

Yapo is using regular power rectifier diodes as RF switches, like PIN diodes. When they're forward-biased or even zero-biased, they pass RF AC with no problem. When they're reverse-biased, the depletion region grows, the junction capacitance drops, and they block RF AC (up to some rolloff frequency, anyway). So you can use DC voltage biases to get them to block or pass RF. Then you can use a faster small-signal diode to rectify the RF AC into DC, which you can use for further control signals.

Essentially, you carry two signals from two different power supplies on the same wire at the same time, allowing you to do something thought impossible for decades.

You could argue that this isn't "really" diode logic because you need an external oscillator to drive it. Yapo says this is a bogus criticism — the external oscillator is just another power supply, like how you need regulated 5VDC for TTL and regulated 3V3 or 1V8 for many modern CMOS chips. You don't need more oscillators as your logic gets more complicated.

(Incidentally, I've seen an avalanche relaxation oscillator LED flasher that works by back-biasing the collector-base diode junction of a transistor until reverse breakdown, so I suspect you can get an RF oscillator out of relatively ordinary diodes too, not just exotics like Gunn diodes and tunnel diodes.)

It occurred to me that maybe you don't even need two different kinds of diodes for this trick. You can use different regions of the response curve of a single kind of diode. You can use a capacitor (with more capacitance than your back-biased diodes) to move an AC signal from riding on one DC voltage level to another. If the DC level is close to the diode's forward drop, it rectifies the RF signal. If it's above the diode's forward drop, it passes the RF signal; if it's below it, it blocks it.

This is kind of tricky because it seems like it could be hard to get amplification with just one kind of diode this way. Unless you're going to use transformers, the RF voltage needs to be high enough to, when rectified, switch a diode from blocking RF to passing RF. I was thinking that this wasn't really a problem because you can use an arbitrarily small DC voltage to build up an arbitrarily large charge as you back-bias a diode, but it's actually a bit trickier than that — the small DC voltage will stop building up the large charge once the voltage created by that charge gets high enough. But I think you can use a standard voltage multiplier circuit (Cockcroft-Walton generator) made of diodes and capacitors to solve this problem. (I say "I think" because I'm not sure if this would require a different kind of diode.)

A standard 1N4148/1N914 handles 10 mA at .75 V forward and can peak at 100 mA at 1.1 V forward, withstands up to 75 V reverse, and

has .9 pF junction capacitance and 4 ns reverse recovery time. I think this means it can usefully rectify signals up to about 60 MHz. Common LEDs can also pulse up into the tens or hundreds of MHz. Schottky diodes don't have a reverse recovery time but have more capacitance; a 1N5819 has 150pF and can handle 1 A at .4 V forward. That capacitance will pass 1 A at .4 VAC at 2.7 GHz, although presumably their lead inductance will start to be a problem well before that, and you probably don't really want to run your logic circuits at 400 milliwatts per diode anyway, and lower currents will make the capacitance proportionally more important — 27 MHz already passes 10 mA.

(2.7 GHz? Is that really true? To charge 150 pF up to a .6 volt peak, I guess you need 90 pC, which an amp would deliver in 90 picoseconds, which gives you a waveform period of about four times that, which is indeed about a third of a nanosecond. Wow.)

There are smaller Schottky diodes with correspondingly smaller capacitances. The 1N6263 offers 0.1 pF and can carry 1 mA, which hits the corresponding transition at 3.9 GHz. Amusingly, at the other end of the scale, things look better: the MBRP40045 can carry 400 amps (!) and claims only 3500 pF, which at an AC RMS voltage equal to its 540 mV forward drop, would only start carrying 400 amps RMS at 34 GHz. But 3500 pF would resonate in series with its own leads at 2.7 GHz with only one picohenry of parasitic lead inductance.

Using higher radio frequencies allows you to use smaller capacitors to pass them or smaller inductors to block them. At 10 MHz, for example, 22 pF is 700 Ω, and 100 μH is 6000 Ω; at 20 MHz, 10 pF is 800 Ω and 47 μH is 6000 Ω.

The effective switching speed of logic circuits built this way might be able to reach a tenth of the carrier frequency of the RF power supply. The rectifier output needs to be smoothed over intervals in that ballpark, and the "DC" signals need to be separated from the "RF" by at least that much.

(Speaking of inductors, square-hysteresis-loop magnetic logic had somewhat similar characteristics, using a DC signal to push a magnetic core into saturation and thus pass or block an AC signal, also restoring the signal edges with the sharp hysteresis. It was much slower, though, because magnetic domains take a while to move around, like nearly a millisecond. This approach seems like it might have the potential to reach into the MHz.)

The AC current produced by a small AC voltage across a diode riding on some DC bias is an exponential function of that DC bias, which will then produce a nicely exponential AC voltage if fed into, say, a resistor or capacitor. This suggests a sort of alternative approach: rather than trying to suppress the RF entirely by back-biasing the diode, just move down closer to the threshold voltage to attenuate it more, but not so close that you're effectively rectifying. I am not sure if this will work. Let's try to work it out.

Let's see if we can fit a curve to the 1N4148 figures I gave earlier. The current should grow by a factor of e every 25.3 mV, according to my understanding of the Ebers-Moll equation; in fact, though, it grows only by a factor of 10 over the 0.35 volts from .75 to 1.1 volts, when actually it should be growing by a factor of a million. Horowitz & Hill has some diode curves, including LEDs, in figure 2.8; it gives the 1N914 (supposedly the same as the 1N4148) as ramping up to

about 30 mA at something like 0.7 volts.

I measured some points on the curve in the Gimp. 0V is 97 pix and 1 V is 240 pix and 2 V is 384 pix, for 143 or 144 pixels per volt; 5 mA is 374 pix, 10 mA is 301 pix, and 15 mA is 230 pix, for about 144 pixels per 10 mA. So using the formula ((x - 97) / 143.0, (301+144-y) / 14.4) we can transform points measured on the curve with Gimp's crosshairs; we get 0.48 V, 0.1 mA; 0.59 V, 0.6 mA; 0.66 V, 1.4 mA; 0.71 V, 2.5 mA; 0.75 V, 5 mA; 0.79 V, 7.8 mA; 0.80 V, 10.3 mA; 0.85 V, 20 mA; 0.86 V, 30 mA.

This suggests that, at some temperature, a voltage wiggle between 0.59 V and 0.66 V (70 mV) will result in a current wiggle of 0.8 mA (11.4 mʊ̄); a voltage wiggle between 0.66 V and 0.71 V (60 mV) will result in a current wiggle of 1.1 mA (18.3 mʊ̄); a voltage wiggle between .71 and .75 V (40 mV) will result in a current wiggle of 2.5 mA (63 mʊ̄); a voltage wiggle between .75 and .79 V 2.8 mA (70 mʊ̄); between .79 and .85 V 12.2 mA (200 mʊ̄); and presumably continuing from there.

(This amounts to a factor of 5 increase in current over 270 mV, from 590 mV to 860 mV, which would be an increase by a factor of e every 168 mV, not evey 25.3 mV.)

Let's leave aside the delicate question of biasing the circuit to 0.48 V or 0.59 V or whatever rather than 0.45 V or 0.65 V, which are points that shift with temperature. Let's suppose it's feasible.

The thing I'm not sure about here is that I feel like we don't really get a place with more or less rectification along this curve. As long as dI/dV keeps growing exponentially, an AC waveform of some fixed voltage will always have less conductance on its lower half, in fact by always exactly the same ratio, so it will always be the same percent rectified, leaving aside frequency-dependent effects like reverse recovery time. But I guess that if we put a resistor in series with the diode, the resistor-diode series unit will gradually become more symmetric as more of the voltage is across the rectifier. And of course diodes have their own internal resistance, which has the same effect, even if it isn't visible from the curve there yet.

Again I am feeling skeptical about amplification, though. At 800 mV DC and 10.3 mA, the control signal costs 8.2 mW. If we are switching a 120 mV p-p RF waveform, which turns out to be roughly 17 mA p-p, are we really getting amplification? It's dissipating only about 0.25 µW in that diode... but maybe we can rectify that to about 6 or 7 mA DC and run it through two or three volts of other diodes in series (three or four diodes) as a control signal? Or pump it up to 1600 mV in a 13-stage Cockcroft-Walton generator?

The thing that's confusing me here is that I confuse the energy *dissipated within* the device with the energy *controlled by* the device. In theory we could be driving those 17 mA ac (rms) through any number of other diodes in series; but I don't have a clear idea as to how.

By contrast, it's totally clear to me that the mechanism of reverse bias and reverse recovery time exploited by Yapo provides amplification: the energy to maintain a diode in reverse bias is just the energy to replenish the leakage current — for the 1N4148 that's 10 nA at 20V reverse bias, which would be 200 nW, and less if you're only reverse-biasing it to 2V or so — and the energy to maintain it at DC ground is zero. But if you put a 125MHz sinewave at 1V RMS across it, it will pass it almost without resistance when it's not back-biased,

but block it when it's reverse-biased. This gives you near-infinite power gain, like a MOSFET.

(Yapo is actually using the 1N4148 for his high-speed rectifier and a 1N4007, a hefty power rectifier diode, as his switch, because he's using only 4.5 MHz as his RF frequency.)

I think I have a clearer idea of how much power you can control with such a switch now. Consider a switch with some resistance in general. When its output is shorted, it's controlling no power, because there is no voltage across the load; similarly when it's open-circuited, because there is no current through the load. As we add conductance starting from an open circuit, the current starts to creep up, but since the current causes some voltage to be dropped across the switch, the voltage across the load starts to fall. Load power is at its maximum when precisely half the voltage is across the load, and as we move further toward a short circuit, although current continues to increase linearly with the conductance, power starts to drop. The overall shape is a parabola; this is easily visualized as being the product of two linear ramps, one from zero current at open circuit up to the current from the switch's conductance at short circuit, the other from zero voltage at short circuit up to all the voltage at open circuit. Those are the roots of the quadratic, from which it immediately follows that its extremum is halfway in between.

Things get a little more complex when the switch impedance is partly imaginary, but I think the difference is relatively small, not orders of magnitude — except of course that the switch doesn't dissipate power from the imaginary part of its impedance.

So the power that a switch can control to a load is at or near its maximum when the switch itself is dropping the same amount of voltage. So, for our example earlier, if the part of our waveform across the switching diode is 120 mV p-p, it could have another part across the load of another 120 mV p-p for optimal power, which means that at 17 mA p-p it can be delivering uh 0.354^2 120 mV 17 mA = 0.255 mW of power to that load, just as it's dissipating in the switching diode, about 3% of the DC bias current. So, basically, no, that part of the curve will not work for amplification.

Yapo's "diode-diode logic" design, by contrast, reverse-biases the switching diodes to empty out a generous depletion region around the junction in order to block the RF energy. This is essentially static — a 1N4007 can, according to Vishay's datasheet, carry 1000 mA forward and presumably an even larger amount as RF, and leaks 5 μA when back-biased to 1000 V. At the -15 V of Yapo's design, according to Yapo's "DDL01 DDL Hex NOR Gate" datasheet, it should presumably be more like 75 nA of bias current and 1.13 μW, while the 12 Vpp RF ends up as 4.2V RMS at something like 8 mA, which works out to 34 mW, about 30 000 times larger. Nevertheless, the circuit barely works — he had to resort to two stages of amplification per gate and over 20 components, including inductors, and supports fanout of up to about 5.

Notes on Óscar Toledo G.'s bootOS

Kragen Javier Sitaker, 2019-10-07 (updated 2019-10-08) (28 minutes)

Recently Óscar Toledo G. released bootOS, an MS-DOS-like operating system with a built-in filesystem and hex editor; it provides some basic OS services and can launch programs, and fits entirely into the 512-byte boot sector of a floppy disk.

Background

The author is a wizard from a secretive underground society of wizards known as the Familia Toledo; he and his family (it is a family) have been designing and building their own computers (and ancillary equipment like reflow ovens) and writing their own operating systems and web browsers for some 40 years now. Unfortunately, they live on the outskirts of Mexico City, not Sunnyvale or Boston, so the public accounts of their achievements have been mostly written by vulgar journalists without even rudimentary knowledge of programming or electronics.

And they have maintained their achievements mostly private, perhaps because whenever they've talked about their details publicly, the commentary has mostly been of the form "This isn't possible" and "This is obviously a fraud" from the sorts of ignorant people who make a living installing virus scanners and pirate copies of Windows and thus imagine themselves to be computer experts. (All of this happened entirely in Spanish, except I think for a small amount which happened in Zapotec, which I don't speak; the family counts the authorship of a Zapotec dictionary among their public achievements.) In particular, they've never published the source or even binary code of their operating systems and web browsers, as far as I know.

This changed a few years back when Óscar Toledo G., the son of the founder (Óscar Toledo E.), won the IOCCC with his Nanochess program and four more times as well. His obvious achievements put to rest — at least for me — the uncertainty about whether they were underground genius hackers or merely running some kind of con job. Clearly Óscar Toledo G. is a hacker of the first rank, and we can take his word about the abilities of the rest of his family, even if they do not want to publish their code for public criticism.

I look forward to grokking BootOS in fullness and learning the brilliant tricks contained within! Getting a full CLI and minimalist filesystem into a 512-byte floppy-disk boot sector is no small achievement.

It's licensed under the two-clause BSD license.

The significance of bootOS

If you have a PC with BIOS and a floppy disk, but no software and no other computer, you have a paperweight, because you have no way to program it. bootOS is sufficient to program it, albeit in hexadecimal machine code, and to store your programs on the disk so

that you don't have to start from scratch every time the machine loses power. And it's close to the bare minimum amount of software to provide a programming environment you could actually use.

A brief listing of bootOS in octal

Here's `od -b os.img`:

```

Some commentary

It would be remiss not to mention that Toledo has written and self-published a book about this kind of programming.

Cold-boot code

```
061 300  216 330  216 300  216 320  274 000 167
```

This is `ax ^= ax;  ds ← ax;  es ← ax;  ss ← ax;  sp ← 167 000`. Presumably this means the BIOS doesn't reliably set the segment registers or stack pointer to sensible values, and that it loads the boot sector with a CS of 0. Also presumably there should be a cli/sti pair protecting the last couple of instructions.

```
374  276 000 174  277 000 172  271 000 002  363 244
```

This is memcpy (`rep movsb` — 363 244) of 002 000 bytes (in cx, register 1) from 174 000 (in si, register 6) to 172 000 (in di, register 2) with ascending addresses (374, `cld`); this copies bootOS itself, as explained in the comments in the source. BIOS loads programs at 174 000 (0x7c00) and perhaps bootOS wants to load programs in the same place so that if a program is written to run as a boot sector it will still run under bootOS.

After this point, everything can assume bootOS is in place at 172 000.

```
276 354 173   277 200 000   261 006   245   253   342 374
```

This loop sets up the interrupt vectors, each of which is 4 bytes, IP then CS, starting at address 000 200. bootOS uses a separate interrupt vector for each system call, unlike MS-DOS and the BIOS; MS-DOS does provide a deprecated int 0x20 (040) to exit a program, and bootOS uses this same number for its own warm-boot system call. (bootOS programs exit by warm-booting, like CP/M programs.)

This loads register 6 (SI) with the address of the six interrupt vectors toward the end of the boot sector, at 173 354, then register 7 (DI) with the interrupt vectors, and CL with the number 6. (We're justified in assuming CH is 0 because we just got here from the rep movsb above.) Then 245 (movsw) copies 16 bits from [SI] to [DI], incrementing both pointers, and 253 (stosw) stores 16 bits from AX, which is still 0 from the 061 300 instruction at the beginning of the program, so all the CS fields of the interrupt vectors will be 0, as they should be.

`ver` command

```
276 274 173   350 106 001   315 040
```

This is actually the code for the "ver" command; it's placed here so that, now that we're done with the 35 bytes of system initialization code that set up the interrupt vectors, we display the version banner before displaying the prompt (by warm-booting with 315 040, int 0x20). 173 274 is the address of the ASCIZ string "bootOS" below (142 157 157 164 117 123 000), and 001 106 is a PC-relative call offset to the `output_string` routine below (254 315 042 074 000 165 371 260 015 315 042 303).

CLI

```
374   016 016 016   037 007 027   274 000 167
```

That's the warm-boot code, invoked by 315 040 — it runs CLD (374) and copies CS (loaded from the interrupt vector if necessary) into DS, ES, and SS via the stack, and then resets the stack pointer. This seems a little hazardous to me — if you suspect SS or SP may be pointing somewhere random, I'd think you wouldn't want to write to the stack. Also I'd think you'd want to have interrupts disabled.

Interestingly, this sequence is two bytes shorter than the cold-boot sequence that does the same thing using AX, but that sequence also

clears AX. At this point AX may have crap in it, which has consequences for the loop over built-in commands below.

Even though it's usually invoked by an interrupt instruction, it never returns from the interrupt, and since it forgets where the stack pointer was pointing, it can't.

```
260 044  350 006 001
```

This sets AL to 044 '$' and calls `input_line` with a PC-relative call. So now we are well and truly into command-line handling.

```
200 074 000  164 354
```

This is a special case for empty commands so you can hit Enter at the prompt and not get an error message or run a file whose name is the empty string; it's checking to see if the first byte in the buffer pointed to by SI is a NUL.

```
277 310 173
```

This sets register 7 (DI) to 173 310, where there's a list of built-in commands, each followed by its address.

```
212 005 107 045 377 000 164 021  221 126 363 246 165 004  377 025 353 327
    001 317 107 107 136  353 347
```

This is a loop over the built-in command names. We have DI pointing to a length-prefixed command name and SI pointing to the (non-length-prefixed!) command line. First we load AL (low register 5?) indexing 0 with DI, then increment DI (107: register 7). To see if the length byte was 0, we use 045 377 000, ANDing AX (register 5) with 000 377, which would seem like a strange way to write `test al, al`, but remember that AH may still have crap in it, and shortly we are going to use all of AX as the count for a `rep` prefix. In the case that the length byte was 0, indicating we've come to the end of the command list, we jump 021 bytes (164 021) and out of the loop, to the next code following; but if not, we 221 (`xchg ax, cx`), save SI with 126 (`push si`) and use `rep cmpsb` (363 246) to compare the command name. (The comparison uses ascending addresses because we ran `cld` at the top of the warm-boot code, and nothing clears it.)

If the command name didn't match (and note that this is a prefix match!) we jump 4 bytes to the second line of the loop above with 165 004. But if it did, it does an indirect call via DI (377 025) which has now been incremented off the end of the command name, and then does an unconditional jump up to the warm-boot code above.

On the second line of the loop, DI is pointing somewhere into the middle of the command name, where we found a mismatch. To correct this, we add the leftover counts in CX to it with 001 317 (`add di, cx`, CX being register 1 and DI being register 7), increment DI twice (107 107) to step over the command handler address, 136 (`pop si`, register 6) to recover from the earlier 126, and jump 031 (=25) bytes backwards to the beginning of the loop to try another command.

Note that if we do invoke a built-in command due to this prefix match, we do so without restoring SI — so SI points to the text after the command, so it can take arguments.

You'd think that maybe switching the roles of SI and DI would make sense here, since the beginning of the loop is basically `lodsb` but with DI, but it might not save you enough to be worth the swizzling.

```
211 363  277 000 174  315 043  162 002  377 343
```

So now that we've exhausted the possibilities of built-in commands, let's try to load a file to handle the user's command. We have an ASCIZ string at SI, which we transfer to BX (211 363), then load a buffer address (174 000, the boot sector loading address) into DI, and then invoke the load-file interrupt (315 043). This routine indicates errors by setting the carry flag, so if that's set, we jump forward two bytes (162 002) to the next line; otherwise, we do an indirect jump through BX (377 343).

Although this has the same opcode byte 377 as the indirect call above, it really is a jump and not a call; nothing is left on the stack. So the newly launched program must return control to bootOS via the warm-boot interrupt or not at all.

```
276 303 173  350 003 001  315 040
```

This puts 173 303, the address of ASCIZ "Oops", into SI, then calls the `output_string` routine with a PC-relative call; then it warm-boots.

And that's the whole CLI loop: 67 bytes, including the warm-boot code. Everything that follows is subroutines and data; the bulk of it is the filesystem.

Commands, system calls, and the filesystem

These layers are kind of mixed together, which is probably somewhat unavoidable within the 512-byte limit; some orderings can allow you to use short jumps, too, or (as with the `ver` command above) omit jumps and just use fallthrough.

`del` command

```
211 363  254  074 040  164 371  315 045  162 355  303
```

That's the "del" command; it just invokes the deletion interrupt routine. It starts out with 211 363 `bx ← si`, which is presumably because the `delete_file` call takes its argument in BX, not SI.

Then it has a five-byte loop 254 `lodsb` 074 040 `al == ' '` 164 371 `jz $-7` which skips over spaces, overwriting BX again if necessary. This arrangement was somewhat puzzling to me at first, since you'd think it would make just as much sense to set BX once, outside the loop, once we really knew what we wanted to set it to (the position after we've skipped over the spaces). This doesn't really matter for efficiency, but it puzzled me that it was done in this non-obvious way. Eventually I realized that this repeat-until loop topology leaves BX with the *unincremented* value of SI. (This of course means that there would be no advantage to making `delete_file` take its argument in SI.)

Once that is achieved, it invokes the `delete_file` system call 315 045, reports any errors by jumping into the CLI loop's error handler if the carry flag is set 162 355, and then 303 returns.

`dir` command

```
350 240 000  211 337   200 075 000  164 005  211 376  350 346 000
    350 156 000  165 361  303
```

First this calls `read_dir` below with a PC-relative call. `read_dir` overwrites bx with the pointer to the disk sector in memory, and the next instruction 211 337 is `di ← bx`.

The rest of the function is a loop followed by 303 `ret`; the main body of the loop is 211 376 `si ← di`, 350 346 000 `call output_string`, and 350 156 000 `call next_entry`. `next_entry` advances di to the next directory entry and sets the carry flag if it's passed over the whole directory — and, implicitly, the zero flag if it has. 165 361 is a jump conditional on the *zero* flag, back to the beginning of the loop. (This suggests that the `stc` instruction in `next_entry` could be eliminated by making all of its callers use the zero flag instead of the carry flag — unless there's someplace where the *BIOS* disk routine's use of the carry flag to indicate errors is propagated to the caller.)

`next_entry` does not skip empty directory entries, so before the loop's main payload, `dir` does a 200 075 000 `byte[di] == 0` and a 164 005 to jump past the loop's main payload to the `next_entry` call in that case.

This compact code is enabled by the fact that `output_string` and the directory entries both use ASCIZ strings; it would be even more compact if `output_string` were to use `di` rather than `si` to point to its string.

opendir (filesystem routine)

```
126  061 311   254  101  074 000  165 372   136  277 000 170  303
```

In the source code this is called `filename_length`, but I thought that was somewhat misleading. It does count the length of the ASCIZ filename at SI (in CX), using 254 `lodsb` 101 `cx++` 074 000 `al == 0` 165 372 `jnz .loop`, rather than using `scasb`, for reasons I don't yet understand; around this it wraps a 126/136 pair to preserve SI (register 6). But it *also* sticks the pointer to the disk sector buffer `read_dir` uses into di: `di ← 170 000` before 303 returning, presumably because that value in di was useful in more than one filesystem routine.

load_file

```
127  006  350 100 000  264 002
    007  133  162 003  350 204 000
    211 345  320 126 004  317
```

This is an interrupt routine, so it returns with 317 `iret` rather than the usual 303. Moreover, it actually has three separate entry points: `save_file` merges with it at the beginning of the second line (`shared_file`), while `delete_file` merges with it at the beginning of the third line (`ret_cf`).

`iret` restores not only CS and PC (uh, "IP") off the stack, but also the flags? This means that `load_file` and its brethren need to mutate the saved flags in order to achieve this with `rcl byte[bp+4], 1` (320 126 004), having previously pointed bp at the stack with 211 345 `bp ← sp`. This presumably has the bizarre effect of shifting one byte of the flags register by 1.

XXX

save_file

```
127 006 123 315 045 133 350 325 377
    046 200 075 000 164 007 350 067 000 165 365 353 335
    127 363 244 350 132 000 137 350 062 000 264 003 353 317
```

delete_file

```
350 012 000 162 321 271 020 000 350 103 000 353 311
```

find_file

```
123 350 067 000 136 350 245 377  126 127 121 363 246 131 137 136 164 017
    350 003 000 165 361 303
```

next_entry

```
203 307 020 201 377 000 172 371 303
```

get_location

```
215 205 020 210 261 004 323 340 100 221 303
```

format command

277 000 170 271 000 002 350 014 000 273 000 172 111 353 022
```

This has a short jump at the end of it (a tail call, say) that would have had to be long if it had been more than 128 bytes from the target.

read_dir

```
016 007 264 002 353 006
```

write_zero_dir/write_dir/disk_dir/disk

These four entry points are connected by fallthrough to save space.

```
260 000 363 252  264 003  273 000 170 271 002 000
    120 123 121 006 260 001 061 322 315 023 007 131 133 130 162 360 303
```

input_line

```
315 042 276 200 167 211 367  074 010 165 002 117 117
    315 041 074 015 165 002 260 000  252 165 357 303
```

input_key/output_char

```
264 000 315 026  074 015 165 006  260 012 315 042 260 015
    264 016 273 007 000 315 020 317
```

output_string

```
254 315 042 074 000 165 371  260 015 315 042 303
```

`enter` command

This is the hex editor. For some reason I don't seem to be getting it to work in QEMU; I don't know if I'm using it wrong and it's not giving me an error message, if it's buggy, or if QEMU is buggy.

```
277 000 174  127 260 150 350 274 377 137 200 074 000 164 022
    350 034 000 163 357 261 004 322 340 221 350 022 000 010 310 252 353 356
    260 052 350 237 377 126 133 277 000 174 315 044 303
```

xdigit

This function is partly necessitated by the choice of hexadecimal, but it also skips spaces:

```
254 074 000 164 015 054 060 162 367 074 012 162 005 054 007 044 017 371  303
```

Data tables and the trailer

A couple of ASCIZ strings, "BootOS" and "Oops":

```
142 157 157 164 117 123 000
117 157 160 163 000
```

Then the table of built-in commands and their absolute addresses:

```
003  144 151 162               172 172
006  146 157 162 155 141 164   016 173
005  145 156 164 145 162       173 173
003  144 145 154               156 172
003  166 145 162               043 172
000
```

Finally, the table of interrupt vectors:

```
053 172  131 173  135 173  235 172  261 172  325 172
```

Then filler and the boot-sector signature 125 252:

```
117 117 117 117 117 117  125 252
```

Examination of a shitty USB car charger

Kragen Javier Sitaker, 2019-10-24 (13 minutes)

I found a car-cigarette-lighter USB charger on the street with a missing contact spring and some broken plastic. It's labeled as having one 1-amp USB port and one 2.1-amp USB port, although in fact these are wired strictly in parallel. It's fairly transparently a simple buck converter on a single-sided PCB (silkscreened "HT-668"), built around a buck-converter through-hole 8-pin chip labeled "LC51", followed by some kind of fraction-like sigil. There is some residual flux from sloppy hand soldering on the bottom of the board.

"LC51" is not a useful marking for finding the correct datasheet on search engines; it turns up many datasheets for chips used in this application but they all have the wrong pinout.

Circuit netlist and pinout reverse engineering

C1 is a 22-µF 25-V electrolytic across the nominally-12-volt input, with its - terminal on pin 4 of the IC and its + terminal on pin 6. L1 is an unmarked ferrite-core inductor across pins 2 and 3, and "D1" (with the "1" silkscreened upside down) is what looks like an ⅛-watt rectifier (labeled, I think, "N5 MI") across pin 4 (ground) and pin 2 (the stripey end of the diode package). "CS" is a 100-µF 10-V electrolytic on the output, which is connected to pins 4 (on its - terminal) and pin 3. There is a blue LED connected across pins 4 and 5. Pins 1 and 7 are shorted to pin 6. The USB connector shield is tied to pin 4.

Amusingly, there are no resistors.

So I infer the following pinout for the chip:

- 1: Vin
- 2: switched Vout
- 3: feedback sense
- 4: ground (common between input and output)
- 5: current-regulated? power LED indicator output
- 6: Vin
- 7: Vin
- 8: no connection

Except for the indicator LED, this is a textbook buck converter circuit. It seems strange to me that there are 3 pins for Vin and only 1 pin for Vout, but I guess most of the output current (7/12 at nominal 12V input) really flows through the diode and not the chip. Still, one would hope that the amount of current flowing to ground through the chip's internal circuitry is at most a few milliamps, not hundreds of them, so you'd want the same number of input and output pins.

Observed behavior

None of the components have any visible damage, but on connecting it to a 12-volt power supply sourcing an amp or two to a

LED illumination panel connected in parallel, the onboard blue LED lights up, but there is no 5-volt output. None of the components heat up noticeably.

After unplugging, some residual voltage is visible on both capacitors, tens to hundreds of mV, so they are not shorted.

The diode reads as a 170-mV voltage drop with this multimeter a friend lent me, but I'm not sure how correct that is. That seems too low to be a working diode. But in the other direction it looks like an open circuit, so I suspect the meter. However, unless I'm reading this wrong, the meter is telling me not only that the diode has an implausibly low forward voltage drop but also that it is installed backwards, i.e., passing current in the +5V-to-ground direction. Maybe the diode is blown and the voltage I'm seeing is actually from reverse-biasing the output electrolytic, or some kind of input protection circuit in the SMPS chip itself?

Design commentary

If we assume that the ⅛-W rectifier diode is a 300-mV Schottky, then it can carry an average of 417 mA, which means that the whole board can only supply 12/7 of that — 714 mA — without overheating the diode. So the "2.1 A" output rating molded into the plastic is probably unreasonably optimistic. There is also nothing connected to the data pins (two of them may be shorted together, but this looks like an accident) so no smart current negotiation can be going on here, but even without current negotiation, you could plug two 500-mA devices in at once, which would mildly overheat the diode.

It probably isn't really okay to use a 25-volt electrolytic on the input of this charger, either, because car electrical systems are reputed to have inductive spikes that go higher than that. You'd probably be okay if you never left it plugged into the cigarette lighter when the car was turning on and off.

So the design seems a bit dubious.

Most of the chips that come up in the "LC51" datasheet search use fixed-frequency oscillations in the tens to hundreds of kHz. Maybe if I hook this up to a voltage source I could observe its oscillation frequency.

I don't know the inductance of the inductor, so I don't know how fast its voltage would ramp up and down, but at 1000 mA difference between input and output you would drain the output 100-µF capacitor from 5 V down to 0 in 500 µs, and from 5 V down to 4.5 V (which I am inferring is probably about the limit of the acceptable voltage deviation, although I don't remember from the USB spec) in 50 µs. So it seems like a fair bet that the chip's designed oscillation frequency is at least a few tens of kHz to keep the thing from falling over without a larger output cap.

The inductor presumably needs to be able to ramp its current up and down between 0 and 1000 mA over a similar time period — otherwise it wouldn't be able to respond fast enough to things being plugged and unplugged. So a sensible inductor size would be in the neighborhood of 50–100 µH. When the chip's switched output pin is floating, the inductor has to maintain some significant fraction of its ≈1000 mA against ≈4.7 volts (the 5 volts of the output capacitor minus the presumably 300 mV of the rectifier) for ≈50 µs, which would require at least 250 µH or so. When the

chip's switched output pin is high, the inductor's current would have to be able to ramp up from 0 to ≈1000 mA when driven by ≈7 V (12 V - 5 V) in ≈50 µs, which would require no more than 350 µH. In practice the frequency is probably considerably higher, so the time period is probably more like 5–10 µs, with a correspondingly smaller inductance.

(But there's no guarantee that they did in fact use a sensible inductor size.)

If the inductor were 100 µH, the LC time constant $\sqrt{(LC)}$ would be 100 µs. I think the resonant frequency is $1/(2\pi\sqrt{(LC)}) \approx 1.6$ kHz, so it is surely much lower than the frequency being used.

Presumably its feedback pin is divided down internally and compared to a temperature-compensated internal bandgap reference; this feedback (plus rectifier and capacitor leakage currents) is the only open-circuit load on the power supply, and so it might be designed to be a heavy enough load to maintain regulation when nothing is plugged into it. The chip, though it's a through-hole DIP, is a super tiny through-hole DIP, and although its package seems like ceramic rather than epoxy, it's probably not capable of dissipating more than ¼ W, which implies a maximum current of 50 mA into the feedback pin, and probably more like 5 mA.

Prospects for hacking

These are probably obvious, and maybe a bit goofy given that the thing is apparently broken.

Presumably the duty cycle of the chip's switched output is variable from under 10% to at least 50% (probably 100%), and this is controlled by the voltage detected on the feedback pin. By cutting a trace on the board and hooking up the feedback pin to the center tap of a pot between the output and ground, it should be straightforward to get a more or less regulated, temperature-compensated output from 5 V up to at least 50% and probably 95+% of whatever the input voltage is; I've inferred that the current through the internal feedback divider is probably several milliamps in order to satisfy the minimum-load requirement of the internal circuitry, so the current through the pot would probably need to be tens of milliamps if you want it to be very precise. But that would imply a pot < 1kΩ, which would be hard to find.

Lower output voltages would require pulling the feedback output up toward some higher voltage. The simplest approach might be to totally fake the feedback — hook up a variable voltage divider across the input that lets you generate a voltage somewhere around 5 V to feed to the feedback pin, and use an external resistor to fulfill whatever minimum-load requirements the switcher has. That might work, but depending on the feedback scheme, it might always rail at Vout = 0 or Vout = Vin. Including some of the real output voltage in the summing junction should make it possible to stabilize it in such cases. Any of these schemes depend on a regulated input voltage, since the divided input voltage is going to be compared against its internal bandgap.

You might be able to get a regulated output current rather than voltage by the usual trick of floating the circuit's ground at a distance below its filtered output determined by a current-sensing resistor in series with that filtered output. For example, if you want to set the

output to 100 mA, you'd use a 50-Ω resistor. I'm not sure the circuit will start up properly in this situation, though, and because there's 5 volts across the resistor, it's potentially going to burn up a lot of power.

Soldering in a bigger diode would probably enable higher output powers, although without current negotiation, compliant USB devices will not really take advantage of that. Amplifying the output with a large output transistor to get tens of watts of output power might be a fun thing to try, too, though at the cost of losing the overcurrent protection presumably included in the chip.

If the output frequency is fixed, a resonant LC notch filter or two across the output should be able to attenuate the EM noise from the switcher by 20 dB or so.

Presumably you should be able to use the chip as a decent class-D audio amplifier by adding the audio input signal into its feedback pin in order to modulate its output voltage, which, as I said above, needs to be able to respond across the whole audible spectrum in order to avoid output overvoltage when you unplug USB devices. It should be able to output 5 watts or more of output at efficiencies of around 90% into impedances in the usual 4–8 Ω range, but you will need an ac-coupling capacitor on the output to avoid a humongous 5-V dc bias on the speaker output.

Depending on what the output frequency actually is, and whether it's fixed or variable, you might also be able to use it as a micropower AM or FM radio transmitter if you bias the audio input into the right range (and add in the appropriate fraction of the filtered output voltage, if necessary) on the feedback pin. Even if the baseband output frequency isn't in the right band, one of its harmonics may be, and by finely adjusting the duty cycle you can finely adjust the harmonics' amplitudes. (See Processing halftoning (p. 915) for some notes on this in the spatial domain.)

Giving Golang a second look for writing a mailreader (in 2012)

Kragen Javier Sitaker, 2012-12-17 (updated 2013-05-17) (2 minutes)

In 2012, starting again with golang.

• The email address parsing functionality is a little tied into the email system; you apparently have to make a fake header.
• go doc is pretty cool, but looking at the actual library source is even better in most cases.
• Type equivalence is by name, so even if a mail.Header *is* just a map[string][]string, you still can't mutate it. But you can construct a new one.
• for x := range somearray makes x range over the indices of somearray, not its values. You want _, x :=.
• How do you find the length of an array? Oh, Pythonwise, len(array).
• Okay, so suppose I want to do the equivalent of this Python:

```
def main(outbox, inbox):
    important_senders = recipients(outbox)
```

I guess I need to be able to open the outbox file and accumulate stuff in a map. Hmm, isn't there a thing about named return values? How does that work? Oh, (name type, name type, name type) after the argument list.
• How do I open a file? os.Open.
• How do I print messages to stderr and return failure from main? Looks like log.Fatal does that, and even log.Printf prints to stderr. (Presumably fmt.Printf doesn't.)
• Now that I have the file open, how do I get messages from it? Looks like the file is already an io.Reader, so I'm good.
• Hmm, now it seems like I'm suffering from email parsing problems, from apparently trying to parse a header starting in the middle of a subject line. I guess I need to read that message body.
• But hmm, io.Reader.Read(p) reads up to len(p) bytes. How do I make a slice (?) that I can pass in there? (Looks like make([]byte, 16).) Oh, there's an ioutil.ReadAll? That solves the problem. But now I still have no addresses! ... Also related to problems like these: bufio.NewReader(os.Stdin) and r.ReadString("\n").
• Oh, hmm, this is just message parsing, not mailbox parsing. I still have to do mailbox parsing myself, and provide an io.Reader interface? Well, there's an io.LimitReader in the library.
• Cool, the I/O 2011 talk mentions an SDL binding for Go.
• Looks like the email message parsing chokes on this:

Running your regular desktop in QEMU?

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

So I've been playing with QEMU, which lets you run a virtual computer inside your normal computer. At the moment I'm using it to create a reproducible development environment on a project I'm working on.

Among QEMU's features is the ability to save a virtual machine snapshot, which includes the entire state of the virtual computer: memory, CPU, even disk. This seems similar to KeyKOS's checkpointing facility, although it seems to be a bit slower, maybe to the point of being less useful. (It seems to do all of its I/O before continuing to run, rather than doing some kind of copy-on-write. It seems like fork() might be sufficient to get good copy-on-write performance.)

(In one case, a VM snapshot of a 128MB VM took 53MB of space.)

But suppose you ran your normal GUI session inside of QEMU. Maybe every few minutes, you could do a backup of your live session to a server somewhere nearby.

Benefits

If you do this, you can transport your GUI session from one machine to another --- something the term "VNC", an abbreviation for "Virtual Network Computer", promised but never delivered. If your machine ever crashes or gets stolen, you can restore from the previous checkpoint; sometimes this might be worth doing even if only a single application within it has crashed. And you can have a large number of GUI sessions for different users in suspended animation on your disk.

This kind of thing could give users in, for example, an internet cafe, the freedom to really customize their environment. Rather than storing all of their state on a web site, they could store much of it on the servers at the internet cafe itself, as if they owned it. They could install software, keep their files, and so on; and whenever they came into the cafe, their session would be waiting for them, just as it was when they left it.

Problems

There are a lot of times these days where you'll want to run stuff that doesn't run very well inside QEMU: MPlayer, Art of Illusion, anything with SSE, MMX, or 3-D acceleration. I think that's kind of a minor problem, since the data involved in that part of the system (the latest frame of a movie, say) is usually quite transient and easy to recreate.

Also, it's not uncommon these days for a GUI session to fill up gigabytes of RAM, and all of that RAM could in theory change its contents about once a second. So you still might end up copying all or the vast majority of the memory pages during a snapshot.

Schimmler parallelism asymptotic gain

Kragen Javier Sitaker, 2007 to 2009 (1 minute)

In Dan Bernstein's grant proposal to the NSF from 2001, Circuits for Integer Factorization: A proposal, he writes:

A philosophical note. I always thought that common general-purpose computers were the pinnacle of realistic computational power. Special-purpose computer architectures, such as Lehmer's bicycle chain sieve or Pomerance's Cracker or Shamir's TWINKLE, were at best a constant factor faster. Quantum computers are asymptotically faster for many computations, but it is unclear whether they can actually be built.

I also thought that parallel computing reduced the *time*, not the *cost*, of computations. Ten processors might perform a computation in one tenth the time of a single processor, but they are ten times as expensive, so the cost of the conmputation remains the same.

I was wrong. Schimmler's machine, with m^2 processors, can be built for $m^{2+o(1)}$ dollars, just like a single-processor computer with $m^{2+o(1)}$ bits of memory. It can sort m^2 numbers in time $m^{1+o(1)}$, while the single-processor machine needs time $m^{2+o(1)}$. The cost of the computation has dropped from $m^{4+o(1)}$ to $m^{3+o(1)}$.

I have a hard time believing this, but Bernstein is pretty reliable; maybe I should go back and read more about Schimmler's machine.

Passive ultrasound sonar

Kragen Javier Sitaker, 2016-12-28 (1 minute)

Up to a quarter megahertz, ultrasound attenuates in air at about 20dB/ft/MHz, which is 66dB/m/MHz. The Airy limit is $\sin\theta = 1.220\lambda/D$ for a circular aperture. Mach 1 is 331 m/s.

Could you do passive ultrasound sonar at a reasonable resolution? At 100kHz you have 6.6dB/m of attenuation, so you only have about 20 meters of range where a detectable amount of sound is going to reach you. λ = 3.3 mm, so the Airy limit for a 100mm aperture is 0.040 radians, about 2.3 degrees. You'd need a much larger aperture to get close to the theoretical far-field limit of what 100kHz could resolve.

At a higher frequency, like 1MHz, you only have a couple of meters of range, so you'd have to get super lucky to have an ultrasound source in range. 1MHz in air has a 330-micron wavelength, so your limit would be 4.2 milliradians, about a quarter of a degree, and then you really could see stuff with subcentimeter resolution at a meter of distance or so. But in practice you probably need an active ultrasound source for that.

Topics

Constant-space grep

Kragen Javier Sitaker, 2014-02-24 (3 minutes)

Grep reads an input file consisting of arbitrary-sized lines and outputs those lines which contain a given pattern. Related utilities like mboxgrep and glimpse do a similar job. One thing they all have in common is that when they reach the beginning of a new line (or other record), they do not yet know whether that line will be output or discarded; and they may not know until reaching the end of the line.

Two simple approaches to this problem are to limit line length and to allocate memory dynamically. Limiting line length is practical, but the arbitrary limit produces problems later on when you run into it. Allocating memory dynamically is also practical, but can use arbitrarily large amounts of memory.

But the problem can be solved in constant space, for different kinds of constant space, with different degradations of the usual grep features.

Sequential-access read-only rewindable input

If your only writable memory is small, but the input file is stored and seekable, the best you can do is to keep track of how many bytes you are into the current line, and rewind the input back to the beginning of the line ("record") when you find a match. This requires, in the worst case, one seek for every record in the input file, and two reads of every byte.

If the input file isn't even stored, grep is impossible, because computing the first output line can require an arbitrarily large amount of data to be stored.

Two sequential-access bidirectional temporary files

With two tape drives, you can solve the grep problem as follows, although you lose grep's normal pipeline promptness. Each record from the input is copied into a temporary file T1, followed by its length and a boolean carefully whether it contains a match or not. Then, we read T1 backwards, copying the matching records (in reverse order) onto a second temporary file T2. Since we're reading it backwards, we read the boolean before each record, so we know whether to copy it or not. Finally, we read T2 backwards, copying its contents to the output.

Under some circumstances, the file T2 itself (the backwards grep output) might be adequate as output to the next stage; in those cases, we can make do with a single sequential-access bidirectional temporary file.

Two sequential-access unidirectional temporary files

In this case, we copy the input records into a temporary file T1,

while writing match booleans to a second, much smaller, temporary file T2. Then, we rewind both and read them sequentially and in parallel, using the match booleans from T2 to tell us which records to output from T1.

Ice pants

Kragen Javier Sitaker, 2017-04-04 (updated 2019-01-22) (17 minutes)

Some people have serious difficulty with some naturally occurring levels of heat. The CEO of Singapore, Lee Kuan Yew, has credited air conditioning with allowing his (tropical) country to develop economically; and in recent years, as I age, I find myself suffering increasing levels of impairment and ill-being from the Buenos Aires summer. But air conditioning has some disadvantages. It requires large, capital-intensive machinery; it consumes a lot of energy to cool large spaces, and a lot of power to cool spaces with a lot of surface area to a hot outdoors; and it isn't portable to many places people would like to go.

Years ago I read a 2007 Mother Jones article by Dennis Gaffney about hypermilers in which the protagonist, Wayne Gerdes, sometimes wears an "ice vest", "which he uses at the nuclear plant when he has to work in really hot rooms," because, says Wayne, "You can drive at 95 degrees [Fahrenheit; 35°] with an ice vest, and it doesn't feel like 95 [35°].... No electricity, no air, no fans."

Also in 2007, my then wife, Beatrice, was suffering from the Buenos Aires summer heat in our house. I don't remember if we didn't yet have an air conditioner in the bedroom, or if it wasn't powerful enough, or if the power was going out, but she took to freezing plastic bottles in the freezer and wrapping them in a towel to snuggle up to at night, a trick which I've used to great effect ever since.

What if you had an optimized, portable version of this? Could you eliminate the need for air conditioning? What would such a design look like?

Wikipedia tells me:

> However, in situations demanding one is exposed to a hot environment for a prolonged period or must wear protective equipment, a personal cooling system is required as a matter of health and safety. There is a variety of active or passive personal cooling systems;[14] these can be categorized by their power sources and whether they are person- or vehicle-mounted.
>
> Because of the broad variety of operating conditions, these devices must meet specific requirements concerning their rate and duration of cooling, their power source, and their adherence to health and safety regulations. Among other criteria are the user's need for physical mobility and autonomy. For example, active-liquid systems operate by chilling water and circulating it through a garment; the skin surface area is thereby cooled through conduction. This type of system has proven successful in certain military, law enforcement, and industrial applications. Bomb-disposal technicians wearing special suits to protect against improvised explosive devices (IEDs) use a small, ice-based chiller unit that is strapped to one leg; a liquid-circulating garment, usually a vest, is worn over the torso to maintain a safe core body temperature. By contrast, soldiers traveling in combat vehicles can face microclimate temperatures in excess of 65 °C and require a multiple-user, vehicle-powered cooling system with rapid connection capabilities.

I think I want one of these for daily use.

Rough calculations and background

An adult human normally must consume about 2000 to 2500 kcal per day (8.5–10.5 MJ) to remain normally active without losing weight. Only athletes or people with very extremely demanding jobs

eat significantly more than this. Essentially all of this energy is converted into heat inside our bodies — either by bacteria in our intestines, by the various metabolic activities of our brain, liver, muscles, and other tissues, or by damping work done on our bodies. And there are no other significant thermal influxes under normal circumstances.

These last two points deserve some elucidation. The other day, I walked up 12 flights of stairs because the power was out in the elevator, about 50 meters. I weigh about 110 kg, so this amounted to about 54 kJ of mechanical work. Roughly speaking, as I walked up the stairs, my leg and butt muscles converted about 220 kJ of glucose and other metabolic fuels to exhaust — carbon dioxide and water — and converted about three-quarters of this directly into heat. The other one-quarter, however, was converted into the gravitational potential energy of my body.

So, you could argue, if I kept walking up stairs all day long, only about three-fourths of the calories I had consumed would be converted to heat. I could probably walk up about 900 flights of stairs in a 12-hour day of walking up stairs, at which point I would have done about 4 MJ of mechanical work and gained about 4 MJ of potential energy, and I would have expended about another 12 MJ of heat. I would be very hungry and my knees would hurt a lot.

I would also have reached an altitude of 3750 m above where I started, a bit less than climbing Mauna Kea or Mount Ranier. At some point, I would probably have to come back down, which would convert my gravitational potential energy back into mechanical energy, in my leg and butt muscles. Since my leg and butt muscles are not equipped to convert mechanical energy back into glucose, they would convert it back into heat.

(There are cases where the mechanical energy is eventually dissipated in something that isn't your body — when you go swimming or kayaking, for example, or if you're climbing a stair climber instead of actual stairs. Or if the power comes back on and you take the elevator down instead of the stairs. But these are unusual cases.)

I say there are no other significant thermal influxes under normal circumstances because when you put people in an environment where they cannot reject body heat to the environment, they die, usually in minutes to hours. So the net heat flux in a survivable situation is always from your body into the environment.

"Literature" "review"

Porticool is a brand name for a liquid-CO_2-cooled vest marketed to HAZMAT specialists and other emergency responders, developed on a DHS SBIR Phase I grant, using an open-loop system that releases 500psi gaseous CO_2 from some of the tubes running through the vest, after running it through non-porous tubes as a liquid.

While other cooling solutions (ice vests, cooled air vests and liquid circulated garments) tested have shown favorable responses, none provide the flexibility and mobility afforded by the Porticool PCS. Nor could they compete with the light weight and thin garment size that the Porticool PCS achieved.

This doesn't sound like something you could safely wear all day, if at all ever, because you'd have to be replacing the liquid CO_2 and you'd be constantly at risk of being poisoned by it. (I guess I should

calculate how much CO_2 is emitted, but I think the answer is in the range of a few kilograms or cubic meters per day, therefore liters per minute.)

The DHS published a superficial TechNote on personal cooling systems in 2013. It divides them into "passive systems" (like ice vests) which contain no moving parts and "active systems" which do, for example because they involve a circulating fluid, and therefore need a power source. (I suppose directly applying Peltier coolers would also be "active" and without moving parts, but that wouldn't be practical, so probably nobody does it.)

It mentions evaporative cooling systems with "water absorption crystals"; vests with phase-change material pockets, usually with paraffin, which last up to 2 hours; "gel or ice pack vests", erroneously implied to not be phase-change materials; "ambient air systems", which blow ambient air under your clothes; and "liquid circulating products" with vapor-compression or thermoelectric cooling, or ice, to chill the liquid. It shows a Veskimo ice-backpack-powered cooling vest as its example of this last category. Apparently ASTM F2300 is the testing standard.

In 2014, Adam Savage of Mythbusters and some other guys talked about building a cooling suit. The background is that, when he went to ComiCon in a hot costume, he was trying a gel-vest system made of "Polysorb... like probably diaper crystals" and although "it's a brilliant design" he nearly passed out from heat exhaustion because he didn't have a freezer to freeze it in previously. He said it should have been able to keep him cool for an hour if he had frozen it. He also mentions a liquid-circulating cooling shirt called "CoolShirt" which is sold for (auto?) racing, with "recirculating pumps that are too big"; he didn't think it was up to the job.

The video is a waste of time; it's just three guys talking on microphones for half an hour, and they haven't even built the suit.

The Veskimo cooling vest mentioned in the DHS report runs microtubing through a thin vest. It explains:

> NASA pioneered the use of garments employing circulating chilled liquid in the 1960's to keep astronauts cool during space walks. The design and construction of these systems are well documented. Systems of similar construction are currently in use by military personnel in aircraft and armored land vehicles. These systems are very expensive because they use compressor-based refrigeration units to chill the circulating liquid coolant. By substituting ordinary ice to chill the water, the cost and complexity of the system is greatly reduced, making Veskimo Personal Cooling Systems affordable, yet still truly effective.
>
> ...The Veskimo Personal Microclimate Body Cooling Vest is made from lightweight breathable mesh fabric that will not inhibit the evaporation of perspiration, and has a thickness of less than one-quarter inch, so it fits easily under any close fitting garment or protective gear. Its zippered front and adjustable-length elastic side straps make it easy to take on and off and adjust for best fit, comfort and the desired degree of tube-to-skin contact.

Their page also mentions "evaporative garments" usually use sodium polyacrylate crystals, like diapers, flowerpots, and maxi pads. Because apparently the Veskimo people aren't scientifically illiterate like DHS employees, they class ice vests with other "phase-change garments". They say their ice "backpack or cooler" is "typically enough for 4 hours or more".

More details on the Veskimo system:

> Approximately 8 pounds of ice can fit in our 4.4 Quart Hydration Backpack, and as much as 16 pounds in the 9 Quart Cooler. The useful heat capacity of 8 pounds of

ice is approximately 400 Watt-hours, and 800 Watt-hours for 16 pounds of ice. Studies performed by NASA and the US Military conclude that 100 Watts of cooling power is effective in maintaining body core temperature in all but the most extreme heat conditions. The Veskimo Personal Microclimate Body Cooling Vest is capable of providing over 100 Watts of body cooling. If the system and the user are well insulated from the external environment, the useful cooling duration is approximately 4 hours (400 Watt-hours / 100 Watts) for the Backpack and 8 hours for the 9 Quart Cooler System at 100 Watts cooling output. If the user wears a lightweight windbreaker-type jacket over the vest to minimize loss of cold to the atmosphere (which we recommend), these are reasonable estimates for the system's cooling performance. Some users have reported even longer cooling duration because they had their system adjusted to provide less than 100 Watts of cooling.

They run their pump on 4 watts on a 12-volt Li-ion battery. Their list price is US$1116 for the Veskimo vest and backpack, and on top of that they're out of stock, so a homemade substitute would be worth considerable work.

Pants or shorts

A possible alternative to an ice vest would be ice pants, which would be less of a weight burden (since only your legs would carry the weight, not also your back) but perhaps more cumbersome. Your legs are similar in surface area to your torso and have very substantial blood flow to them.

Peltier devices

A 100-W Peltier device is typically 10 A at 12 V and costs about US$15 retail, but you need to run Peltier elements at substantially less than their maximum rating to get reasonable efficiency; at $\Delta T = 0$ and $I/I_{max} \approx 0.3$, $Q/Q_{max} \approx 0.5$ and CoP ≈ 3.0 (that is, 3 joules of heat are removed from the cold side of the reservoir for every joule of electrical energy dissipated). So maybe the 100-W device can give you 50 W of heat rejection at 4 A (and, I suppose, very close to 12 V, since thermocouples are closely approximated as constant-voltage devices.) As ΔT rises, the CoP falls, eventually past 0 as the resistive heating effect of the current outweighs the Peltier effect.

In the case of a human in an environment that is only mildly hostile — say, 30°–40° — $\Delta T \approx 0$, so this might be a reasonable region to work in. (XXX is it actually going to be adequate to keep your skin at 30° or 35°, or is that going to result in dangerously low heat transfer rates from the body core? What skin temperature is adequate? Presumably it's about the same as the bearable air dewpoint.) CoP ≈ 3.0 means that you only need ≈30 W of battery power to reject 100 W of heat to the environment, which means that each hour of cooling consumes about 110 kJ of battery. (The energy cost of pumps and fans was 4 W in the Veskimo case, which is small compared to the Peltier devices, though not insignificant.)

An 18650 cell typically weighs 47 g and costs about US$10, and is commonly 2000 mAh and 3.7 V, for an energy capacity of 27 kJ, so you'd be emptying on the order of 4 18650s per hour, weighing 190 g. This compares very favorably to the 1080 g of ice (100 W / (333 kJ/kg) = 300 mg/s = 1081 g/hour) that you would need to carry to absorb the same amount of heat by melting. Ice is, of course, substantially cheaper; equaling the four-hour 100-W capacity of the 4-kg-of-ice Veskimo unit described above would require 16 18650s at

a price of about US$160, plus another US$100 or more for the Peltier modules and other materials. But weighing only 750 g rather than 4 kg could be a decisive advantage for the battery-driven unit under normal weather conditions.

However, the humans require for comfort not just a low temperature, but a low dewpoint; cooling the air next to the skin reduces the temperature but not the dewpoint, at least until condensation begins. A dewpoint of 15–20° is required, which I think means that the cooling vest or pants actually need to reach a *temperature* of 15–20°. With an external temperature of 35°, that's a ΔT as high as 20°, so according to Meerstetter's guide we can't expect a CoP of better than about 1.2, and that at (again) I/Imax ≈ 0.30, at which point Qh/Qmax ≈ 0.35 and Qh/Qc ≈ 1.75, so Qc/Qmax ≈ 0.20. So we'd need 5 "100W" Peltier elements to reject 100W of heat, and we need 83 W of battery power, emptying 11.1 18650s per hour, for a weight of 520 g of batteries emptied per hour. This is still almost twice as dense as the ice, but much pricier; your 4-hour unit now needs US$440 of batteries in it. Also, you have the potential safety issue of carrying 1.2 megajoules of highly volatile lithium batteries strapped to your body.

Under extreme conditions like those described in the Wikipedia article (as high as 65°) the ice-based system would continue to function exactly as well, while the Peltier-based system's efficiency would degrade enormously, and it might cease to work entirely. But perhaps under normal weather conditions the Peltier approach might work better.

Compressing a screen update with a tree of dirty bits

Kragen Javier Sitaker, 2017-06-21 (1 minute)

Suppose we build up dirty bitmaps of screen areas starting from some leaf size?

If we use the 8×8 pixel tile used in JPEG as our basic unit, and the 64-bit size of an amd64 register as our treenode size, then the next level up the tree is 64×64 pixels, then 512×512. My screen is 1920x1080 pixels, so to fill it, you need just under four such tiles from left to right and just over two from top to bottom.

So to describe a screen update, you could use twelve 64-bit words to list which parts of the screen you want to update, then another 64-bit word for each of those up-to-768 areas of 64×64 pixels you want to update, and then probably just pixel data for each 8×8 area. The worst case for small updates is 13 64-bit words of overhead plus an entire 8×8 area (128, 192, or 256 bytes); for large updates, the 6240 bytes of 1 bits at the beginning don't amount to much, one bit for every 41 pixels. (And in RAM of course you can keep those 6240 bytes always allocated.)

I'm not sure how useful this is now that we're often repainting the whole screen every frame.

Topics

Time series data type

Kragen Javier Sitaker, 2016-08-26 (3 minutes)

In work with financial market data, I often want to do computations on time series data. I'd like to be able to specify the computations in a way that isn't, for example, coupled to a sampling rate. I'd like to be able to specify a computation once and then efficiently perform it on any of the following, without editing the code:

- Real-time data as it becomes available.
- Regularly sampled historical data.
- Irregularly sampled historical data on my laptop.
- Irregularly sampled historical data on some Amazon EC2 nodes.
- Conservatively approximated historical data.
- Specific randomly generated data.
- Specified mostly continuous (though not necessarily piecewise-constant) functions.
- Probability distributions of data.
- An incremental variation of a previous dataset.

Also, I want to be able to interactively create models and visualize the results.

I'm not sure I will be able to achieve this, but I can achieve most of it.

There are three main time-series data types I am dealing with:

- Partial functions, which map some subset of the timeline to values such as $301.50, Wednesday, false, or 3%, with at most a countable number of discontinuities.
- Finite mostly-continuous subsets of the timeline, which can be thought of as boolean partial functions that happen to be defined everywhere.
- Events, which are countable numbers of points on the timeline.

There are functions between these data types. The discontinuities of a function or the beginnings and endings of a subset are events; given start events and end events you can create a subset; a boolean function can be converted to a subset of the timeline, and you can extract the domain of any function; you can restrict a function to be valid only within a subset; and you can discard events outside a subset.

Operations on the values mapped to by partial functions can be lifted to operate pointwise over those functions, intersecting their domains.

Finally, you can coalesce partial functions, SQL-style.

All of the above operations are nearly memoryless. However, there are also a set of *causal* operations available. The simplest is simply a lag, applicable to functions, subsets, and events; but others are also available. They are defined as a generalization of integration (in some sense numerical integration rather than symbolic integration), with an arbitrary semigroup operation used in place of addition, and another arbitrary lifting operation used in place of multiplication by a step size. This permits, for example, computing a window of the last ten

minutes of updates.

Requiring the "multiplication" operation to be a semigroup operation (i.e. associative) permits efficient parallelization and incrementalization.

Compressed sensing microscope

Kragen Javier Sitaker, 2016-10-06 (7 minutes)

By using a fairly rigid aperture grille with sparse randomly placed holes of different sizes, including a large number that are very small, it should be possible to do very high resolution microscopy, including subwavelength near-field light microscopy of flat objects, using only low-resolution, low-quality lenses or mirrors to focus light.

You put the grille on top of the sample, in contact with it, and shine light through the sample and the grille, taking a picture of the starfield pattern that comes through. Where a hole is over a clear spot in the sample, a white point of light will show; where it's over a transparent red spot, a red point of light will show; where it's over an opaque part, no light will show. The holes are much smaller than the camera pixels, but they are sparse enough that typically only one hole or less makes a significant contribution to each camera pixel. The consequence is that moving the grille by a hole diameter or so scans many such high-resolution pixels over the sample, and by taking many such frames, eventually the whole sample can be covered redundantly by many holes.

It's necessary to estimate the relative positions of the holes to deep subpixel resolution, and it may be necessary to do this simultaneously with estimating the image of the surface, a problem similar to the simultaneous localization and mapping (SLAM) problem in robotics. Alternatively, if the grille is rigid enough, it may be possible to estimate the hole positions ahead of time, using, for example, a known microscopic image or many high-resolution photographs of the grille.

Using a variety of different sizes of holes in such a grille is a way to reduce the difficulty of this estimation problem. The larger holes provide a blurrier image, but their positions are much easier to estimate to the desired precision, and the blurry image helps in estimating the position of the smaller holes.

A very practical way to produce such a grille is by perforating a thin metal surface, such as gold leaf; aluminum foil peeled from a gum wrapper; the aluminum coating on metallized Mylar/boPET or polyimide, such as a discarded potato chip bag; or the silvering of a first-surface mirror. A very practical way to perforate such a metal sheet is with a short-lived arc, triggered by bringing an electrode close to the surface; the hole diameter, if not its position, can be controlled fairly precisely by controlling the energy released in the arc, which can be measured fairly precisely by measuring the charge and voltage loaded onto a capacitor before the discharge.

Gold leaf is typically 0.2 microns thick; Mylar is commonly 10 microns thick, but only about 0.5 microns of that is the metallized film, sometimes as little as 0.1 microns. Regular kitchen aluminum foil is on the order of 20 microns thick. Vaporizing a 1-micron-diameter hole in an 0.5-micron-thick metal film requires vaporizing about 0.4 $(\mu m)^3$ of metal, which at 2.7 g/cc for aluminum works out to about a picogram. Solid aluminum's specific heat is 24.20 J/mol/K, its heat of fusion is 10.71 kJ/mol, its heat of vaporization is 284 kJ/mol, and it boils at 2470°, so we're looking at

(2470 - 20) K 24.20 J/mol/K + 10.71 kJ/mol + 284 kJ/mol = 354 kJ/mol, and its atomic weight is about 27.0 g/mol, so that's 14 kJ/g = 14 nJ/pg = 14 nJ per hole. That's the energy of a 280 pF capacitor at 10 V.

If the capacitor's capacitance were to increase or decrease by 1% (for example due to temperature, ferroelectric, or soak effects), which is a typical precision for low-capacitance capacitors like this, that would increase or decrease the diameter of the hole by about ½%. It should be straightforward to measure the charge deposited on the capacitor during the charging process to within about 0.1%.

I say it's probably not practical to control the location of the hole precisely because you need to bring the electrode close enough to the foil to provoke a dielectric breakdown of the air; for 10 V to be adequate, for example, the distance needs to be about 3 microns. But if the tip has a spherical radius of 3 microns, then a corona discharge will be occurring around the tip at the same time. This seems undesirable to me for a variety of reasons (uncontrolled loss of energy, ionic erosion) so it would be better to make the tip diameter much larger than this. But this means that the position of the arc will be uncertain to within several microns, controlled by small asperities on the tip or on the foil or by stray ions that wander by. You're depending on the positive feedback of the arc itself to channel all the energy into a small area, but that same positive feedback creates unpredictability.

Using lower voltages would help if it were possible, but it probably is not practical; Paschen's law has its minimum for nitrogen at about one torr cm and about 300 V. An atmosphere is 760 torr, so we reach one torr cm at about 13 microns. Using higher voltages makes the lateral uncertainty larger.

XXX now that I know about Paschen's law I need to rethink the above for a higher voltage.

Coloring the grille black, for example with a layer of carbon black deposited by smoke, should reduce stray light contamination which will damage SNR and require algorithmic rejection after the fact. This should be especially helpful for imaging using reflected light rather than transmitted light.

This approach doesn't seem like it would offer any advantages for electron microscopy, and without very exotic materials, it probably doesn't extend very far into the ultraviolet.

Doing telescopy rather than microscopy with this approach probably will not work very well, because diffracting light through small holes like that will lose a lot of information about which direction it came from. But in telescopy, the whole point is to determine which direction it came from. A more purely diffractive approach, where the incoming light diffracts through a random aperture grille and then falls on a focal plane with no intervening lens, might work better.

Seeing the Apollo flags from Earth would require a telescope 27× the size of the Gran Telescopio Canarias

Kragen Javier Sitaker, 2019-04-10 (updated 2019-04-16) (2 minutes)

The Apollo missions left six nylon flags on the moon, which are probably intact today. They're about 1.5 meters long by 0.9 meters tall, meaning that the stripes are 69 mm tall. The first flag was blown over during the takeoff of the lunar lander. The LRO in 2012 showed that the three flags it imaged remain intact and erect.

What would it take to get 500-mm resolution from a terrestrial telescope? Suppose we can use 300-nm blue light. The Airy limit is $\sin\theta = 1.220\lambda/d$ for a circular aperture, and the moon is 384 megameters away, so our angular resolution needs to be about 1.3 nanoradians. This gives the telescope aperture diameter $d = 280$ m.

The largest single-aperture optical telescope currently is the Gran Telescopio Canarias, which is 10.4 meters in diameter.

In the last 30 years, substantial progress has been made on long-baseline optical interferometry, and there is one such telescope in the US with a sufficient baseline: the Navy Prototype Optical Interferometer with its 437-meter baseline, which has a resolution of a few milliarcseconds. This is unfortunately not quite good enough: 1.3 nanoradians is about 0.27 milliarcseconds. The Very Large Telescope in the Atacama, the first telescope to image an etrasolar planet, has comparable resolution, down to a single milliarcsecond. But these telescopes are designed to image bright objects such as stars, not dim objects such as points on the moon.

Resistor assortment

Kragen Javier Sitaker, 2018-06-17 (4 minutes)

The electronics shop around the corner from GM Electronics sells resistors in quantity 10 and up, for AR$8. https://www.digikey.com/product-detail/en/stackpole-electronics-inc/CF14JT10K0/CF14JT10K0CT-ND/1830374 is a typical resistor: a 10kΩ ¼W 5% axial through-hole resistor. Its price is 10¢ in quantity 1, 4¢ in quantity 10, down to 0.7¢ in quantity 1000 (US$7 for the 1000).

40¢ is AR$10, so AR$8 is a reasonable price in quantity 10, slightly cheaper than Digi-Key actually.

I think I should ask for:

```
10 1Ω   $8
10 2.2Ω $8
10 4.7Ω $8
10 10Ω  $8
10 22Ω  $8
10 47Ω  $8
10 100Ω $8
10 220Ω $8
10 470Ω $8
10 1kΩ  $8
10 2.2kΩ $8
10 4.7kΩ $8
10 10kΩ  $8
10 22kΩ  $8
10 47kΩ  $8
10 100kΩ $8
10 220kΩ $8
10 470kΩ $8
10 1MΩ   $8
10 2.2MΩ $8
10 4.7MΩ $8
10 10MΩ  $8
```

That's 22 separate values, totaling AR$176.

I should probably also include some other basic components: opamps, microcontrollers, voltage regulators, capacitors, transistors.

Opamps: the most popular opamps on Digi-Key are the TI TSV321RILT (US$0.58), the TI LM2904DR (US$0.39), and the TI TL072CDR (US$0.62). I don't recognize any of those names. The most popular non-TI opamp is the ST LMV321ILT (US$0.51), which I assume is a TI LM321 clone. So maybe I should ask for an LM321 and expect to pay AR$15 for it. The LM741 is the one Electrocomponentes says is standard.

Digi-Key's most popular µC is STILL a PIC12, a 74¢ one. But the top three PIC12s are followed by a $4.34 Cypress CY8C4245AXI-483, whatever the fuck that is (apparently a Cortex-M0), then an $3.56 STM32 (also a M0), and then finally a $12.35 ATMega2560. All the cheapest µCs are AVRs, though — an ATTiny5 for US$0.17, an ATTiny102 for US$0.30, an ATTiny10 for

US$0.34. So if I don't want to hassle with PICs, I should probably ask for AVRs. Electrocomponentes does have ATTiny11s, 13s, 2313s, and ATMega32s (which I guess are ATMega328s). ATtiny13s cost US$0.40 at Digi-Key.

Voltage regulators: probably I want programmable ones, plus maybe some 7805s. The top pick among linear regulators is the US$0.72 LM317 with 350k in stock. Even more popular among switchers is the US$0.70 EZBuck AOZ1280CI from a company I've never heard of. No boost regulators seem to be super popular.

Capacitors: I should probably get a bunch of 0.1µF ceramic bypass caps. These seem to cost about 10¢ apiece in quantity 10 and 5¢ apiece in quantity 100.

For MOSFETs, I should probably get some 2N7000s or similar. These seem to cost about US$0.51 in quantity 1 (9.4¢ in quantity 1000), and they're good to 60V, 115mA. Also, for higher power, maybe some IRF530s (100V) and IRF630s (200V) and their P-channel partners IRF9530 and IRF9630.

For BJTs, the most popular and cheapest are currently apparently something called an MMBT3904, a 10¢ part good to 40V, 200 mA, with a PNP counterpart called the MMBT3906 or PMBT3906. An order of magnitude faster are the 47¢ Rohm 2SC5662T2LPs, with fT of 3.2 GHz, good to 11V, 50 mA. There are also the 12¢ BC846 and BC849, NPN 65V and 30V 100mA transistors, and their PNP counterparts the BC858 and BC856, more or less; but these are only good to 100MHz. The traditional BJT is I think the 2N3904 (200 mA, 40V) and its PNP partner the 2N3906.

Oh, I guess I should get some diodes: 1N4007 (the big 1N4001) and 1N4148 at least, and maybe some Schottky 1N5819s. Maybe 100 of each. Maybe not from the place that doesn't guarantee their semiconductors though.

Connectors for wires are called "borneras"; for pins are "conectores".

Some thoughts on SDF raymarching

Kragen Javier Sitaker, 2019-11-11 (updated 2019-12-10) (31 minutes)

After writing Interval raymarching (p. 1342), I just wrote my first raymarcher with signed distance functions ("SDFs"), intentionally a pretty minimal affair. It was a lot quicker to write than My Very First Raytracer, taking about an hour and a page of Lua to initially get working, rather than all night and four pages of C. Some of that difference is being able to build it on top of Yeso, so it doesn't have to include code for image file output; some of it is that Lua is a bit terser than C; some is that the raymarcher doesn't support color; half a page of it is the input file parsing in the C raytracer; but most of the reason is that a minimal SDF raymarcher is simpler than a minimal Whitted-style raytracer.

Disappointingly, although it does manage to do full-motion video, it's a great deal slower than the precise raytracer, although I haven't added specular reflections, lighting, color, or texture to it yet. I don't yet know if that's because it's an iterative approximation method or because LuaJIT is producing somewhat suboptimal code. In this very simple scene, it's only doing an average of around 9.5 SDF evaluations per pixel, which is comparable to the number of intersection tests the precise raytracer needed per ray; this weighs on the side of blaming LuaJIT.

Of course it's a bit silly to be rendering real-time 3-D graphics on the CPU in 2019, even if your GPU *is* just a shitty little Intel Gen8 (see Notes on the Intel N3700 i915 GPU in this ASUS E403S laptop (p. 2033)), but it's still enough experience to provoke me to write a bunch of things.

Rounding corners and inexact SDFs

In iq/rgba's notes on the topic, he frequently mentions the importance of using exact SDFs, which provide you with the exact distance to the nearest scene object, rather than inexact SDFs (I think the original sphere-tracing paper calls these "distance underestimate functions"), which merely provide you with a lower bound. He explains that this is important because using correct Euclidean SDFs will speed up the raymarching process dramatically.

Now, this may be true, but unfortunately many of the attractive modeling features of implicit surfaces involve transforming functions in ways that do not preserve SDFs' exactness. In particular, union (minimum of SDFs) is exact, but intersection and difference (maximum of SDFs and of an SDF and a negated SDF) are not exact. The SDFs generated by other very appealing features, like surface perturbations, bounding volume hierarchies (including IFS rendering), smooth union, and twisting space, are also usually inexact.

More unfortunately, other attractive modeling features of SDFs — such as the ability to round corners by subtracting a constant, or the ability to compute a constant-thickness shell by taking the absolute value and subtracting a constant — depend on the SDFs'

exactness. Consider a sphere whose SDF is $\lambda\vec{p}.|\vec{p}-\vec{c}_0|-r_0$ and another whose SDF is $\lambda\vec{p}.|\vec{p}-\vec{c}_1|-r_1$. Each of these is exact. If we take the CSG difference as $\lambda\vec{p}.|\vec{p}-\vec{c}_0|-r_0 \vee r_1-|\vec{p}-\vec{c}_1|$ (where $x \vee y$ is the maximum of x and y) such that the first sphere has a second-sphere-shaped bite taken out of it, we get an inexact, lower-bound SDF. It's straightforward to see that attempting to round the sharp corner where the cut penetrates the surface by adding a constant will not work; addition distributes over maximum and minimum, so $(a-k_0 \vee k_1-b)+r = a-(k_0-r) \vee (k_1+r)-b$. That is, all the level sets of this SDF can be reached by increasing one radius while decreasing the other. So the hoped-for rounded edge at the intersection line never appears.

(I say "it's straightforward" but it surprised me when I saw it on the screen.)

A brute-force solution to this problem is to resample the inexact-SDF-generated geometry into some kind of numerical approximation that admits efficient exact SDF computation.

Automatic differentiation

I mentioned autodiff briefly in Interval raymarching (p. 1342), but now that I've actually written an SDF raytracer, I feel like I have a better understanding of the situation.

With SDFs you don't easily know which object you've hit. So if you want to do something that depends on the surface normal, such as Lambertian lighting, you don't have a straightforward way to find it. Moreover, even if you do have a way to find which underlying primitive you've collided with, its SDF $d(\vec{p})$ doesn't immediately tell you how to find its normal. You need the *gradient* of the SDF, $\nabla d(\vec{p})$. Autodiff can give you that, at the cost of only doubling the computational cost, rather than quadrupling it, which is the cost of the standard approach.

However, as I said in Interval raymarching (p. 1342), using affine arithmetic might actually work better than the instantaneous derivative in this case, in order to avoid aliasing artifacts. iq/rgba has shown compelling demonstrations of how using a too-small box to estimate the gradient can cause aliasing.

(If your final top-level SDF is a tree of $\wedge$ and $\vee$ operations, where $a \wedge b$ gives you the lesser of a and b while $a \vee b$ gives you the greater (since real numbers have a total order), you could very reasonably trace the final result of the $\wedge/\vee$ back down the tree to its origin, finding the non-CSG surface it originated from. If you retained the computed values, you can do this in linear time in the length of the path you trace, which is probably faster than annotating each value with its origin on the way through this tree, effectively applying the $\wedge/\vee$ operations to (d, id) pairs rather than just d values.)

To me, one of the appealing aspects of successive-approximation algorithms like SDF raymarching and any kind of Monte Carlo simulation is that they can be used as "anytime algorithms" in order to guarantee responsiveness at the expense, if necessary, of quality (see Anytime realtime (p. 803) and Patterns for failure-free, bounded-space, and bounded-time programming (p. 925) for more on this). My current implementation does not do this. How can I get this in practice?

Using autodiff, you could perhaps "subsample" the SDF

evaluations of the final image, for example tracing a single ray through the center of a 5×5 pixel square; at the final point of contact, rather than just extracting the gradient of the SDF with respect to the (x, y, z) scene coordinates, you could carry the autodiff computation all the way through to the (r, g, b) color value and then compute its Jacobian with respect to the (u, v) pixel coordinates on the screen. This Jacobian gives you a color gradient value at the center of that 5×5 square, and so you could perhaps get an image that looks like a badly compressed YouTube video frame, which is considerably better than you would get by just downsampling an image from 640×360 to 128×72 (same number of samples) or 221×125 (same amount of data).

However, running on the CPU, you can *adaptively* subsample. If you reached the surface in a small number of SDF evaluations, you didn't pass close to any other surfaces, and the surface isn't sharply angled to the ray where you're hitting it, so you can probably get by with fewer samples.

Propagating SDF values to neighboring rays

Even without autodiff, computing an *exact* SDF $d(\vec{p})$ at some point $\vec{p}$ tells you a great deal about its values in the neighborhood of $\vec{p}$. At any displacement $\Delta\vec{p}$ in any direction, we know $d(\vec{p} + \Delta\vec{p}) \in [d(\vec{p}) - |\Delta\vec{p}|, d(\vec{p}) + |\Delta\vec{p}|]$, because the highest it can be is if $\Delta\vec{p}$ follows the gradient away from the object (and the gradient remains constant over that distance), and the lowest it can be is in the opposite direction. (No such pleasant bound holds for inexact SDFs, neither the upper nor the lower bound.)

(Here by $|\cdot|$ I mean the Euclidean L_2 norm, as before.)

Still, though, even with an inexact SDF, we know that an entire sphere of radius $d(\vec{p})$ around $\vec{p}$ is devoid of, as they say, "geometry". This means that if you compute a non-tiny value from an *exact or inexact* SDF for a ray shot from the camera, you have computed a bound for a whole view frustum around that point; a single SDF evaluation is enough to advance the whole wavefront around that point up to the bound of a sphere around that point, at least the part of the wavefront that has successfully *entered* that sphere. It may be worthwhile to use a conservative approximation of the sphere, such as a ball made from a weighted sum of the L_1 norm (whose balls are octahedra) and the L_∞ norm (whose balls are cubes). I think there is a cheap weighted-sum norm whose balls are these irregular polyhedra with 32 triangular faces — "frequency-2 geodesic spheres" in Buckminster Fuller's terminology, except that the underlying polyhedron whose triangular faces were subdivided into four triangles is an octahedron, not a dodecahedron.

You can build a Z-buffer and pick arbitrary points in it and evaluate the SDF at them; each SDF evaluation digs a big crater in the neighboring Z-buffer values, but only those values that are initially within the ball defined by that SDF value.

A fun way to do this might be to start with a very-low-resolution Z-buffer (3×2, say), then repeatedly double its resolution, perhaps using pairwise min to compute the newly interpolated pixels. Each doubling, you tighten the termination threshold for SDF iterations so that it's comparable to the new pixel resolution, and iterate over all the Z-buffer pixels until you've hit that termination condition on

each of them. This might be able to keep the total number of (primary) SDF evaluations per pixel down to 1–3, instead of the 9.5 I'm seeing or the 100–1000 commonly seen in the demoscene. If this can be combined with the adaptive subsampling mentioned above, it should be possible to get in the neighborhood of 0.1 SDF evaluations per pixel.

I understand that on the GPU it's dumb to try to do things like that because communication between pixels is super expensive. On the CPU, though, it might be a sensible thing to do.

A *much simpler* way to propagate SDF values to neighboring rays

The above algorithm with its various resolutions of Z-buffers and so on would seem to require a lot of memory management complexity. But one of the appealing things about both raymarching by sphere tracing and Whitted-style raytracers is the simplicity of their memory management: every ray is traced totally independently, though the process of tracing a ray may result in tracing some more rays, recursively.

It occurred to me that this recursive structure is potentially a good way to handle the multiple resolutions. Initially trace a cone that's big enough to encompass, say, a 16x16-pixel region, by marching a ray down its center. When this ray encounters a low enough SDF that the corners of that region are, say, closer to objects than they are to the ray you're marching, split it up into four rays, one marching down the center of each 4x4 quadrant, with a narrower cone; trace one of them at a time. When one of those rays encounters a low enough SDF that the corners of its region are maybe closer to geometry than they are to the ray, break down into 2x2 quadrants, which break down into pixels. And when one of those rays reaches its destination, you invoke a pixel-found callback, or store a value in the single, full-resolution Z-buffer, and backtrack to complete the recursion.

And of course you don't really start at 16x16. You start at 512x512 or 1024x1024 or 2048x2048, whatever your screen is.

The amount you advance is less than with standard SDF sphere tracing, because you want to make sure that you aren't smashing any of the corners of your current pixel region into an object. The simplest bound is to advance from point p by $d(p) - r$, where d is the SDF and r is the distance from p to the furthest corner of the projection of the current pixel region onto a sphere of radius $|p|$ (assuming the eye is at 0). But this is a pessimistic bound; the precise bound is the positive solution for e of the quadratic equation $(e + |p| - |p| \cos\theta)^2 + (|p| \sin\theta)^2 = d(p)^2$, where θ is the angle from p to the corner of the region, as seen from the eye. When the angle is large, this could give a significantly better bound, but when the angle and the SDF are small, the improvement in the bound is also small in absolute terms, and the angle is almost always small. However, this small improvement is probably usually close to a factor of 2, and my guess is that it might cut the recursion depth needed by a factor of 3 or so in typical cases. So the tighter bound might be worth the extra complexity, or it might not.

This doesn't fit well into a fragment shader, which may be the reason I haven't seen it discussed even though it seems obvious in retrospect, but it seems like it should fit beautifully into a CPU. It's

somewhat less optimal than the more complex approach described earlier with the multiple Z-buffers, but it's also enormously simpler, and it's embarrassingly parallel.

Multithreading and SIMD

On this three-torus scene, I'm getting 5.5 frames per second on my laptop.

I'm not attempting to use SIMD operations like SSE and AVX, and the algorithm is expressed in such a way (with data-dependent iteration bailouts) that I would be very surprised if LuaJIT were finding a way to take advantage of them. I don't think SSE 4.1 (which LuaJIT has) or even SSE 4.2 (which my CPU has) support half-precision 16-bit floats, so probably a 4× speedup for reasonably coherent vectors is the most I can expect from SIMD. (Again, see Notes on the Intel N3700 i915 GPU in this ASUS E403S laptop (p. 2033).)

The CPU also has four cores, so in theory I should be able to get an additional 4× speedup from multithreading, as long as the pixels aren't too interdependent.

So in theory I should be able to get a 16× speedup just by applying brute force, working out to 88 fps (at 320×240).

Automated fabrication

There's another major reason I'm interested in SDFs that's actually not real-time graphics at all: automatic fabrication. Historically manufacturing has largely been concerned with the *geometry* of parts, because steel, fired clay, concrete, glass, and polyethylene — the best materials for many purposes — are sufficiently uniform and isotropic that their geometry is most of what you need to know. (Heat treatment is important, but commonly applied to an entire article; similarly painting, galvanizing, etc. Surface finish is sometimes important, but that's in some sense a question of geometry too. Work hardening, for example from cold forging, is extremely important.) Moreover, for metals in particular, merely achieving a desired geometry is often a difficult and expensive proposition.

So algorithms that make contending with geometry tractable are of great interest.

(I think one of the really interesting possibilities of automated fabrication is actually that we can make things out of nonuniform and anisotropic materials.)

The existing libraries, algorithms, and user interfaces for dealing with 3-D geometry in computers are utter shit. "Sketching", "lofting", "extrusion", "press/pull", "pocketing", "filleting", and so on, are terribly unexpressive; achieving even the most basic compound curves is often beyond their capabilities. The interactive sculpting user interfaces in things like Blender and ZBrush are more expressive, but incapable of handling any demands for precision. The triangular bounding surface meshes and NURBS commonly used as the internal data representation are humongous, bug-prone, and — for any given level of humongousness — terribly imprecise; furthermore, doing topological optimization is basically impossible with them. The available libraries are buggy as shit and crash all the time. Half the time when you export a mesh from one program to import into another it turns out not to be "manifold", which is to say, it fails to

represent a set of solid objects. Voxel representations are, if anything, even worse, but at least they can handle topopt and don't have the fucking "manifoldness" problem.

Christopher Olah's "ImplicitCAD" is an attempt to remedy this situation by using SDFs (and Haskell). I'd like to play with the approach and see what I can get working, but without Haskell.

So, what would it take to import an STL file into an SDF world? How about a thresholded voxel volumetric dataset?

SDFs in two dimensions

Before I ever heard about 3-D raymarching using 3-D SDFs, I read a now-lost Valve white paper about rendering text "decals" in games using 2-D SDFs. The idea is that you precompute a texture containing a sampled SDF for the letterforms you want to use, and in your shader, you sample from that texture, with the built-in bilinear interpolation the GPU gives you. Then, instead of just using the sampled value as a pixel color, *you threshold it to get an alpha value*. This allows you to use the bilinear interpolation to interpolate sharp letterform boundaries in between texels.

Moreover, by thresholding it *softly*, you can get antialiasing. A similar effect comes into play with 3-D SDFs if you stop marching the ray when the SDF falls below about the scale of pixel spacing projected on the surface: the SDF sphere smooths over surface detail smaller than a pixel or so, preventing its high spatial frequencies from aliasing down into lower frequencies on the screen.

A problem with this technique as described is that the bilinear interpolation inevitably kind of rounds off sharp corners where you would want them on the letterforms; to deal with this problem, you can use two or more color channels to approximate different parts of the letterform boundary with smooth curves, which cross at the desired sharp corners. There's an open-source "mSDF" software package for generating these "multichannel SDFs".

I wonder if there's a way to carry the analogy through to 3-D raymarching with SDFs. Perhaps, for example, it could somehow provide a solution to my problem with rounding off edges.

Use in Dercuano

I'm pretty sure now that I can implement SDF-based sphere-tracing raymarching in JS on `<canvas>` to get reasonable 3-D diagrams (see Dercuano drawings (p. 64) and Dercuano rendering (p. 2300)). `<canvas>` has a typed array interface for raw pixel access I used in Aikidraw, so you don't need a DOM call for every pixel you draw. I think I can render raster graphics into that interface pretty easily, fast enough at least for still images.

Specifically, you can call `ctx.putImageData(data, x, y)` on a 2d `<canvas>` drawing context, where `data` is an `ImageData` object made out of a width `.width`, a height `.height`, and a `Uint8ClampedArray` in RGBA order `.data`; there are also `ctx.createImageData(w, h)` and `ctx.getImageData(x, y, w, h)` methods. The `ImageData` constructor is more experimental but available in Web Workers.

Computing normals from a Z-buffer

The raycasting process from any given pixel produces, at least, a z

-coordinate or distance at which the first intersection was found. (Maybe it also tells you things like how close the ray came to other objects, or how many iterations it took to converge, or which object it hit, and what the x and y coordinates were too, but at least it has a z-coordinate.) So this gives us a map from screen coordinates (u, v) -> z, which is pretty much exactly a Z-buffer.

Suppose we have nothing more than such a Z-buffer and we want to know the surface normals. A first crude approximation comes from the first backward differences: Z[6, 2] - Z[5, 2] gives us some kind of approximation of dz/du at (5.5, 2), and Z[5, 3] - Z[5, 2] gives us some kind of approximation of dz/dv at (5, 2.5).

These two sets of first differences have three problems:

• They can't distinguish discontinuities (from running off the edge of an object, for example) from smooth differences. If we're rendering smooth objects, this is an important difference.
• They're expressed in screen space. What we have is (roughly) dz/du and we want dz/dx. $x = uz$, so $dx = u\,dz$, so we need to divide by z. (Analogously for y.)
• They're offset by half a pixel from the pixels we want.

I think we can remedy problems #1 and #3 by, from the two adjacent gradient pixels at (5, 1.5) and (5, 2.5), choosing the one with the *smallest absolute value*. So, for example, if Z[5, 1] = 14, Z[5, 2] = 16, and Z[5, 3] = 15, we have deltas of +2 and -1 on each side of (5, 2), so we pick -1. If Z[5, 4] = 13, that gives us a delta of -2, so from -1 and -2, we pick -1 for the gradient y-element at (5, 3).

This will jitter some of the normals by half a pixel one way and others by half a pixel the other way, and it eliminates discontinuities unless there are discontinuities on both sides of the pixel, in which case it will pick the smaller discontinuity.

(This jitter is sort of like morphological erosion of these depth-gradient values, but by half a pixel rather than an integer number of pixels, and using the absolute value rather than the signed value. Maybe there's some kind of morphological dilation of depth-gradient values that could compensate, but I don't know how to dilate by fractional pixels.)

So this gives us an estimate of the gradient of the z-coordinate with respect to x and y. But what we want is the surface normal. Let's say $dz/dx = d$ and $dz/dy = e$. Now vectors tangent to the surface include $(1, 0, d)$ and $(0, 1, e)$; their cross-product is a normal, which if I'm not confused is $(-d, -e, 1)$, but that one points the wrong way, so we want $(d, e, -1)$, which points toward the camera. So you can normalize that $(\div \mathrm{sqrt}(d^2 + e^2 + 1))$ and you have some kind of reasonable approximation of the surface normal.

Per pixel, this approach requires two subtractions, two binary-minimum-by-absolute-value operations, a reciprocal (of z), two multiplications by it, two squarings, two additions, a reciprocal square root, its negation, and two multiplications by it, 15 operations in all, two of which (the reciprocal and reciprocal square root) are slow. This is probably faster than automatic differentiation of the SDF, and it gains the benefit of antialiasing that the centered-differences approximation has.

A simpler and cheaper function that might still provide a useful illusion of three-dimensionality is to take the gradient of z with

respect to (u, v) thus estimated and use it directly for, say, red and cyan color channels, as if the object were illuminated from the right with a red light and from above with a cyan one. Unfortunately, it's signed and may have a large dynamic range. The dynamic-range problem can maybe be handled by running it through some kind of sigmoid, like tanh or erf or something, although those only expand the dynamic range by like a factor of 2 or 3 or something; signedness can then be handled by truncating it with ReLU, i.e., $s \vee 0$. To get a third light coming from the camera, a simple approach would be to take the un-truncated sigmoid values and subtract the average of their absolute values from 1, although of course the actually correct thing would be to take the square root of 1 minus the sum of their squares.

Super cheap non-photo-realistic rendering from a Z-buffer

Suppose that instead we want to outline objects at discontinuities of depth and discontinuities of slope. The above gradient estimate attempts to smooth over single-pixel discontinuities by eroding them away, but if we skip that step, we can just use the total absolute gradient value (the L_1 norm; its Euclidean norm would be more correct) to select where to draw lines. You could use quickselect to find, say, the 96th and 97th percentiles of absolute gradient values, then use a piecewise-linear "smoothstep" to highlight the pixels with those values.

But that only gives us discontinuities *of depth*. If we want discontinuities *of slope*, we need an additional level of derivation, to calculate the second-order derivatives of the z-value with respect to (u, v), which are $\partial^2 z/\partial u^2$, $\partial^2 z/\partial u \partial v$, and $\partial^2 z/\partial v^2$, each of which is a single subtraction if we're satisfied with backward differences, as we should be. These values will be very large for two pixels at depth discontinuities, and somewhat large for one pixel at slope discontinuities; this may be a useful way to approximate the "thick inked lines outline figures, thin inked lines show detail within figures" rule from cartoon drawing.

In this case, although we have three values, we probably shouldn't map them to R, G, and B; it makes some visual sense to have an object diffusely illuminated from different directions with red and cyan lights, but it would make no visual sense to draw vertical lines in red, horizontal lines in blue, and saddle points and edge intersections in green. Instead we should take some kind of norm of this four-element Hessian matrix (which has only three distinct elements because it's symmetric).

Some kind of contouring may be a useful way to help make curved surfaces legible in diagrams; the simplest might be a checkerboard pattern in x, y, and z, formed by frobbing the pixel's brightness a bit with the XOR of some bit from each of the three coordinates. Which bit is chosen determines the scale of the checkerboard pattern along that dimension; if the bits are too significant, the whole image will be within a single cube, while if they're too insignificant, they're much smaller than a pixel, so it amounts to aliasing noise. So ideally you want them to be on the order of 32 pixels in size at the relevant distance.

A drawback of that kind of contouring is that one of the spatial

depth cues traditionally used in the visual arts is the amount of detail: foreground objects are drawn in more detail, as if the background objects were out of focus. (Also, they're often reduced in contrast and shifted toward the background color, which makes their details harder to see.) But the suggested checkerboard does just the opposite, putting the most detail in background objects. The standard XOR texture, the three-dimensional version of the Hadamard–Walsh matrix (the parity of the bitwise AND of the three coordinates), and similar fractal volumetric textures seen in a million 1024-byte demos and in My Very First Raytracer are one way to escape from that: they provide detail at a wide range of scales, or even all scales. But I'm not sure how to adjust the level of detail of such a volumetric texture to be coarser at further distances.

Another way to reduce the detail of background objects, related to the sphere-tracing algorithm rather than shading, is to roughen the sphere-tracing termination threshold with distance. If you do this merely proportional to distance, you just get cone-tracing antialiasing, but if you include a faster-growing term such as a quadratic term, you could maybe get background objects to lose surface detail faster than perspective shrinks that surface detail.

A third possible way to add more detail to foreground objects is to perturb the scene SDFs slightly with some kind of noise field to give the surface some kind of texture, but make the noise function drop off at larger z-coordinates, or possibly even middle-clip it ($a - (-b \wedge a \vee b)$, where a is the original noise function and b is the middle-clipping threshold) with a threshold that grows with distance.

In *Happy Jumping*, iq/rgba demonstrated a technique for perturbing SDFs slightly with a roughly isotropic volumetric texture made from a wavefunction with a feature size that was small relative to the objects but large relative to nearby pixels; the SDF perturbation was tightly clipped, so only its zero-crossings produced a relief on the surface. Thus, it formed smoothly curved random blobby contours on the surface whose foreshortening helped greatly to visually indicate the orientation of the surface. If you were doing such a thing I think you could reduce the level of detail with distance by reducing the amplitude of the higher-frequency components of the wavefunction.

Evaluating DSP operations in minimal buffer space by pipelining

Kragen Javier Sitaker, 2018-12-18 (updated 2018-12-19) (20 minutes)

I was thinking about how to implement a cascade of short-memory filters in C, how to manage all of their circular buffers, and it occurred to me that I can actually use the same circular buffer for all of them. Furthermore, especially if I'm willing to accept a few samples of extra latency, this allows me to move samples from one stage of the pipeline to the next with zero cost.

Suppose, for example, that I'm cascading the three FIR filters y(n) = x(n) - x(n-1), y(n) = x(n) - x(n-5), and y(n) = x(n) + x(n-15). Let's suppose our circular buffer b, indexed by index bi, has a size that is a power of 2 with bitmask m, so the current input sample is at `b[bi & m]`. It's convenient to invert the polarity of our first filter: y(n) = x(n-1) - x(n). We can implement this as follows:

```
b[(bi - 1) & m] -= b[bi & m];
```

This converts the sample at bi-1 from being x(n-1) to being y(n).

Now our second-stage filter, y(n) = x(n) - x(n-5), is being fed an inverted signal. So if it, too, is inverted, to y(n) = x(n-5) - x(n), we can implement it as follows:

```
b[(bi - 6) & m] -= b[(bi - 1) & m];
```

This converts the sample at bi-6 from being x(n-5) to being y(n). Note that this is the value we computed in the previous step, so it doesn't need to be loaded from RAM. The inversion of sign in this step cancels the inversion of sign in the previous step.

Then, our final stage, y(n) = x(n) + x(n-15), can be implemented similarly:

```
b[(bi - 21) & m] += b[(bi - 6) & m];
```

This converts the sample at bi-21 from being x(n-15) to being y(n).

Finally, you need to delay the output from the pipeline for 21 samples. Here I'm also dividing it by 4 to compensate for the amplification by the above filters.

```
if (bi >= 21) buf[bi - 21] = b[(bi - 21) & m] >> 2;
```

Here's a loop doing the above pipeline, although I haven't verified that it performs the desired DSP function:

```
for (bi = 0; bi != n; bi++) {
  b[bi & m] = buf[bi];
  b[(bi - 1) & m] -= b[bi & m];
  b[(bi - 6) & m] -= b[(bi - 1) & m];
  b[(bi - 21) & m] += b[(bi - 6) & m];
  if (bi >= 21) buf[bi - 21] = b[(bi - 21) & m] >> 2;
}
```

amd64 assembly

Here's what it looks like compiled with GCC, 92 bytes:

```
  400653:   74 5a                 je     4006af <filter+0x89>
  400655:   4d 89 c1              mov    %r8,%r9
  400658:   ba 00 00 00 00        mov    $0x0,%edx
        ; LOOP START
  40065d:   41 0f be 01           movsbl (%r9),%eax            ; load buf[bi]

ontire)

  40068e:   42 03 04 94           add    (%rsp,%r10,4),%eax    ; b[(bi-21) & mo
o] + ...
  400692:   42 89 04 94           mov    %eax,(%rsp,%r10,4)    ; store it
  400696:   83 fa 14              cmp    $0x14,%edx            ; bi >= 21?
  400699:   76 09                 jbe    4006a4 <filter+0x7e>
  40069b:   89 c9                 mov    %ecx,%ecx             ; 2-insn NOP
  40069d:   c1 f8 02              sar    $0x2,%eax             ; b[...] >> 2
  4006a0:   41 88 04 08           mov    %al,(%r8,%rcx,1)      ; buf[
  4006a4:   83 c2 01              add    $0x1,%edx             ; bi++
  4006a7:   49 83 c1 01           add    $0x1,%r9              ; ++&buf[bi]
  4006ab:   39 fa                 cmp    %edi,%edx             ; bi != n?
  4006ad:   75 ae                 jne    40065d <filter+0x37>
```

It seems like %edx is being used as our loop counter `bi`, %r9 is being

used as the input counter `&buf[bi]`, and %edi is being used for n, the limit. My index mask `m` is 255, so GCC is implementing the masking with `movzbl` instructions. Each stage of the pipeline requires 6 instructions, for whatever that's worth in 2018, and there's an additional 4 instructions or so of loop overhead, for a total of 28 instructions inside the loop.

ARM assembly

The Cortex-M4 equivalent is as follows, 80 bytes and 29 instructions, 25 inside the loop:

```
  22:   b334        cbz r4, 72 <filter+0x72>
  24:   f105 3eff   add.w   lr, r5, #4294967295 ; 0xffffffff
  28:   2300        movs    r3, #0
  2a:   aa01        add r2, sp, #4
    ; LOOP START
  2c:   f81e 1f01   ldrb.w  r1, [lr, #1]!        ; buf[bi]
  30:   b2d8        uxtb    r0, r3               ; bi & m?
  32:   f842 1020   str.w   r1, [r2, r0, lsl #2] ; b[bi & m] = ...
  36:   1e58        subs    r0, r3, #1           ; bi - 1
  38:   b2c0        uxtb    r0, r0               ; & m?
  3a:   f852 6020   ldr.w   r6, [r2, r0, lsl #2] ; load b[(bi-1) & m]
  3e:   1a76        subs    r6, r6, r1           ; subtract r1 from it
  40:   f842 6020   str.w   r6, [r2, r0, lsl #2] ; store b[(bi-1) & m]
  44:   1f98        subs    r0, r3, #6           ; bi - 6
  46:   b2c0        uxtb    r0, r0               ; & m?
  48:   f852 1020   ldr.w   r1, [r2, r0, lsl #2] ; load b[bi-6 & m]
  4c:   1b8e        subs    r6, r1, r6           ; subtract r6 from it
  4e:   f842 6020   str.w   r6, [r2, r0, lsl #2] ; store b[bi-6 & m]
  52:   f1a3 0015   sub.w   r0, r3, #21          ; bi - 21
  56:   b2c0        uxtb    r0, r0               ; & m?
  58:   f852 1020   ldr.w   r1, [r2, r0, lsl #2] ; load b[bi-21 & m]
  5c:   4431        add r1, r6               ; add r6 to it
  5e:   f842 1020   str.w   r1, [r2, r0, lsl #2] ; save it
  62:   2b14        cmp r3, #20              ; bi > 20?
  64:   bf84        itt hi                   ; conditional, unsigned greater
  66:   1089        asrhi   r1, r1, #2           ; r1 >>= 2
  68:   f80e 1c15   strbhi.w    r1, [lr, #-21]; store buf[bi-21]?
  6c:   3301        adds    r3, #1
  6e:   42bb        cmp r3, r7
  70:   d1dc        bne.n   2c <filter+0x2c>
```

This uses 5 instructions for each stage of the pipeline, against AMD64's 6, and unlike implementations of AMD64, I think that number actually does mean 5 clock cycles under normal circumstances.

Actually, on further thought, I think my concern about the 21 samples of latency was unfounded. There's a data path straight through the loop from buf[bi] to what ought to be buf[bi] but is instead buf[bi-21]. There's *additionally* a delayed path through the FIFOs, which is as it should be.

(I fixed that bug and removed the >> 2 and verified that the impulse response was as it should be.)

Recursive filters

Recursive filters can also be implemented with this structure. Suppose we have a cascade of two humble integrators, y(n) = x(n) + y(n-1), as we might for the beginning of a Hogenauer filter. Of course, we could implement this as follows:

```
y1 += x;
y2 += y1;
```

But if we stick to this staged-FIFO structure so that we can implement arbitrary lags, it looks like this:

```
void filter2(char *buf, int n)
{
  enum { bufsiz = 256, m = bufsiz-1 };
  int b[bufsiz] = {0};

  for (unsigned bi = 0; bi != n; bi++) {
    b[bi & m] = buf[bi];
    b[bi & m] += b[(bi - 1) & m];          // ∫1
    b[(bi - 1) & m] += b[(bi - 2) & m];    // ∫2
    b[(bi - 7) & m] -= b[(bi - 1) & m];
    b[(bi - 12) & m] -= b[(bi - 7) & m];
    buf[bi] = b[(bi - 12) & m] >> 3;       // compensate for 25× amplfier
  }
}
```

The ∫1 line computes the new y(n) value from the new x(n) value and the previous y(n) value; the ∫2 line does the same thing, but for the second integrator. Absent any further transmogrification, it leaves a trail of second-order integrator values behind in the buffer. Then, immediately below, we have two feedforward comb filter lines, which tame the wild integrators and convert them into a mild-mannered triangular-kernel FIR filter, completing the structure of a second-order (CIC) Hogenauer low-pass filter, although in this case without the usual decimation step.

In ∫1, because we don't need to preserve x(n), we can transform it into y(n), saving a memory load. But in the ∫2 stage, we do need to preserve x(n) (the previous stage's y(n)), so we just overwrite y(n-1) instead.

Again, in the comb filters, we're inverting the sign here for convenience — instead of computing y(n) = x(n) - x(n-5), we're computing x(n-5) - x(n), which requires no extra work because we have an even number of such inverting comb filters in the pipeline.

This filter function ends up as follows on amd64 with -Os:

```
  9b:   48 81 ec 18 04 00 00    sub    $0x418,%rsp
  a2:   48 89 fa                mov    %rdi,%rdx

  a5:   b9 00 01 00 00          mov    $0x100,%ecx             ; buffer size to
o zero
  aa:   64 48 8b 04 25 28 00    mov    %fs:0x28,%rax
  b1:   00 00
  b3:   48 89 84 24 08 04 00    mov    %rax,0x408(%rsp)
  ba:   00
```

```
  bb:   31 c0                   xor    %eax,%eax
  bd:   48 8d 7c 24 08          lea    0x8(%rsp),%rdi

  c2:   f3 ab                   rep stos %eax,%es:(%rdi)        ; zero the buffe
or
  c4:   48 89 d7                mov    %rdx,%rdi

```

Looks like it has 6 stores, 5 fetches, and 30 instructions inside the loop to realize this four-stage pipeline, but again only 5 or 6 instructions per stage of the pipeline. I was hoping to reach some kind of conclusion here about whether recursive filtering was going to be slightly costlier, but I really have no idea.

It looks to me like GCC has given up on register allocation in part of this code and is just emitting redundant loads, which is weird.

However, this is definitely less costly:

```
y1 += x;
y2 += y1;
```

And if you're doing a Hogenauer filter, you should probably not only do that, but you should also decimate the stuff downstream from the integrators.

But you can use this approach for other kinds of recursive filtering, too.

On one core of my laptop, this code filters 100 mebibytes (of malloced, mostly uninitialized memory) in 785 ms. That's about 134 million samples per second, or about 12 clock cycles per sample, or about 3 clock cycles per sample per pipeline stage. Presumably the number on a Cortex-M4 would be more like 6 clock cycles per sample per pipeline stage, due to in-order execution.

This suggests that processing a signal at 44.1 ksps would require about 132 kHz of amd64 clock per stage or 266 kHz of Cortex-M4 clock per stage. This seems like it might come in at the sub-MIPS level I was hoping for in the Bleep modem.

Multirate processing

So here's a Hogenauer filter with a twist — it's tuned to detect one particular frequency (19110 Hz) and null another one (17640 Hz). At least, that was the intention. I haven't tested this C code, just code in Python that purports to be equivalent, except that it uses floating-point (!!).

```
unsigned filter3(signed char *buf, int n)
{
  enum { bufsiz = 256, m = bufsiz-1 };
  int b[bufsiz] = {0};
  uint64_t d1=0, d2=0, d3=0, d4=0, i1=0, i2=0, i3=0, tmp, tmp2, c2=0, c3=0;
  int bi5=0, bo=0, odd=0;

  for (unsigned bi = 0; bi != n; bi++, bi5++) {
    tmp = buf[bi];
    tmp2 = tmp - d1;            /* Differentiator 1 */
    d1 = tmp;
    tmp = tmp2 - d2;            /* Differentiator 2 */
    d2 = tmp2;
    tmp2 = tmp - d3;            /* Differentiator 3 */
    d3 = tmp;
    tmp = tmp2 - d4;            /* Differentiator 4 */
    d4 = tmp2;
    i1 += odd ? -tmp : tmp;     /* Integrator 1 */
    odd = ~odd;
    i2 += i1;                   /* Integrator 2 */
    i3 += i2;                   /* Integrator 3 */

    if (bi5 == 5) {
      bi5 = 0;
      /* First comb filter: y(n) = x(n-2) - x(n); note inversion */
```

```
      b[bi & m] = i3;
      b[(bi - 2) & m] -= i3;
      /* Second comb filter: y(n) = x(n-1) - x(n); canceling inversion */
      tmp = c2 - b[(bi - 2) & m];
      c2 = b[(bi - 2) & m];

      /* Third comb filter: y(n) = x(n) - x(n-1), this time not inverting; but no
ow into the output buffer */
      buf[bo++] = tmp - c3;
      c3 = tmp;
    }
  }
  return bo;
}
```

This rather alarming C comes out to this perhaps even more alarming assembly:

```

27a:    c3                      retq
```

So, this has an 8-stage per-sample pipeline (which will be shared with the other ultrasound signals I want to detect), followed by a decimator and a three-stage per-output-sample pipeline. The loop overhead is 7 instructions per sample at the end and 3 instructions per sample at the beginning; the 9-stage per-sample code is 20 instructions; then the decimated code is 18 instructions, averaging 3.6 instructions per loop. All in all this should run in 33.6 instructions per sample, which would be about 17 amd64 clock cycles per sample if the same ratio held as for the previous code whose performance I actually measured. Also that works out to 12 pipeline stages, which means about 3 instructions or 1.5 clock cycles per stage, definitely an improvement over the earlier numbers.

It probably isn't necessary to use 64-bit math in here, and definitely not for all the variables it's being used for. But I haven't done the analysis yet to be sure I understand the Hogenauer overflows.

This suggests that doing the full demodulation this way will require a bit over a Cortex-M4 MIPS.

The differentiators on the front end might not be necessary; they're there to filter out the (commonly much more powerful) low-frequency noise.

Notes on scraping the Codex Arundel to preserve it

Kragen Javier Sitaker, 2017-08-22 (1 minute)

The Codex Arundel is a codex of manuscripts from Leonardo da Vinci, made of 283 sheets of paper, each with a recto and a verso side. The British Library has scanned it at 8579×6250 pixels, divided into 256-pixel-square tiles with one pixel of overlap, each about 12 kilobytes, fetchable using wget. This works out to 34×25 tiles per side of a page, so the total number of tiles is (* 34 25 283 2) = 481,100, and the total weight of the work should be about 5.8 gigabytes.

Initially each of the 566 images loads as an image of about 1800×800, about 2.7% of the total size. It would make some sense to fetch these low-resolution images first (totaling 160 megabytes) before making the possibly doomed effort to fetch the whole dataset.

The page for the thing is at https://www.bl.uk/manuscripts/FullDisplay.aspx?ref=Arundel_MS_00263.

Incremental MapReduce for Abelian-group reduction functions

Kragen Javier Sitaker, 2015-09-03 (4 minutes)

MapReduce is a batch-processing framework. Manuel Simoni wrote about incremental MapReduce in 2008 and is working on it still. He explains that in Damien Katz's proposed solution, "you have to store intermediate results and do recomputation when the inputs change," but you can avoid this if "map() stays the same, but reduce() is extended so that it takes a diff of the map outputs from before and after a document update." Simoni's design has an additional benefit over Katz's: Katz's will nearly always involve re-executing the entire reduce() stage. Simoni's design does, however, involve storing the final reduce() output.

This is a very interesting idea. Simoni comments that it has a drawback:

> [R]educe functions get more complex in this scheme, but the Google papers on MapReduce and Sawzall suggest that map functions are much more often user defined than reduce functions.

There's actually a whole algebraic landscape associated with this statement.

To summarize algebra in a few lines, a magma that's associative is a semigroup, a semigroup that's commutative and idempotent is a semilattice, a semigroup with identity is a monoid, a monoid with inverses is a group, and a commutative group is an Abelian group.

In many cases, you can construct your reduce-function by composing an Abelian group operation with some other operation. Undoing an Abelian group operation is relatively trivial: because the operation is associative (because semigroup) it doesn't matter what order the operations were done in, and because it's commutative, it doesn't even matter where in the sequence the removed element was. So you can just apply the inverse of the removed element to the previous reduce-function result.

As one broadly applicable example, if we extend bags over some set A, $A \to \mathbb{N}$, to allow negative multiplicities, $A \to \mathbb{Z}$, then any bag has its antibag which is its inverse under extended bag sum $\uplus$.

So if you store the result of the Abelian group operation, you can apply the diff to it, then redo the final operation.

For example, to maintain the set of unique words present in a set of documents, you can maintain in storage an extended bag that counts the number of times each word occurs, and then just discard the multiplicities to produce the final result.

As another example, if you want to know the largest one-second price jump from a large collection of stock-market data, you can divide your input data into shingles that overlap by a second, use a map function that outputs just the largest jump in each shingle, and then use a max-by-jump-size as your reduce function. Unfortunately, max, like semilattice operations generally, does not admit element inverses. A general incremental solution for this at the point of reduce would involve maintaining, at least, a max-heap of existing records, to which you could add and remove records.

Max-heaps, then, are the Abelian group needed here. But this has the same space cost (modulo overhead) of Katz's solution of storing previous map results and re-executing affected reductions.

If you cannot decompose your reduce-function into an Abelian group operation, the problem is more complex; but in fact reduce-functions in MapReduce are almost invariably intended to be commutative and associative, because the order in which the different map-results are presented to them is more or less arbitrary.

The max-heap example points up an inadequacy in the group-based, or even magma-based, analysis of incrementally updatable reduce-functions: it requires that the things coming from the map-functions be of the same type as the internal state of the reduce-function. In Haskell, `foldl` has type `(a → b → a) → a → [b] → a` — it takes an initial `a`, produces a final `a`, and in the middle it folds a list of `b`s into it using an `a → b → a` function. For example, `a` could be a max-heap of stock-market price moves, and `b` could be a single stock-market price move.

Replacing fractional-reserve banking with a bond market disintermediated with a blockchain

Kragen Javier Sitaker, 2019-07-03 (6 minutes)

I was reading Jonathan Stray's account of Jon Hicks's possibly fictional 1989 account of the how banking and modern money came to be, and it occurred to me that the bond market might be an alternative to the borrow-short lend-long model of fractional-reserve demand-deposit banking.

That is, if you have some money that you want to keep liquid but also earn interest on, one possibility is to deposit it in a bank as demand deposits. The bank lends (most of) it out at higher interest, keeping a small ("fractional") reserve on hand in case some depositors show up one day to close their accounts, and pays some (lower) interest to you and the other depositors for the use of your money. (Modern banks have been able to mostly eliminate depositor interest, as their oligopoly on payment systems, and in some case government regulations, obliges people to deposit their money in banks even if they don't earn interest.) The risk you take is that there might be a bank run — if too many depositors show up demanding their demand deposits at once, the first ones will get paid in full and the last ones will get their share of whatever is left over from the bankruptcy.

Given the existence of a liquid trading market, bonds, such as corporate bonds, might be a reasonable alternative. Instead of depositing your money in a bank account, you buy some bonds. Instead of withdrawing it, you sell the bonds on the market. Bond prices go up and down a bit — usually measured in basis points — and occasionally companies will go bankrupt (or countries will go into sovereign default) and again you're just a bankruptcy creditor, but you can diversify to minimize this risk. Lending to companies is overall mostly profitable, and the interest rates are higher than you get with a checking account.

This is why money-market accounts are popular, but there's no fundamental reason that retail investment in the corporate-bond market needs to be intermediated by banks or brokers; that's just an artifact of the limits of 20th-century information-processing technology. Intermediating retail access to corporate bonds in this way just adds risk — your bank or broker is far more likely to go bankrupt than the entire basket of companies you lend to, and additionally they're in a position to cheat you in a variety of ways, including bucket-shop tactics (that is, fractional-reserve banking, but in a way that is illegal in the US), front-running, and paying bonuses to their executives just before bankruptcy.

How would this differ in practice from a bank account? Blue-chip corporate and sovereign bonds typically fluctuate in value only by basis points, so the chances of a significant loss of capital in this way is fairly small, and you can diversify the risk across many different

debtors. The big difference is what happens when there's a "bank run": in the money market, those lenders who are most eager to liquidate their holdings are often the ones who take the losses, while in a demand-deposit bank run, the most eager lenders are the only ones who get paid. A temporary selloff in the bond market doesn't directly affect the companies whose bonds are being sold, unless they are floating a new issue of bonds at that moment, which they usually aren't. If the selloff is indeed temporary, rather than a result of the debtor's impending insolvency, those lenders who held during the selloff will preserve their capital (the precise opposite of a bank run), and those who risked buying the bargain-priced bonds are rewarded.

In the modern commercial paper market, though, clearing of trades is not instantaneous; the US corporate and municipal debt markets mostly clear via DTC, the Depository Trust Company, which acts as a counterparty to most transactions in corporate and municipal debt, permitting settlement to be delayed for two days or longer. As I understand it, the London Clearing House's EquityClear SA, despite its name, plays a similar role in Europe. Such clearing houses centralize debt-transaction counterparty risk in much the same way that banks and bank clearing houses centralize counterparty risk for cash transactions; without clearing houses, buyers of debt would be taking the risk that sellers would take the money and run without ever handing over the bonds they were ostensibly selling.

Clearing house insolvency is a likely outcome of the next world war, however, and represents the kind of systemic risk that it's very difficult to diversify away.

The obvious solution is to clear the trades with the Ethereum blockchain or something similar, so that the transfer of debt title from the seller to the buyer is a single atomic transaction with the transfer of funds from the buyer to the seller. This eliminates counterparty risk from the bond markets as long as the blockchain's integrity remains secure.

The actual coupon payments on the bonds, or title to collateral to secure those payments, *could* be incorporated into the same smart contract, but this is much less essential — the lenders are at least theoretically aware of who they're lending to and assuming the risk that that counterparty (the borrower, that is, the issuer of the bonds) will default. The whole purpose of the borrower issuing debt in the first place is so that they can invest the money thus raised, so you would expect that for most of the lifetime of the bond, they won't have an account with enough money in it to pay off the bond. So there's little point in making the coupon payments nominally automatic via a smart contract.

Installing Debian GNU/Linux on an ASUS E403S

Kragen Javier Sitaker, 2016-10-23 (10 minutes)

I have this new Asus laptop that says it's model E403S, and unfortunately it comes with Microsoft Windows 10 installed. These are my notes on trying to install Linux (specifically Debian GNU/Linux 8.6, a version of "jessie") on it.

So far I have gotten Debian to boot on it, despite UEFI, but I have not been successful installing it to the disk. Also, X is running at 800×600 (on a 1920×1080 screen), and the touchpad doesn't work.

By contrast, the current Linux Mint installs fine and everything works (encrypted install including swap, 1920×1080, touchpad, Wi-Fi, sound input and output, access to the 100GB SSD, webcam) except hibernation. I may return to Debian at some point.

Downloading the Debian live CD image

This step can take a while; for me it was a bit under an hour. Start it first unless you're on a very-high-speed internet connection. Some of the other steps can be done in parallel.

The best way to download Debian CD images is using zsync, and the best image to download is typically one of the "+nonfree" ones which have the drivers you need in order to bring up Wi-Fi successfully. These are "unofficial" because Debian does not condone the use of non-free software.

I did this with this command:

```
time zsync http://cdimage.debian.org/cdimage/unofficial/non-free/cd-including-firo
omware/8.6.0-live+nonfree/amd64/iso-hybrid/debian-live-8.6.0-amd64-standard+nonfreo
oe.iso.zsync
```

The resulting ISO file was 494927872 bytes and had the following cryptographic hashes:

```
sha256sum 496bef6cba35d5348d5cb2662f649f1949b0d9ee4a4b4ea7addf46b369a70507 debiano
o-live-8.6.0-amd64-standard+nonfree.iso

sha1sum   60e52866683d7205adabc6c41d2f0ce04d159b77 debian-live-8.6.0-amd64-standao
ord+nonfree.iso

md5sum    d79befa133725bb07251feb81a980ccc debian-live-8.6.0-amd64-standard+nonfro
oee.iso
```

The "standard" live "CD" doesn't bring up a GUI environment, but it's half the size of the alternatives that do (472 megabytes vs. 1.1+ gigabytes).

zsync is the best option because it detects and can recover from data transmission errors, and can restart after an interruption after taking only about 20 to 200 seconds to resynchronize. If I understand

correctly, it checks the truncated MD4 of each block of the file and the SHA-1 of the whole file. It's like a less demanding version of rsync.

Creating a UEFI-bootable USB stick for Debian

The Debian Live images are in "hybrid ISO" format, which means they are bootable under ancient BIOS from either USB or CD/DVD. Unfortunately, although the official instructions don't mention this, they are not bootable via UEFI, so I followed the following steps to get Debian to boot from USB under UEFI, as explained by Desmond86 in a Debian User Forums thread.

I formatted the USB stick as FAT32 (so UEFI would understand it) using `sudo cfdisk /dev/sdc`, creating a type-0c partition filling the entire disk, and then running `sudo mkfs -t vfat /dev/sdc1`. Then I mounted it with `sudo mount /dev/sdc1 /mnt` and copied `Shell.efi` from https://svn.code.sf.net/p/edk2/code/trunk/edk2/ShellBinPkg/UefiShell/X64/Shell.efi into `/mnt`.

In SVN revision 22855, `Shell.efi` is 909280 bytes and has the following checksums:

```
sha256sum 889a1f28051955fc33a9512901b2d0f5a5d500750e09fb7caf21defb1fd3b657 Shell.efi
sha1sum   6621d657f470c3902ab1bc2423e45e74d5c286cc Shell.efi
md5sum    8f2922f6d148c5a5776cf16c8952a1f4 Shell.efi
```

Then, I mounted the Debian ISO with `sudo mkdir /iso; sudo mount -o loop debian-live-8.6.0-amd64-standard+nonfree.iso /iso` and copied its contents onto the USB stick.

This was tricky; here's the command that finally worked:

```
time sudo cp -iLr /iso/{a*,.d*,di*,[f-z]*} /mnt/
```

The weird filename specification is to avoid copying the circular symlink called `debian` (which, fortunately, isn't strictly necessary) or the `..` directory entry. I used `-r` rather than `-a` to avoid errors about not being able to set ownerships on FAT32. The `-L` flag is to avoid errors about not being able to create symbolic links on FAT32. The missing symlinks might prevent some firmware files from being found (although it wasn't necessary to get my Wi-Fi working the first time around). The `-i` flag is to stop and tell me what's going on if there are clashes with files already there (like if I forgot to delete this stuff previously). This copying takes about five minutes (with one of the larger images, the Mate one) on my USB stick, most of which is copying `/iso/live/filesystem.squashfs`, although that depends on the speed of the USB stick in question. Mine is only writing at 5 megabytes per second, as shown by `iostat 10` in another window.

The following command was useful for watching the progress of the copying and figuring out what went wrong; it will go wrong itself if you have another `cp` command running somewhere.

```
watch -d -n .1 'sudo lsof -p $(pidof cp) | tail'
```

Things I tried for copying that didn't quite work:

• `cp -a …`, which spews lots of error messages about failing to create symlinks (because FAT32 doesn't support them) and failing to set file ownership (because FAT32 doesn't support that either).
• `cp -iLr /iso /mnt`, which puts everything in `/mnt/iso`.
• `cp -iLr /iso/{.,}* /mnt`, but it ends up trying to copy my entire filesystem onto the USB stick, including `/usr` and whatnot.
• `cp -iLr /iso/{*,.[^.],.??*} /mnt/`, which almost works, but copies everything into both `/mnt` and `/mnt/debian`, doubling the space usage.

Then I created a text file called `/mnt/liveboot.nsh` containing just this line:

```
live\vmlinuz initrd=live\initrd.img append boot=live components
```

Disabling hiberboot in Microsoft Windows 10

This isn't actually necessary for what I'm doing, since I'm going to erase Windows completely. I thought I had to do this to get into the BIOS setup, but I was wrong. It is necessary, however, to avoid filesystem corruption if you want to dual-boot and have any filesystems available to both Windows and Linux.

In Windows 10, I got to this via Settings (Windows → Settings) in System → Power & Sleep → Additional Power Settings, which takes me to Control Panel → Hardware and Sound → Power Options, from which I choose "Choose what the power buttons do" in the left sidebar, followed by "Change settings that are currently unavailable", which makes a "Shutdown settings" section appear, containing a checkbox for "Turn on fast startup (recommended)", which I unchecked, followed by clicking the "Save changes" button. The rumors that a locked filing cabinet guarded by a leopard is involved are unfounded.

Then I shut Windows down from the Windows → Power menu.

Entering BIOS setup

During the ASUS splash screen, before the blue-background Windows booting screen starts, pressing Esc gives a "Please select boot device" menu, one of whose options is "Enter setup".

Booting from USB

This part is tricky and dangerous, because the BIOS

Once I had the UEFI-bootable USB stick and disabled secure boot (in BIOS setup, under "Security", "Secure Boot menu", set "Secure Boot Control" to "Disabled") I was able to add the EFI shell as a boot option as follows. In BIOS setup, in "Boot", with the USB stick plugged in, I selected "Add New Boot Option", whose resulting menu contains "Add boot option" (prompting for an arbitrary but mandatory name, such as "walnuts") and "Path for boot option", which allowed me to navigate to "PCI(14|0)\USB(0,09)\HD(Part1,Sig0D30060D)" and then select the "Shell.efi" file I'd put on the USB stick in the previous section. Then I selected "Create", used Esc to get back to the previous menu

and see that my new boot option was selected. Upon pressing F10 to reboot, I got the UEFI Interactive Shell, which has the USB stick mapped as FS1: and apparently the internal disk mapped as FS0:; I can `dir FS0:\EFI` and see Microsoft in there, while `dir FS1:` shows me the contents of the USB stick.

Typing `liveboot` and hitting "enter" runs the liveboot.nsh batch file mentioned in the previous section, booting Debian.

Updating the ASUS E403S BIOS

The BIOS version on this machine is 213, which ASUS's page (see below) tells me is from 2015-11-10.

The Debian kernel isn't seeing the disk, and AskUbuntu suggests that this may be fixed by upgrading the BIOS.

So I loaded version 301 of the BIOS, date 2016-10-21, from ASUS's page. This page says it's for model E403SA, but the tag on the laptop says the model is both "E403S" and "E403SA-US21". The file I got is 2847438 bytes and has the following cryptographic checksums:

```
sha256sum a9f49a64fae2d915a2b9b6f7c515bfd4473a50f1ba4db071fa6e554397045113  E403SAAS301zip.zip
md5sum    3204c1bb9527bba7777cd89a4a528dbb  E403SAAS301zip.zip
sha1sum   a8f6ffc513d14e47b2771e737c753ecc40c5a55b  E403SAAS301zip.zip
```

The option to update the BIOS is in the BIOS setup under "Advanced": "Start Easy Flash". This is supposed to be able to read the above zip file from USB media. Unfortunately it insists on being plugged in to AC power, and I left the adaptor elsewhere tonight. So for now I'm kind of stuck at this point, although I can run a live Debian system from USB.

Launching the Debian installer from the login prompt

For whatever reason, the Debian Live USB image I booted (`debian-live-8.6.0-amd64-standard+nonfree.iso`) gives me a login prompt instead of automatically launching a desktop or an installer. I logged in with the login name `user` and the password `live` (these are documented on Stack Overflow) and ran `sudo debian-installer-launcher`.

A few steps into the installer, it queried me for the wireless network configuration, bringing the network up successfully. From this point on, things basically worked, except that it couldn't find the disk to install on, as documented above. I had to tell it my network was "WPA/WPA2 PSK", as most are these days, rather than "WEP/Open Network", the poorly-chosen default.

At this point I'm stuck, as mentioned above, because I can't get Linux to see the disk I want it to install on.

I did manage to get Mate running (from a different Debian live image), but the touchpad mouse doesn't work and the display only supports a resolution of 800×600, which is 23% of its native resolution of 1920×1080 and also blurry and smushed. Alt-F1 brings up the main menu despite the touchpad not working.

Nested inheritance

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

From "Scalable Extensibility via Nested Inheritance", by Nathaniel Nystrom, Stephen Chong, and Andrew C. Myers:

In our work on the Polyglot extensible compiler framework [27], we found that ordinary object-oriented inheritance and method dispatch do not adequately support extensibility. Because inheritance operates on one class at a time, some kinds of code reuse are difficult or impossible. For example, inheritance does not support extension of an existing class library by adding a given field or method to all subclasses of a given class. Inheritance is also inadequate for extending a set of classes whose objects interact according to some protocol, a pattern that occurs in many domains ranging from compilers to user interface toolkits. It can be difficult to use inheritance to reuse and extend interdependent classes.

Nested inheritance is a language mechanism designed to support scalable extensibility. Nested inheritance creates an interaction between containment and inheritance. When a container (a namespace such as a class or package) is inherited, all of its components — even nested containers — are inherited too. In addition, inheritance and subtyping relationships among these components are preserved in the derived container. By deriving one container from another, inheritance relationships may be concisely constructed among many contained classes.

I've thought for a while that one of the advantages of Bicicleta's language is that it supports this kind of extensibility. However, their approach causes a class that "overrides" a class from another container to inherit from that other class, unlike Bicicleta's approach, which seems to be more similar to the "virtual class" mechanism of BETA and "Genericity in Java with virtual types".

Predictions for future technological development (2008)

Kragen Javier Sitaker, 2008-04-19 (11 minutes)

Here I'm going to try to write down some of my predictions for future technological development, so that I can check them later. I'm assigning things I'm more sure about a higher "certainty level or 'CL'", which I'm thinking will be in a range of 0–9.

Inspired by http://kk.org/ct2/2008/04/digital-things-ive-been-wrong.php.

2008-04-19

Second Life (or equivalent): going to be the basis of a lot of socialization in 10 years, if they can make it decentralized (CL 2); primarily among groups of people who know each other in real life, but aren't physically co-located at the moment (CL 2).

Spore: going to be a huge seller (CL 3) and even bigger influence on newly designed games (CL 4) (and maybe other programs (CL 2)) over the next 5 years.

Automated fabrication (one-off production of goods without direct human intervention): starting around 2010 and by 2013, it's going to replace more than 5% of traditional manufacturing, measured by value (CL 4). Price-sensitive goods will continue to be made by traditional manufacturing unless and until automated fabrication gets cheaper than traditional manufacturing plus transportation (CL 5), which I don't think will happen in 5 years and probably not in 10 (CL 3).

Version control: in five years, the mainstream version control systems will include SVN (CL 5), Git (CL 5), and Mercurial (CL 4), but not Darcs (CL 3), Bazaar (CL 3), any other arch variant (CL 4), CVS (CL 2), or Perforce (CL 4). They already don't include RCS, PVCS, SCCS, CSSC, Aegis, Vesta, or BitKeeper. There will be important new alternatives that I haven't heard of yet (CL 4) but none of them will be as popular as Git (CL 4). A lot of things that aren't traditionally considered source code will be stored in these version control systems, like textual documents.

Perl 5 will still be in wider use than Perl 6 five years from now (CL 2), but neither will be in as wide use as Ruby or Python (CL 3).

DiSo will have a lot of users in 5 years (CL 1) but still won't be as popular as Facebook (CL 3) or MSN Messenger (CL 5) and won't be as popular as some social networking system I haven't heard of yet (CL 3).

General-purpose consumer microcomputers that are popular in the EU will cost between one and four barrels of light sweet crude (CL 3), and computers at that price will still execute single-threaded code at under 5 billion basic blocks per second (CL 5). Today's equivalents (which cost a bit more) can typically do about 8 threads at full speed; five years of Moore's law would make that 32, but I think that computers at that price five years from now are likely to be able to run at least 128 threads at this 5G-basic-blocks-per-second speed (CL 4). Multithreading will provide a decisive performance advantage to

software written in a variety of ways that aren't currently mainstream, such as Erlang's model, Verilog, and array-processing languages (CL 3), rather than providing an equally large performance boost to software written with shared-everything threads and locks, as Herb Sutter predicted. High-performance software being written in this way, combined with a lot of experience with server virtualization, will create an opportunity for new CPU architectures that don't directly support x86, ARM, or MIPS instruction sets --- whether a relatively traditional design like the Tera MTA or something wild like FPGAs, the SeaForth, tagged dataflow machines, or concurrent linear graph reduction machines --- so at least one such architecture will have total market sales 1% or more of the x86-compatibles' market sales (CL 3).

In five years, devices like cell phones, portable computers with embedded radios in which the user does not have ultimate control over the software, will be the way that most people access the internet most of the time (CL 5; this is already true except that most people don't access the internet yet) and will sell ten times as many units per year as the traditional kind of computer in which the user is ultimately responsible (CL 3).

In five years, electoral campaign success in the US at every level except presidential campaigns will be largely determined by word of "mouth" (using electronic communications whose receivers solicit them, rather than paid advertisements) rather than paid advertisements (CL 3). Presidential campaigns will be too (CL 2). In ten years, both of these will be true (CL 4).

In five years, intellectual property restrictions, not terrorism, other aspects of human rights, or agriculture, will be the most controversial issue in international negotiations. (CL 2)

I don't know what to predict about peer-to-peer systems like Vipul's Razor and BitTorrent. I suppose that they will continue to exist, and the kind of people who thought jazz and tango music were scandalous will continue to oppose them (CL 6). And fragile centralized systems like DNS and Google will continue to exist too (CL 6). Whether the mix will change, and how it will affect society, I have no idea.

In the last few years, there have been several hobbyist UAVs and other robots for remote sensing, of which Art van den Berg's glider is probably the most impressive. In the next five years, there will be more of them (CL 5) and some of them will be even more impressive than van den Berg's project (CL 2). Governments will worry and some will make new laws restricting model aircraft (CL 4). Some people will commercialize the technology (CL 3), use it to advance the state of knowledge in some scientific field (CL 3), or do things with it that benefit s lot of people (CL 3). Possible applications include inexpensive high-quality aerial remote sensing, deep-sea exploration, substituting for radio towers and communication satellites, and rapid, inexpensive delivery of small, light items, especially to inaccessible places.

Five years from now, solar energy will be a cost-effective source of electricity in countries that currently derive much of their electrical energy from natural gas or oil (CL 5), because the prices of those commodities will have risen (CL 6). I mean to say that it will be cheaper than those fossil fuels without any government subsidies. It

will probably be cost-effective in countries like the US which get most of their electricity from coal (CL 4), because people will figure out how to bring the cost of solar electric systems down and their efficiency up (CL 4).

Five years from now, other renewable sources of electricity will be cost-effective, too (CL 4). Maybe wind, geothermal, old-oil-well geothermal, tidal, wave power, or even biomass.

Five years from now, digital cameras will surveil all urban public places in the OECD countries (CL 4), probably because random individual people will carry digital cameras around with them and always turned on (CL 3), not just because of cameras placed permanently by the owners of those spaces.

Five years from now, despite the rising prices of fossil fuels (see above, CL 6) long-distance transport will remain affordable for most of the world's food (CL 6), so "locavorism" will not become an economic imperative (CL 6).

Five years from now, China will have experienced at least one recession (two consecutive quarters of negative economic growth) (CL 3), as some aspect or other of its current strategy falters.

Within five years, extrajudicial executions of innocent citizens by the police in both the US and Britain will have provoked considerable furor (CL 3), but the general public in both countries will be in favor of such policies (CL 5).

Within five years, the most-widely-consulted cartographic resource will be a community project like Wikipedia (CL 4), and OpenStreetMap will be the most-widely-consulted community cartographic resource (CL 4). Most important scientific papers in hard-science fields will be published first in open-access media such as arXiv, open-access institutional repositories, or open-access journals (CL 4). The same thing will be true of most important academic papers in less scientific disciplines such as history, psychology, and sociology (CL 2). Significant non-open-access journals will still exist, even in hard-science fields, and will still publish some important new results (CL 5).

Five years from now, most people who enter text into computers will still use QWERTY keyboards or phone keypads (CL 4), not Morse code, Dvorak, speech recognition, or something else exotic.

DHTML will still be a widely-used format for new applications five years from now (CL 4) and will not have been eclipsed in popularity by one of the various new alternatives that are being marketed now (CL 3) such as Silverlight and Flash.

Over the next five years, computer and network security will be a bigger and bigger problem (CL 5) as organized crime makes more and more use of computer security vulnerabilities to get money and power (CL 4).

Five years from now, illegally copied software will still be ubiquitous, even in OECD countries, on computers that are controlled by their users (CL 5).

I'm not sure what's going to happen with agriculture. There are clearly better ways to go about it than the Green Revolution approaches, especially in marginal areas like New Mexico, Iraq, much of Jordan and the West Bank, the llanos of eastern Colombia, and so on. Whether those approaches will catch on, who can say?

Five years from now, there will be at least one change that is as

important as anything I've mentioned here, but that didn't occur to me (CL 3).

Five years from now, Communist China still will not have produced any proprietary software that is widely used in the rest of the world, except software bundled with hardware, (CL 4) and probably no large piece of widely-used free software either (CL 3).

Five years from now, quantum computers will not be a practical alternative to conventional computers for general tasks (CL 6), nor will they be in ten years (CL 5), but in five years we'll see them do some impressive things (CL 3). (It's possible that they will instead fail to work; if that happens, it will reveal a fundamental weakness in our understanding of quantum physics (CL 4).) Ten years from now, they will do some practically useful things (CL 2).

Why you can't run a diesel engine on water and diesel fuel with electrolysis

Kragen Javier Sitaker, 2019-11-24 (2 minutes)

Is it energetically feasible to run a diesel engine on diesel fuel combusted with oxygen derived from electrolysis of water, driven from the engine itself? Although there's no fundamental thermodynamic reason such a thing is impossible, presumably it isn't, or military diesel submarines would do it.

NEL Hydrogen claims their commercially available electrolysis apparatus electrolyzes hydrogen gas from seawater at 49 kWh/m³ at STP; this presumably means it also produces oxygen from water at about 98 kWh/m³, which at 1.429 g/ℓ is about 68.6 kWh/kg. This is 247 MJ/kg, which is about 6× the specific energy from burning common fuels such as diesel fuel (43 MJ/kg) with oxygen.

It gets worse, though, because burning those fuels requires a much larger amount of oxygen than the fuel: a CH_2 unit, weighing 14 daltons, becomes a CO_2 molecule and an H_2O molecule, using 48 daltons of oxygen. So actually burning diesel fuel gives you 43 MJ per kg of diesel, but only $43 \times 14 \div 48 = 12.5$ MJ per kg of oxygen. So you only get back about 5% of the electrolysis energy when you use the oxygen. That's really, really far from being viable.

So you can't run a diesel engine on water and diesel fuel.

There *are* things that have such a strong affinity for oxygen that you can burn them with oxygen from water for a net energy gain; sodium is probably the best-known example. As far as I know, all of them pose serious practical problems for use in a heat engine.

World War III is starting (?)

Kragen Javier Sitaker, 2016-10-17 (2 minutes)

World War III is starting.

• in mid-2014 old Vlad said a third world war was imminent because of the collapse of the institutions that had prevented it since 1945, and that precision-guided munitions were as dangerous as nuclear weapons;
• in late 2015 old Frank said that Christmas was a charade because the world was at war and on a path to more war;
• last week Daesh, who Russia is currently bombing in Syria and feuding with the US about, sent a mass-market precision-guided munition against the peshmerga and, although it didn't work properly, it killed two of them anyway;
• Turkey, a NATO member since 1952 and the one with the second largest military (and 90 nuclear weapons which theoretically belong to the US), is refusing to withdraw its troops from Iraqi territory; today old Recep is insulted Iraq's prime minister, and he's demanding that the US deliver up old Fethullah because they say he was plotting the coup that was recently attempted.

Also, not shown in these links, largely as a result of the ongoing war in Syria and Iraq and its refugees, Turkey is suffering an unprecedented crackdown on human rights, and Europe and the US are experiencing levels of xenophobia unprecedented since the lead up to WWII, resulting in a resurgent fascist movement, which incidentally Russia blames for the most recent coup in Ukraine and used as justification for reannexing Crimea, and which got their candidate nominated as the US Republican Party's presidential candidate. And the European Union is splitting apart. Also, two nuclear powers are fighting in Jammu and Kashmir.

On top of all this, related to old Vlad's point about PGMs but not fully explained in it, war tactics have changed so much since the last war between great powers that it is inevitable that some great-power militaries have doctrines that are likely to just get their people slaughtered, as happened to the Iraqi army in the US invasions, or more evocatively the futile bayonet charges in the Russo-Japanese war and World War I. That means that nobody can predict what the outcome of a possible conflict will be, which increases the chances that both sides think they can win it.

Accelerating Euler's Method on linear time-invariant systems by exponentiating matrices

Kragen Javier Sitaker, 2019-03-24 (updated 2019-04-02) (7 minutes)

These were some notes on a numerical method that at first I was excited about, but which didn't pan out; it was a way to compute trajectories of systems of ordinary differential equations with high accuracy, but it turns out not to apply to any interesting systems (at least, none that I can find so far). It can't possibly work for anything that isn't linear and time-invariant (when augmented with some set of auxiliary state variables), which I think means it is limited to systems whose solutions are sums of complex exponentials.

Basics

The Euler method for approximating solutions of differential equations is just a matter of

```
x[0] = a
for i in range(1, n):
    dxdt = f(x[i-1], t)        # calculate derivative at previous point
    x[i] = x[i-1] + h * dxdt   # extrapolate according to derivative
    t += h
```

which of course has some error if the derivative isn't constant, an error proportional to h^2 and d^2x/dt^2 — according to the professor lecturing yesterday, precisely $\frac{1}{2}h^2d^2x/dt^2$ at some point within the (open) extrapolated-over interval, although this obviously depends on at least the second derivative in question being continuous.

The second-order Taylor method attempts to correct for this by adding in $\frac{1}{2}h^2d^2x/dt^2$ computed at the beginning of the interval, on the theory that the second derivative changes slowly enough through the interval that calculating it at the beginning is probably good enough. And of course you can use third-order or higher-order Taylor methods, although you start to risk oscillations.

The Euler method, which is the first-order Taylor method, has an error proportional to the interval size h^2; the nth-order Taylor method has error proportional to h^{n+1}. Since this error accumulates over many intervals, at a given distance from the initial conditions (as opposed to a given number of timesteps) it's actually proportional to h^n, at least. This still means that if you want to simulate accurately, you need some absurdly tiny interval size.

A variant of Euler's method that I had some success with for the special case of computing sin and cos was to represent the transition function for a timestep as a matrix. It happens that d/dt[sin t] = cos t and d/dt[cos t] = -sin t, so that if we have a vector-valued $\vec{x}$ containing a purported (cos, sin) pair, Euler's method would amount to multiplying it by a matrix M(h):

$$\begin{bmatrix} 1 & -h \end{bmatrix}$$

A problem is already evident in that this matrix's determinant is $1+h^2$, but if h is smallish, that can be a very small error. But if h is smallish, you have to do the multiplication a largish number of times.

However, since it's a matrix, you can compute a power of it efficiently. For example, by squaring it 16 times, you can compute $M(h)^{65536}$, or by squaring it 32 times, you can compute $M(h)^{4294967296}$. This approach allows you to start with an exponentially small incremental angle and thus compute with an exponentially small error proportional to that angle. This is sort of similar to using an order-4294967296 Taylor method, but I'm not sure if it's actually equivalent.

It occurred to me that you could take this approach with the Euler method in general: augment your system's state vectors with extra state variables that are the Nth derivatives of the original state variables (with respect to time), and then use the Euler method in this matrix form in order to get absurdly tiny timesteps.

In some cases, you'll run out of (nonzero) derivatives pretty quickly, or you'll be able to write the new derivatives in terms of the known ones, and you'll get the same exponential-order characteristic as with sin and cos. In other cases, you'll need to stop taking derivatives at some point in order for the transition matrix you're exponentiating to fit into your L1D cache. (Or, since the transition matrix is $O(N^2)$ in the number of elements and will be dense after a few iterations, you might run into a problem of diminishing returns.)

It also isn't going to be efficient for systems that intrinsically have a lot of degrees of freedom, even if their derivatives are simple. For example, if you have a 100×100 grid of values, your state vector has 10,000 variables in it before you start augmenting it with derivatives, which means that your transition matrix is 10,000×10,000, containing 100 million elements; though maybe its initial state is pretty sparse, it gets dense pretty quickly.

In some cases, you'll have derivatives that are polynomials made of multiple terms. It may be advantageous to add each term, without its coefficient, as a separate variable, as an auxiliary variable, rather than adding the derivative as a whole. For example, if $y'(t) = 2y(t) - 5\sin(t)$, then rather than adding a $2y(t) - 5\sin(t)$ row (and column) to the matrix, you can just add a sin(t) row, sticking +2 and -5 in the appropriate matrix cells. (Then you'll need to add a cos(t) row in the next step, and then you're done, because cos(t)'s derivative is -sin(t).) For this purpose you might want to multiply out more complicated derivatives into polynomials or ratios of terms.

In the sin/cos case and in the $2y(t) - 5\sin(t)$ example, the transition matrix was constant, so neither it nor its exponent needed to be recomputed. For more general systems, that may not be the case.

Somewhat annoying example: $y' = \cos t^2$

Suppose $dy(t)/dt = \cos(t^2)$, i.e., $y = \int \cos(t^2)\,dt$. After five more differentiation operations, we have seven functions from which we can construct one another's derivatives, and this allows us to construct a 7×7 matrix for taking an arbitrarily small step of Euler's method:

$y' = \cos t^2$

```
y''   = 2t cos t²
y'''  = 2 cos t² - 4t² sin t²
f     = t² sin t²
f'    = 2t sin t² + WTF
```

Further investigation shows that my 7×7 matrix was bogus and this method does not actually work for the cases I was interested in. It does work for some cases that already have closed-form solutions.

Substantially more annoying example: $y' = \cos y^2$

Very annoying example: $y' = \cos (1/y^2)$

Relation to other methods of numerical integration of ODEs

I think this is not the same as the extension of the Euler method to higher-order differential equations, although it has in common with it the idea of augmenting the original variables with some derivatives; it is not the same as Taylor methods (though it shares with them the idea of correcting the first derivative using higher derivatives) and it has nothing in common with the Runge-Kutta method. It is not a multistep linear method; the transformation matrix (including any power of it) implements a transition from a *single* previous state to a *single* new state.

This is very similar to exponential integrators, but I think it is not the same thing.

Topics

FM chirp sonar

Kragen Javier Sitaker, 2017-07-04 (1 minute)

Linear FM chirp sonar is cool.

If you emit a sound chirping linearly from 6 kHz to 10 kHz over the course of two seconds, and it bounces off some object 1.72 meters away through air, the 10-ms-delayed echo signal will be 20 Hz lower than the outgoing signal; if the amplitudes are within an order of magnitude or so, this will result in audible 20 Hz beating between the outgoing signal and the echo. If you jump back down to 6 kHz at the end of the two seconds, you'll have a 10-ms length of time where the beating sound disappears, but that's still a 99.5% duty cycle.

(This is a chirp rate of 2 kHz/s; 343 m/s is 172 m/s in round-trip meters, so this works out to about 11.66 Hz/m.)

You should probably be able to distinguish by ear a difference of ½ Hz as long as it's more than about 10%; this would limit you to 10% distance resolution at far distances and 43 mm distance resolution at near distances. A higher chirp rate would give you tighter distance resolution, but you would also run out of audible frequencies sooner.

Writing a C program to generate such a chirp took a few minutes, and in practice I don't seem to be able to do this by ear.

Constant space flexible data

Kragen Javier Sitaker, 2018-04-27 (5 minutes)

One of the difficulties with the Lisp memory model used by most mainstream programming languages today is that memory usage is fairly unpredictable, and allocation is fairly ubiquitous. This means that writing code that cannot fail is pretty difficult.

The nested-objects memory model used by COBOL and used with some modification by C avoids this problem, but it's much less flexible. Every object has a fixed size, so you're always running off the ends of buffers, which is another way for your code to fail.

The Z-machine memory model used by Zork is an interesting alternative. Z-machine objects are normally all allocated at compile time, but linked together into a linked-list nested container hierarchy reminiscent of the DOM at runtime, and each object has a sort of property list which you can mutate but not add to or remove from. In games like Zork the container hierarchy is used for possession and location: your book might be contained in your bag, which is contained in you, who is contained in the entry hall, which is contained by the universe and which also contains a handkerchief and two exits.

In the Z-machine, objects are never created or deleted, but merely move from one container to another. Moreover, inserting the object into its new container is a constant-time operation involving the setting of three pointers. Because none of those three pointers is "prev", removing an object from its current container is a variable-time operation. Here's a graphviz diagram:

```
digraph zorkish {

    node [shape=record, label="{\N|{<parent>parent|<child>child|<sibling>sibling}o
o}"];

    universe:child       -> hall        ; hall:parent                -> univers o
o e;

    hall:child           -> player      ; player:parent              -> hall   o
o ;

    player:child         -> bag         ; bag:parent                 -> player o
o ;

    bag:child            -> book        ; book:parent                -> bag    o
o ;

    player:sibling       -> handkerchief; handkerchief:parent        -> hall   o
o ;

    handkerchief:sibling -> exit1       ; exit1:parent               -> hall   o
o ;

    exit1:sibling        -> exit2       ; exit2:parent               -> hall   o
o ;
```

```
}
```

You could imagine generic functions that work over such a structure. For example, you could write a filter function that cleaned any contents out of a container that didn't pass a given criterion, moving them into a given wastebasket, or a sort function.

We could modify the structure somewhat. We could use these nodes to represent relationships between entities rather than entities in themselves — originally we had only a "contains" relationship, but we could include relationships such as "has as title", "has as acronym", etc. This gets us quite close to the Python or Lua or JS data model, but if we adopt that data model directly, we have the problem that it doesn't allow duplicate properties in a dict.

Consider this example JSON:

```
{
  "glossary": {
    "title": "example glossary",
    "GlossDiv": {
      "title": "S",
      "GlossList": {
        "GlossEntry": {
          "ID": "SGML",
          "SortAs": "SGML",
          "GlossTerm": "Standard Generalized Markup Language",
          "Acronym": "SGML",
          "Abbrev": "ISO 8879:1986",
          "GlossDef": {

            "para": "A meta-markup language, used to create markup languages such
o as DocBook.",
            "GlossSeeAlso": [
              "GML",
              "XML"
            ]
          },
          "GlossSee": "markup"
        }
      }
    }
  }
}
```

It contains a list, GlossSeeAlso. Suppose we represent that with multiple values for the property GlossSeeAlso of the GlossDev entity, by which I mean the object that is the GlossDev property of the other entity:

```
{ ...
  "Acronym": "SGML",
  "GlossDev": {

    "para": "A meta-markup language, used to create markup languages such as DocB
ook.",
    "GlossSeeAlso": "GML",
```

```
    "GlossSeeAlso": "XML"
  }
}
```

This change to the data model eliminates the need for separate lists. In effect, all property values are implicitly lists.

That fragment might look like this:

```
digraph arcs {
    node [shape=Mbox; label="\"\N\""];
    GML XML SGML paraval;

    paraval [label="\"A meta-markup language, used to create markup languages suc
h as DocBook.\""];
    {
        node [shape=record, label="{type \N|{<kid>kid|<sib>sib}}"];
        "root":kid       -> Acronym;
        Acronym:kid      -> SGML   ; Acronym:sib      -> GlossDev     ;
        GlossDev:kid     -> para   ;
        para:kid         -> paraval; para:sib         -> GlossSeeAlso ;
        GlossSeeAlso:kid -> GML    ; GlossSeeAlso:sib -> GlossSeeAlso2;
        GlossSeeAlso2 [label="{type GlossSeeAlso|{<kid>kid|<sib>sib}}"];
        GlossSeeAlso2:kid -> XML;
    }
}
```

This change to the data model means that removing an arc from an entity (and not deleting it) or adding an existing arc to an entity can no longer fail. Furthermore, fetching a property from an entity cannot fail either; it can only return an empty list.

In a 16-bit world, these nodes probably take up 6 bytes each. If we expand the "kid" pointer to be a hash table of 4 or 8 entries, we lose the sequencing among different properties, but we can still retain sequencing within a single property. We use more memory, though still much less than Python, but property lookup becomes instantaneous on small objects.

Matrix exponentiation linear circuits

Kragen Javier Sitaker, 2018-12-18 (4 minutes)

Reading Physical Audio Signal Processing, I was struck by [the]matrix equation for the impulse response]o of the linear state-space model:

$$h(n) = D \text{ if } n = 0 \text{ else } CA^{n-1}B$$

Here D is the direct coefficient matrix from inputs to outputs (not mediated by the system state), A is the state space transition matrix, B is the matrix of input gains (inputs to their effects on state variables), and C is the matrix of output gains.

The equation looks obvious, but suddenly I understand what a vibrational mode is — it's an eigenvector of A, so it survives A^{n-1} unchanged except in phase and magnitude — and I see how to use matrix exponentiation to speed up the simulation of linear circuits.

Maybe I've actually done this before, actually. Specifically, to cut down on errors due to time discretization, you can start with the equations for some time step size, such as a millisecond — maybe $dV(C_1)/dt = 5\ V(L_3) + 2\ V(C_2)$ — so in a millisecond you have .005 and .002 entries in your matrix. But of course $V(L_3)$ and $V(C_2)$ are changing during that millisecond, which generates errors proportional to their second derivatives and the square of the time interval. So, a thing you can do is to divide these deltas by, say, a million, getting the state-transition matrix for a nanosecond — the matrix becomes six orders of magnitude closer to the identity matrix. But simulating the circuit nanosecond by nanosecond instead of millisecond by millisecond would run a million times slower.

So — and this is the clever part — you *square the matrix* to get a matrix for the 2-ns change. (Disregarding the influence of B for the time being, that is.) This matrix is not quite the same as the one you would have gotten by dividing by 500 000 instead of a million, because it includes second-order effects; it precisely captures the effect of doing the 1-ns change twice. Then you square it again, 19 more times, and you have a new matrix for 1.048 576 milliseconds, which allows you to simulate just as fast as before, but with discretization errors that are 12 orders of magnitude smaller.

Taking a really simple example, consider an object whose coordinates are (cos t, sin t). dx/dt = -y and dy/dt = x, so we could try using the matrix

```
[[1 -1]
 [1  1]]
```

which will of course produce immense errors immediately, generating an exponential spiral through the powers of 2. But suppose we divide the derivatives by a factor of 1048576, to get the transition matrix for about a microsecond:

```
array([[ 1.00000000e+00, -9.53674316e-07],
```

```
       [ 9.53674316e-07,  1.00000000e+00]])
```

And then we execute the above procedure. Now we have this:

```
array([[ 0.54030256, -0.84147139],
       [ 0.84147139,  0.54030256]])
```

The correct values of cos(1 rad) and sin(1 rad) are closer to 0.5403023 and 0.8414710, but being correct to six decimal places is nothing to sneeze at. You can make a point orbit with this rotation matrix for many, many generations before it has spiraled outwards much.

(Is this just CORDIC?)

Of course, in this case, we could have corrected the spiraling behavior by noting that the matrix determinant was 2 and thus dividing by $\sqrt{2}$, giving us:

```
array([[ 0.70710678, -0.70710678],
       [ 0.70710678,  0.70710678]])
```

And that is definitely a rotation matrix, and it doesn't lose or gain "energy" (which is squared radius in this case), but it's also definitely not a rotation of one radian.

Topics

Whistle detection

Kragen Javier Sitaker, 2018-06-06 (updated 2018-12-02) (18 minutes)

I can whistle from about 600Hz up to about 1600Hz. There is often substantial unintentional amplitude modulation on my whistle around 25–100 Hz. The vibrations can't ramp up or down by 10dB in less than about 8 cycles, even when I'm releasing a tongue stop, and more typically take 20 or 30 cycles, suggesting a Q factor of somewhere around 10–20. Second, third, and fourth harmonics are detectable, but weak; even the second harmonic is 52dB down from the fundamental. I can easily ramp up from 800Hz to 1600Hz in 1.3 seconds. Doing the same ramp in 100 milliseconds is feasible with more effort.

(Semitone resolution is a Q factor of about 17, so using a linear filter with a lower Q factor would fuzz out frequency selectivity too much to be useful.)

A particular 70-millisecond segment of low whistle had a frequency peak at 615 Hz at -29.3 dB, falling off to -35.6 dB at 610 Hz and -38 dB at 628 Hz. This suggests a Q factor of around 60 during the whistle itself. (Maybe even a bit higher.)

This suggests that the "window size" I should be looking at to detect a whistle could be up to about 20 or 30 cycles or milliseconds in length, and I could band-pass filter the signal to a bandwidth of about 1000 Hz as a first step. Then I could measure the distance between zero crossings or calculate some autocorrelations or something, or run a PLL.

Using high frequencies like this reduces the signal detection latency.

Efficiency questions

I'd like to run this all on an Arduino. So, to reduce the computational cost of this, probably I should start by downsampling to about 4–8ksps. (The Arduino could perhaps capture natively at this rate.) Then, maybe I could resample to 2ksps with downconversion from 600Hz to baseband, but maybe that's not a good idea — among other things, it might increase latency.

There are a variety of possible things you can do from there. You can run a software PLL. These can be quite simple and efficient; this one does 7 simple operations per sample and sort of works to track my voice frequency; you need a few more operations to detect presence or absence:

```
/* A PLL in one line of C. arecord | ./tinypll | aplay */
main(a,b){for(;;)putchar(b+=16+(a+=(b&256?1:-1)*getchar()-a/512)/1024);}
```

You can do STFTs, but that's never going to be fast. (At least within barely more than a single octave, you don't have a terrible tradeoff of window width; you can just use a window of about 30 ms). You can count zero-crossings, but that throws away most of the information in the signal. You can calculate the autocorrelation function for particular frequencies of interest, or when multiplication is slow, the sum of absolute differences. Or you can use particle

filters.

Particle filters

A simple particle-filter-based scheme could measure prediction error of each sample based on various candidate lags, taking the last 20 or 30 cycles (or whatever) as the predictor. If you used 32 cycles, you could calculate the prediction like this:

```
s16 total = 0
  , lag = p.lag  // 12.4 fixed-point
  , lagi = 0
  ;
for (u8 i = 0; i != 32; i++) {
    total += latest_x[(lagi += lag) >> 4];
}
return total >> 5;
```

But that is kind of shitty because you have to do shit 32 times: 64 16-bit additions, 33 4-of-16 bit shifts, 32 indexed byte fetches. It'll take hundreds of cycles to calculate the prediction for a single particle. (Also, you get some aliasing, because you're effectively resampling your signal with nearest-neighbor resampling.)

Incremental prediction

A better approach might be to incrementally update the totals. I will explain.

Suppose we're at 8ksps and our range of frequencies of interest goes from 700 to 1400 Hz. Then each cycle is from 5.7 to 11.4 samples; 32 cycles are from 183 cycles to 370 samples. A frequency in the middle of the range like 1000 Hz will have a cycle every 8 samples. So its current prediction is almost the same as the prediction from 8 cycles ago — it will be adding up almost the same samples. If it cycles through an array of 8 totals, it can update the current total by subtracting the sample 32 cycles ago that fell off the end of the window, then adding the sample from 1 cycle ago. Then it can make the prediction based on that.

The same kind of logic applies for cycles of exactly 7 samples (1143 Hz), exactly 9 samples (889 Hz), exactly 6 samples (1333 Hz), exactly 10 samples (800 Hz), and exactly 11 samples (727 Hz), although some of these will need an array of more totals, up to 11, while others will cycle through less.

Non-integer numbers of samples are trickier, since we don't want to count back by strides of 8.2 samples from the present — by the time we get even 3 strides back, we're no longer looking at the same sample that we looked at the last time we were at this phase, so subtracting the sample 32 strides back from the total makes no sense — it wasn't part of the total to begin with. The solution that occurs to me is to maintain in each phase, associated with the running total, two accumulators like the variable `lag` in the above code, one for the beginning of the window and one for its end. So then the update code for a single phase accumulator becomes something like this:

```
return (p->total += x[(p->head += p->lag) >> 4 & xmask]
                 - x[(p->tail += p->lag) >> 4 & xmask]) >> 5;
```

This is 9 operations per particle update instead of hundreds. However, it omits the logic to select the proper phase, which I think sometimes needs to update two phases.

4 bits of fractional sample allows resolving between lags of 8 samples, 8.0625 samples, and 7.9375 samples — 1000 Hz, 992.2 Hz, and 1007.9 Hz, respectively. This is excessive precision for 32 cycles. We probably can't do better than about half a cycle during our window of frequency precision, which is to say 4 samples out of 256, which means that we really only need 3 bits.

An alternative that avoids the need to track the tail is just to exponentially decay the totals, maybe in a cascade of two or three; that's what the PLL given above does.

Sinusoidal phase detection for PLLs

If you change the particle-filter approach to try to follow the signal by modifying the period of a particle, rather than by spawning new particles with slightly different periods, you end up with a PLL. A simple thing to do would be to look at the prediction error and compare it to the derivative. If the prediction error is of the same sign as the derivative (of either the signal or the prediction), you're falling behind the signal and need to speed up. If it's of the opposite sign, you're getting ahead of the signal and need to slow down. And the prediction error from the phase error will be proportional to the derivative, which has two contradictory implications:

- When the derivative is large, you should expect a large prediction error from a small phase shift, so you should consider prediction errors less important.
- When the derivative is large, the prediction error is less likely to be due to noise and more likely to be due to an actual phase shift, so you should consider prediction errors more important.

I think #2 wins out.

I think all of this will only really work right if your waveform is pretty simple, though, like somewhere in between a triangle, square, sawtooth, and sine wave. Waveforms with weird shapes with negative local maxima and positive local minima will cause trouble. Fortunately, we're kind of filtering those out anyway in this case, and my whistles are 99.75% sinusoidal, as I said at the beginning, even without bandpass filtering.

So it might make sense to just run a sinusoidal oscillator instead of using an average of previous samples as the prediction. (But maybe using previous samples is cheaper.)

A simpler PLL phase detector supporting weird waveforms

Suppose we have an estimated waveform which is the average of the last few cycles (say, a simple moving average of 16 cycles), and we want to know if we're early or late on the phase. Well, we can subtract the sample x_i from the estimate at this point in the waveform e_i and get an estimation error: $e_i - x_i$. Suppose it's positive. Does that mean we're early or late? It depends on the average derivative over the relevant timspan. But what is the relevant timespan? It depends on how big the error is; if the error is small, it's short, and if the error is large, it's long.

It would be relatively straightforward to average derivatives over different spans: for example, (e[i + 4] - e[i - 4]) >> 3, and (e[i+8] - e[i-8]) >> 4, and so on. But perhaps a simpler solution, given that we have a whole estimated waveform, is to look forward and backward in time for the next and previous place the curve crosses x_i. Once we find it, it directly gives us a phase error estimate for that sample. We could get more elaborate and guess how reliable that estimate is, based on how steep the slope is at that point and how many other nearby crossings there are, and indeed we could even compute a whole probability distribution for the phase error and use it to update our prior probability distribution, but it's probably adequate to just use some kind of moving average or median of the phase-error estimates.

Transfer oscillator

An approach sometimes used in analog electronics to precisely measure unreasonably high frequencies is the "transfer oscillator technique", in which "you phase-lock the nth harmonic of a VCO to the input signal, then measure the VCO frequency and multiply the result by n," according to Horowitz & Hill. It seems like you could also do something like this in the digital realm. Suppose you're trying to detect a whistle in the 600–1600Hz range, and you have a candidate frequency, say 1400Hz. You can do a phase detection every *four cycles*, which is to say at 350Hz (every 2.86 milliseconds) to see which way you're slipping out of phase. This could reasonably be done with a modern low-power fast-wakeup microcontroller that goes to sleep in the middle.

It seems like this approach may have some big drawbacks, though. One is that, with the Q factor of 10–20 of my mouth's whistle, you are going to have a really hard time detecting short whistles this way.

Flying saucer sounds

Amplitude-modulated whistles (by vocalizing with the larynx while whistling) are something else entirely; they have the strongest peak at the whistle frequency, but in one signal I looked at, the sum and difference components were only about 10dB weaker, while being 20dB stronger than the valley in between. And the sum and difference components for the second harmonic of the vocal sound, while another 20–30 dB weaker than the upconverted first harmonic, were still 10–20 dB stronger than the valleys in between. The frequencies in this case were 1349, 1476, 1604, 1732, and 1866 Hz, with spacings of 127, 128, 128, and 134 Hz, respectively. The most striking feature, though, is that these inharmonic overtones moved together with the whistle when it changed frequency.

I did try changing my larynx frequency without changing the whistle frequency, but I wasn't successful.

An amusing note: if I could whistle more consistently, with a Q of, say, 60, I could undersample the signal in such a way as to alias the notes down into a much smaller bandwidth than the 1000Hz they occupy now. Each note would only need 40Hz or so, so all 17 would probably fit in a bit under 700 Hz, requiring just 1500 samples per second. (Because they're not linearly spaced, there's some wasted spectral space.) There are a couple of downsides of this: first, a whistle that goes slightly astray from its pitch would be detected as a different note, more or less at random; second, the required Q of 60

also applies to the filtering, and I think it might impose a really large latency; third, you need to bandlimit the signal to just the whistle band, and broadband noise within the whistle band will be impossible to remove.

Musical notes

In A440 12-tone equal temperament, the notes in the 600–1600Hz range are:

- 622.25 Hz
- 659.26 Hz
- 698.46 Hz
- 739.99 Hz
- 783.99 Hz
- 830.61 Hz
- 880.00 Hz
- 932.33 Hz
- 987.77 Hz
- 1046.50 Hz
- 1108.73 Hz
- 1174.66 Hz
- 1244.51 Hz
- 1318.51 Hz
- 1396.91 Hz
- 1479.98 Hz
- 1567.98 Hz

A quick whistle test in front of my laptop with Audacity had me whistling a short melody (from the Myrath song "Endure the Silence") at 1130Hz, 1137Hz, 1235Hz, 1127Hz, 1103/1072/1075 Hz, 1072Hz, 973Hz, 898Hz, 849Hz, 752Hz, 728Hz, and 781Hz, which is about as far from A440 as it's possible to get. As the 1103/1072/1075 indicates, the spectral peak frequencies reported by Audacity are perhaps somewhat noisy. In 12-TET semitones relative to the frequency of the first note, this is 0.00, 0.11, 1.54, -0.05, -0.86, -0.91, -2.59, -3.98, -4.95, -7.05, -7.61, -6.40. While it's possible I'm 46 cents out of tune on some of the notes, I suspect that another reasonable hypothesis is that Myrath is using 24-TET.

Are these frequencies really that unreliable? Upon examining the (last) 1072Hz note again, it appears as 1077Hz, or -0.83 semitones from the first note, so Audacity's noise in that case amounted to 3 cents. Upon further examination, 33 cycles in the middle of it lasted 1352 samples (at 44.1 ksps), zero-crossing to zero-crossing, or 30.658 ms, giving the frequency there as 1076 Hz. 20 cycles at a later point in the same note lasted 809 samples, giving a frequency of 1090 Hz there. 962 samples earlier on in the note contained 24 cycles, giving a frequency of 1100 Hz. So actually they are pretty reliable.

After applying a gentle 12dB/octave rolloff below 600Hz and 1600Hz, the vast majority of the signal power was in the whistle; it was typically 30dB louder than anything else, despite the major traffic noise. Second and third harmonics were still visible.

How's my rhythm?

I was tonguing the notes to get very definite start times.

The time interval from the start of the first note to the start of the

second was 21167 samples. From the second to the third was 21746; from the third to the fourth was 21312; from the fourth to the fifth was 21505; from the fifth to the sixth was 25652; from the sixth to the seventh was 11139; from the seventh to the eighth was 10752; from the eighth to the ninth was about 10728, though it's fuzzy; from the ninth to the tenth was 10873; from the tenth to the eleventh was 10536; and from the eleventh to the twelfth and last was 11210. If we take our nominal quarter-note time as 21505 samples, which is the median of [21167, 21746, 21505] and 2*[11139, 10752, 10728, 10873, 10536, 11210], then the errors here are -1.6%, +1.1%, 0, +3.6%, -.05%, -0.23%, +1.1%, -2.0%, and +4.3%, except that 25652 is 1.193 beat times, which is a pretty weird number. The other errors might be just as much from the mouse selection skillz I'm using in Audacity to mark the time intervals as from actually being off the beat.

The notes mostly each ended a bit before the succeeding note, but I think there was a significant amount of room echo.

The great thing about this is that it provides *plenty* of margin of error for identifying beat timings. If the standard deviation of being on-beat is ±2.0%, as it is in this case, then we can be pretty confident in identifying which beat a note is starting on.

Tapered thread

Kragen Javier Sitaker, 2015-09-03 (updated 2019-06-10) (4 minutes)

Was just watching Dan Gelbart's video on building large structures with adhesives (http://youtu.be/EeEhS3zmnDg), and he demonstrated a flexural clamp he uses: a waterjet-cut slot with a tapered round hole drilled and tapped in the middle of it, parallel to the edge of a rectangular hole. Screwing a tapered thread into the round hole expands it, curving the edge of the rectangular hole inwards. Incredibly simple and with an unbelievably huge mechanical advantage.

NPT, the US standard for tapered pipe threads, is tapered at 62.5mm/m, or 1:16. A common ½" pipe (inside diameter, since that's what determines the pipe's capacity) is tapped at 14 threads per inch, or 0.55 per millimeter; one full rotation of the pipe will advance it into or out of the hole by 1.81mm. You could very reasonably use a 10cm-radius lever arm or gear to turn the pipe, which would make a full rotation 62.8 cm along the outside, which is a mechanical advantage of 346 to the linear axial movement of the pipe. Divide that by the 1:16 taper, and the total mechanical advantage is 5540.

That means that you have a very simple device with two moving parts and no backlash that can amplify your tactile positioning precision of perhaps 100µm down to 18-nanometer resolution (over a total travel of maybe 2mm), and perhaps just as important, amplify your perhaps 1kN bodily strength into 5.5 MN, a bit above 600 tons — although, again, with a travel of only about 2mm.

The pipe won't stand up to that much, though, even if you stuff it with concrete. Regular Schedule 40 ½" mild steel pipe has a 2.77mm-thick wall, maybe 19mm of length on the thread, but you might be bearing that whole force on 7mm of width across the 21mm total width at some point in the movement, only 147 mm², for about 37 GPa. ASTM A36 mild steel can have as little as 152 MPa (0.152 GPa!) of compressive yield strength. You can improve the situation somewhat by using bigger pipes, harder steel (or 2.5 GPa cast iron? or carbide?), and having less travel so the force is better distributed, but basically I think the limitation is going to be the strength or hardness of the metal.

(In the following video, Gelbart says most steels yield at 10 or 20 tons per square centimeter, which is actually a GPA or two. Alumina can get up to 5.5 GPa. I don't think anything makes it to 37 GPa.)

With two of these positioners arranged at right angles to push on arms, rather than to squeeze a hole, you could position a stylus in two dimensions to 18-nanometer precision, for example for scribing microfilm; with three, you could position a stylus in three dimensions. There are a lot of possible sources of positioning error in this system, such as lubricant entrainment, vibration, and thermal expansion, but I think you can probably make it work.

One of the more interesting things I think you can do is emboss a pattern from a hard die into a soft pattern material, using the flexural positioner to drive a stone or whatever, or to press a sheet between two dies (or a die and a soft material). In particular, this might be a feasible way to rule small optical diffraction gratings without the

difficulties attending the standard ways of doing it.

In a later video http://youtu.be/nCfVupLt-Pk/ Gelbart claims that silicone mold-making material has "molecular" resolution, which would make it an ideal inexpensive material for further reproductions.

Immediate-mode PEG parsers in assembly language

Kragen Javier Sitaker, 2019-12-10 (updated 2019-12-11) (21 minutes)

I think I've reinvented an interesting design for how to do parsing efficiently and straightforwardly in machine code; it seems eminently workable and quite efficient, at least for grammars without an unusual amount of ambiguity, probably achieving parsing speeds of dozens of megabytes per second with easy-to-write assembly code. It's an approach to parsing analogous to the IMGUI approach to building user interfaces --- or, from another point of view, a slight tweak on traditional recursive-descent parsing that adds some expressivity.

I've been working with Meredith Patterson and Andrea Shepard on the Hammer parsing engine. This isn't intended as a proposal for Hammer, but it is certainly inspired by Hammer. Andrea's been working on an LLVM backend for Hammer, and that, along with the difficulties Jeremiah Orians reports in writing interpreters in assembly, has led me to think about these problems.

In Immediate mode productive grammars (p. 898) I wrote about how to use a similar design for *bidirectional* parsing *and deparsing*, that is, serialization. Deparsing is not considered in this note. I also considered a vaguely similar idea for compiling a syntax tree into machine code that iterates over it in Optimizing the Visitor pattern on the DOM using Quaject-style dynamic code generation (p. 1508).

The basic correspondence

Consider the design of Hammer. Hammer is a relatively traditional parsing combinator library in C; you call a bunch of Hammer functions to incrementally build up an object graph representing your grammar, in much the same way a user of a traditional widget toolkit calls widget-creation functions to build up an object graph representing their GUI. Is there an alternative that would look more like IMGUI?

The fundamental combining operations of PEGs are greedy choice, concatenation, indirection, and negation. These are pretty close to the usual programming operations of conditionals, sequencing, subroutine call, and iteration; although negation and iteration do not correspond, the others do. It would be nice to directly implement concatenation of languages with sequencing of programs, so that you could compile the tiny language `'h' 'i'` into, for example:

```
mov $'h, %al
call letter
mov $'i, %al
call letter
```

That much is fairly easy to do: the `letter` subroutine checks the next byte of input, explodes if it's not 'h' or 'i', and otherwise advances the input pointer, something like this:

```
letter:
    mov (%esi), %cl
    cmp %al, %cl
    jne explode
    inc %esi
    clc
    ret
```

This takes seven instructions per character on the happy path; you probably want a sentinel EOF character which, if you want to recognize it, gets handled specially. (The `clc` is explained later.)

Choice and backtracking

Backtracking can't be done quite as simply as 'h' 'i' / 'j', because somehow the failure of 'h' needs to know to backtrack to the 'j' instead of somewhere else.

Well, it *could* be done that simply by no-opping the intermediate operations, just as in IMGUI toolkits you can call a bunch of functions that don't draw anything because they are off the screen or something, or just as you can null out the effect of all future writes to a file descriptor by closing it (they just get back EBADF). All your side effects need to be indirected anyhow in case you have to backtrack (see the section "Data store" below). But I think a more efficient and more comprehensible approach is something more like this, if I can figure out how to make it work:

```
    jc 1f
    mov $'h, %al
    call letter
    mov $'i, %al
    call letter
1:  call backtrack
    jc 1f
    mov $'j, %al
    call letter
1:  ret
```

The idea is that, on entry to the parser subroutine, the carry flag is initially cleared; but, if 'h' or 'i' fails, the subroutine is restarted with the carry flag set, which leaps to the call to `backtrack`. That redoubtable subroutine clears the carry flag, updates the backtracking state, and returns. If instead it is reached with the carry flag *clear*, because execution fell through all the `letter` calls successfully, it knows that its immediate caller has succeeded, and so it returns *from* that caller, never returning *to* it.

The disadvantage of this approach is that it requires the parsing subroutine to be called specially, via a magic parsing-subroutine-calling subroutine which saves the initial backtracking state, clears the carry flag, and upon the subroutine returning, discards that backtracking state. (Although this would be needed in any case if you want Packrag memoization.)

A less magical approach would look like this instead:

```
    call choice
    jc 1f
```

```
    mov $'h, %al
    call letter
    mov $'i, %al
    call letter
1:  call nextchoice
    jc 1f
    mov $'j, %al
    call letter
1:  call endchoice
    ret
```

This requires you to bracket your alternatives with `choice`/`endchoice` calls, which will return twice if backtracking is needed but are otherwise ordinary. Once one of the choices succeeds, the following `nextchoice` calls skip over the following bodies (by setting the carry flag, as before) until `endchoice` is reached.

This approach has the disadvantage that you can forget the `endchoice` call, particularly if you have multiple return paths, and it requires writing a couple more instructions per choice. It has the advantages that parsing subroutines can call each other directly, you can nest choices, and failure propagation to parents is faster and more straightforward to implement.

This use of the carry flag is the reason that the `letter` routine given above clears the carry flag; otherwise a carry left over from its `cmp` instruction might result in spurious reports of parse failures.

(I think this is more or less the aproach of the Warren Abstract Machine used for Prolog, but I don't understand the WAM, so I might be wrong about that. I should probably read about it to see if I'm reinventing it in a way that is known to be broken.)

Negation

Negation requires the same kind of backtracking transaction to be set up that choices do; the difference is that negation always aborts the transaction, but it fails if any of the choices succeeded. I think we can make this work with a `negatechoice` subroutine; for example, to parse `!keyword identifier`:

```
    call choice
    jc 1f
    call parse_keyword
1:  call negatechoice
    jc 1f
    call parse_identifier
1:  ret
```

Repetition

I'm not *absolutely* sure of this, but it's a belief I have about PEGs. Because repetition and alternation prune alternatives in the same way, strictly speaking, if you have recursion, repetition is unnecessary; these two grammars parse the same language:

```
aab <- 'a'* 'b'.
aab <- 'a' aab / 'b'.
```

But the first one only saves a single backtracking state, which gets repeatedly updated, while the second one saves an arbitrarily large stack of useless backtracking states. I'm not sure it's possible to implement that behavior in terms of the `choice`/`nextchoice`/`endchoice`/`negatechoice` primitives described earlier, so there might need to be a `repetition` subroutine to in effect commit the in-progress transaction so far and start a new one:

```
    call choice
    jc 1f
2:  mov $'a, %al
    call letter
    call repetition
    jc 1f
    jmp 2b
1:  call endchoice
    mov $'b, %al
    call letter
```

I'm not sure if you can just use an `endchoice`/`choice` pair instead; I think it will do the wrong thing by propagating the failure of the last greedy advance. There might be a tweak that makes it work.

More terminals

Of course in practice you will want things like Hammer's `h_literal` which matches a literal string and `h_ch_range` which matches any byte within a byte range. There are lots of ways these could be handled; for example:

```
    mov $('a | 'z << 8), %ax
    call range

    .data
t:  .ascii "const"
t_end:
    .text
    mov $t, %eax
    mov $(t_end - t), %ecx
    call literal
```

Byte classes, like regexp character classes, are also likely useful; these would have a string either in memory or in a register of the bytes they could accept.

Hammer supports parsing by bitfield rather than by byte, but I think a significant number of things don't require that.

Data store

Generally you want to build up some kind of AST or something as you parse; the failure of a "transaction" ought to efficiently backtrack whatever you did when you were building that AST. One reasonable way to handle this is to build up the AST in a pointer-bumping allocation arena (like Hammer's arena allocators, GCC's obarrays, or the Java GC's nursery) and bump the pointer back when a transaction fails. This is only safe if all the pointers into the backtracked part of the arena also become inaccessible, so it's also necessary to supply some

kind of variable-bindings construct that gets backtracked too.

Maybe the following API would work well for within-transaction code:

• new(*nbytes*) -> fresh *pointer* to a node of *nbytes* bytes;
• dup(*pointer*, *nbytes*) -> fresh *pointer*; creates a copy of the *nbytes* at the old *pointer* so that you can modify it in the new transaction;
• put(*opaque*, *pointer*); updates the "variable" "named" by *opaque* to have the value *pointer*;
• get(*opaque*) -> *pointer* to the current value associated with *opaque* (the last thing you called set() with for that value of *opaque*), or 0 if none exists.

You can have a relatively small number of distinct *opaque* values ("variable" "names"), for which you can use function pointers or something else guaranteed to be unique; this is pretty similar to thread-local storage. They can be stored in an alist in arena nodes. If you have five of them, for example, each associated with a five-word node, you have 25 state variables for your parse. (Maybe you'd want to bloat the alist a bit to bound the depth to which you'd have to search it to the number of variables, or twice the number of variables, or something.)

This approach permits the backtracking of the arena state by resetting two pointers, the head of the alist and the allocation pointer.

With such an implementation, you can also easily supply an additional backtrackable operation that is probably frequently useful in parsers:

• pop(*opaque*); undoes the latest put to *opaque*, restoring it to its previous value. This could be useful, for example, for indentation levels. This requires the bindings for each variable to be linked together in a separate list from the list that unites the current bindings of all the variables.

To some extent you might be able to entirely avoid using the variable store, since you can return pointers to arena nodes in registers.

In addition to the calls above for code *within* transactions, you need the usual begin/abort/commit calls for transaction management.

This allocation approach is, however, entirely incompatible with Packrat memoization. The transactional variable-store thing could maybe survive, but the deallocation thing can't, because the memoized return values of nonterminals invoked from within a transaction that later failed would need to survive. Memoizing a nonterminal that might depend on the state of the variable store would be sort of dubious, too, though.

Overall parsing context

I think we can do most of this entirely in registers, which should speed it up considerably. You need:

• PC, which tells you where you are in the parsing of the current nonterminal;
• the stack pointer, which tells you what other nonterminals you're in the middle of parsing, when you get done with this one, with their PC values;

• the input pointer, assuming the data to be parsed is in RAM;
• the backtracking stack pointer, which might be a pointer into the PC stack;
• the allocation arena pointer;
• the current variable bindings pointer;
• the "skip" flag (the carry flag above), which indicates that we want to skip a choice, either because it has failed or because an earlier choice has succeeded.

That's six or seven registers, only three or four of which are general-purpose, plus the skip flag. This should fit even the impoverished i386 register set.

Of these, all but the skip flag would be saved and restored for backtracking. This suggests that the context-save code, part of `choice` and `nextchoice`, might look something like this on i386:

```
pop %eax              # pc
push %ebp             # backtracking stack pointer
push %esi             # input pointer
push %edi             # allocation arena pointer
push %ebx             # variable bindings pointer
push %eax             # pc
mov %esp, %ebp        # point backtrack stack to newly allocated state
push %eax
clc
ret
```

A similar sequence of about ten or so instructions would be needed to backtrack. This suggests possible parsing performance in the neighborhood of 20 clocks per byte on modern CPUs, which could conceivably reach speeds of hundreds of megabytes per second, but probably won't.

(I think there might need to be a bit in that backtracking state record where we can note that it corresponds to a choice that has *succeeded* and we are just skipping over the remaining branches. Also, there isn't enough information there to tell when our arena is full; presumably arena allocations need a check for that unless it's okay for them to just crash or overwrite other data when it gets full, which is how execution stacks are often handled, I guess. So we might need an additional register for that.)

Arbitrary computation

Although we have to be careful not to have any effects we might wish we hadn't had if we backtrack, we can freely intersperse pure computation with the parsing, and even use it to decide whether or not to continue with a parse or fail. This computation can freely read and write the transactional data store described earlier, which might include information like type information for identifiers or indentation levels.

In particular, we can consult some other data structure to decide what to try to parse; for example, an in-memory grammar. We can even translate the choice backtracking to traversals of that in-memory grammar, as long as we keep track of our traversal state in something that backtracking restores correctly, such as the data store. If the backtracking stack is stored on the execution stack, as in the example

code above, then your traversal will need to recurse in order to backtrack properly.

Another less pure thing we can freely do is to skip the read pointer to arbitrary places in the input text; the read pointer will be restored automatically if we backtrack, just as it would for normal sequential reading. This is interesting for things like parsing PDF files, which store byte offsets in their structure for random access to the object tree. (This is, of course, inspired by some work with Hammer to parse PDF files.)

Suspend and resume

If we want to suspend parsing to do something else for a while --- for example, read more input from somewhere else, or parse something else for a while --- nearly all the state we need is either in the context data structure saved for backtracking, in the arena, or on the stack. Doing some other thing that can be done by calling a subroutine that doesn't interact with the arena or unwind the stack is perfectly safe --- that's pretty much just an instance of "arbitrary computation" in the previous section --- but if you need to switch to a different arena or stack, all you need to resume the parse (restoring the stack) is the pointer to the backtracking context. And maybe the arena pointer, if that's not saved in the context.

Immediate-mode PEG parsing in other programming languages

As described above, this sounds like an approach that's pretty strongly tied to assembly language (although not any particular assembly language) because it relies on being able to manipulate stacks and control flow in a counterintuitive way. But it turns out to map in a reasonable way onto *some* other programming languages.

Doing it in C

You can do most of these things in C; `choice`/`nextchoice` require using `setjmp`/`longjmp`, and you'd probably want to use an integer return value from them rather than the carry flag. And of course you can't do alloca()-like things or keep your allocation pointer in a register, and C function calls are usually a lot more expensive, though, e.g., things like `__attribute__((fastcall))`, `__attribute__((regparm(3)))`, and the amd64 ABI can help. The rest is pretty much the same:

```
if (choice()) letter('h'), letter('i');
if (nextchoice()) letter('j');
endchoice();

void *rv = 0;
if (choice()) parse_keyword();
if (negatechoice()) return parse_identifier();
```

In C++ or Rust or D, you might be able to use RAII to automatically do the `endchoice()` calls for you (though I'm not sure Rust or D have the requisite `longjmp` equivalent, although presumably you can invoke `setjmp` and `longjmp`; and using them in C++ is pretty risky because of the profusion of invisible destructors you might be jumping over); in C the only way to do that is to abuse the

preprocessor. Which brings us to macro assembly.

Or macro assembly

A macro assembler with enough of a context-stack facility to implement if-then-else and do-while should enable you to write a PEG grammar in a fairly literal fashion, maybe something like this:

```
expr: either(go(term); either(eat('+'); or eat('-')); go(expr)
             or go(term)); ret
term: either(go(atom); either(eat('*'); or eat('/')); go(term)
             or go(atom)); ret
atom: either(number; or eat('('); go(expr); eat(')')); ret
number: some(range('0', '9')); ret
```

This would keep you from accidentally failing to balance your `choice`/`endchoice` pairs, leaving out a `jc`, or jumping to the wrong label.

Doing it in Scheme

Earlier I said that `longjmp` was in short supply in modern languages; but Scheme of course has `call-with-current-continuation`, which is a generalization of `setjmp` that could easily be used to implement the above. Scheme also has a solid macro system. So Scheme is in some sense the best-suited language to this, except that all Scheme implementations are slow.

Or Ruby

Yeah, Ruby also has call/cc, and it's designed for embedded DSLs like this, although it uses reflection and a lightweight closure syntax rather than a macro system.

Or Forth

Brad Rodriguez published an article in 1990 about "BNF parsing" in Forth in something like this way, in three or four screens of code, including language concatenation by execution sequencing, and I read it sometime in the 1990s but didn't understand it. However, a lot of the details are different. (He uses the "no-opping the intermediate operations" approach I rejected above, as well as the "accept an alternative by returning from the caller's caller" technique.) I think the implementation technique described here might work better (more efficiently, more flexibly) in Forth than Rodriguez's method does. Like C, Forth implementations typically have the equivalent of `setjmp` and `longjmp`, and I suspect they're less dangerous due to the rarity of stack-allocated variables in Forth; and, of course, Forth is ideally suited to embedded DSLs.

How about Python, JS, or Lua?

Python of course doesn't have call/cc, setjmp, macros, or a reasonable lambda syntax. What it does have is generators, which have been adopted by JS now as well, and which are pretty straightforward to use to lazily generate candidate parses of strings, handling backtracking by resuming a generator rather than trashing it. This is a pretty different paradigm and I'm not sure how to map the immediate-mode stuff above onto it; it almost seems easier to do general context-free parsing by backtracking that way, although by default that will take exponential time.

Lua has "coroutines" which are really full-fledged cooperative threads, which provide similar functionality to Python generators but with per-thread stacks, but it doesn't have call/cc or anything similar.

Topics

Dercuano stylesheet notes

Kragen Javier Sitaker, 2019-04-28 (updated 2019-05-09)
(72 minutes)

I wanted to spiff up the Dercuano display a little so that it would be pleasant to read, but more with the objective of being like a book than being like an advertising brochure. [When I started writing this, the only CSS thing I'd done was give it a max-width to keep the lines from being 2000 pixels long.]

But what does a book look like? What does a good web page look like? Are they different?

Medium

Marcin Wichary of Medium wrote an article entitled, "Crafting link underlines on Medium," in which he talks about how to get link underlines to work. He describes a CSS hack using background images "synthesized *via*" gradients, and also describes a further hack using a white CSS text shadow to make it clear descenders, which they apparently don't actually use — but Gwern does something like this, see below.

I looked at Medium to see how they're doing things. They set the article title and article text in a serif font (falling back to Georgia if their proprietary font fails to load) and article section titles in a sans-serif font (falling back, similarly, to Helvetica); everything uses rgba(0, 0, 0, 0.84) except for the line underneath the title in gray and the pullquotes. (0.84 is the fourth root of ½.) The article had a font-size of 21 pixels and a line-height of 1.4; the main article title had font-size of 46 pixels; and the subtitles were somewhere in between in size. The subtitles were somewhat bold and left-aligned.

The article section titles have some vertical whitespace around them, but I don't remember how much.

Article category links are at the end of the article in light gray boxes with rounded corners, generally all on the same line.

They're using a different serif font with Clarendon slab serifs for drop-caps, and to get hanging punctuation on paragraphs that open with open-quotes, they use a paragraph-opening-with-open-quotes class to set text-indent to -0.4em.

The body text is set in a single column with a max-width of 700 pixels, which works out to 33 ems. It's centered with `margin: foopx auto` at the appropriate level of nesting; inline images are also centered but in a wider column, so they can reach the margins on a small screen (Wichary pompously dubs this "our signature full-bleed, blurred images" in his post). Despite using a serif font like a real book, they use a ragged right margin, at least in Chrome — possibly a concession to the lack of hyphenation.

At times they use thin spaces around their em dashes, as I do.

Medium goes to some trouble to use hanging punctuation, like Gutenberg, but it only works sometimes.

Font files: ET Book!

I looked at downloading Noto to bundle, but Noto is humongous; the whole bundle is 1.1 GB, and even just a CJK ideograph bundle is 100+ megs. So I pretty much have to rely on system fonts for

Dercuano, since keeping the download bundle self-sufficient and small is pretty much the whole point. (Also, I can't find a Noto subset that includes the Latin letters this text is written in.)

Later, though, on Fernando Irarrázaval's blog, I found the ET Book Bembo-like font family, which has been released under the MIT license by Edward Tufte and its authors, Dmitry Krasny and Bonnie Scranton. The four fonts I'm including, three of which I'm using, gzip to 180K, even though they cover all of Latin-1, plus a bit more! And it's beautiful, especially the italic, and it has old-style figures. It even has ligature glyphs, although mysteriously the browser doesn't use them, apparently because the font isn't specifying the necessary context rules.

So I've switched to ET Book. But the 22px size I was using before (DejaVu Serif, the system default) is a lot bigger than the 22px size of ET Book. The equivalent ET Book size is nearly 28px. Now DejaVu Sans Mono looks dramatically oversized, its x-height being nearly as tall as the Antiqua capitals. So I twiddled several things to compensate:

- I used ET Book 26px as the default, reducing the line-height from 1.5 to 1.4 to compensate;
- I reduced <pre> and also <code> to font-size: 80%;
- I shortened max-width from 45em to 35em.

These are somewhat suboptimal if ET Book doesn't load for some reason (maybe your browser doesn't support .ttf webfonts, although Firefox and Chromium do, or if you're experiencing a Firefox bug, as I think I am at the moment) but not catastrophic. In particular the line length in ET Book is a little longer than I would like so that it's not uncomfortably short if ET Book fails to load.

Characters not covered by ET Book are typically problematic, e.g., the lowercase Greek in the title of Plato was not particularly democratic; ἄρχειν is not "participating in politics" (p. 1707), because they are taller, wider, bolder, and have less stress than ET Book, at least on my machine. I'm not sure what to do about that; shipping Cardo is not an option, as it would add a megabyte or more to the package size. I might be able to scale the letterforms and bearings in ET Book by 125% to fix it (and undo the stylesheet changes).

The biggest coverage problem is the numeric superscripts: $^{0}{}_{123}{}^{456789}$. ET Book covers ¹²³, while the others come from a fallback font, with fairly disastrous effects on the readability of things like "x^{62}", which looks more like "$x^{6}{}_{2}$" than the intended "x^{62}".

Mark Shoulson points out that in addition to lacking ligature tables, leading to the same missing ligatures I complain about in *The Grammar of Graphics*, the font also lacks kerning tables, leading to kerning that looks precisely like the kerning I complain of below in *Tick, Tock*.

Books

There's an interesting question as to whether type should be larger or smaller on a computer screen than in a book. On a computer screen, of course, you never run out of paper; the "paper" is free; so maybe you should use larger type. But often the screen is smaller than a two-page spread in a book, and if you have two books open at

once they have to share the same screen; so maybe you should use smaller type. But often the screen is of much worse resolution, so maybe you should use larger type. And maybe the screen is further away, so maybe you should use larger type.

But probably the differences from standard book practices for books should be justifiable. For example, books don't have to be readable on a cellphone screen, and when they can take advantage of color or even grayscale, it adds substantial extra cost, and it suffers a substantial loss of resolution due to halftoning. Furthermore, printing with movable type *on top of* a color or even grayscale background, as opposed to inserting figures, is basically impossible. So there might be reasons other than imitating sales brochures for using color.

In the other direction, common browsers (notoriously Chromium) still don't do hyphenation, and their paragraph-filling algorithms are minimialistic at best, and justification in browsers never adds letter-spacing, so enabling justification in CSS gives you wildly varying word spacing, which looks shitty. So if you're targeting web browsers you need to suck it up and accept ragged right margins. Or, if you're sufficiently eccentric, ragged left or ventilated prose.

The rigors of five and a half centuries of metal type printing, concurrent with the birth of capitalism, salutary as they have been for human attempts at civilization, have not been kind to typography. The aesthetic experience of reading has been compromised by first one and then another vulgar commercial innovation — lining numerals, sans-serif fonts, copyright, typewriter fonts, banner ads, paywalls, product placement — while the limitations of metal type have been embraced as virtues by generations of typographers. Rubrication is no longer red, but black, and color is indeed omitted almost entirely; swashes are rare flourishes; illustrations are separated from text by rigid rectangular borders and even omitted altogether; drop caps and other initials are abjured or relegated to extreme rarity, perhaps one per thousand pages; border ornamentation is minimal when it is present at all; marginalia are omitted; justification of lines can only be done by altering spacing rather than stretching glyphs; letters are present only in one to four sizes rather than a full variety; etc.

The major overall limitation, really, is that in movable-type printing, things cannot overlap. Swashes cannot overlap other letters or margins; words cannot protrude into margins; text blocks cannot overlap illustrations; descenders of one line cannot overlap ascenders of another, creating a pressure toward greater and greater x-heights, destroying much of the beauty of minuscule; diacritics cannot overlap multiple letters; and only through the hacks of kerning and ligatures could we even get reasonable spacing for most letter combinations involving capitals and "f".

To be sure, these last centuries have brought beneficial innovations as well. The ample use of whitespace to improve readability, beginning with division into paragraphs; boldface for scannability; the elimination of scribal abbreviations, and especially the abominable Tironian notes, which saved precious parchment at the price of promoting ignorance among the people; the improved calligraphic quality of commonplace fonts over all but the best scribal calligraphy; photographic printing; four-color halftoning; data plots, and especially the work done by Tufte to improve them; algorithmic

rendering; the modern language of mathematical formulas; hyperlinks; simulation; animation; interactivity; but most of all, mechanical reproducibility.

TEX: the Program

This book is arguably some kind of referent for readable typesetting, but maybe not the copy of it I'm looking at. On my monitor at a comfortable zoom, the line spacing in its paragraphs is about 32 pixels, the x-height is about 11 pixels, and the spacing of lowercase "m"s is about 25 pixels; and a line is about 1350 pixels wide, which is a bit wide for my taste (about 19 words per line!) but certainly helps with the justification. And the paragraphs in the book are mostly very short, so long lines don't impede readability as much as they might.

If we take the font size (1 em) to be nominally 24 pixels, that works out to a CSS line-height of 1.33 (ems), a width of 56.25 ems, an "m" of 1.04 ems, and an x-height of 0.46 ems, which is pretty readable.

At this zoom, the page is 285 mm wide, which is 1.36× the 210-mm width of A4 paper and 1.32× the 216-mm width of US letter-size paper it was most probably formatted for, and those 1350-pixel lines are 217 mm wide, which is 161 μm per pixel (158 dpi). We can conclude that the book was set in type of around 24 pix · 1.32 · 161 μm/pix = 5.1 mm = 14.5 PostScript points.

Each section (of which most consist of a single paragraph) begins with a boldfaced paragraph number for hyperlinking, and some of them also include a boldfaced topic for that "part", which is typically several pages' worth, and begins at the top of a new page. This inline "part header" is the same size as the rest of the text. Between sections, there is a blank space (a vertical skip) of about a line in height, and there is a smaller vertical skip between text and code. Code is annotated below with a backlink in smaller type: "This code is used in section 726," and sometimes also, "See also sections 20, 26, …". The smaller type is reduced in size by about a factor of 1.4.

There is no further rubrication other than the index and table of contents at the end of the book.

TickTock

This is a Dean R. Koontz thriller, or possibly a comedic satire of thrillers. The copy I have here is a Ballantine paperback, justified with narrow margins (9 mm) in a traditional curved-serif font, with paragraph indents and no extra vertical space between paragraphs. The apostrophes are poorly kerned with too much space to their right; combinations like "ov", "Vi", and "To" are also kerned, or rather not kerned, with too much space — perhaps if Koontz had known his book would be printed like this, he wouldn't have named his main character "Tommy". There are 32 lines per page; the last 31 of them measure 147 mm in total height, giving 4.7 mm or 13.4 PostScript points per line; the spacing between letters "m" is about 4.0 mm or about 11 points. This suggests that the book is set in 12-point type with about an extra 0.12 ems of leading between the lines.

This book was printed in 1996, so it doesn't have any vertical typewriter quotes; all of its quotes and apostrophes are of the proper 9, double 6, and double 9 types.

Each page holds about 290 words, which works out to 9.1 words per line; within paragraph bodies (excluding indents and last lines) the average is closer to 10. The lines measure 85 mm wide, which would be 20 ems if my 12-point-type guess above is correct. Typically there are zero to two hyphenations per page, so at times the word spacing is a bit uneven, but the average word length is pretty short, so it's not as bad as you'd think; to illustrate the word length, here's a randomly chosen paragraph on p. 210:

"But I *don't* believe they come all the way across the galaxy to kidnap people and take them up in flying saucers and examine their genitals."

There are abundant italics, but outside of titles, there is no boldface.

The main book title on the title page (in bold capitals) has a line-height of about 15 mm (43 points), and the author's name is set below it (in bold capitals) with a line-height of about 11 mm (31 points). Each chapter title ("ONE", "TWO", "A NOTE TO THE READER", etc.) is set (in bold capitals) with a line-height of about 7 mm, underlined with the same small illustration. Chapter titles start on new pages, but many start on even pages, leaving no pages blank. Other than page headers, there is no other rubrication or division in the book, such as horizontal rules or lines of asterisks.

The book feels a bit crowded with its 2-em margins, short lines, narrow leading, and no vertical skips. But I suppose lulling you into too much tranquility would defeat the purpose of the book, as well as cutting into Ballantine's profits with extra paper costs.

The Grammar of Graphics

This is a recent (2005) semi-academic book published in hardcover by Springer, with, unusually, bright white glossy paper and color — apparently finely halftoned CMYK, on every page. That's because it's a treatise on the visual display of quantitative information, and the authors have dedicated a great deal of care to its visual appearance; they set it in Times Roman and Times Italic with FrameMaker. There is a strong hierarchical structure to the book, with numbered section headings that frequently run four levels deep ("*6.2.5.3 Fisher's z Scale*"), which are all in Times Italic. There are occasional subheadings before level-4 headings, which are not numbered. Paragraphs are indented (except when following a heading) and justified, but with no extra vertical skip between them.

There are about 46 lines per page, although there is extra leading around headings, figures, equations, and blockquotes, and the text never runs for an entire page without being interrupted with headings, figures, equations, or blockquotes. Lines are 115 mm long, typically containing about 12–14 words, and the lines within a single paragraph are rather tight; 10 lines are 40 mm high, giving 4.0 mm or 11.3 points as the line height, and the escapement of an "m" also measures 4.0 mm. (XXX apparently it's more like 3.0 mm?) Hyphenation is quite frequent, so whitespace is very consistent despite justification. Margins are a generous 20mm to the sides and 22mm at the bottom of the page; the top margin below the page heading is smaller, more like 9mm, but there's another 15mm above the page heading.

This suggests that the text is set in 11-point Times Roman with no

leading and 30-em lines.

Level-1 headings ("14. Time") are chapter headings. The chapter number is set in bold italic with a line height of about 16 mm (44 pt), while the chapter name is set below it below an 8-mm skip in medium italic at about 8 mm (22 pt). Both of these parts of the heading are right-aligned. The page heading above the chapter title is omitted, and blank pages are used to ensure that chapters always begin on odd pages. Below the chapter heading, there is a skip of some 24 mm above the body text.

Level-2 headings ("14.1 Mathematics of Time") are set in italic, with the heading number in bold, and are set somewhat larger than the body text, perhaps twice the point size (8 mm, 22 pt), though it seems to be about 25% smaller than the chapter title somehow. There is only a small extra skip below them, but about a one-line skip above them. There is an extra large space, about a quad, between the number and the title; they also do this after bullets in bulleted lists, and Knuth also did it after section numbers.

Level-3 headings ("14.1.1 Deterministic Models of Time") are set in the same bold/bold-italic combination of styles, but in a slightly smaller font-size, again by about 25%, but still about a 50% larger point size than the body text. These *do* have extra leading below them, though less than above.

Level-4 headings ("14.1.1 Orbits and Vibrations") are set entirely in bold italic, and the body text is smaller than they are by about 25%. Perhaps the bold is intended to add contrast with the body text to compensate for the smaller difference in size, or perhaps bold was not used in the larger titles simply to avoid overwhelming the reader. Again, they have extra leading above and below.

Level-5 subheadings (e.g., "Updates" on p. 438, within §14.3.3.1 "Data") are the same size and with apparently the same leading as level-4 headings, but without numbers.

FrameMaker's typesetting of the equations is very much inferior to T_EX's, with poor kerning, parentheses that fail to enclose and whose line thickness never varies (though that of the letters and digits does), and so on. Aside from that, though, its layout is much the same.

The leading above headings, of course, goes away when they are at the top of a page.

They use a monoline sans-serif font for the names of their data series.

Figures are captioned below in italic; text never flows around figures.

I think a good approximation of the layout can be expressed as follows:

• Body text is 11-point Times Roman with 30-em justified paragraphs. Paragraphs that don't follow headings are indented by two ems. Body text has no extra leading, even between paragraphs.
• The text sizes of headings of levels 4, 3, 2, and 1 are a geometric progression ending at 22 points; this would make them 13.1-point, 15.6-point, 18.5-point, and 22-point, or, expressed in ems of the body text, 1.19 ems, 1.41 ems, 1.68 ems, and 2.0 ems.
• Except that chapter numbers are on a separate line in 44-point text.

• Chapter headings are right-aligned with page breaks to an odd page

before them. All other headings are left-aligned with leading above them equal to their line-height and leading below equal to the line-height of the body text.

Occasionally two headings (of different levels) occur in succession.

Although the fonts used are pretty nice, and the layout and design are reasonable (aside from the truly lamentable formulas), the text is mysteriously entirely missing ligatures; "fi" and "ffi" do not appear as joined "fi" and "ffi" as they should.

How to Make a Telescope

This is a 1957 English translation, published in the US by Interscience Publishers, of Jean Texereau's 1951 French text *La construction du télescope d'amateur*. This copy was apparently acquired by the Northtown–Shiloh Library in Dayton in 1958 (and rebound by The Kalmbacher Bookbinding Co., in Toledo), so it was probably printed in 1957. Like *Grammar of Graphics*, it's printed entirely on glossy paper, although it's yellowed a bit in the ensuing 60 years; the purpose is again fine halftoning, but this time only in black and white.

Its body text is set in a serif font in justified paragraphs with about twice as much space after periods and colons as between words. The paragraphs occasionally have figures centered in the middle of them; they never flow around figures, and they are all indented, by about three or four ems. More surprisingly, section headings within chapters ("II-18. The Polishing Operation" — bold, in the same size as the body text, with leading below and even more extra leading above) are also indented by the same amount as the paragraphs. 10 lines occupy 42 mm, so the line spacing is 11.9 points — might as well call it 12 points.

The chapter titles ("II. Making the Main Mirror") are preceded by page breaks to put them at the top of an odd-numbered page, and with a page-width vertical rule underneath the (right-justified) Roman numeral, below which is a vertical skip of some 17 mm, and right-justified, given extra letter-spacing, in a sans-serif font, in all capitals, in a somewhat larger text size (perhaps 16 points rather than 12), is the title. Beneath the title is another 20mm of leading and then the section heading of the first section of the chapter.

The Roman numerals at the openings of chapters are still larger than the chapter titles themselves; perhaps they reach 24 points.

Some of the numbered sections are contain unnumbered subsections, indicated in the table of contents; the subsection titles occur at the beginning of a paragraph in italic.

References are given in footnotes in a somewhat smaller font, perhaps 9 pt.

Data tables are captioned above in all capitals (in the same font as the body text) and divided into sections with page-width horizontal rules. Columns are separated by whitespace with no rules. Figures are captioned below in the same smaller font used for footnotes.

The Palmer Method of Business Writing

This book was published in 1915; the copy I'm looking at was digitized from the collection of the University of California, and I downloaded the DjVu from the Internet Archive. A Microsoft

watermark contaminates every page. It's a penmanship textbook. Both its layout and its textual tone are considerably more bombastic than the other specimens I looked at above.

I don't have a reliable way to determine its absolute size, since I have only a DjVu scan.

Sans-serif fonts make no appearance whatsoever, except possibly in the legend on the original book cover, "THE A. N. PALMER COMPANY, New York, …", which I can't be sure of because DjVu has corrupted it too badly. The book is full of black-and-white photos (presumably halftoned) and illustrations (which are not); at times the text flows around them, but usually they are placed above and below the text.

The pages are, unusually, in landscape orientation, and seem to have been bound on a short edge; the ratio is about 5 parts length to 3 parts height. Although the typography is somewhat inconsistent, often varying in the body text size from page to page, it is mostly set in two columns, with extra spacing separating sentences (plus spaces inside quote marks), but headings and most of the abundant illustrations span both columns. Occasionally body text also spans both columns, typically for very short sections. Boldface is used liberally, for all the headings and occasionally for emphasis in the body text, while italic is entirely absent.

The body text is set fairly tight with no apparent leading. The columns are about 35 ems wide, and separated by about two ems. The paragraphs, even the first, are indented by about three ems, and are of course justified, with only very occasional hyphenation, resulting in substantial variation in word spacing. Occasionally there is a vertical skip of a line or so between paragraphs, but not usually. Evidently no concern has been given to preventing widows and orphans, as they occur frequently, while unequal column lengths never occur at all.

The headings found throughout the book ("LESSON 80", "Drill 95") are centered and boldfaced. Typically each section has a title ("LESSON 76") which may be broken onto two lines ("LESSON 70", "Drill 85") or written on a single line with an em dash, and may sections also have a subtitle ("TO RELIEVE MUSCULAR TENSION"); the subtitle is about 1.5 times the point size of the body text, and the title is about 1.5 times larger than that. These headings have equal and miserly leading above and below.

Semantically the "Drills" are subordinate to the "lessons" in the sense that some lessons contain more than one drill, and may contain other sections, whether or not headed by what I've called a "subtitle", that aren't part of a "drill".

Many pages have a centered boldface injunction at the bottom in the same point size as the body text, saying things like, "It is not Palmer Method if the lines are tremulous. Study the instructions for speed requirements." On p. 19 instead this same injunction is repeated in large boldface type at the top of the page, with the period removed so it will fit. Truly, the typographic crimes of this manual are manifold.

Some paragraphs, though indented as usual, begin with an inline heading in boldface followed by an em dash or colon:

Height—Reference has already been made to one-sixteenth of an

To the teacher: If you have studied the lessons in advance, have

As an interesting side note, where arrows are present in the

diagrams, they are fletched.

Standard Handbook for Electrical Engineers

This is the 1922 Fifth Edition, scanned from a copy at the University of Toronto library. It's printed by The Maple Press of York, PA, but copyright by the McGraw–Hill Book Company.

It does use italics, as well as small caps, but still has no sans-serif fonts.

The book is divided into "sections" rather than "chapters". Section titles are centered, bold, in all caps, with extra letter-spacing and a largish vertical skip above them, and a short centered horizontal rule below them above the subtitles, if present, and body text. The title is about 1.5 times the point size of the body text. Paragraphs are indented (by about one em), even the first, and justified with generous hyphenation, and line spacing is somewhat loose. Margins are very narrow (on p. 377 the operator scanned their finger, and much of the material near the spine is lost to the Scribe's glass join). There is extra spacing between sentences, and quotes seem to be concatenated apostrophes, perhaps with extra whitespace inside of them. There are places where letter-spacing is compromised for the sake of justification, as on p. 62.

(Because p. 19 has a ruler printed on it, I can report an absolute text size for this book: at "300%" zoom, 30mm of the original book is 58mm on my screen, so the actual zoom is 193%. 9 lines of body text being 37 mm on my screen means that they were 19.1 mm in the original book, so the body text was printed at the minuscule size of 6 PostScript points!)

Section subtitles are centered, bold, in all caps, at a size intermediate between that of the body text and the section title, so about 1.2 times the point size of the body text. At times there is an additional sub-subtitle in centered italics at the normal body text style. There is some inconsistency. We have:

SECTION 2
ELECTRIC AND MAGNETIC CIRCUITS
BY VLADIMIR KARAPETOFF,
Professor of Electrical Engineering, Cornell University, Fellow, American Institute of Electrical Engineers
CONTENTS

Here "SECTION 2" is what I've been calling a "section title", "ELECTRIC AND MAGNETIC CIRCUITS" is formatted at the same point size but bolder and without the extra letter-spacing; the author's byline is formatted at the intermediate font size I called a "subtitle" before; his credentials are centered, wrapped, in italics; and "CONTENTS" is formatted as a subsection heading as described later. But then, on the next page, we have:

SECTION 2
ELECTRIC AND MAGNETIC CIRCUITS
ELECTRIC POTENTIAL

And here we have returned to the formatting I described above: section title, rule, subtitle, subsection heading.

Sections are mostly divided into subsections, which have their own (centered, bold, all-caps) headings, usually at the same point size as the body text, with a little extra leading above and below — especially above, in cases where the page is a bit loose. In some cases they use a larger font, as on p. 576, and may have a subsection subtitle (centered, all-caps, bold, at the size of the body text), as on p. 897, where it gives

the author's name.

Within the body of the book, paragraphs are numbered and begin with a boldface title, which sometimes forms part of a sentence, e.g., "**5. The English weights and measures** are based upon old Roman weights and measures." Paragraph numbering does not restart after subsection headings. At times the numbering becomes hierarchical, perhaps to maintain numbering compatibility across editions, with numbers such as **2.**, **3(a$_1$)**, **3(b$_2$)**, and **3(B)**, which inexplicably comes between paragraphs **3(b$_2$)** and **3(c$_1$)**. Hyperlinks between paragraphs also use bold for the paragraph number: "(Par.**102**)." In the introductory part, a larger text size is used, making the paragraphs about 25 ems wide, but in the body of the book, the paragraphs are about 32 ems wide due to their smaller font size.

Occasionally an numbered "paragraph" is divided into multiple typographical paragraphs, each indented and commonly with a boldface title.

Text flows around figures, which are captioned below and numbered using small caps for the abbreviation "Fig.". The caption is typically formatted as a wrapped centered paragraph, but sometimes justified.

Footnotes are used frequently to cite sources, separated from the body text on the page with a page-width horizontal rule; they are not numbered but use the symbols *, †, ‡, §, ‖, ¶, and then **, ††, etc. In other cases sources are simply cited in the body text, or in a bibliography at the end of a section. (In one case Simpson's Rule is given in a footnote stretched across two pages.)

Equations are centered, inserted into the middle of sentences with no extra leading, and some of them are numbered on the right. The line before the equation is not justified, as if it ended a paragraph (difficult to avoid in cases where it consists simply of, say, "or", as on p. 59), but the line after it is not indented, and typically continues the sentence containing the equation. In some cases, the line with the equation ends with a comma or semicolon that forms part of the sentence.

Amusingly, integrals are sometimes written using "∂" for the differential, sometimes written with an italic *d*, and sometimes omit the differential entirely.

Boldface is used within paragraphs for emphasis, perhaps to aid skimming:

11. **The meter** was selected as a length equal to the **ten millionth part** of the **northern quadrant of the earth**, or distance from pole to equator…

Page headers have the section title, centered in italic caps, and on the side away from the fold, give the section and paragraph numbers in bold, e.g., "Sec. 1–5 *UNITS, FACTORS, AND TABLES*" or "*UNITS, FACTORS, AND TABLES* Sec. 1–11".

Extra leading is often but not always used between paragraphs, perhaps to stretch the page to the right height; in these cases extra leading is also used above subsection headings, as mentioned above.

Ordered lists are usually indicated with parenthesized italic letters (*a*) (*b*) (*c*) and occasionally with numbers and periods 1. 2. 3. or numbers with parentheses (1) (2) (3). Occasionally they are split into a paragraph (not part of the normal paragraph numbering) per item, and those paragraphs are indented as usual. Occasionally, as on p. 1505, the list items are given a hanging indent of another couple of

ems (so the first line is indented by one em and subsequent lines by three), and even nested lists are found, with the nested list items indented to an intermediate level. No extra leading is used in any case. Bulleted lists do not occur.

Tables generally use both horizontal and vertical rules to separate rows and columns, broken at intersections, and are usually printed in landscape mode. They are numbered and captioned in bold above. Table column and row headings are centered but otherwise use the same typography as table contents. Table section headings (spanning all columns) are additionally boldfaced. In some cases, instead of horizontal rules, they use dot leaders, or are split into five-row groupings using whitespace. Table borders are heavier rules. Numerical table columns are usually decimal-point-aligned, using lining ("capital") figures. Sometimes table contents are flowed across multiple "supercolumns" separated by double vertical rules.

The mini-table of contents at the start of section 2 is split into two columns and uses hanging indents to continue subsection names across lines.

On p. 881 we have a tree structure depicted with braces "{" for branching and blocks of text for the nodes.

Unidirectional arrows in diagrams are usually fletched, but not always. Dimension arrows are not fletched and use the long-short-long dash pattern which to me indicates a center line. Open-triangle arrowheads (with a line through the middle), single-barbed arrowheads, and open-line arrowheads both appear, but solid-triangle arrowheads do not.

Plots of quantitative data are uniformly grid-ruled, with the rules often broken to preserve readability of legend text that runs along a plotted line. In places, as on p. 584, an area of the grid is removed to make space for a plot caption, but plots are usually just captioned externally as figures. Qualitative plots usually have only the axes ruled.

The Book of Useful Knowledge: A Cyclopædia of Six Thousand Practical Receipts

This book, by an Arnold James Cooley ("Practical Chemist"), was published in 1850 in New York, Philadelphia, and Cincinnati, a reprint of the original London edition (and thus presumably done without the consent of the author). The full title and subtitle is "The Book of Useful Knowledge: A Cyclopædia of Six Thousand Practical Receipts, and Collateral Information in the Arts, Manufactures, and Trades, including Medicine, Pharmacy, and Domestic Economy. Designed as a Compendious Book of Reference for the Manufacturer, Tradesman, Amateur, and Heads of Families." This is centered on the title page in somewhere between eight and twelve different fonts, one of them a blackletter, but of course no sans-serif fonts.

The scan is, unfortunately, by Google, so the scan quality is very poor, and I have no idea of the original physical size.

The main body of the text is a series of alphabetized entries, each beginning with an all-caps headword, set in two columns of 68 lines with a vertical rule between them; most paragraphs within each entry begin with an italicized header. Paragraphs, even the initial paragraph of each entry, are all indented by about one em. No leading seems to

be used. The columns are only about 20 ems wide, and of course are justified with heavy hyphenation.

Occasionally an entry is subdivided into sequences of paragraphs with a centered italic header with a blank line above it.

The end of the body text is followed by the notation, centered, in boldface, in all capitals, with extra letter-spacing, near the bottom of the page: "THE END."

Frequent use of italics for emphasis gives an impression of great excitability:

> then spread it *thinly* on a dish, and expose it before the fire, or to a current of dry air, until nearly dry. It will then keep for years in wide-mouthed bottles or pots, covered over with bladder. For *use*, a little is dissolved in water.

There is extra spacing betwee sentences, and it also uses thin spaces before the colons and abundant semicolons and following open double- and single-quotes, as in "do the ‘ important’ at".

A typical entry begins:

> ABRASION. A superficial injury of the skin, resulting from the partial removal of the cuticle by friction.
> *Treat.* When the injured surface is small, and unexposed, no application is generally required,…

Trailing punctuation goes inside close parentheses:

> not only suffers refraction at the spherical surface, (called spherical aberration,) but the different colored rays, forming the beam of light,

Each page has a horizontal rule above its body text, above which are the guidewords for that page (or their first three letters, at any rate) and its page number.

Page margins are fairly generous, but column margins are quite cramped — perhaps a single em of column separation, with that vertical rule running down the middle of it.

Tables have horizontal rules delimiting them and separating their header, but not separating their rows; by contrast, they separate their columns with vertical rules, but usually have no vertical borders. Often table row boundaries are indicated only by braces "}", and intermittent dot leaders facilitate column-to-column traversal. They are neither numbered, but sometimes captioned above. As in the *Standard Handbook*, tables are sometimes flowed into "supercolumns" separated by double vertical rules. Lining figures are used. Decimal points are vertically centered: "its sp. gr. about 1·069 or 1·070;", and numeric columns are aligned by them.

Some simpler tables (e.g., the alkaloids on p. 47) are simply two columns of text joined by dot leaders with italic headers at the top.

In a few cases, the columns end to make room for a large table, like the table captioned "I. *French Decimal Measures of Length*", on p. 419.

Text flows around small figures; large figures interrupt paragraphs. As with tables, figures are neither numbered nor captioned, but sometimes they include a legend set in smaller type below them.

Footnotes are set in smaller type below a horizontal rule at the bottom of a column; they are linked with * and †.

Hyperlinks to other Cyclopædia entries are at times merely indicated with notations such as ", (which see.)" or even "; to each of which the reader is referred, in their alphabetical places.". Small caps are used frequently for synonyms and surnames and I think they may

also indicate hyperlinks, as they traditionally do in dictionaries: "(See BREWING.)" Sometimes they seem to merely indicate emphasis, as in the bipartite name given for the almond tree.

Ordered lists are sequences of paragraphs, indented as usual by about an em, but beginning with the ordinals "1st.", "2d.", "3d.", "4th.", etc., or the Hindu-Arabic numerals "1.", "2.", "3.", etc., or italicized letters "*a*.", "*b*.", etc., or the Roman numerals "I.", "II.", "III.", etc. Commonly these varying forms of numeration indicate nested list structures, but no typographical cues as to the hierarchy are visible.

Bulleted lists do not occur, though simple tables fulfill their function. On p. 108, for example, we have this table of plants for attracting bees:

Shrubs, &c.
Rosemary,
Broom,
Heath,
Furze,
Fruit-blossoms. *Flowers.*
Mignonette,
Lemon thyme,
Borage,
White clover,
Bean-flowers.

The book uses a number of ideograms that are no longer in use, although perhaps surprisingly, Unicode has them. Its rendering of "%" uses a horizontal bar, and many recipes are given in apothecaries' weight, using lower-case j-terminated Roman numerals, in scruples (written as "℈", as in "℈iv"), drachms (written "ʒ"; now often called "drams", though using that spelling now implies you're talking about avoirdupois drams), and ounces (written "℥"). This is explained on p. 561. Thus "ʒij" means "two [apothecaries'] drams", which is to say, a quarter of an apothecaries' ounce (which was the same as the troy ounce) or 7.78 g in modern units. The Roman numerals here also represented ½ with "ss".

Greek words appear commonly in the etymologies of terms, but the Greek font used is to my eye quite poor; it has serifs, but its capital height is just a little taller than the x-height of the Roman font used, and its own x-height is smaller still. Typically it is oblique. The forms also seem somewhat crude and irregular to me, but that may be merely an artifact of the very poor scan quality common to Google Books scans and the small font size.

The Mechanism of Weaving

This book was unfortunately scanned by Google, so the scan is of extremely poor quality.

Published in London in 1894 and in New York by MacMillan. Everything is Roman or italic except the word "London" on the title page, which is blackletter and includes many fonts, and the lettering in the illustrations. Headings are all-caps, bold, centered, and at times with extra letter-spacing. The table of contents uses indentation to show structure, with sparse dot leaders, as well as small caps for top-level headings; and the index, set in two columns separated by a vertical rule, also uses indentation to show structure. The index has a

blank line before each new letter.

Line spacing is somewhat loose. There are 33 lines per page. Paragraphs are justified and indented by about two ems, except for (at times) the first paragraph after a heading, whose first word is instead rendered with small caps. In one unusual case on p. 250, the section heading begins a sentence completed in the body text; the same thing happens with a subsection heading on p. 311. Paragraphs are not separated by extra leading. There is extra spacing between sentences, and thin spaces before semicolons and colons and inside double quotes. Hyphenation is sparse, and word spacing is consequently somewhat uneven.

The text is divided into parts, which are divided into sections, which contain subsections. Any of these may begin in the middle of a page. Subsection headers are in small caps of the size of the body text; section headers are slightly larger (say 1.2× the point size), in caps; part headers ("PART I") are slightly larger still (say 1.5× the point size of the body text), also in caps, with a bit of extra letter-spacing. All three types of headings are centered and given extra leading, about a line's worth; part headers have even more extra leading above them, maybe two lines' worth. Subsection headers may have a little extra leading above them, but perhaps only when preceded by a paragraph; it varies from page to page.

Widows occur frequently, and on p. 56, there's a totally avoidable orphan due to placing a figure between the first line of text and the other four lines on the page.

Illustrations are numbered below in small caps ("FIG. 1"). Unfortunately they are rarely on the same page as the text about them, even though text sometimes flows around them. Italics are used in the text for letters referencing figures, and mysteriously at the end of the preface for the word "September", but barely used at all for emphasis, though occasionally for Latin phrases like *vice versa*.

Illustrations contain hand-inked letters and digits which do not have serifs, though they are rarely monoline, so you could reasonably argue that this book *does* include sans-serif text. But the first occurrence of a sans-serif letter in text as such is an "X" in the middle of p. 138 ("fulcrumed at X"), and it happens again on p. 391, though, as I said before, typically italic is used for this. (Of course, the multiplication sign × is always monoline and never has serifs.) You could argue that sans-serif is playing a role here similar to the role played by typewriter text in modern texts about programming.

(This book was printed in 1894. Sometime between 1890 and 1898, the Berthold Type Foundry released Akzidenz-Grotesk, one of the "German sans-serifs" that started appearing toward the end of the 19th century, and the first one to become popular. But it was intended for use in advertising rather than running text. Wikipedia tells me that "Egyptian"-style letters — meaning primitive monoline sans-serif letterforms modeled after surviving inscriptions from classical Egypt and Italy — became popular for advertising signs in England in the late 1700s. Caslon released his "Two Lines English Egyptian" font in 1816, but it is only known from specimen books.)

Tables have ruled borders, ruled column separators, and a rule between the headers and the table body, with rules interrupted where they would cross, but no ruled row separators. They are not numbered or captioned. Lining figures are used in tables and text,

though page numbers use old-style figures. Decimal points are vertically centered ("1·125") but vulgar fractions ("1⅛") are used more often; inversely, periods are used at times in formulas to indicate multiplication, though "×" is used more often.

Tables with no rules occur occasionally as well, in the form of a non-indented paragraph set in smaller type with extra leading above and below, consisting of many nearly identical lines with the identical parts replaced with ditto marks (double low 9 quotation marks, here.) An example is on p. 121. In a more unusual case on p. 264, the table has a horizontal rule and a total placed beneath it, and the paragraph continues from there.

In one case, a numbered list ("1.", "2.", "3.") is indented by the same amount as a paragraph, but then a hanging indent is used so that later lines in the list are indented more deeply. They have short vertical skips above and below them, but as with paragraphs, none within. In another case (p. 275–8) the list items are paragraphs leading with a parenthesized number ("(1) Power consumed.") which function as headings for the following paragraphs, but are not otherwise typographically distinguished.

Formulas, when interrupting a paragraph, are set in slightly smaller type, but are not numbered. Sometimes tall formulas in running text are accommodated with more leading.

Inches are indicated by oblique double prime signs, which differ from the "" signs used for quotes; similarly, the prime signs used to indicate parts of figures are distinct from apostrophes. Em dashes are used (often immediately after colons) and almost never have spaces around them (except once on p. 326), but en dashes are not used; on p. 119 and p. 167 a hyphen is instead used to indicate a range of years. (Conversely, on p. 247 there are spaces around two otherwise ordinary hyphens, and again on p. 249 and p. 260.) The ideogram "∴" is used to mean "therefore", and "a:b::c:d" is used to mean "a÷b = c÷d". Arrows are extensively fletched, but otherwise the visual language of the illustrations is quite modern — dashed lines indicate hidden lines; gears are indicated by a circle at their pitch radius plus dash-dot lines at their root and outermost radii; hatched potato-chip cutaways are used to suggest round shafts; in one place a line alternating short and long dashes indicates the line above a center of rotation; hatches up to a line suggest a solid surface.

First Folio *The Tragedie of Othello*

Looking at this scan from Shakespeare's First folio from Wikipedia , which is set in a Humanist roman and italic, I see vertical and horizontal rules around the whole page. The play's title is split across two page-width lines: "THE TRAGEDIE OF", in large roman type with large but somewhat uneven letter-spacing, and below "Othello, the Moore of Venice", in smaller type. The body text is set in two columns with an additional rule between them, mostly with a ragged right margin due to the iambic pentameter of the text, but justified where the text runs to longer lines. There is a act/scene title running across both columns, "Actus Primus. Scœna Prima." between horizontal rules, and on the facing page, "Scene Secunda" is in the same italic font, with column-wide horizontal rules above and below. Italics are used to distinguish characters' names and, strangely enough, nationalities. Spaces are somewhat uneven, but generally there is

extra space after sentence-ending periods, and spaces appear before colons, semicolons, and question marks, though sometimes they are omitted entirely around colons and commas. Occasionally spaces occur inside parentheses and occasionally not outside. There is no boldface and of course no sans serif.

Hyphenation is occasionally used. The spelling and lettering is as you'd expect for the 17th century: i/j, u/v, ſ/s are alternate forms of the same letters governed by position, and ligatures include ff, ſt, ct, ſh, ffi. (I don't actually see any "j"s, but I assume they would occur if a word ended in an "i".) On one occasion, perhaps to save a bit of space, "my" is spelled "ỹ". Most nouns and occasionally adjectives are capitalized.

"THE TRAGEDIE OF" is about four times the point size of the body text, and "Othello, the Moore of Venice" about twice the point size of the body text. "Actus Primus.", etc., is about 1.4× the point size of the body text. The first paragraph is begins with an ornamental capital "N" from Rodorigo's opening line, "NEuer tell me,I take it much vnkindly", which is about three and a half lines tall.

These titles have a bit of extra leading above and below: the play title has about half a line above, half a line below its second line, and almost a whole line below its lower line. At times stage directions are centered in a column, in italics, with a line of leading above and below; other times they are simply italics on a normally spaced line. No extra leading is used between lines of body text; each time a new character speaks, it begins a new indented paragraph, again set tight with no extra leading. There are 66 lines per column (not counting catchwords) at the normal line height.

Wikipedia tells me that the First Folio has a page height of 320 mm. About an eighth of that (≈40mm) is a margin at the bottom of the page, and about another sixteenth (≈20mm) at the top, so only about 260 mm holds those 66 lines, so the line height is about 3.9 mm, or 11 PostScript points. Just as in *Tick, Tock*, about 9–12 words fit into a column, when the lines aren't being broken to fit into iambic pentameter.

Wikipedia

Wikipedia regrettably uses almost exclusively sans-serif type. Figures are very frequent, and almost always floated right, with captions below in the regular body text style. My tables of contents, like Gwern's, are directly modeled on MediaWiki's. (I don't remember if UseModWiki had them.)

Wikipedia has `border-bottom: 1px solid #a2a9b1` to underline its `<h1>`s and `<h2>`s. (The rule applies to other headings, but for them it's overridden with a `border-bottom: 0`.) This is not entirely unobtrusive, but it's less obtrusive than horizontal rules in black ink typically are in books.

They also have navigational links in the left, top, and bottom margins of the article; these margins are a somewhat darker background color. Category links are at the bottom of the article. Since these margins take up a lot of screen real estate, Wikipedia uses a totally different style on hand computers.

Wikipedia tables have a variety of formats, but commonly (class="wikitable") they are captioned above in bold (and not

numbered), have uniform-width rules around them, separate both rows and columns with rules, and use a darker background (#f8f9fa) than the surrounding text's #fff — darker still for the headers (#eaecf0), which are bold and centered; they have substantial padding (`padding: 0.2em 0.4em`) in the table cells.

Gwern

Gwern's website is set in a serif font (body text and headers too) with justified paragraphs, indented where they follow other paragraphs (`p+p { text-indent: 2.5em }`); headings with some extra leading; drop caps (in some cases, like magnesium, quite elaborate ones); no leading between paragraphs; and browser-provided hyphenation. Some of the headings use small caps (with `font-feature-settings: 'smcp'` rather than `font-variant: small-caps`), though this varies by epoch; others use caps. He mostly uses old-style numerals (`font-variant-numeric: oldstyle-nums`). These would be unremarkable choices for a book, but on a web page they seem radical. There is more leading above headings than below. He's also using quite a number of less book-like choices: right-aligned second-level headings (underlined in black) (though several of the books I've looked at have some right-aligned headings), darker backgrounds with borders for blockquotes, underlined links, bulleted lists with four-pointed star bullets, varying gray levels in text, letter-sized logotype icons inserted into text, looser line spacing (line-height: 1.5), relatively long line length (50 ems or so).

His `<h3>`s are a bit outdented (as well as bold and all-caps), and his `<h4>`s are also outdented, which could in theory make them stand out when scanning visually.

Generally there is an abstract of a few hundred words beneath the metadata, next to the table of contents (see below), in a double-bordered gray box, before the article proper begins.

When he has nested blockquotes, the inner one has an even darker background than the outer one, which is achieved with a `blockquote blockquote` rule rather than alpha-blending. (It would appear that his blockquotes actually alternate in color.)

He's also using the hack mentioned earlier for underlining links: `text-decoration: none` to disable the normal underline, then a background image synthesized from gradients, with 12 overlaid white text-shadows to make holes in the underline around descenders. (This hack is unnecessary in recent versions of Chromium, which perforate the default link underline for descenders.)

Unlike Wikipedia and Medium, he puts his category links at the top of the article, after a brief summary paragraph in italics (a summary rather like the extended titles in Victorian-era books, more than 100-word abstracts of modern research papers).

Often Gwern captions his figures below in bold, with syntax-highlighted source code above (generally R with ggplot, sometimes Haskell, sometimes CSV); the source code plays the role of equations, but it is not centered; instead it is formatted as is conventional for source code, except on a light grey (#fafafa) background with a box around it (and limited in height, with scrollbars for overflow). On the occasions when he does use equations, they are typically done with MathJax (including its fonts: MJXc-TeX-math-Iw sure gives nice italics, and it seems to be 19K),

and when they are not inline, they are centered with 1.25 ems of leading (`margin: 1.25em auto`), which I think may be MathJax's default. (See Dercuano formula display (p. 495) for my thoughts on what to do for this.)

In the rare case where Gwern has tables, they are very fancy indeed, with an italic centered caption at the top with heavy rules above and below (matching a heavy rule at the bottom of the table) with half a line or so of leading, bold column headers with sorting buttons in them (switching from black-on-white to text-shadowed white-on-blue when activated), alternating light-gray and white row backgrounds with a smaller font size, and about half a line of leading above and below data rows (`padding: 7px 10px`) except in very long tables, and a short gap (≈2px) in the gray background between columns. Additional mouseover handlers add dotted outlines to table rows and light-blue background to table headers. The sorting (and probably the mouseovers) is done with something called tablesorter.js via jQuery. The only real imperfections are that the sorting defaults to ascending, the table headers can scroll out of view, and numeric columns are left-aligned (but correctly sorted numerically!) He's using `font-variant-numeric: tabular-nums` but I think I'd prefer the old-style numbers.

For headers and body text, he uses Source Serif Pro (by Frank Grießhammer, licensed under the SIL OFL by Adobe in 2014; it's 72 kilobytes, though that seems to be just ASCII and an accent or two, and it's just the Roman; the italic is another 38K, and there are seven more variants), falling back to Baskerville or Libre Baskerville; for source code, Liberation Mono, falling back to Consolas or even Courier. The roman Source Serif Pro is very nice, but its italic is insufficiently italic for my tastes, more like a oblique/italic hybrid. Actually, I'm not totally sure his italic font doesn't vary from article to article.

His tables of contents are similar to mine, but he flows the text around them, and uses varying text weights, sizes, and colors to distinguish importance levels — outline numbers are in light grey, text in a lighter grey. He does use sans-serif fonts for the table of contents.

Eccentrically, he adds a light gray background to `<q>`s.

Fernando Irarrázaval's blog

Fernando Irarrázaval has a very pretty blog. He's using ET Book (it's where I first saw it), falling back to Palatino for characters like ∞, and he has a .newthought class to make the first word of a blog post small-caps and half a magstep larger (1.4 rem, while the body text is 1.2 rem). He takes advantage of the ample margins on modern screens to replace "footnotes" with "sidenotes" in the margin, in smaller text (1 rem), with the numbers in red ink. (The ample margins are due to the fact that they basically don't support multi-column text. I don't know what his hand computer strategy is; hand computers barely have enough room for a single column.) Source code blocks have a light grey background, and syntax highlighting done server-side with Pygments. As you'd expect from a Tufte fan, tables have a single thin rule separating headers from body. Figures are centered but sometimes are "captioned" in the margin to the right, as well as having source code above. His `<ul>`s are without bullets, but with

plenty of whitespace, to the point of having uncomfortably short line lengths.

Firefox default styles

Firefox's default for body text on my laptop is 16 pixels with font-weight 400, for <h1> it's 32 pixels with font-weight 700, and for <h2> it's 24 pixels with font-weight 700.

As I said before, my pixels are about 161 μm, so 16 pixels is 7.3 points, which seems pretty small to me. The 14.5 points at which T_EX is set seems more reasonable, and the 19 points to which I had it zoomed is eminently readable.

Firefox's default margins for <h2> etc. are equal on top and bottom, which is semantically wrong, though it duplicates formatting that is common with T_EX; headings belong to the text below them, not the text above them. Right now I have an <h2> with 29.6px margin-bottom and a font-size of 35.7px, and an <h3> with 29.4px margin-bottom and a font-size of 29.4px. And the <h1> on top of everything has a 28.1px margin-bottom and a font-size of 42px.

Typewriter type

One complicating factor is that I use Markdown's typewriter type <pre> fairly often to "quote" things from character-cell terminals, which normally have at least 80 columns. It would be nice for those quotes to fit into the column. Here's an 80-column box:

```
0123456789 123456789 123456789 123456789 123456789 123456789 123456789 123456789
|                                                                              |
0123456789 123456789 123456789 123456789 123456789 123456789 123456789 123456789
```

If that doesn't fit nicely into the column of text, the aesthetic experience is suboptimal. With a max-width of 40em and the same font size among the paragraph text and the typewriter text it only fits up to about column 66, so I need about 21% more width, or 17.5% less, from the other point of view. Right now, I'm using 21-pixel body text, which is pretty ideal from a readability point of view. I should be able to make a reasonable compromise and get things to fit: 6.6% larger body text, 6.6% longer lines, and 6.2% smaller typewriter text; that works out to about 43em width, 22px body text, and 19px typewriter text, giving a total compression of 24.5%.

That worked nicely! And 22 pixels (which Firefox is indeed interpreting as 22 of the literal screen pixels) is still only 10 points on my screen, and I still get 25 or 30 lines in the browser window, so the larger size doesn't compromise readability.

Later I switched this to "80%" and applied it to <code> too, because once I switched to the old-style ET Book font with its small x-height, the much larger x-height of DejaVu Sans Mono made it jump out of lines unpleasantly. 80% works out to 18px rather than 19px at the default font size of 22px; at the new larger 26px size, it's 21px.

A possible tweak might be to add 10% (I don't know, 0.03em or so) of letter-spacing to body text to reduce the number of words per line, since at 43em it's a bit longer than I think is ideal.

Looser letter spacing

As Aristotle Pagaltzis taught me, to some extent, we can trade off text size against letter spacing; one of the bottlenecks in reading is apparently the crowding of information per unit area in the fovea. So text can be hard to read because, although each letterform is individually fine, there are too many of them in too little space. This means that if you shrink the letterforms but leave them at the same number of letters per square inch, you can maintain the same readability, up to a point.

I may try this with the body text: add an extra 10% letter-spacing and line-height and reduce the font-size by a corresponding 9.1%.

As it says in *The Palmer Method* I examined:

> [S]tudents sometimes think that large figures are necessarily plainer, but such is not the case. Examine carefully the diagram. At the left are figures that are absolutely plain; one could not be mistaken for another, and yet their extreme size in the small spaces makes them difficult to read. At the right are the same figures, no more perfect, but not so large. Please note carefully that these, surrounded by white paper, and much smaller, are more legible, even at a distance, than the large figures at the left.

I tried that, and also a more extreme version where I changed max-width from 45em to 54em, the font-size from 22px to 18.3px, the line-height from 1.4 to 1.68, and added .2em of letter-spacing. The result still took up about the same space and was still readable from the same distance as the normal text, but it feels noticeably less comfortable. Instead of spacious, it feels fussy. The looser line-spacing does seem like an improvement, so I increased it to 1.5.

Smaller headings

Since yesterday I've been using these sizes, which closely coincide with the size hierarchy from *The Grammar of Graphics*:

```
h1 { font-size: 2em }
h2 { font-size: 1.7em }
h3 { font-size: 1.4em }
h4 { font-size: 1.2em }
h5 { font-size: 1.1em }
h6 { font-size: 1em }
```

However, because most articles only use a single <h1> and some <h2>s and occasionally an <h3>, most headings are 1.7em and 1.4em, which is a bit large. Since I'm using a sans-serif font for all the headings (except <h1>), there's little danger they'll blend into the body text in any case, so perhaps I should make the last three levels the same size as the body text, distinguished only with different typography (say, bold, roman, and italic), permitting the use of sizes like 1.4em and 1.2em for <h2> and <h3>.

(At the moment, actually, only Low-power microcontrollers for a low-power computer (p. 2602) even used <h5>, and it only does so once; nothing used <h6>.)

So that's how I ended up with these somewhat less extreme font styles for headings:

```
h1 { font-size: 2em }
h2 { font-size: 1.59em }
```

```
h3 { font-size: 1.26em }
h4, h5, h6 { font-size: 1em }
h4 { font-weight: bold; font-style: italic }
h5 { font-weight: normal; font-style: italic }
h6 { font-weight: normal; font-style: normal }
h2, h3, h4, h5, h6 { font-family: Helvetica,Arial,sans-serif }
```

Later, after spending probably an unhealthy amount of time looking at medieval manuscripts, incunabulae, and other printed books (from many centuries), I switched to using serif fonts for headers, just with small caps, extra letter-spacing, and red ink to make them stand out. (I'm not daring enough to use the #c54 kinds of bright reds used for headings and other rubrication in incunabulae and medieval manuscripts, but #600 seems like it should work.)

Here's the current cascade from <h3> on down, with some sample body text I didn't write:

Waltz, nymph, for quick jigs vex Bud <h3>

He made also ten lavers, and put five on the right hand, and five on the left, to wash in them: such things as they offered for the burnt offering they washed in them; but the sea was for the priests to wash in.

Waltz, nymph, for quick jigs vex Bud <h4>

And there were six steps to the throne, with a footstool of gold, which were fastened to the throne, and stays on each side of the sitting place, and two lions standing by the stays:

Waltz, nymph, for quick jigs vex Bud <h5>

And the Philistines gathered themselves together to fight with Israel, thirty thousand chariots, and six thousand horsemen, and people as the sand which is on the sea shore in multitude: and they came up, and pitched in Michmash, eastward from Bethaven.

Waltz, nymph, for quick jigs vex Bud <h6>

The hand of the LORD was upon me, and carried me out in the spirit of the LORD, and set me down in the midst of the valley which was full of bones,

Slotted tape with skewed involute roulette bristles as an alternative to hose clamps and possibly screws

Kragen Javier Sitaker, 2014-07-02 (6 minutes)

An invention that could replace hose clamps and maybe screws and nails: roulette-bristle slotted tape.

If you wrap sticky tape around a thing, you can form a sort of hose clamp holding the thing, but the tension in the clamp is limited by the fact that the stickiness of the tape prevents the tape from sliding not only to loosen, but also to tighten. (The constant-tack nature of most sticky-tape adhesives also means that tape joints like this will tend to creep over time if under stress, losing whatever tightness they may have originally.)

Velcro has similar behavior, but it doesn't creep. It does loosen a bit by a fixed backlash distance upon being first attached, though.

In both cases, the clamping force is limited to the force you applied pulling the tape tight when you first made the joint, multiplied by the number of rounds the tape goes around.

But suppose instead that the bottom layer of tape has an array of round rods sticking out of it, like widely-spaced Bristle Blocks, which fit through round holes in the top layer of tape. This eliminates the creep and backlash problems, and also potentially gives you a bit of mechanical advantage: if the rods don't quite line up with the holes so you have to bend them backward to fit through the holes, then the rods form a sort of ramp that tightens the tape as it slides down them. (If it so happens that they don't quite line up in the other direction, the ramp loosens the tape, instead.)

This is a bit awkward, though, because the holes travel in an involute of the shape you're wrapping the tape around, while the rods, so far, are straight. But, with things like a 3-D printer, you could form the rods in an involute shape so that the holes in the tape naturally slides over them with no resistance.

If you skew them ever so slightly from perfect involutes, they naturally become the ramps I earlier suggested you could bend them into; this can serve to tighten the tape as it closes over them. It also means that tension on the tape tends to lift it up along the bristles. If the final upper-tape-thickness or two of the bristle is a backward ramp instead of a forward ramp, then the tape will instead tend to stay there under tension.

If the holes are more like lengthwise slots in the tape

then there is some slop in where the bristles can pass through. If you make the spacing of the bristles along the bottom tape slightly larger than the spacing of the holes along the top tape, then the tape will stretch progressively as you wrap it over further and further bristles; the slot shape then can allow the earlier bristles to slide back

in the slot as the tape stretches, avoiding the problem with sticky tape.

Ultimately you could have the tension of the tape held by the final, say, fifteen rows of bristles; if you are able to wrap the tape separately over each row (perhaps with a curved tape shape and bristles more resembling a cycloid than the involute of a circle) then you could apply the downward force on the tape against only one row of bristles at a time. (Ideally the rows would be diagonal so that this is a smooth experience.) If the ramp of the bristles, relative to the involute or cycloid or whatever, is 20:1, then the row of bristles gives you a mechanical advantage of 20:1, while the 15 rows of bristles give you an additional mechanical advantage of 15:1, for a total of 300:1.

This is better than the mechanical advantage of a screwdriver with a 25mm-diameter handle driving a 1-mm-thread-pitch screw, which is only about 79. It's more like using a small 5-cm-long wrench to drive a 1-mm-thread-pitch screw. That is to say, this is a fastening device that could easily replace the screw in many applications, unless I'm overlooking something.

If you can wrap the tape, say, five times around, before putting the holey part on top of the bristley part, then you have potentially an additional 5:1 mechanical advantage, which is like using a 25-cm-long wrench to drive a 1mm-thread-pitch screw. I'm not quite sure how you could do this, but I suspect it's possible.

If you have lateral freedom in where to connect the holey tape and the bristley tape, the aforementioned diagonality of the bristle rows can give you fine-tuning of the distance, with greater precision but less convenience than a screw. If the bristles are 1mm diameter with 2mm spacing and the rows are 20 bristles wide, then each bristle to the left or right in a row could be 50μm ahead or behind of its neighbor, providing you with that degree of fine-tuning of the distance, at the cost of some loss of strength (or doubling the width of one of the tape components).

Compact code cpu

Kragen Javier Sitaker, 2017-07-19 (3 minutes)

Suppose we have a non-stack-oriented VM intended for dense code; now maybe we can afford 16-bit instruction words (instead of Smalltalk's 8) because we don't need to spend half our words on stack manipulation and fetching local variables. We can avoid three-address instruction formats in a few different ways; the most appealing is to use something like the Mill's Belt for instruction results.

In particular, I think that the usual instruction format could probably have two operands, and I think that part of the namespace of operands should be devoted to the belt, while another part should be devoted to a traditional set of normal registers, handled perhaps in the usual way; perhaps you'd have 8 belt registers and 8 normal registers. As an alternative to handling them in the usual way, each function could have its own set of registers, or you could use rotating windows like the SPARC.

The Smalltalk VM additionally has a bunch of implicit context that goes with a method execution: you implicitly have the object's instance variables mapped into your bytecode namespace, and the method is associated with a vector of method selectors that it can invoke with its bytecodes. This may save space in the bytecode, although for the indirection to pay for itself, you probably need several methods to share the same vector.

If we take a more traditional approach, we could pack two 12-bit instructions into a 24-bit word in the usual case, or three 11-bit instructions into a 32-bit word (with one bit omitted). This gives us three or four bits of opcode plus 4 bits per operand. A special tag bit could indicate a 23-bit or 31-bit literal, at the cost of making half the opcodes (or operands) illegal in a given position. (Literals go onto the belt.)

If we estimate that each of these VM instructions are roughly equivalent to two stack-bytecode instructions, then we are getting 1⅓ to 1½ times the standard Smalltalk bytecode density, which is already world-beating. Then there's just the issue of what those 8 or 16 opcodes should do, exactly.

(Alternatively, we could pack two 16-bit instructions into a 32-bit word, leaving us a very generous 6 bits for the opcode and 5 for each operand, or 4 bits for the opcode and an even more generous 6 for each operand. This is just the same instruction density as Smalltalk.)

We at least need to be able to do arithmetic, load and store values into registers, and do conditional jumps, or at least conditional returns.

Probably at least one of the opcodes would do well to invoke a method/"send a message". Smalltalk lumps arithmetic and array access into this, too: if the object you're sending the message to happens to be a number, and the message is an arithmetic message, then it does arithmetic; if it's an array, and the message is an array element access message, then it accesses array elements.

Archival with a universal virtual computer (UVC)

Kragen Javier Sitaker, 2014-06-29 (17 minutes)

How can we keep Nintendo games playable and WordPerfect 5.1 files readable in the 23rd century?

There's a page on Wikipedia entitled "UVC-based preservation". "UVC" stands for "universal virtual computer", and the idea is that you keep old file formats from becoming unreadable by writing readers for them that run on a virtual machine that never changes. That way, if someone in 2251 discovers a long-lost WordPerfect 5.1 document containing crucial historical information, they can run it through a WP5.1 reader written in the 2010s to run on the UVC. The UVC implementation they use in 2251 will be different from the UVC implementation we use in the 2010s, but they will be compatible.

The idea here is to emulate the hardware platform WordPerfect ran on with a UVC program, which seems sensible, and the Koninklijke Bibliothee has been working on an x86 emulator using this approach, and they have JPEG and GIF87 decoders working. They've also, bizarrely, been trying to develop file-format exporters that convert things from old file formats to XML. (Raymond Lorie's reason for wanting this is that, you know, it's better to have the parse tree and text of the WordPerfect file than just the pixels that emulated WordPerfect puts on your emulated screen.)

What's necessary for a UVC from the 23rd Century to be compatible with a UVC we write today? It seems like the UVC itself needs to be well documented, contain a bare minimum of functionality, be easily testable for compliance, and have very, very few special cases in the specification, since special cases are opportunities for incompatibility; but despite that, it needs to be a reasonable target to write a compiler for. Finally, I argue that a UVC ought to have predictable performance.

The impracticality of Raymond Lorie's UVC

Lorie's UVC is specified to some extent in his paper, "A Methodology and System for Preserving Digital Data"; he explains in his rationale:

> In order to run the UVC on a future machine, an emulator of the UVC on that machine will be required; but writing such an emulator is much simpler than writing an emulator for a real machine....
>
> What is important however is that it does not need to be implemented physically. Therefore there is no actual physical cost. For example, the UVC can have a large number of registers; each register can have a variable number of bits plus a sign bit, the sequential memory, also, can be as large as desired. Speed is not a real concern since machines will be much faster in a distant future, and an emulation of the UVC on a future machine will run faster, much faster, than a machine language program running on today's machines.

And then:

> Since a UVC interpreter will need to be written in the future, the definition of the UVC must be precisely specified and preserved. ... Only the UVC machine

language is part of the Convention (although we implemented a high-level assembler, and could develop, at any time, a compiler supporting a high level language in vogue.)

But then he sort of loses the plot:

> The design goal for the UVC was not to define a minimal general-purpose computer. Instead, the idea was to develop an intuitive computer with rather powerful and flexible instructions for handling bit streams, and to take advantage of the fact that it is virtual and that performance is of secondary importance. ..., without secondary features often introduced for improving the execution performance and the memory usage. It also tries to be intuitive. ... The memory is bit addressable; there is no notion of byte, word or alignment. This is extremely convenient for manipulating bit streams. ... The interface allows for variable length registers, allowing for manipulation of large addresses, and of course, large integer data items. A register expands to the left when needed. There is no overflow condition. ... The instruction length is also variable; it may have a variable number of operands.

This seems rather strongly opposed to the primary goal of "Since a UVC interpreter will need to be written in the future, the definition of the UVC must be precisely specified and preserved." Instead he has created a virtual machine specification that is unnecessarily difficult to implement, unnecessarily difficult to specify precisely, and impossible to test — while you can verify that an implementation of the UVC correctly handles, say, 128-bit integers or 256-bit integers, you can't test that it correctly handles integers of all possible lengths. And in fact it is nearly guaranteed that it will not. (The machine I'm typing this on has RAM and disk sufficient for a single 1.2-petabit integer, and is pretty much guaranteed to not be able to execute an operation involving two petabit integers.)

Plauger explained in one of his books why the C standard only required compilers to handle things up to certain limits: block nesting up to a certain depth, variable names of a certain length, and so on. Some earlier standard (I am guessing ALGOL-60 or perhaps Pascal) had required compilers to handle arbitrarily long names successfully. Somebody published standards-compliance test suites that included a test for long names, but since they couldn't test arbitrarily long names, they tested names of some large but finite length: 16 letters, maybe. And all the compiler vendors made their compilers pass the tests.

So, in effect, there was still a limited portable name length, even though the standard specified that there shouldn't be such a limit. This requirement in the standard simply resulted in the limit being undocumented.

Lorie ends up with 21 machine instructions and a segmented memory model. The instruction encodings are not specified in the paper, making it impossible to implement a UVC interpreter from the paper. He admits that his UVC emulator limits registers to 32 bits, memory segments to 8 megabytes and 100 registers each, and so on. Also, he neglects to mention crucial things like what happens when the "divide" instruction gets a division by zero.

It seems to me that if you take seriously the ideas that "speed is not a real concern,", "the definition of the UVC must be precisely specified and preserved,", and "develop a compiler," you will end up with something quite different — something much closer to a "minimal general-purpose computer", with no thought whatsoever given to "powerful and flexible instructions" and "develop an intuitive computer". Instead you'd want a virtual machine that was very easy to write an emulator for, very easy to test an emulator for,

and unlikely to have subtle bugs or implementation-dependent behavor.

In short, you'd want something much more like Brainfuck, Wireworld, or Urbit Nock, than like the UVC in Lorie's paper.

Brainfuck

Brainfuck (inspired by Wouter van Oortmerssen's FALSE) is specifically designed to be as easy as possible to write an emulator for. The original implementation, written in 1993 by Urban Müller for AmigaOS, was 240 bytes, and was a compiler. Several Brainfuck compilers under 200 bytes have been written; Brian Raiter's 166-byte Linux compiler is notable. It has 8 instructions with no operands, two registers, simple linear memory, and I/O. The memory cells are guaranteed to be 8 bits, and you're guaranteed at least 30,000 of them.

Brainfuck is very hard to program in (thus its name) but people have written real programs in it; Linus Åkesson wrote the Game of Life, for example, and Daniel B. Cristofani wrote a Brainfuck interpreter in Brainfuck, and an anonymous author wrote a implementation of DVD CSS decryption in Brainfuck.

If you somehow managed to write an Nintendo NES emulator in Brainfuck, you could be sure that any future computer could play NES games as soon as it had a sufficiently fast Brainfuck interpreter. Implementing a Brainfuck interpreter is easy (I wrote my first one in 22 minutes, in C, at 4 AM, and now I am running the Game of Life in it, veerrrry slooooowly) and so we can be sure that programmers in the future will be able to do it too.

But Brainfuck, Turing-complete and I/O-enabled though it may be, is probably not a reasonable compilation target. It lacks not only function pointers (as I think Lorie's machine does) but also functions and, in some sense, pointers, and it isn't clear to me how to, say, implement a linked list.

And even Brainfuck has incompatibilities between interpreters. Some interpreters, for example, provide bignum cells, which means you can't zero an arbitrary cell just by repeatedly incrementing or decrementing it until it reaches zero (e.g. with `[-]`); and there are different, incompatible, and ambiguous ways of handling end-of-file on input (0, -1, or unchanged, any of which could be a valid input byte).

Brainfuck is also a challenge to implement efficiently; copying a value from one cell to another, for example, involves alternating between decrementing the value in one cell and incrementing the value in the other. Recognizing this idiom can speed up your interpreter by a couple of orders of magnitude.

Wireworld

The Wireworld cellular automaton is, in some sense, even more extreme than Brainfuck: when you start, it's a challenge to figure out how to AND two bits together, adding two numbers is at least a one-day project, and even a single bit operation on a naïve implementation takes many thousands of instructions. It has the unfortunate problem that your circuit has no external memory; it cannot expand.

Wireworld also has even less predictable performance than Brainfuck, in the sense that a "smart" implementation can recognize

progressively bigger patterns.

Nock

The Urbit virtual machine named Nock is the first serious attempt I've seen to define a minimal computational machine for purposes of interoperability and preservation. Nock, unlike Brainfuck, is pure-functional; its data model can be expressed in OCaml as:

```
type noun = Atom of int | Cell of noun * noun
```

except that Nock, like Lorie's machine and unlike OCaml, uses arbitrary-precision integers. (Yarvin writes that it's "common" to represent whole text files as atoms, so we should expect integers of hundreds of thousands of bits at least.)

Nock has five instructions: `*` function invocation, `?` type dispatch, `+` increment, `=` equality testing, `/` array indexing; but function invocation has 11 opcodes defined (as the numbers 0 through 10, as atoms) which do things like function composition, the S combinator, and the ternary operator.

Open Firmware/OpenBoot

Open Firmware defined a Forth bytecode "FCode" for non-x86 PCI card BIOS drivers. However, its core functionality is ANS Forth, and as such, it's relatively large and complicated. There's no chance people will stop introducing subtle changes in the semantics of Forth operations over the next few centuries.

The λ-calculus and the ς-calculus

In light of the above horrors, perhaps it might make sense to use something like the λ-calculus or core Lisp (cons, car, cdr, atom, null, cond, eq, nil, lambda, label, quote) as our UVC? Or, if we were interested in human-editability, Abadí and Cardelli's ς-calculus or object calculus might be an almost equally simple choice?

The problem with these as they stand is twofold:

- Implementing them on real computers, while achievable and in fact achieved many times over, is substantially less trivial than implementing Brainfuck. Nobody is going to write a 166-byte λ-calculus compiler.
- You need to augment them with some kind of numerical operations. Brainfuck has increment, decrement, and while-nonzero. Nock has increment and equality-test.

Performance

Most of the things I've mentioned so far require loop analysis to get decent performance — adding X to Y by repeated incrementation will take X steps with a simple interpreter, but only 1 step with an interpreter that is able to analyze the loop's performance.

While it's unavoidable that different implementations of a virtual machine will differ in performance by potentially large factors, I don't think it's unreasonable to ask them to be in the same big-O complexity class! So I think you probably want at least addition in the basic operations.

(In some sense, if your fundamental data items are limited in size, then this O(N) slowdown becomes an O(1) slowdown; 255 increments is still only a constant factor larger than a single addition.)

So I think it might be worthwhile to consider RAM machines with some kind of built-in arithmetic.

This also argues against including garbage collection in the basic model, which is necessary for computational models like the λ-calculus, pure Lisp, and Nock. Maybe it's not a strong argument, though.

SUBLEQ, an OISC

SUBLEQ is of the family of one-instruction-set computers. It's an assembly instruction that is sufficient to construct arbitrary computations without needing any other instructions.

The SUBLEQ or SBN instruction is "subtract and branch if less than or equal to zero": `SUBLEQ a, b, c`, where all three operands are memory addresses, subtracts the value at a from the value at b, branching to c if the result is negative.

This instruction is sufficient for arithmetic, conditional and unconditional jumps, and memory transfer; but it does not, in itself, support indirection of either memory reads, memory writes, or program transfer. So it doesn't give you pointers, arrays, structs, or functions.

There are several ways to get them, though. You can use self-modifying code to modify any of the addresses in an instruction, although not to pass a return address to a subroutine. You can redefine the instruction's addresses to be indirect, or indeed support multiple addressing modes. You can memory-map the program counter.

MOVE machines

Once you start memory-mapping core parts of the processor, though, you're getting into MOVE machine territory (aka "transport-triggered architecture"). MOVE machines are another kind of OISC. If you map the following things into fixed places in memory:

- the program counter;
- an index register;
- the memory cell pointed to by the index register;
- a "subtractor" register which subtracts upon write rather than overwriting;
- a "signum" register which reads as -1, 0, or 1 after having a negative, zero, or positive value written to it, or alternatively after the subtractor produces such a result;

then you have a Turing-complete machine that supports pointers, array indexing, function calls, function pointers, arbitrary arithmetic, loops, if-statements, structs, exception handling, multithreading, dynamic dispatch, and so on. You handle a pointer by writing the pointer to the index register and then reading or writing the indirect cell. You zero the subtractor by subtracting it from itself. You get array indexing by subtracting an offset from the "base address" of the end of the array. You get conditional values by array indexing with the signum register, and if-statements by moving such a conditional

value to the program counter. A function call copies the stack pointer to the index register, copies the program counter to the cleared subtractor register, adds a fixed offset to it, saves the subtractor output on the stack, and then moves a constant to the program counter. And so on.

You can try to cast that into a set of instructions and/or addressing modes, but you're going to end up with more than the five things listed above.

Historically, MOVE machines have been parallel with tricky timing constraints that vary from one version to the next, and so they might not seem like great candidates for a UVC. But this one is defined in a strictly serial fashion.

Interrupts and I/O

Interrupts are arguably just an efficiency hack: instead of scanning the keyboard every so often (as the actual NES did) the keyboard invokes an interrupt handler, which context-switches away from the user code. They're frequently a source of nondeterminism and behavior that varies between processor versions.

I think that probably the right solution is just to have memory-mapped input and output ports.

Tagged dataflow

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

The whole tagged-token dataflow thing explains how to do something I'd been wondering about for a long time. It's too bad I didn't find out about it earlier!

One of the big problems in these tagged-token machines seems to be how to avoid filling up your memory. It occurs to me that some node types never increase the number of outstanding messages, others never decrease them, and a few may do one or the other according to some conditional.

If there is a scheduling executive in charge of deciding which pair to next consume from memory, it can use this node type characteristic to manage the size of memory at run-time, and thus perhaps the available parallelism. When it has available memory, it can run node types that won't decrease the outstanding messages, as long as there are any pairs of those types; and when it doesn't have available memory, it can run node types that won't increase the outstanding messages, as long as there are any pairs of those types.

The tricky node types can be handled by splitting them into three node types. Given an original node type T, we create TD, which does the same thing as T in the cases where it decreases the number of outstanding messages; TI, does the same thing as T in all other cases; and TC, which evaluates the conditional to decide which path would be taken, and then creates a pair invoking either TD or TI with the same arguments.

I think we can still end up with cases where one execution order results in filling up memory with unmatched messages, while a different execution order would chug along indefinitely inside some constant space bound. I don't know how to avoid that inside the dataflow paradigm.

XXX update with eeprom/tinycpu/fpga ideas (you can reduce code-switching overhead in a machine with small code memory by processing a lot of nodes of the same type all at once)

Exponential technology and capital

Kragen Javier Sitaker, 2016-02-18 (updated 2017-07-19) (8 minutes)

Capital goods are a feature of human life that goes back millions of years; their existence doesn't require exchange between people, or even multiple people. Capital accumulation is the fundamental mechanism that drove the Industrial Revolutions, which dramatically improved material abundance, quality of life, and life expectancy over the last several centuries. However, in the next decades, capital will be eclipsed by another factor of production, one which is often misclassified as merely another form of capital: knowledge, which behaves more like plant cultivars than like capital. This is the most significant change in the material conditions of human existence since the beginning of the Stone Age, a hundred and fifty thousand generations ago, and it is likely that people after this eclipse will not be what we recognize as "human" today, differing from us as much as chimpanzees do.

Capital goods are a feature of human life that goes back millions of years

"Capital goods" are durable goods that are only used as a factor of production, rather than being consumed and thus having a use value in themselves. At least 2.6 million years ago — a hundred and thirty thousand generations — we began splitting river-smoothed cobbles in half to get sharp-edged stones to butcher animals with, among other things. Those tools were capital goods: what we consumed was the meat from the animals, which required labor to produce, but less labor with the tools, which also required labor to produce. By taking some time off from butchering animals to make tools, paradoxically, we could butcher more animals.

This is a recursive process. You can cut green wood with a hand axe held in your hand, but if you make an adze blade and mount it on a wooden haft, you can cut green wood much more easily — including making more hafts for more adzes. So accumulating some capital increases the productivity with which you can accumulate more capital. The "Primitive Technology" video blog demonstrates this process.

Knowledge is central to this process, as indeed it is central to hunting or gardening even without any capital goods.

During the Stone Age, it seems that capital accumulation was largely limited by available knowledge. One stone adze can make you much more productive at cutting wood; two adzes can perhaps make you a bit more productive still if they are suited for different purposes; but you run into diminishing returns fairly quickly. Adzes don't appear in the fossil record until the Mesolithic. So from 2.6 million years ago until only 20 000 years ago — over 99% of the history of capital — people were apparently using choppers and hand axes without hafts, so accumulated capital perhaps did not yet recursively facilitate the accumulation of further capital; our

productivity was determined more by our knowledge than by how much capital we had accumulated.

Capital goods don't require exchange between people, or even multiple people

It should be apparent from the above that even if you are Robinson Crusoe alone on a desert island, accumulating some capital is likely to be useful. Indeed, the "Primitive Technology" video series shows a guy doing more or less just that, albeit with survival support from modern society. Beginning with only land, its anonymous author successively constructs hand axes, a rainproof shelter, a hafted stone adze and a hafted celt axe, a pottery kiln, and a cob house with underfloor fire heating and a ceramic-tile roof. He singlehandedly recapitulated the entire technological development of the Stone Age, reaching the level of our ancestors about 12000 years ago — six hundred generations — in a bit over a year. This shows convincingly that the primary limiting factor of production throughout the Stone Age was knowledge rather than capital or materials.

The principle of investing some percentage of your production in capital goods rather than consumption goods in order to achieve an exponential improvement in your material standard of living is thus not limited to scenarios where you can trade with other people; it is a principle that has worked to some extent for millions of years, recursively since the Neolithic, and spectacularly since the 18th Century.

And the reign of this principle, this fundamental aspect of our human nature, is coming to an end — not in millennia or centuries but in decades.

Capital accumulation drove the Industrial Revolutions

From the time agriculture triumphed in the Neolithic until the Industrial Revolutions began in the 1700s, the primary constraint on economic productivity was land. Land was wealth; landowners called themselves the "nobility". The agricultural productivity of the land, which changed only slowly, determined its population, which would shrink when it periodically descended into wars of Malthusian desperation when food was scarce.

[XXX: okay, if that's so, then why did the First Industrial Revolution even matter at all? Did people start living longer? They weren't fertilizing their fields with industrial products, were they?]

In the 1700s, steam engines became capable of doing useful work, first sucking water out of coal mines and then driving boats and wagons around. This distinguished a new factor of economic production, one which had previously been confused with labor — what we now call "energy". Although we had used draft animals, water wheels, and windmills to do heavy work before, steam engines immensely increased both the total wattage available and the total wattage manageable per worker. The marketing of motive energy as a commodity in the form of coal enabled economic production to be limited only by the necessary human labor to operate the machinery — and so machinery became immensely more complex

and expensive in order to be able to turn energy into consumable goods with use value.

From the 1770s until, let's say, the 1970s, the primary constraint on economic productivity was no longer land, labor, energy, or knowledge, but rather capital goods. The First Industrial Revolution pioneered mass production, as in Adam Smith's pin factory, and mechanized the production of many goods; and the recursivity of capital goods increased dramatically, as the tools, materials, and processes used by machinists to make machines advanced in leaps and bounds; but the actual machines in question were relatively specialized, and the stock of them grew only slowly. The Second Industrial Revolution reduced the need for both labor and capital to reach a given level of productivity by way of "mass production", which to a large extent was a matter of things like digging with a bigger shovel and never leaving it idle. This was the age when it was reasonable to value a publicly traded industrial or transportation company in large part by its book value, the accounting value of its assets, largely capital goods.

The Industrial Revolutions dramatically increased material abundance

The Industrial Revolutions improved material quality of life and life expectancy

Capital will be eclipsed by knowledge in the next decades

Knowledge behaves more like plant cultivars than like capital

The eclipse of capital by knowledge is as big as the Stone Age shift to capital

The end of the human race as we know it

I think I understand how to use libart's antialiased rendering API now

Kragen Javier Sitaker, 2007 to 2009 (10 minutes)

I've been trying to puzzle out the libart2 API for antialiased rendering in `art_svp_render_aa.h`. I think I understand it now.

Basically, the problem it's trying to solve is that rendering a bunch of antialiased shapes that share borders is kind of a pain.

The Alpha-Blending Approach

Rendering one antialiased shape is pretty straightforward: you just alpha-blend the edges with whatever the background happens to be at the moment. Rendering multiple antialiased shapes that are supposed to share borders, well, you end up with these "cracks" where the background shows through, as follows.

Suppose you have a black background and two light gray polygons, say 80% white and 90% white, and we're looking at three adjacent pixels, A, B, and C. If the border between the two polygons falls neatly between, say, B and C, then A is 80% white, B is 80% white, and C is 90% white. No problem.

But suppose the border runs down the middle of B. Now A is still 80% white and C is still 90% white, and ideally you'd like B to be somewhere in between, say 85% white. But with the alpha-blending approach, here's what you get. First, you render the 80% white polygon, which takes B (currently at 0%) and alpha-blends 80% white into it with a 50% alpha corresponding to its 50% coverage of B, leaving B as (B * (1 - 50%) + 80% * 50%) = 40% white. Then, you render the 90% white polygon, which also covers B to a 50% extent, and so B gets ((B = 40%) * (1 - 50%) + 90% * 50%), or 65%. 65% is not between 80% and 90%. B's color ought to be composed half and half of the two polygons' colors, but instead it's composed of three-eighths of each of their colors and one-quarter the background color.

This is, for example, the approach the `<canvas>` tag in Firefox and Safari take, and it results in transparency artifacts whenever you try to do 3-D rendering on top of it.

Other Approaches

There are other simple approaches you can take. You can decline to do antialiasing, or you can do antialiasing by rendering non-antialiased to a much larger pixel buffer and then downsampling. You can randomly sample one or several points inside each pixel rather than just using the center point. And `art_svp_render_aa` has a different approach.

art_svp_render_aa

The most transparent function in `art_svp_render_aa.h` is the following:

```
void
art_svp_render_aa (const ArtSVP *svp,
                   int x0, int y0, int x1, int y1,
                   void (*callback) (void *callback_data,
                                     int y,
                                     int start,
                                     ArtSVPRenderAAStep *steps, int n_steps),
                   void *callback_data);
```

An ArtSVP is a "sorted vector path", which is the kind of thing you reduce everything else to in libart as the last step before you try to render it into pixels.

An ArtSVPRenderAAStep is this:

```
struct _ArtSVPRenderAAStep {
  int x;
  int delta; /* stored with 16 fractional bits */
};
```

So I made an ArtSVP from an ArtVpath representing a diamond between (160, 0), (240, 120), (160, 240), and (80, 120), and I called art_svp_render_aa with a callback that just dumped out the arguments it got, scaling the delta argument down as suggested by the comment (and scaling down the 'start' argument in the same way). The results looked like this:

```
y=0 start=0.5 n_steps=3
  x=159 delta=-85
  x=160 delta=-1.52588e-05
  x=161 delta=85
y=1 start=0.5 n_steps=5
  x=158 delta=-21.25
  x=159 delta=-212.5
  x=160 delta=-1.52588e-05
  x=161 delta=212.5
  x=162 delta=21.25
y=2 start=0.5 n_steps=4
  x=158 delta=-170
  x=159 delta=-85
  x=161 delta=85
  x=162 delta=170

   ...

y=25 start=0.5 n_steps=6
  x=142 delta=-21.25
  x=143 delta=-212.5
  x=144 delta=-21.25
  x=176 delta=21.25
  x=177 delta=212.5
  x=178 delta=21.25

   ...
```

And so on until the last scan line in the region. It happened that the x-coordinates were roughly where the boundaries of my shape were

on those scan lines.

It turns out that libart wants your Vpaths to be counterclockwise, and that's why the values are negative; and the start value is 0.5 to make rounding work properly.

So this gives you a sort of map of how inside the shape each pixel is. The start value tells you how inside the shape you are at the start of the scan line, with 0.5 being "completely outside" and 255.5 being "completely inside", and the ArtSVPRenderAAStep items tell you where the degree of insideness changes along that scan line. You'll notice that, except on the first line where the scan line kind of gently touches my shape, the negative numbers always total to 255, as do the positive numbers, because each scan line goes all the way into the inside-out shape (once) and all the way back out of it.

So this is sufficient to do antialiased rendering of a single shape in the dumb alpha-blending approach explained at the top: the start and delta values give you your alpha, although on kind of a funny scale. Maybe this is how `art_rgb_svp_alpha` works; I don't have access to the libart source at the moment. But you can do it like this:

```
struct alpha_blending_shape_info {
  art_u8 *buffer;
  art_u8 r, g, b;  /* foreground! */
  int x0, x1;
  int rowstride;
  enum { even_odd_rule, art_rgb_svp_alpha_rule, interesting_rule } rule;
};

// callback for art_svp_render_aa for the antialiased polygon rendering
void alpha_blending_shape_callback(void *callback_data, int y, int start,
                                   ArtSVPRenderAAStep *steps, int n_steps) {
  struct alpha_blending_shape_info *info = callback_data;
  int value = start;
  int x = info->x0;
  int ii = 0;
  int new_x, alpha;
  for (;;) { // N + 1 fills for N steps
    new_x = (ii < n_steps) ? steps[ii].x : info->x1;
    switch (info->rule) {
    case even_odd_rule:
      alpha = 256 - abs((((unsigned)value >> 16) % 512) - 256);
      break;
    case art_rgb_svp_alpha_rule:
      // same winding rule as art_rgb_svp_alpha.  if I were literate I
      // would probably know what it's called.
      alpha = abs(value >> 16);
      if (alpha > 255) alpha = 255;
      break;
    case interesting_rule:
      // This shows more clearly what's going on under the covers with value.
      alpha = value >> 18;
      break;
    }
    if (alpha) {
      art_rgb_run_alpha(info->buffer + y * info->rowstride + x * 3,
                        info->r, info->g, info->b, alpha, new_x - x);
```

```
    }
  if (ii >= n_steps) break;
    x = new_x;
    value += steps[ii].delta;
    ii++;
  }
}
```

The Iterator Interface

But there are other functions in `art_svp_render_aa.h` as well:

```
ArtSVPRenderAAIter *
art_svp_render_aa_iter (const ArtSVP *svp,
                        int x0, int y0, int x1, int y1);

void
art_svp_render_aa_iter_step (ArtSVPRenderAAIter *iter, int *p_start,
                             ArtSVPRenderAAStep **p_steps, int *p_n_steps);

void
art_svp_render_aa_iter_done (ArtSVPRenderAAIter *iter);
```

Those look like a classic iterator pattern in C. First you have a function to initialize the iterator; then you have a function to step the iterator and get some output values from it (although no way to tell when it's exhausted); and a function to discard the iterator when you're done.

And, as you'd expect, it turns out you can reimplement `art_svp_render_aa` on top of the iterator interface as follows:

```
void svp_render_aa(ArtSVP *svp,
                   int x0, int y0, int x1, int y1,
                   void (*callback) (void *callback_data,
                                     int y,
                                     int start,
                                     ArtSVPRenderAAStep *steps, int n_steps),
                   void *callback_data) {
  ArtSVPRenderAAIter *iter = art_svp_render_aa_iter(svp, x0, y0, x1, y1);
  int y;
  int start;
  ArtSVPRenderAAStep *steps;
  int n_steps;
  for (y = y0; y < y1; y++) {
    art_svp_render_aa_iter_step(iter, &start, &steps, &n_steps);
    callback(callback_data, y, start, steps, n_steps);
  }
  art_svp_render_aa_iter_done(iter);
}
```

And it seems to work the same as the original. (I wish I had the source of libart handy; I imagine it's not very different.)

But this iterator interface is useful because it allows you to iterate through the scan lines of several different shapes, possibly in different colors, in parallel. Which means that you can calculate, for each

boundary pixel, what percentage of it is occupied by each shape. So you can get results without cracks between them in the case where the shapes share some border, unlike the alpha-blending approach, but without using a humongous amount of memory or processor time, as in the supersampled-rendering approach.

However, the interface still doesn't tell you whether a pixel is 50% occupied by shape A and 50% occupied by shape B because the two are on opposite sides of a shared border that runs through the middle of the pixel, or because shape A has a diagonal border running from upper left to lower right, while shape B has a diagonal border running from lower left to upper right, both through the center of the pixel. So at least one of those two cases will be rendered incorrectly. Perhaps more seriously, if you have two shapes in different colors but with the same border, the straightforward way of using this information will give you a jaggy border where the color of the bottom shape leaks through. I think you can avoid these cases by cleverly manipulating the geometry of the shapes so that they do not overlap before you try to render them.

Additionally, I'd think that if you were using it this way, you would want some kind of iterator in the x direction over the various ArtSVPRenderAAStep[]s that describe the scanline you're currently on. But there doesn't seem to be such an iterator facility defined in libart.

Solar computer 2

Kragen Javier Sitaker, 2017-07-19 (3 minutes)

Solar panels are now down below US$1 per watt; some of them are 22% efficient, which works out to about 220W/m² in full sunlight. The Dell Inspiron Mini 10 netbook I'm typing this on is 26.8cm × 19.7cm, or about 0.05 m²; a solar panel occupying that space would yield almost 12 W in full sunlight. The keyboard is big enough to type on comfortably.

Suppose you wanted to design a computer in this form factor that could run off such a solar panel, without a battery. If you covered one side of it with a US$10 solar cell, then at times it might have up to 10 watts available, but often it would need to run on 1W or less, and it would have to handle the loss of power well: ideally without the screen going blank or losing data or anything. Even 1W is a lot better than you can reasonably provide with a handcrank, and it's solid state.

Probably you need an E-Ink screen (so you can keep reading without using energy), a couple of different processors, a physical keyboard, some capacitors, and Flash storage would be in order (although FRAM, MRAM, or PCM might also work; I suspect MRAM has longer retention; but NAND Flash is huge compared to the others. Any kind of HTML5 site is going to suck shit at best.

E-Ink screens

https://www.digikey.com/product-detail/en/EA%20EPA20-A/1481-1130-ND/4896769 is a 172×72 pixel SPI e-paper display http://www.lcd-module.com/fileadmin/eng/pdf/grafik/epa20-ae.pdf of 59.2mm × 29.2mm for US$46.28; it runs on 3.3 volts. This is unacceptably lame compared to a Swindle screen.

http://www.aliexpress.com/item/Best-quality-6-0-eink-screen-ED060SC3-for-ebook-reader-eink-display/544963786.html is a US$50 E-ink display which is supposedly 6", 1280×1024, 5ms response time, and 16.7 million colors, which I don't trust one word of except that they'll take your US$50.

http://www.aliexpress.com/item/Original-ED060SC4-ED060SC4-LF-6-e-ink-ebook-LCD-screen-for-Amazon-kindle-2-for-PocketBook/32242651648.html is a "100% Original ED060SC4 ED060SC4(LF) 6" E-link EBook LCD screen for Amazon kindle 2 for PocketBook 301 plus for Sony PRS500 600". For US$14. I think I believe this one. The PocketBook 301+, from 2009, has an 800×600 16-level grayscale display, and this does seem to be it.

A datasheet at http://essentialscrap.com/eink/ED060SC4V2.pdf reveals details. It's 122.4mm × 90.6mm (or 137.9mm × 104.1mm around the outside), about 21% of the size of this netbook, so using two might be good: 1200×800 total pixels for US$28. (Or maybe three.) 800 pixels over 122.4mm is 153µm/pixel, so a 12-point letter is about 28px tall by 14px wide. It has a 39-pin interface, needs negative and positive 20 volts or so to run it, updates in 1000ms, and uses

600–1250mW while it's doing so, so about 1 J per screen update, or about 2µJ per pixel update, 48 µJ per tiny 4×6 letter displayed, 80 µJ per small 5×8 letter displayed, or 784 µJ per 12-point letter.

That datasheet does not reveal the protocols to use to control it, but those should be available from somewhere, or for some similar display. They're clearly parallel, so you need about 25 GPIOs to control it.

784µJ per letter is 4.7 mJ per 6-character word, so reading at 350wpm would consume 1.6 joules per minute, or an average of 27mW.

(Hmm, somewhere else I was thinking

Quasicard: a hypothetical reimagining of HyperCard and TiddlyWiki

Kragen Javier Sitaker, 2017-04-18 (updated 2017-06-09) (18 minutes)

Quasicard is a hypothetical reimagining of HyperCard and TiddlyWiki, born out of my combined frustration and contentment with reading textbooks and taking lab notes on an iPhone and doing exploratory data analysis and algorithm design in IPython/Jupyter.

Reading textbooks on an iPhone

I'm currently reading Horowitz & Hill's "Art of Electronics" on this iPhone. Using whatever downtime I have on public transport to read a page or two is a fantastic way to gradually come to understand things that have mystified me for years, sometimes decades. And, unlike most things on the iPhone, the PDF reader app doesn't break all the time when internet access is disabled. But it is frustrating.

The column width of the PDF is such that about a column and a half of text fits on the screen in landscape mode at a comfortable reading size; in portrait mode the text is slightly too small if a whole column width is on the screen, but about 36 lines of about 10 words fit (360 words). At the larger but more comfortable size where a column width fills the landscape screen width, 11 lines fit (110 words). This leads to a lot of uncontrollable fits of interaction, sliding the words on the screen around every five or ten seconds, and the sense of reading the whole book through a peephole.

While the text is still not unreadable when shrunk so that both columns are visible side-by-side on the landscape-mode screen, it is uncomfortably small, and the other column is usually not useful — the two chunks of text are not linearly sequential, unless most of the top or bottom of the page is taken up by a figure. Indeed, the text is still readable with a magnifying glass when the entire page text is shrunk onto the screen in portrait mode, but this is not comfortable.

The iPhone's Notes app fits 15 comfortably readable landscape-mode lines on the screen at once with about 12 words per line, for a total of about 180 words, with space spent on screen furniture on all four sides.

So the optimal reading experience is having somewhere around 200 words visible. However, this is still kind of shitty in the textbook case, because the book is full of schematics and graphs, and the text refers frequently to them; following these references is so much trouble that I merely accept that I will have to read through the text again more than once to understand it.

For example, p.669 contains the end of §9.8.3C, all of §9.8.3D, the beginning of §9.8.3E, two footnotes, and Figure 9.86. The §C text at the top of the page continues from a sentence that began on the previous page, refers to a footnote at the bottom of the page and the TOP201 controller chip simplified block diagram in Figure 9.83 on p.666, neither of which is visible at the same time as the §C text. The footnote refers to the second edition of the book for material that was

omitted from this edition. §D also refers to several details of Figure 9.83. The §E text continues to describe Figure 9.83, and also refers to Chapter 1x, which is published in a separate book forthcoming later this year, another footnote (which for a change is simultaneously visible), Figure 9.85 on p. 667, and Figure 9.86, which is adjacent but which requires zooming out to fit on the screen; then it continues to the next page in the middle of the sentence.

This page 669, which contains about 80 or 90 lines of text (about 800 or 900 words) and one figure, thus contains eight references to things that the reader cannot see in the PDF viewer but must remember, refer to, or hope to buy later; one of these is on the same page, and another one (the rest of §C) is on the facing page 668. This level of hypertextuality or allusivity is, I think, typical of this book, although the book is probably several levels more hypertextual than an average textbook, which doesn't have "Chapter 1x" or refer you to previous editions or put the student exercises in a separate book by a different author.

Reading this book, I was struck by the realization that printed books require such compromises due to their imposition of a fixed linear order on the underlying mangle of interconnected ideas. Such a linearization will unavoidably sometimes put significant distances between a drawing like Figure 9.83, which calls for many pages of explanation, and most of that explanation.

But the benefit of computerized hypertext systems is ostensibly precisely that they liberate us from such enforced linearity. Yet, looking at Wikipedia's page on the same subject, I find that such references to invisible things are present within the first few lines — it begins with an anatomy of an ATX power supply, and by the time I have scrolled down enough to see "D: output filter coil;", I can no longer see D, the output filter coil, in the photograph. Most of the many links in the first paragraph similarly refer to things I must remember or refer to to understand it, and unlike in the Horowitz & Hill PDF, I can tap my finger on them to see the definition; but this takes me away from the paragraph I am reading. Scrolling down to the first citation, I can tap on it to display the citation at the same time as the article; the citation window then remains unless I dismiss it, although it can change to display a different citation.

This kind of multiwindow mode could potentially be a useful mode for, for example, viewing the relevant parts of a figure as you scroll through the relevant parts of its explanation. It was attempted on the WWW with "framesets" and later iframes, but these did not work very well except for niche uses like advertising; most of the problems were not fundamental to the concept.

Beyond the issues of mere concurrent visibility of referents, there are missed opportunities. Textbooks like this one are full of formalized models of real-world phenomena in the form of equations, tables, and graphs. To learn how these models behave, it would be useful to be able to experiment with them (for example, to simulate the behavior of a switching power supply, perhaps to design one to fulfill an exercise) and use them to calculate solutions to real-world problems, without having to convert them into machine-readable form by hand, with the possible errors that entails.

Taking lab notes on the iPhone

I'm using the same iPhone to take notes on the things I try in the pottery studio, with words, interspersed photos, and time-lapse videos. Typically I take photos and videos during my studio time, then crop them and compose the text afterwards on the way home. As Bush predicted in 1945, "A scientist of the future records experiments with a tiny camera fitted with universal-focus lens." Or, anyway, that's what I'm aspiring to be doing; I can't really call myself a "scientist".

The photos and videos are extremely valuable for watching the progress of a piece through the traditionally slow process of shaping clay, and for recording the setup for many parallel experiments that can take weeks.

Unfortunately, there are a lot of things that lab notebooks really need that are clumsy or impossible on the iPhone. The iPhone can't be backed up (except to Apple's proprietary system), can't export to HTML, can't produce an audit log so that particular material can be confidently dated, can't interface with data acquisition equipment to record measurements, and can't do automatic calculations in the way that VisiCalc did on an Apple][in 1979 in 32K of RAM. It can, at least, switch back and forth between taking notes and doing calculations with its pictures-under-glass facsimile of an infix scientific calculator.

The calculation facilities needed for a lab notebook are similar to those needed for a textbook, except that you need some kind of assurance that the results of the calculations haven't changed since you took the notes.

On top of these problems, this app silently reduces the resolution of the photos you store in it, which is a potentially fatal problem if you're, for example, photographing something with text on it.

Exploratory data analysis and algorithm design in IPython/Jupyter

In IPython with Numpy and Scipy, I can load up measured data consisting of tens of thousands of data points, plot them, and immediately apply a whole panoply of signal-processing, statistical, and linear-algebra algorithms to them, plotting the results. It's far better than anything else I've seen for this, except sometimes Matlab. And it also lets me include notes in pidgin Markdown with pseudo-LaTeX for equations, and Sympy can output formulas and equations in pseudo-LaTeX or LaTeX as well.

Powers like these would be extremely valuable for a lab-notebook application.

Unfortunately, code in an IPython notebook isn't reusable for other IPython notebooks, because the atomic unit is the notebook. They can be sort of source-controlled in Git, but the file format mixes source code and output, the diffs are not readable, the diffs include ubiquitous spurious changes, and there was a backward-incompatible notebook file format change within the last few years, so the promise of auditability or even file compatibility across machines is false. Also, the results are not reproducible, because they depend on the entire Python installation, as well as the sequence of evaluations of "cells" within the notebook.

Also, of course, IPython/Jupyter is not equipped for photography,

audio recording, or other data acquisition.

Existing or Previous Hypertext Systems

HyperCard was, in Nielsen's 1995 nomenclature, a "frame-based" hypermedia system, unlike the WWW, which is a "window-based" system. The unit of hypertext was a fixed-size "card", which did not scroll (it was the size of your screen) rather than a scrollable arbitrary-size document that your screen was a window onto. To write things that were longer than a screenful, you would normally organize them into multiple different cards with links between them, although, in versions of HyperCard 2.1 and later, you had the option of putting your text (if it was just plain text) into a scrollable text field.

TiddlyWiki is a "personal nonlinear web notebook" based on WikiWikiWeb. Unlike other Wikis, the unit of editing in TiddlyWiki is smaller than an entire web page; it's a "tiddler", and you can have many "tiddlers" visible at a time, just as Twitter displays many "tweets", Facebook displays many "narcissists", or Slack displays many "messages". Rohit Khare's understanding of the 2008 web as fragmenting its "atomic" pages into "subatomic" units gave him the name "Ångström" for his startup, acquired in 2010 by Google, which I worked on briefly.

It is not a coincidence that Twitter refers to the link previews it displays with some "tweets" as "cards".

In Nielsen's terminology, TiddlyWiki is a "frame-based" system that simply displays multiple frames simultaneously:

> Nodes are the fundamental unit of hypertext, but there is no agreement as to what really constitutes a "node." The main distinction is between frame-based systems and window-based systems.
>
> Frames take up a specific amount of space on the computer screen no matter how much information they contain. Typical examples are the KMS frames and the HyperCard cards. Often the size of the frame is defined as the size of the computer screen, but that determination may not hold in all systems. Since the frame has a fixed size, the user may have to split a given amount of information over several frames if it cannot fit into one. The advantage of frames is that all user navigation takes place using whatever hypertext mechanisms are provided by the system.
>
> In contrast, window-based systems require the user to use a scrolling mechanism in addition to the hypertext mechanisms to get the desired part of the node to show in the window. Because the system can display only a (potentially small) part of the node through the window at any given time, the node may be as large as needed, and the need for potential unnatural distribution of text over several nodes is eliminated. Guide and Intermedia are typical window-based systems.
>
> A great disadvantage of window-based hypertexts is that the hypertext designer has no control over how the node will appear when the user reads it since it can be scrolled in many ways. The advantage is that windows may be of different size depending on the importance and nature of information they hold. One can imagine a window-based system that did away with scrolling and thus kept most of the advantages of both display formats.
>
> The real world is not quite as simple as the clear distinction between frames and windows. HyperCard is mostly frame-based but includes the possibility for having scrolling text fields as part of a card. Hyperties uses a full-screen display without scrolling but instead requires the user to page back and forth through a sequence of screens in case the node is too big to fit on a single screen.

Bush's original Memex proposal was a frame-based hypertext system that could display two frames simultaneously on two separate screens (or more: "he has several projection positions") in order to enable the user to add links between them.

Quasicard

Quasicard is a card-based hypertext system — currently in initial design stages — similar to TiddlyWiki, but with some important differences.

First, Quasicard card titles are optional. This sounds dumb, but it turns out to have a profound effect on the way the system can be used. (Imagine trying to use a version of Twitter that asked you to invent a globally unique title for every Tweet!) Although there isn't a hard character limit like Twatter, Quasicard cards are intended to be small enough that several of them can fit comfortably on a cellphone screen at once — about a sentence or two in length, like a line of chat, rather than a paragraph or a document. Something like 128 to 256 characters, or half that in CJKV languages. To accommodate this, Quasicard makes it easy to split an existing card into new cards with Previous and Next links, automatically generating new IDs for those cards.

Second, Quasicard normally doesn't scroll text. Instead, it displays up to however many cards will fit on your screen at once, closing whichever ones were least recently used. The last several closed cards are displayed in a list; you can look further back. Quasicard tries to find a reasonable layout on the display to accommodate the most recently used cards.

Third, Quasicard cards can include special non-interactive links which open other cards automatically as soon as they are opened, or maintain those cards open.

Fourth, Quasicard cards, like WWW URLs, can take parameters. In the case of image cards, this just allows them to be cropped to a particular area and zoomed to a particular minimum size when they open; but there are also calculation cards, which can take input data and perform some calculation on it, presenting the result in some format.

Fifth, there are calculation cards in Quasicard. You can tap on arbitrary numbers on the screen to add them to a calculation stack, enter new numbers, then apply arithmetic operations to them to create a calculation. Moreover, you can tap on other kinds of datasets to calculate on them, too.

Sixth, you can create cards in Quasicard by taking photos, recording videos, taking screenshots, recording sounds, recording your geographic location, and adding files, as well as typing text.

Command interaction

In the Quasicard user interface, commands (invoked by keyboard commands or mouse clicks or finger taps) take no arguments; the equivalent is to create a new ephemeral card with input fields in it, which can be filled by typing, drawing, or drag-and-drop; and it can have buttons. The card can then react, but it acts only with the authority it brought with it and the authority you granted it by dragging things onto it. Similarly, command output is generally provided by creating a new card. This makes Quasicard dramatically less modal than other interfaces.

The internal data of a card can easily be orders of magnitude larger than the 128–256 bytes displayed, which means that in some sense they can contain many other cards within themselves.

Topics

Smooth hysteresis

Kragen Javier Sitaker, 2019-06-11 (13 minutes)

I was looking at my example code for The Bleep ultrasonic modem for local data communication (p. 966) and came across a mention of hysteresis, which triggered the following thoughts in me.

Hysteresis in the Schmitt-trigger sense is deeply discontinuous, and maybe it would work better if it were more continuous.

And also:

How would you parallelize the computation of hysteresis over a long signal?

Continuification

In digital electronics, hysteresis on digital inputs — Schmitt triggers — is used to prevent noise on a slow transition from converting that transition into multiple transitions. Without hysteresis, you set the 1/0 threshold at some level, like 1300 mV (the TTL level), and consider anything above that level a 0, and anything above it a 1. This means that, if the voltage level being impressed on the wire by the gate you're connected to is 1295 mV during some interval, noise of anything over 5 mV can in theory result in many, many transitions between 0 and 1 and back again. You could imagine that a transition from 0 V to 5 V with a roughly linear ramp over 10 ns would result in being in the 1295–1305 mV range for about 20 picoseconds, and so you might see hundreds or thousands of glitch transitions between 0 and 1 during those 20 ps, which would be fine for combinational logic that ultimately feeds into a synchronously-clocked flip-flop, but potentially disastrous for logic intended to do something like gate a pulse train into a divide-by-10 counter.

Of course, this doesn't normally happen, because if the gate sending the signal takes 10 nanoseconds to transition, the gate receiving it normally isn't going to be able to transition in 20 picoseconds, much less 20 femtoseconds. But it can happen sometimes; for example, if there's a heavy capacitive load on the line, if the input signal doesn't come from a logic gate, if the input signal is from a much slower logic family, or if your noise situation is just totally off the hook.

So, in those situations, we use a Schmitt trigger, which moves the threshold once you cross it. Say the input is initially low and the threshold is initially at 1350 mV; once the rising voltage gets past 1350 mV, the input reads as a 1 and the input threshold snaps down to 1250 mV, and it won't read a transition back to 0 unless the voltage moves back down by those 100 mV. This means that as long as your noise voltage never quite exceeds that 100 mV of hysteresis (peak to peak), your input voltage can transition as slowly as you like without turning the noise into multiple transitions. The only thing noise will do is make the transition happen a little sooner and with a little more jitter.

So how high should you set the hysteresis so that this never happens, so your circuit will work reliably? Suppose your signal suffers from interfering additive white Gaussian noise, and the noise's bandwidth (in theory infinite, but not in practice) that includes some frequencies considerably faster than your signal transitions.

Trick question! Gaussian noise will occasionally exceed any given limit (with probability exponentially small in the square of that limit), and white Gaussian noise will occasionally exceed it twice, in opposite directions, during any given interval size. Given that all circuits are subject to non-band-limited additive white Gaussian noise (from Johnson noise and from antenna pickup of thermal radiation, if nothing else) why does this work so well, even with the 100-mV hysteresis common on the inputs of things like the STM32 microcontroller line (200-mV for 3.3-volt inputs; see Notes on the STM32 microcontroller family (p. 3176))?

Again, we are saved by the limited speed of our circuits. A sufficiently short pulse of 100 millivolts or even 10 volts won't trip the Schmitt trigger because even the Schmitt trigger, though fast, can't respond instantly. Its output is a continuously-changing signal (in the sense that over a sufficiently short time interval, the change to the output is arbitrarily small) whose response to input changes is also continuous (in the sense that an arbitrarily small change to the output can be achieved with a sufficiently-small change to the input). So it isn't enough for the input voltage to jump randomly to 10 volts for a femtosecond; it needs to stay there long enough to overcome the small but finite time delays inside the circuit.

This is aided by the local linearity of the responses: if the input jumps by 1 volt for a picosecond, the output changes about five times as fast as if it jumps by only 200 millivolts for that picosecond, assuming a picosecond is fast enough to mostly avoid nonlinear effects. Since a one-volt jump is much less likely to happen due to noise than a 200-mV jump, it provides much more information if it happens.

Contrast this with what I'm doing in my Bleep prototype code:

```
def _schmitt(diff, size):
    val = 0  # presume diff starts negative
    for item in diff:
        threshold = size/2 if val == 0 else -size/2
        val = 1 if item > threshold else 0
        yield val
```

There's no continuous output transition time here that happens faster if the input is stronger. And, I suspect, this makes the code more susceptible to noise.

But does it really? The signal being processed there is a linear function of several neighboring input samples, which means that in some sense it's an average of the signal over that window. (Hopefully of the signal, that is, rather than of something else.) Although the *transition* isn't continuous, the *probability* that a given noise sample *causes* a transition *is* continuous in its amplitude, because the average of its neighboring samples is a continuously distributed random variable. So, perhaps the smaller response to smaller signals is already sufficiently present.

And, beyond some limiting frequency — Nyquist if nothing else — high-frequency noise is increasingly filtered out before it gets to the Schmitt trigger routine. So a totally lazy way of reducing the probability of noise-induced glitches is to decimate the signal a lot, ideally after low-pass filtering it. If you decimate it to, say, four

samples per expected transition time, then at most you can only get four glitches per expected transition. This introduces more jitter, of course.

Bistable and Schmitt-trigger systems as continuous differential equations

Suppose that, instead of thinking in digital space, we think in continuous space for a while. What's the simplest system that exhibits the kind of bistable behavior we'd like to see from a logic gate, say, a buffer?

Functions

First, let's consider memoryless systems — functions — before moving on to Schmitt triggers, which are by necessity stateful.

Simply $y = x$, like an idealized buffer op-amp, won't quite cut it, because that doesn't have any signal restoration — any noise on the input will be faithfully reproduced on the output. We want something that restores signal levels somewhat, so that at least if we hook up a chain of them in series, the signal will approach the discontinuous threshold behavior we expect from logic buffers — values close to 0 or 1 should converge to 0 or 1, while values close to 0.5 should be repelled from 0.5.

We can do this as a piecewise-linear system: `x < 0.25 ? 0 : x > 0.75 ? 1 : 2*x - 1`. We can do it as a trigonometric system: $\frac{1}{2} - \frac{1}{2}\cos(\pi x)$. Or we can do it as a polynomial: $-2x^2 + 3x^2$. Wait, where did that come from?

Well, our function must have attractive fixed points at $x=0$ and $x=1$, and we'd like one around $x=\frac{1}{2}$, too. That the fixpoints are *attractive* is to say that the absolute value of the derivative there should be less than 1; and we'd like the fixpoint at ½ to be repulsive. The smallest polynomial (other than just $f(x) = x$) that's going to be able to give us three fixpoints is going to be a cubic, $ax^3 + bx^2 + cx + d$. If we use Hermite interpolation, we can arbitrarily choose values and derivatives at two points of a cubic; let's choose $f(0) = 0$, $f'(0) = 0$, $f(1) = 1$, $f'(1) = 0$. This is a simple enough case of Hermite interpolation that we can do it directly: $f(0) = d = 0$, and $f'(0) = c = 0$, so we have just $ax^3 + bx^2$, whose derivative is $3ax^2 + 2bx$; so we have $f(1) = 1 = a + b$, so $b = 1 - a$, and $f'(1) = 0 = 3a + 2b = 3a + 2(1 - a) = a + 2$, so $a = -2$, and $b = 3$.

So we have $-2x^3 + 3x^2$, with the derivative $-6x^2 + 6x$. As it happens, this function *does* have a fixpoint at $x=\frac{1}{2}$, and its derivative there is 3/2, which makes it a repulsive fixpoint. This is fortunate, but if that weren't the case, we could use Hermite interpolation with $f(\frac{1}{2}) = 0$ and some arbitrary value for $f'(\frac{1}{2})$, deriving a quintic.

We can't do two attractive fixpoints at 0 and 1 with just a quadratic $ax^2 + bx + c$, because its derivative (a linear function $2ax + b$) must average 1 over that interval to hit the fixpoints, so if it isn't identically 1, it must be less than 1 at one fixpoint and greater than 1 at the other.

Ordinary differential equations

So suppose that our output, instead of being a pure function of the input, is instead some quantity y that varies over time in a continuous way: $\mathrm{d}y/\mathrm{d}t$ always exists, though it might depend on different things.

In particular, if we want it to be attracted to some target value v,

the simplest thing to do is to set $y' = (v - y)/\tau$, where τ is some positive time constant, which is necessary for the units to be consistent. This causes y's distance from v to exponentially decay, regardless of its initial state, if v is constant. So, for example, $y' = (-2x^3 + 3x^2 - y)/\tau$ would be a reasonable description of this logic-buffer system. (It's a terrible approximation of the behavior of real-world TTL or CMOS logic gate inputs, but it has some key characteristics in common with them.)

Even if v is not constant, y will move toward it, but the rate of convergence may not be exponential. Consider, for example, $y' = (-2y^3 + 3y^2 - y)/\tau$. If you start it somewhere in the interval [0, 1], it will converge to whichever endpoint of the interval was initially closest.

Now suppose we combine this with a tendency for y to move toward x, the input: $y' = (\alpha(-2y^3 + 3y^2) + (1 - \alpha)x - y)/\tau$. When $\alpha = 0$, y exponentially decays toward x, and when $\alpha = 1$, it exponentially decays toward whichever of 1 or 0 is closer to its initial state, as before. For intermediate values of α, this single-equation system displays a kind of Schmitt-trigger-like behavior (XXX verify this) in which y follows x, but tends toward the endpoints; for any given constant value of x, y may have either one or two attractors (XXX verify this). For $\alpha > 0$, y has two attractors at $x = ½$, but (XXX I think) for $\alpha < 1$, sufficiently extreme values of x will force it to have only a single attractor.

If this equation describes a single "logic gate" and its x input is an affine function $x = \Sigma_i a_i y_i + b$ of some other gates' outputs, this can be made to converge to an arbitrary logic function, provided the Schmitt-trigger behavior isn't too overwhelming. If the a_i are nonnegative, it can only compute a noninverting logic function. (This is reminiscent of the universal-approximator theorems for neural networks, and in fact it might be a special case of them.) See Snap logic (p. 2580) for more details on such logic. XXX in this case we might as well use the a_i for the feedback path too and dispense with the separate α and the unnecessarily linear feedthrough.

Human memorable secret sharing

Kragen Javier Sitaker, 2019-08-10 (2 minutes)

Suppose you wanted any three of your six grandchildren to be able to decrypt your will, so you generated a 96-bit random key to encrypt it, then used Shamir secret sharing to split the key into six subkey shares. How big would these subkey shares have to be?

Clearly you can use the Galois field of a 97-bit prime, such as GF(131083052269145407673490965609†), and then all your polynomial coefficients and polynomial points can hold 96 bits. But your grandchildren then have to memorize or otherwise safely store 96 bits, which is a pain. For example, bitwords.py encodes the random 96-bit number 263087975429510937799940094 96 as "lock fall alpha index piano verb cups barns", which is clearly memorizable but also clearly nontrivial to memorize. (And actually they need to memorize a few more bits so that we know which coefficient or point they hold.) Couldn't we do with less, since we're putting in 291 bits and only getting out 96?

Not really. Suppose we come up with some scheme such that each grandchild only has to memorize 48 bits ("hans graph na laugh", "turns high sat lust"). Now, two grandchildren colluding can rent a supercomputer and run the secret-sharing computation with their two keys and each of 2^{48} possibilities from a third grandchild. On average, 20% of the way through the search space, they'll hit one of the other grandchildren's shares, decrypt your will, and possibly hatch a plot to kill you or or one of the more favored grandchildren.

This reasoning is entirely independent of the secret-sharing algorithm — it doesn't depend on any special features of Shamir's protocol — but using a slow KDF (say, 2^{40} to 2^{48} work per decryption attempt, minutes to hours on fast silicon) might slow down the attack by a useful amount, allowing the original secret to be of size 48–56 bits without a loss of security.

† Prime verification was deterministic, but if the factoring code was buggy, I might not know. Rely on this number's primality at your own risk.

Byte prefix tuple space

Kragen Javier Sitaker, 2018-07-14 (updated 2018-07-15) (4 minutes)

Linda was a coordination language for parallel computing where you could "in" some tuples from a global blackboard (or "rd" them, which is the same thing without removing them) and then "out" some tuples; the tuple space served as a sort of hybrid of communication and storage. It's sort of like Prolog, and I think it gave rise to the family of Concurrent Prolog systems. It's really dramatically easier to program than message-passing systems.

Many new software systems are built on ØMQ (ZeroMQ) or LevelDB, which are new minimalistic software designs that combine extreme efficiency with extreme flexibility.

ØMQ is a sort of hybrid of sockets and message-queuing systems like RabbitMQ, one that doesn't necessarily require a message broker as such. Like message-queuing systems, it has message framing, permits publish-subscribe communications, and can queue messages in RAM until they are processed. Like sockets, the messages are mere strings of bytes (rather than serialized data structures with an associated type system), and producers can connect directly to consumers. In order to reconcile publish-subscribe with using mere strings of bytes, the messages can be divided into a key and a value, and the subscriptions are byte prefixes of the key, or if not present, the message.

LevelDB is sort of a modern replacement for ISAM using log-structured merge trees. It stores a set of bytestring keys, each associated with a bytestring value, which may be empty. It provides efficient batch insertion/updates/deletes, which vanilla ISAM can't, and efficient in-order traversal by key.

Both LevelDB and ØMQ are one to two orders of magnitude more efficient than the more elaborate traditional systems they can replace: ØMQ can route two or three million messages per second on my laptop, while implementations of OpenMQ are around a hundred thousand or so, and LevelDB can insert about 14,000 to 300,000 records per second, while Postgres manages about 3000. (This is on an SSD.)

So it occurs to me that it might be interesting to build a "tuple-space" system which is really a "bytestring space". Workers would attempt to "in" or "rd" keys with a given prefix, and if successful might "out" others. The bytestring space might be persisted to disk or purely in RAM, and it might be hosted on a single server, sharded across servers, or even replicated across servers. If the ins and outs are transactional, it might even be possible to make it fault-tolerant.

Zooming down to the other end of the computational scale, there are truly astonishing amounts of computational power available in tiny, cheap microcontrollers at this point (various 48MIPS Cortex-M models from Philips, ST, Atmel, and others cost under US$1 at this point) and they use a tiny amount of power — in theory an STM32L011x3/4, similar in computational power to a Sun-3 workstation from the 1980s, should be able to run at 16 MIPS for a week on a CR2032 coin cell.

But it's difficult to get them to do anything complex because they have a very small amount of memory. You might have 4K to 32K of RAM and a somewhat larger amount of Flash. If you can decompose a system into pieces that fit into the RAM, communicate via message-passing, and can manage with a somewhat sequential access to the messages, you can do decent computations on these things. The problem is somewhat similar to the problem Unix solved with pipes on the PDP-11.

So, in particular, I was thinking that you could hook up an external nonvolatile storage such as a Flash chip storing a "tuple space" and have a set of "actors", each waiting on one or more prefixes, and load a single "actor" into the RAM and feed it items from the space until it's blocked on a prefix that has no existing items. Then you could context-switch to a different "actor" and repeat the process — hopefully keeping the total number of context switches low enough that you spend most of your time running actors instead of context-switching.

Waterproofing

Kragen Javier Sitaker, 2015-09-03 (4 minutes)

Thinking about underground construction: could you fire individual rooms out of porcelain (or salt-fired terra-cotta, if you can somehow detoxify the fumes?) and join them together with silicone caulk/ gaskets to prevent leakage? The water table is high enough here that any hole in the ground becomes a well. For a sufficiently high budget, of course, you can just carve a chunk of granite or basalt out of a mountain, carve rooms into it, and bury it with a little bit sticking out; it will be waterproof, but that fabrication technique is costly! The question is how to get waterproof underground construction at a reasonable cost.

The traditional approach is to build things out of concrete and then pump the water from the inevitable leaks back upstairs.

You could probably use the traditional approach but seal the entire outside with tar or pitch, like an old wooden sailing ship, but that will probably only last a few decades.

If you have a conductive mesh shell around your construction, you could use it to electrolyze the groundwater to deposit minerals encasing your construction. They will preferentially deposit inside cracks that are filled with water thus sealing the cracks. This will only work if you have enough minerals dissolved in the groundwater. In a sense it's similar to the pumping approach, in that it will fail if you have a sustained power outage, but over a much longer timescale: months or years rather than days.

Another possibility would be to seal the entire construction with some kind of flexible barrier, like latex rubber or silicone. Latex will break down spontaneously over decades and maybe biologically over years; I think silicone should be stable over a century timescale, but it is of course more expensive.

Polyethylene might be the ideal material for such a membrane, though. It's even more chemically stable than silicone, it's biologically stable (though less so than silicone, probably: http://www.cigre.org/var/cigre/storage/original/application/883f280o3abeba34bc3bdeb8caf0050c44.pdf, even though silicones can be biodegraded http://www.green-flow.co.il/Documents/Aquatain%20AMF/%D7%o9E%D7%97%D7%A7%D7%A8%D7%99%D7%9D%20%D7%95%D7o%A0%D7%99%D7%A1%D7%95%D7%99%20%D7%A9%D7%98%D7o%97/Degradation%20of%20Silicone%20Polymers%20in%20Nature.po df http://aem.asm.org/content/65/5/2276.full), it's cheap as shit, it's plastic so that it can handle subsidence without cracking, and it's a lot stronger than silicone. If you have a 1mm LDPE or LLDPE layer in your walls, that seems like it should be plenty to keep your walls from ever leaking, at 0.94 kg/m² and €1300/tonne, that's about €1.26/m².

This is apparently called a "geomembrane", and it's usually used for landfill liners to keep stuff *in* rather than to keep stuff *out*. HDPE geomembranes (actually MDPE with filler (typically carbon black) and antioxidants) ship in 6–9 meter width rolls of 1–2.5mm thickness, which are then thermally welded together onsite to form the landfill liner. Where I live, I can buy 5-meter-wide 1mm HDPE

geomembrane for US$4.21/m² from some guy named Pedro Bernaldez up in Salta: http://articulo.mercadolibre.com.ar/MLA-555707538-geomembrana-polietileno-hdpe-500-de-ancho-x-1-mt-x-1000-mic-_JM

(A minimal living space of 16m³ might be something like a cylinder of 2m height and 3.19m diameter: 20.04m² of walls, 8m² of ceiling, 8m² of floor, figure really more like 10m² each of ceiling and floor what with cutting waste, total of 40m²: US$170 of geomembrane. This would involve 20 meters of seams, plus whatever's needed to get people and air in and out.)

A review of Wirth's Project Oberon book

Kragen Javier Sitaker, 2019-02-04 (updated 2019-03-19) (63 minutes)

I'm reading Wirth's *Project Oberon*, feeling it might be useful for BubbleOS.

Certainly I am not going to take the severe approach he claims was essential (p. 8):

> Concentrate on essential functions and omit embellishments that merely cater to established conventions and passing tastes.

To a great extent, whimsy is the entire raison d'être of BubbleOS, thus Tetris (216 lines of C), Toki (some 130, not counting the data tables), and Cuerdas Caóticas; does that doom it? Certainly many embellishments will be omitted, but by no means all. My feeling is that the embellishments are as essential as the functions.

As one simple example, Oberon presents the keyboard as an input stream of characters (p. 11). Perhaps it's an "embellishment" to deliver keyup events as well, but without it, Tetris is substantially less enjoyable. (On p. 19 we find that the Lilith keyboard was connected via RS-232, aka V24 as we find on p. 209, so perhaps it sent ASCII characters rather than multibyte key-event sequences, thus rendering keyup events impossible at the hardware level. Indeed, this is confirmed for the Ceres keyboards on p. 205. On p. 208 we find it used an appalling 300 bps baud rate, implying a horrifying minimum of 33 ms of keyboard latency.)

It's interesting to note that Oberon uses the "viewers" terminology from Cedar — as well as, at least initially, the non-overlapping, column-oriented layout of Cedar.

It's amusing that even in 1992 Wirth felt it necessary to explain what the "so-called mouse" was and how it worked (p. 12), though it had been 24 years since Engelbart's Fall Joint Computer Conference demo — and, moreover, 8 years since the mass-market introduction of the Macintosh. This naïveté perhaps explains the catastrophic "interclick" interaction design in Oberon (p. 96, p. 375, especially p. 386), despite the attention given to usability in, for example, the rejection of modes and hidden state (pp. 13–14) and memorization of abbreviations (p. 15).

I had forgotten that command texts could have textual parameters textually following them (p. 13), parsed when you middle-clicked on the command name.

The mention of traps and leaving global variables in an inconsistent state (p. 13) makes me somewhat queasy. Surely rolling back a transaction is a better response?

The note about how much simpler it is to have an event-loop system rather than preemptive multitasking (p. 14), while correct, seems rather overoptimistic to me; the ostensible consequent elimination of background computations seems like a very heavy price to pay — though at least they made the concession to practicality of an "abort character" to halt runaway infinite loops ("cntl-shift-delete" — p. 208), and p. 18 explains that background tasks such as the garbage collector do indeed exist.

The paean to the versatility of text on p. 15 seems a bit dated; it would be nice to have _hyper_text output, and with reasonable layout and styling at that, so that you can not only copy and paste filenames from a directory listing into a command line somewhere, but also click on the filename to mark it for a mass action or to pop up a menu of available operations.

I'm wary of inheritance, which was not present in Cedar and which Wirth endorses fervently at the bottom of p. 15. I've used inheritance extensively in C++, Python, JS, Java, and Ruby, and I've come to the conclusion that inheritance was a mistake.

The explanation on p. 16 of the benefits of dynamic linking — that each module is present only once in the "store", by which he means RAM — makes me think that perhaps dynamic linking's time has come and gone. I'm typing this on a machine with 4 GiB of RAM. If I have both libjpeg 8.0.1 and libjpeg 8.0.2 loaded, that wastes 360 kB of RAM, one eleven-thousandth of the total. Perhaps some benefits accrue to this flexibility that make it worth the cost? For example, perhaps I would like to test a new version of libjpeg and automatically compare its output to the old version, or perhaps I would like to port my JPEG-using programs to the new version of libjpeg one by one instead of all at once?

Perhaps more urgently, what if I want to load a copy of libjpeg linked with special testing functions for accessing the filesystem, rather than the real functions? This is very important functionality that can easily be provided by dynamic linking, but it would be catastrophic for other arbitrary things that wanted to call libjpeg to inadvertently call the copy of libjpeg under test.

The total size of the core system (p. 18) is very impressive indeed: 12,277 lines of Oberon code (186 pp.) for the kernel, filesystem, windowing system, graphics editor, device drivers, text editor, compiler, and networking stack, plus some undetermined amount of assembly code (4664 bytes, so presumably about 1200 instructions for the NS32k), all compiled together to 131,800 bytes of executable code. Of this, 4000 lines is the compiler. The graphics system in particular (Fonts, Viewers, and Display) total 5324 bytes, substantially less than the 9597 bytes of text in yeso-xlib.a at the moment, much of which has to do with interfacing to Xlib and graphics-file libraries.

The description of viewers on p. 22 makes me think that perhaps Unix processes might simplify some things after all — the `ViewerDesc` type requires a `Handler` procedure for each window to be invoked with events, while in Yeso no such thing is needed, because each window normally has an entirely separate Unix process, and in any case its events can be read by the client as it pleases. (But perhaps cisco's travails getting sshd working on IOS are a better argument.)

On p. 23 the note about inheritance of message types is very interesting — the idea of adding new derived message types as subclasses of existing message types is simultaneously fascinating and horrifying.

It's interesting to read about a stackless "task" on p. 24.

The examples of inheritance on pp. 23–24 are basically closures — they exist in order to allow a task or viewer handler proc (like a WndProc) to maintain per-instance data.

The "system management tool" on p. 32 is interesting; it's more or less a form with clickable buttons, with the nice feature that it's just a

piece of text, typable by the user and WYSIWYG anywhere. (The ↑ glyph for what was described as "A reference-character '^'" on the previous page is interesting — it's from ASCII-1963, obsolete in ASCII-1968, but still in use in Smalltalk until the 1990s or even 2000s — Wirth's sabbatical at PARC, Smalltalk's birthplace, may be relevant here.)

A thought-provoking question is how far you could go with building an editable user interface that consisted of such templates and replacements — a popup menu replacing a menubutton and vice versa. Perhaps when you click on one command button (or press a control key bound in the context), it replaces the whole form it's embedded in with a query result, simply by textual replacement. Some of this could even be done with a simple text template language. And maybe a "reveal codes" toggle would be helpful for hiding the necessary markup at times.

(Similar things existed in Gypsy at PARC at the time; the menu at the top of the screen had a section labeled "*Scan* for {}" and another labeled "*Substitute* {} for {}", where the words "Scan" and "Substitute" were italicized to indicate that they were clickable, and the curly braces enclosed their arguments, which were of variable length.)

No introduction to the syntax of the language has been given before p. 34 as far as I can tell, so the reader is left to guess that # means ≠ and the semantics of the procedure-call mechanism (although it seems to be the same as Pascal's.)

The long sequences of statements on a single line, such as "c := b; b := a; a := (c MOD 509 + 1) * 127 + ORD(s[i])" are not in keeping with my aesthetic sensibilities, but those sensibilities may be a product of C and its assembly-language roots; certainly I wrote a lot of code in such a style in the 1980s myself (in BASIC), and Knuth's "TeX: The Program" (1984) is full of lines like `else begin back_input; cur_tok ← par_token; back_input; token_type ← inserted;`, though somewhat better typeset than the Oberon code.

(This may go some distance to explaining how the Oberon compiler is only 4000 lines of code.)

The password-hashing setup on p. 34 is cringe-inducingly naïve. Also, though, I infer from the code that Oberon's INTEGER type was 16 bits, either at times or always, since all of its variables would fit easily in 32 bits (19 bits I think). See p. 258 for how it's set on the server and p. 260 for why.

The setup of Oberon.User (also p. 34) as ARRAY 8 OF CHAR seems strangely primitive, given that Wirth conceived the system after heavy use of Cedar, from which it gets its tracks and viewers. Why didn't he use ropes? Ropes don't appear at all in Oberon. (Perhaps Wirth was skeptical about immutability in general, or at least when it comes to strings; see the bletcherous inline strtok() code in Call on p. 38.)

I'm suspecting that the "flip" in the names of FlipArrow and FlipStar on p. 35 means "XOR", which I suspect is the meaning of the fifth parameter of Display.CopyPattern, given here as "2"; this could be more explicit. It's somewhat horrifying to see the cursor bitmap sizes hardcoded into the bounding code like this; it suggests that the arrow and the star were the only two sprites in Oberon, so Gutknecht (or Wirth) didn't feel that factoring out a generic

sprite-bounding system was worthwhile. (The DrawCursor function immediately afterward may be the one that's actually used, though; perhaps the Flip variants were obsolete?) (Perhaps not; on p. 40 they're assigned to the Fade and Draw methods of the Arrow and Star markets, reinforcing the XOR hypothesis.) (Further explanation of cursor management is given on p. 59, and on p. 60 we have, "markers are usually painted non-destructively in inverse-video mode.", which I think means using the XOR hack; p. 61 defines Display.invert, explained as the "mode" "s XOR d", as "2", and indeed the fifth parameter of CopyPattern is "mode". Whew.)

On p. 36 we see HandleFiller, which handles events in parts of the screen containing no windows ("viewers"). The IF M IS InputMsg THEN WITH M: InputMsg DO stuff is a bit tiresome by contrast with ML. (I'm increasingly of the opinion that garbage-collected languages should be almost purely functional. Imperative code's advantages, such as they are, are vitiated by GC — maybe there's a local optimum near Golang.) The Display.FrameMsg argument is explained on p. 48.

On pp. 36–37 we see some clearly duplicated code, suggesting that the "dead code" hypothesis for FlipArrow and FlipStar is plausible: OpenDisplay should call OpenTrack twice, but instead duplicates its contents. Perhaps at some point in the past OpenTrack did something that was undesirable in OpenDisplay.

On p. 38 we see some examples of code with added reading complexity due to having no early exits; here Install wants to avoid adding a task to the task list if it's already there:

```
t := PrevTask;
WHILE (t.next # PrevTask) & (t.next # T) DO t := t.next END;
IF t.next = PrevTask THEN T.next := PrevTask; t.next := T END
```

This translates to C as:

```
t = PrevTask;
while (t->next != prev_task && t->next != T) t = t->next;
if (t->next == prev_task) {
    T->next = prev_task;
    t->next = T;
}
```

But I think it would be more natural to write it with an early exit, avoiding the redundant test:

```
TaskDesc *t = prev_task;
for (t = prev_task; t->next != prev_task; t = t->next) {
    if (t->next == T) return;
}
T->next = prev_task;
t->next = T;
```

(I wouldn't call my variables `t` and `T`, though.)

We also see what the authors were talking about when they said that GetSelection was implemented by broadcasting a message to all viewers on p. 38. After the Viewers.Broadcast call, GetSelection fishes the information about the selection out of the fields of the

SelectionMsg — presumably one or more of the viewers mutated it, perhaps conditionally based on the timestamp (which would explain the otherwise strange comments on p. 29 about the definition of the current selection, and indeed the existence of the timestamp field, as well as its initialization here to -1.)

On p. 39 we have some hints about the character encoding, as the main loop has some random code wedged into it to compensate for the difference between the keyboard's character encoding and that used elsewhere in the system. Assuming this PDF is faithful, both encodings are unknown to me; one has € at 0x81 and the other has it at 0x80.

On p. 40 we have the initial construction of the circular linked list of tasks, starting with just the garbage collector. A separate list header structure would have almost required a special case in the task list mutations (the Install and Remove procedures on p. 38 and the task-unlinking case in the main loop near the top of p. 40) because (if Oberon is like Pascal) you can't take a pointer to a struct field — although you can pass it as a VAR parameter, and maybe that would have been adequate.

It's somewhat jarring to find Min (for INTEGERs) in module Oberon on p. 34 and Max (for LONGINTs) in module System on p. 40.

On p. 41 we find the System.SetUser command, which it turns out separates the username from the password with a "/": "WHILE (ch # "/")". (This was actually suggested by the instruction "{ type user/password }" on p. 31.) Interestingly, this constant uses the same doublequotes used for strings, suggesting that in Oberon (as in Python, but very much not as in C or Pascal) a character is a string of length 1. Also we find that the username's length limit is actually 7 characters, not 8, because of the terminating 0X.

We also see the implementation of the rules for input parsing explained on p. 31: System.SetFont (also on p. 41) has a special case for "^", as do SetColor, SetOffset, etc., all implemented with separate calls to Oberon.GetSelection. But they're missing the "@" cases (although perhaps they wouldn't apply.) At least they're all using the same Texts.OpenScanner call to tokenize the parameter text.

A thing conspicuously missing in these user commands is error handling. If the specified font name doesn't exist or isn't supplied, there is apparently no feedback to the user at all that a command was invoked but merely failed, much less why it failed and how to proceed. Omitting error handling is indeed a very effective way to reduce the amount of code in your system, but it may not be a good tradeoff.

On p. 42 we see the bitfield datetime system in its full glory. I'm glad I don't have to do date arithmetic on Oberon.

On p. 44 we have the save-unders problem that accounts for so much of the complexity of both X11 and the Blit: "Any efficient management of overlapping viewers must rely on a subordinate management of (arbitrary) sub-rectangles and on sophisticated clipping operations. This is so because partially overlapped viewers must be partially restored under control of the viewer manager. For example, in Figure 4.1(b), rectangles a, b, and c of viewer A ought to be restored individually after closing of viewer B," although A and B are reversed from the diagram, in which A is on top of B. The Blit

did indeed do this; Microsoft Windows opted instead to dispatch paint messages to the exposed viewer.

The scrollbars on p. 44 would seem to owe a lot to MacOS, although perhaps I'm mistaken and PARC had nearly identical-looking scrollbars. The sans-serif code font on p. 44 and vertical italic email font on p. 45 (perhaps they are in fact the same font?) look like they come from Smalltalk.

The custom one-click shortcuts to print on particular printers or set particular fonts in the editor on p. 44 are particularly appealing.

On p. 48, the Oberon variant of MVC is most amusing: any time any document changes, all viewers are notified so that they can update if necessary, thus avoiding the necessity to register and deregister views of a model. This is a step toward the usual ImGui approach of repainting all viewers on every screen frame. (But see p. 79 for where this falls down, p. 98 for the unification, and p. 385 for a redundant re-explanation.)

We also see that Oberon has an X11-like hierarchy of windows, though it calls them "frames". Oberon windows are pretty lightweight, though; they contain seven words (presumably 28 bytes on the NS32032 they were designing for), so you can have tens of thousands of them if you like. However, the main purpose of this hierarchy in practice seems to be the pairing of inverse-video menu texts with contents panes as a single object, since the other use (vertical tracks of viewers) doesn't seem to really need handlers or really anything other than a global list of widths.

On p. 49 we see an email from "Griesemer" on "30.10.91". Could that be the Golang Griesemer? Yes, Golang Griesemer got his Ph.D. at ETHZ under Wirth and Mössenböck in 1993 on a vector version of Oberon for the Cray Y-MP, called Oberon-V.

On p. 50 we are introduced to the "logical display area". I wonder how decoupled from displays it ended up being in practice; the XOR hack mentioned earlier suggests not much.

On p. 51 we are faced with yet another definition of OpenTrack, or the declaration of one at any rate, this time in module Viewers. What happened to the one on p. 37?

On pp. 54–55 we have a small contradiction: "according to the principle of information hiding an internal data structure is fully private to the containing module and accessible through the module's procedural interface only," yet, "Although there is no language facility to enforce it, the variable *state* is to be treated as read-only by every module other than *Viewers*." I guess once you get a pointer into the internal data structure you can navigate it as you please!

On p. 56 we have an interesting viewpoint on object-orientation:

> Message handlers in Oberon are implemented in the form of "procedure variables" that obviously must be initialized properly at object creation time. In other words, some concrete behavior must explicitly be bound to each object, where different instances of the same object type could potentially have a different behavior and/or the same instance could change its behavior during its lifetime. Our object model is therefore *instance-centered*.

The procedure variables themselves, though, at least in the cases we've seen so far, handle all the messages directed to a given viewer or other frame, not just one. So they aren't the equivalent of a C++ virtual method, but rather of a C++ vtable. This is explained in more detail on pp. 379–81.

(This is in addition to the parallel mechanism for identifying record subtypes at runtime.)

Pascal procedure variables could only be passed down the stack, not stored in records, with the consequence that this style of programming was impossible in Pascal. The reason was that Pascal had nested procedures with block scope, but no garbage collection. The same reason explains why Pascal var parameters — which are pointers that may point inside of stack frames or records, unlike Pascal's heap pointers — can only be passed down the stack, rather than stored in data structures. This restriction would seem to be unnecessary in Oberon.

I'm not a big fan of the four-deep nested IFs at the bottom of p. 56.

On p. 57 we see an observation which is in a sense very trivial from the point of view of the Actors model, but quite a mind-bomb for the Pascal crowd:

> The essential point here is the use of new *outgoing* messages in order to process a given *incoming* message. We can regard message processing as a transformation that maps incoming messages into a set of outgoing messages, with possible side-effects.

(That's all there is to the Actors model, really, except to view all of computation in that way.)

On p. 59 we see why XOR-drawn cursors flicker when something else is being drawn without double-buffering.

On p. 61 the drawing API is explained. It lacks the ability to copy a block of pixel data to or from an offscreen buffer; cursors (and fonts, p. 62) are drawn using CopyPattern, which takes a foreground-color parameter and a one-bit-deep (p. 62) Pattern.

On p. 62 we collide with the Oberon language's lack of slices and consequent weakness in dealing with variable-size bitmap data.

On p. 63 we seem to be considering double-buffered Xinerama-style-unified displays of varying color depths; double-buffering is somewhat surprising for the 1984–8 timeframe when they were building the Oberon system — the Macintosh, the CGA, and the EGA didn't have enough RAM to double-buffer in popular modes, and X-Windows (1984, X11 in 1985) isn't double-buffered — it hurt responsiveness. Working multi-depth Xinerama is surprising even today.

For now I'm going to skip over the complete implementation on pp. 67–77.

On p. 78, where they're starting to talk about texts, they explicitly call out Cedar's influence:

> Motivated by our positive experience with integrated text in the *Cedar* system [Teitelman] we decided to provide a central text management in Oberon at a sufficiently low system level.

On p. 79, they say, "It is important not to confuse this type with the far less powerful type *string* as it is often supported by advanced programming languages." Of course we've already seen a fair bit of NUL-terminated string handling in the previous chapters; and Oberon's Text type is mutable, preventing it from being used for many of the things Cedar used ropes for. Oberon texts have fonts, colors, and "vertical offsets" (which seems to mean superscript or subscript; see p. 102 for an illustration), making them essentially quite graphical objects. They have no implicit line breaks, so they are

intrinsically formatted for a particular line width. However, texts to be displayed in standard text viewers cannot have multiple font sizes! See pp. 100–101 for this disheartening development.

On p. 79 we also see the weakness of their minimalist MVC implementation explained on p. 48: there's an additional observer interface to be notified of changes to Texts — though in this case it's so broken it only supports notifying a single observer. (But see p. 98.)

On p. 80, we see that their text handling is plagued by the same kind of unnecessary multiplication of interfaces as their pixel handling — instead of having a single string type, they have three or more — ARRAYs OF CHAR, Texts (which may have properties or "looks"), and now Buffers.

On pp. 80–81 we are introduced to the Reader type, which, like an Emacs marker, points to a place in a Text without being merely a number. However, I suspect that Reader doesn't have the virtue of Emacs markers: that it moves with the buffer contents when something is inserted earlier in the buffer. We shall see. Certainly there seems to be no possibility of passing Readers instead of integers as positions to procedures that take text-position arguments. (On p. 87 we see that Readers contain a reference into the piece-chain data structure of Texts that would enable them to survive mutations in other pieces undisturbed.)

I am distinctly unimpressed with the bug-prone Scanner sum type, with its 5 different value fields and a sixth tag field to tell which is active.

On p. 82 we have this absolutely fascinating note:

> Typically, readers and scanners are… of a *transient* nature, … This fact manifests itself by the absence of any possibility to reference readers and scanners by pointers.

This is a very surprising note! It implies that in Oberon you can't declare a POINTER TO Scanner type whenever you please; perhaps only their own module is permitted to declare such a type. Presumably, though, you can embed them in other records, and reference those other records with pointers, if you want to, so I am at a loss as to what the benefit of this limitation might be.

Lower on p. 82 we have Oberon's text formatting capabilities, such as they are; they're similar to TeX or Smalltalk in that the favored approach to produce an output of ten tokens (strings, integers, and decimal fractions, say) is to invoke a sequence of ten procedures, passing the same argument.

On p. 83 we find that they have chosen to represent Texts with Bravo-style piece chains.

On p. 90 we have the curious feature that does impedance-matching between the piece-chain structure and keyboard input:

> And finally, typed characters that are supposed to be inserted into a text need to be stored on a continuously growing file, the so-called *keyboard file*.

This doesn't really cover text generated as command output, but I suppose we could have output files for all commands, too.

The keyboard file could be useful for other purposes, too; for example, you might want to look at it, or even have the end of it continuously displayed for a screencast.

We also see the usual conceit of totalizing systems like Microsoft Word: plain ASCII text files are accepted, as input files, but only

"for compatibility reasons". Ugh.

The discussion of file page immutability on p. 90 is also interesting — the piece-chain data structure they're using shares with ropes the feature of being able to include arbitrary amounts of file data without reading it from disk until needed, so for it to be completely safe, it is necessary for that file data not to be modified in the meantime. (Perhaps a change notification scheme would work under some circumstances, but Oberon seems to have no such scheme.) This is expressed on p. 91 as follows:

> Once a file page is allocated it must not be reused (until system restart).

But it's not talking just about reuse *for another file*, but also about reuse for a different version of the same file.

This is an interesting desideratum for filesystems: the ability to retain immutable on-disk snapshots of particular files. The "system restart" backdoor might be thought clearly unacceptable nowadays, requiring as it does regular reboots to prevent the filesystem from getting full. (This is elaborated on p. 163, where file pages are called "sectors".)

It's also interesting in that, although Oberon's Text isn't immutable as Cedar's ROPE is, its implementation depends on immutability — but of disk files. (But note that disk files aren't immutable; see p. 164! So this can fail.) In a way, this seems perverse — it's depending on a more expensive kind of immutability, but doesn't fully deliver the decoupling benefits of Cedar's ROPE, in that you can't just hand out Text references willy-nilly — you'll get aliasing bugs where something you handed it to goes and mutates it later. But it seems like making a copy of a Text might often be a sufficiently cheap operation as to make this forgivable, since only a small number of Pieces need to be copied. (The association of "looks" with Piece objects will multiply the number for fancy documents.)

On p. 98 we have the link between the Text change notification mechanism (p. 79) and the Viewer change notification mechanism (p. 48): changing a Text being displayed in a Viewer invokes Viewers.Broadcast with an UpdateMsg (with the typically painful and repetitive Pascal/Oberon record initialization syntax.) I suppose this means that you can't share a Text between a text frame and another kind of non-viewer user that wants to be notified if it changes, but sharing it between multiple text frames is no problem.

On p. 99 we see concern about flickering, but manifested by using bitblt for scrolling, rather than double-buffering a screen update. This is an example of extra complexity introduced by optimizations that were necessary in 1988 on a 1-MIPS machine that are no longer relevant.

On p. 100 we see the rather dismaying pronouncements:

> 1.) For a given text frame the distance between lines is constant.
> 2.) There are no implicit line breaks.

This means that there is no way to get a title in a larger font to take up more vertical space. This is justified by the desire to display text in a single pass, but is that really worth damaging the formatting quality of the text so severely?

My propfont.c spike does paragraph filling (implicit line breaks) with a proportional font, though not variable line spacing, in grayscale at 22 megabytes of text per second on one core of my 1.6GHz laptop. Assuming 1.5 instructions per cycle, this is about 109 instructions per

letter. On a 1-MIPS workstation, in a 15-millisecond screen frame, this could manage to format about 15 kilobytes of text.

On p. 101 we find that we can't even get a title in a larger font at all:

> line spacing is fixed for every text frame. Therefore, different styles of a base font are possible within a given text frame while different sizes are not.

Watching Larry Tesler's 2017 demo of Gypsy from 1981 I see that Gypsy and Bravo didn't have different sizes or different typefaces either, at least a couple of years earlier, except for italic and bold (and underlined and inverse-video) variants of the same base font.

On p. 102 we see, for the first time I've noticed, that Oberon's Y-coordinates increase upward rather than downward. Also, its font system purports to support hinted outline fonts, but on p. 104 we see that this is not the case; it only supports raster fonts.

We also see another of the lamentable COBOL-style arbitrary limitations on string sizes: font names are 32 characters long.

On p. 104 we see that in the "ultimately stable" font file format, we have a single-byte enumerated value for the font family ("*Times Roman*, *Syntax*, etc.") This seems like a choice that is almost guaranteed to produce incompatibility; since more than 256 font families exist in the world, someone must maintain a registry of font family identifying bytes, which will need new families added to it from time to time, both producing the chance of incompatibility (if two different installations of Oberon start using the same identifier for different fonts) and inflexibility (since you cannot simply add a new font file to your Oberon installation, but must also add the family to the family registry.)

(Of course, the continuous and implicit conflation of "ASCII" with "text" seems quaint in 2019.)

The font file format has a couple of other drawbacks:

- It supports raster fonts only, and apparently monochrome ones without antialiasing at that.
- There is no provision made for output device resolution: the units of "height" are unspecified. (On p. 63 we saw that Oberon output devices supposedly do know their physical height.) This presumably means that they are pixels, so you might use a height-10 font on a standard 75-dpi screen and a height-30 font on a 300-dpi printer; this precludes the kind of adaptation normally needed to preserve readability at small sizes.

The printing graphics model on p. 105 seems rather impoverished compared to PostScript, and presumably the PARC language JaM it derived from; like X11, for example, it provides only unrotated text, and seemingly no facilities for clipping or even color — its primitives completely lack composability! It's also rather depressing that (like X11 but unlike GDI and Quartz) they chose a completely different imaging model for printing and onscreen drawing.

I am skipping for the time being past pp. 105–143, which contain several source-code modules.

On p. 144 we have the Oberon philosophy on dynamic linking, namely, that you should make your linker fast enough that you are not tempted to link things statically. This philosophy does more or less prevail in modern Unix and Microsoft Windows, but it does have a certain amount of cost in the Unix context, where the loading of a

compiled program is conflated with the initiation of a process. `ldd /usr/bin/mate-terminal` on my laptop, which merely runs the dynamic linker to link the 58 dynamic libraries into mate-terminal and prints the results, takes about 30 milliseconds, which is a human-detectable period of time; that's on a CPU core that runs about 2.4 billion instructions per second. Valgrind reports that it takes about 7 million instructions in the last-spawned child process. So on a 1-MIPS workstation this would take about 7 seconds, or about 72 seconds if you believe the 2.4-billion number.

Probably, though, you can use jumps through program linkage tables (called "link tables" here on p. 144) to reduce this cost if it becomes significant; the cost of linking then diminishes to merely a merge of the tables of subroutines in all the libraries; as explained on p. 145, this is the approach Oberon uses. PC-relative addressing on modern processors eliminates the need to use these tables (or a separate library-base-pointer register) for intra-module references. (On p. 147 we see that apparently the NS32k's BSR instruction is PC-relative.)

Indirection through such a table does impose an extra cost on each static inter-module subroutine call (though not necessarily dynamic calls through function pointers.)

On p. 145 we are faced with the question of numbering procedures. How does the linker avoid trying to load module A compiled against version 1 of module B, attempting to link it to version 2 of module B with a different procedure numbering? Because the page says, "Procedure names are not needed, as they have been transformed by the compiler into numbers unique for each module."

On p. 146 we see that Oberon uses two separate registers for intra-library relocation, rather than ELF's single register (which is %ebx on i386 IIRC).

We also encounter something claimed to be microcode; I'm not clear on whether this is the actual microcode for the NS32032 CXP and RXP instructions (it seems to be; the instruction opcodes are given on p. 355), or some kind of Oberon-specific portable assembly.

On p. 156 we encounter the notion of a "rider", which is to say, a file cursor; Michael Franz gives this as one of the great advances in Oberon over other systems, but I don't understand what the difference between a Rider and a Unix file descriptor is, except that in Oberon you need to first call Old (or New) to open the file and then Set to place a Rider, rather than just calling open().

On p. 157 we encounter the presumption of filenames:

> A file system must not only provide the concept of a sequence with its accessing mechanism, but also a registry. This implies that files be identified, that they can be given a name by which they are registered and retrieved. The registry or collection of registered names is called the file system's *directory*.

What do we get if we question this? We've already seen that Oberon does question it somewhat — previously written file pages can continue to be referenced by Texts even when they are obsolete — but what if our files were anonymous? Perhaps we could include references to them in other files (in a way that is explicit to the filesystem), then run a garbage collector.

It seems that all Oberon files are open read-write; even all riders are read-write.

On p. 159 we encounter the horrifying suspicion that perhaps

Oberon files require a function call and return for every byte read — and an inter-module call and return, at that. But p. 157 allays our suspicion — there is a ReadBytes call that takes an (unsafe) variable-length array. This is elaborated on p. 163, which gives the measured speedup on the Ceres-3 as 18× (though still only 2.5 megabytes per second — to RAM! — which seems painfully slow. It's about 7000 times slower than my current laptop's in-cache RAM access of 17 gigabytes per second, according to lmbench's bcopy benchmark.)

On p. 163 we encounter the first clue that Oberon in fact used memory protection after all, though perhaps not virtual memory:

> In this table, every sector is represented by a single bit indicating whether or not the sector is allocated. Although conceptually belonging to the file system, this table resides within module Kernel, because for safety reasons it is write-protected in user mode.

(But see on p. 194 that Ceres-3 had no MMU; p. 197 goes into the details of the memory mapping.)

Also we find that the Oberon startup routine involves scanning the entire filesystem for free blocks, like jffs, to build the in-RAM sector reservation table; this seems that it would not scale well to modern disks with billions of sectors, but perhaps it depends on the locality of the file directory. However, as in Unix, the block pointers ("sector table") and indirect pointers ("extension table") in Oberon are stored in the inode ("file header"), so the locality can't be very good. On p. 190 we are told, "[T]he initialization of the sector reservation table clearly dominates the start-up time of the computer. For a file system with 10'000 files it takes [on] the order of 15s to record all files."

(The whole sector GC thing seems rather bletcherous to me, even for 1984.)

On p. 164 there is a clue as to why Franz thought riders were so awesome: in Oberon, disk buffers are associated with a particular file, rather than with the disk as in typical Unix systems. Clearly associating buffers with a particular file descriptor would lead to inconsistencies (failure to Read Your Writes, among others).

The description of the buffer semantics here make it clear that the immutability property required by Texts on p. 90 is not in fact provided; you can change the contents of a Text by rewriting parts of its underlying disk file, though not by writing an entire new version of the file and then invoking Register to update it.

On p. 174 we see that Oberon's Register includes an fsync() (Unbuffer) to avoid losing data. My recent experiences with recalcitrant USB drives make me wonder if some kind of limit to dirty in-memory data is needed to guarantee responsiveness in cases like this — Oberon's four buffers (4KB) per file, for example, ensures that this Unbuffer call won't take that long.

Also on p. 174 we see that they didn't know about weak pointers, so they hacked the garbage collector's root set to compensate:

> there exists a pitfall that is easily overlooked: all opened files would permanently remain accessible via root, and the garbage collector could never remove a file descriptor nor its associated buffers. This would be unacceptable. We have found no better solution to this problem than to design the garbage collector such that it excludes this list from its mark phase.

On pp. 174–175 we see that they use a 24-way B-tree to map file pathnames (capped at 32 characters) to sector addresses, where their inodes are stored, though it's defined naïvely without hysteresis and

can thus thrash splitting and unsplitting the root when oscillating about a crucial number of entries. This choice is justified on simplicity and efficiency grounds on p. 189 and contrasted with Unix's hierarchical filesystem, but the simplicity grounds make me suspect that the authors never read the Unix filesystem code, which used a linear search through an unordered directory at the time, and indeed in many later implementations.

It's unfortunate that the B-tree code wasn't generalized and exported to provide a general-purpose ISAM facility.

On p. 176 we see that FileDir.Enumerate is in the "non-public" API of FilesDir (the reason being given on p. 183); also, I note that it takes a callback but no userdata. Does Oberon support nested procedures with lexical scope, as Pascal did? The notes about BSR on p. 147 didn't suggest that the regular procedure-call sequence involves passing a context pointer, as nested procedures normally require (except when circumvented with GCC's stack-trampoline hack).

On p. 192 we find an RT-11-style/VMS-style command-line switch "/date"! For the Directory command.

On p. 194 we find some explanation for the earlier ambiguity about memory protection: the Ceres-3 has no MMU!

On p. 195 the memory maps confused me by having 0 at the top and addresses increasing downwards; it led me to wonder whether the Ceres-[123] all had stacks that grew *upwards*, which they don't, as we can see from the "microcode" on pp. 146–7.

On p. 198 we find deep skepticism about the usefulness of MMUs: "a dispensible [sic] overkill for single-user workstations." Yeah, maybe if all your software is written in OCaml. Although I suppose the Macintosh was pretty useful without an MMU from 1984 until MacOS X (1999?).

On p. 199 we are introduced to the garbage collector; surprisingly, they mention reference counting (though giving the algorithm incorrectly) and the mark-and-sweep scheme they use, but not copying collectors. Oberon uses a non-incremental stop-the-world mark-and-sweep collector using pointer reversal.

On p. 202 we are introduced to the heap object format, which has a 4-byte header (ick). Maybe it was hard to do better than that in 1984, although BIBOP kind of did. BIBOP may be easier if you have an MMU, but I don't think it really needs one.

On p. 207 we have the entirely unnecessary SetMouseLimits interface, which has no equivalent in PS/2, USB, or evdev mouse protocols, but the Oberon mouse driver reports absolute rather than relative X and Y. Even if you wanted to limit the memory needed to buffer mouse events, you could buffer a ΔX and ΔY! This unconventional choice of border behavior also implies a lack of awareness of the Fitts's-Law-driven design of 1984 Macintosh menus:

The position "wraps around" in both the horizontal and vertical directions.

To be fair, though, nobody had written about this outside of Apple at the time.

On p. 209 we have "the module's initialization sequence", which I suppose is the block of code at the end of the module; I hadn't realized this was run when the module was loaded, but of course such a thing is urgently necessary in a Pascal-family language that doesn't permit you to initialize values in their declaration. In this case, it's

also being used to install interrupt handlers.

We also see the module V24, for accessing the serial port; its interface is entirely incompatible with those of file access, of handling keyboard events, and of access to Text objects.

On p. 210 I finally realized that "0FFFFC000H" is a LONGINT while "30X" is a CHAR. (This is explained in the scanner on p. 307.)

The serial-port driver on p. 210 is quite compact for a device driver. Its use of a CPU delay loop in Break (p. 211) despite being a driver for a chip with a sufficiently accurate real-time timer on it seems suboptimal. This goes unremarked here, but a similar (but more justifiable) delay loop on p. 216 merits the comment, "This is rather unfortunate."

On p. 211 we have a description of an RS-485 network. They claim to have gotten 230 kbps, close to contemporary Arcnet's 300-kbps performance. It's strange that they claim that clock accuracy limits packet length, though, since they're using SDLC bitstuffing (and in fact the whole SDLC protocol, including its 256-station addressing limit) to ensure adequate transition frequencies to maintain CDR. (On p. 222 we find that the length limit is 512 bytes.)

On p. 216 we have the account of SDLC's alternative to CSMA/CD, whose code is near the top of SendPacket on p. 214:

> Before sending a packet, it must be verified that the line is free by testing the so-called hunt bit. If the line is busy, the line is polled again after a delay. The delay is influenced by the station's address, causing all stations to have a slightly different delay. Actual collisions can only be detected by the receiver through the CRC-check at the end of the packet.

What's not mentioned is that this whole procedure, including the retry delay, blocks the entire machine; presumably this will always happen if the line is faulted in a certain way. There is no retry limit.

During the packet transmission the driver disables interrupts in order to be able to meet the SDLC chip's timing constraints, like the old Linux PIO disk driver. This seems like it could detectably interfere with interactive responsiveness: 512 bytes is 4096 bits, which is almost 18 ms at 230 kbps, and it's possible that we might have to wait for several packets from other senders to finish passing before we can send our own.

I haven't read the SCSI driver on pp. 218–220, but I'm pleasantly impressed that it's only two pages of code.

On p. 222 we find the description of the TFTP-like file transfer protocol; its lack of windowing might slow down file transfer (since the ACK packet will be delayed until whatever user interface task has the receiving processor busy is done) but I'm not sure that the SCC driver described on pp. 211–216 can buffer multiple packets anyway.

The lack of cryptography in the user authentication p. 222 is entirely unremarkable in the 1984–92 context; although it is of course unacceptable nowadays, some web hosts still use unencrypted FTP.

It's amusing that the file transfer protocol includes an instant message protocol (though no group chat). This becomes less amusing when we reach the end of Chapter 10 on p. 230 and realize that the file transfer protocol is the only application protocol supported by their network! (Well, the dedicated server software in Chapter 11 also includes an email protocol and a printing protocol, which the

workstations have the client code for.) This is somewhat disappointing in the 1984–88 context they were designing the code in, which also saw network-transparent windowing in W and X, telephony over Ethernet, and the birth of Novell, and was 16 years after Engelbart's 1968 demo in which he demonstrated screen-sharing of a windowed environment over a long-distance network.

They describe ARP on pp. 222–3, but they're ARPing for a person's initials rather than an IP address.

On p. 231 we begin the description of the dedicated server, and it's astonishing to realize that they don't have a fileserver in the normal sense — a networked facility that appears as a filesystem, just like local disk filesystems, but perhaps supports locking or something, which was the primary service provided in Novell and NFS/NIS networks in the 1980s and 1990s. Wirth had experience with such a system — Cedar's FS was done that way, and its designers report that they only allowed local disks reluctantly as a concession to user demands. Perhaps he didn't think it was a good idea?

They say their server is a Ceres-1 with two megs of RAM (half being the printer's framebuffer) and a 1-MIPS processor on p. 259.

It's amusing that the primary interface between servers is a message queue, though one substantially simpler than AMQP.

On p. 237 we are explained that an Oberon mailbox (for email, not some kind of message queue thing) is structurally restricted to 64 kibibytes and 30 messages; the format is a sort of compound-file-like filesystem-within-a-file with its own block-based free map and directory. I have to say that I think the Berkeley mbox format is both simpler and less limited (though surely less efficient; providing a mailbox directory requires reading the entire file). (Sendmail was a nightmare of complexity compared to the simpler mail server presented here.) Maybe they should have fixed their filesystem so it didn't allocate an entire kilobyte to every file, so they could have just used a file per message. It appears also that it's possible for the mailbox file to be so fragmented that a new message won't fit. (Confirmed on p. 245.)

You could imagine justifying such a complex mailbox file format if it were generalized to support arbitrary tables. For some reason, mailbox formats seem to be an attractive nuisance for ingenious people to overcomplicate, Mork being perhaps the most notorious example but far from the only one.

"Franz" (presumably Michael) appears on p. 238 in an example mail message, as do "Templ" and "Mueller".

On p. 238, we see that for no particularly good reason the mail access protocol seems to be binary: 10H for ACK, 25H for NAK, 26H for NPR, 24H for NRQ, and so on. These are the values of the field SCC.Header.typ.

On p. 252 we see the use of a temporary file (one not registered in the filesystem directory) as a buffer for data:

> it is almost the same as that for handling requests to receive a file. But instead of registering the received file, the file is inserted into *Core.PrintQueue*.

This is the same mechanism I'm planning to use to deliver buffers of pixel data to the Wercam server on Linux.

On p. 253 we see the printer rasterizing operations. (Before PostScript, all raster printers were WinPrinters.) The midpoint circle algorithm makes an appearance (as it does again on pp. 423–424),

though unfortunately the ellipse procedure is omitted.

On p. 258 we see that the cringe-inducing password hash from p. 34 is actually password-equivalent; it has a cringe-inducing justification on p. 260, which also explains that in order to protect the user database from unauthorized access, it's stored outside the filesystem, since the filesystem has no protection. Yet on p. 265, we read, "the impossibility of activating users' programs on the server station significantly reduces the possibilities for inflicting damage from the exterior." But presumably the server stores its software modules in the filesystem for use during boot?

On p. 287 we have RT-11-style command-line switches again (as on p. 192), and specifically they are to disable index and type checks, suggesting that these were major performance bottlenecks at one time. We also see the Algol-68-like expression "the mode of the object", meaning its type.

On p. 288 we see Figure 12.6, the call graph of the Oberon recursive- descent parser, which doubles as a summary of the Oberon grammar.

On p. 289 we finally discover the meaning of the suffixed asterisk on many procedure names at their definition: it indicates that they are to be compiled in such a way that they can be called from another module, so they return with an RXP instruction rather than RET. This implies that even intramodule calls of these procedures must use the slower CXPD; a trampoline function could have been used to avoid this.

In the scanner or tokenizer (module OCS) on p. 307 we have yet another of the tiresome lists of numbered constants, this time in the form of a table of token types: number, NIL, string, ident, ;, and so forth. In Lisp or Cedar you would use atoms (symbols) for this, in modern C you could use an enum, and in ML you would use a sum type. A comment seems like a distinctly poorer form for this information, but I suppose it has the advantage that, being a comment, it doesn't count against the compiler's 4000-line footprint.

The code for OCS is on pp. 307–312.

The hash function described on p. 307 (embedded in the Identifier procedure on p. 308) is very poor, particularly considering that it requires a division by 43 after every identifier character.

On p. 308 we see another peculiar feature of Oberon's grammar: logical AND is written as `&`, while logical OR is written as `OR`, and *binds more tightly than AND*, unless there's an error in the code to scan to the end of the identifier.

It's interesting that Texts has a Read procedure that produces a CHAR rather than a CHAR-with-looks.

Given the simplicity of the compiler as a whole, it seems inescapable that its chief bottleneck must have been this scanner (though the book does not, as far as I can tell, mention a profiler, and even the debugger on p. 368 seems very limited). On that basis it may seem quite surprising that they chose to make a full intermodule function call for every input character; there are 41 callsites for Texts.Read in OCS by my count. An intra-module function call might have been a bit better — both intramodule and intramodule calls had hardware instructions, but I don't know what their timings might have been — but really you'd like to use a piece of code like the following:

```
IF bufPtr = bufLen THEN refillBuffer END;
...buf[bufPtr]...; bufPtr := bufPtr + 1
```

However, you really don't want to put that in the source code itself in 41 places, and Oberon doesn't have a C-like preprocessor, a Lisp-like macro system, or a compiler capable of inlining even an intramodule function call, much less an intermodule function call.

On the gripping hand, the dedicated server in Chapter 11 (p. 231 et seq.) was of their first Ceres-1 generation of workstations and had two megabytes of RAM. The largest module in the system was OCE at 972 lines of code (see p. 18; OCS is listed there as 314 lines, matching well with its 6-page length here). Perhaps 972 lines of code might involve another 972 lines of comments, averaging 60 characters per line, for a total of 117 kilobytes. Reading such a source module entirely into RAM before beginning the scanning process would have used only 6% of the workstation's memory, and would have avoided the problem of file access during tokenization entirely. (Although `*bufp++` is considerably wordier in Oberon than in C.)

On p. 312 we see the initialization of the keyword hash table:

```
BEGIN i := KW;
    WHILE i > 0 DO
        DEC(i); keyTab[i].symb := 0; keyTab[i].alt := 0
    END ;
```

One is forced to wonder how much code could have been eliminated from Oberon by zeroizing module variables, as C does, or all uninitialized variables, as Java and Golang do.

On p. 325 we have the following extremely dubious statement:

> It is the goal of a good compiler to make use of all addressing modes offered by the computer, thereby avoiding the emission of unnecessary instructions for address computation.

Presumably the intent of avoiding unnecessary instructions is either to make the code run faster, to reduce code size, or nowadays to use less energy, but using more addressing modes is not guaranteed to move you toward any of these goals — not in 1984 with microcoded CISCs, not in 1988 with nascent RISC, and certainly not in 2019 with superscalar micro-op-based CPUs.

On p. 330 we see that the author is not American; a procedure is named AssReal.

On p. 345 we find the amusing detail that the NS32k memory block move instruction is called MOVSB, just like the 8088 (though there it's not really a block move without the REP prefix: REP MOVSB).

On p. 355 we see the full Nominal Semidestructor Thirty Two Million CISC instruction set. Sometimes the failure of this chip in the market has been attributed to poor compiler quality: on paper it was just as good as a 68000, but in practice it performed about 25% worse with the vendor's C compiler. It seems to have had a couple of special-purpose base registers (FP and SB), 8 general-purpose registers (like the 8088), and an indirect addressing mode. Unlike the 8088, its instructions are (generally) two-address instructions.

I'm somewhat alarmed by the remark on p. 356, "This solution strictly limits the size of modules" — how small do they have to be?

None of the ones listed on p. 18 was more than about 12 kilobytes.

The code generator itself occupies pp. 357–367, more or less. 56 lines of code seem to fit on a page, but, as commented before, the lines are uncomfortably long.

On p. 368 we are introduced to the very primitive debugger.

Reading p. 369 it occurs to me that perhaps the debug information the debugger reads should be the same information the compiler uses to tell itself where things are stored.

On p. 374 Wirth tells the story of how he saw Chuck Thacker's SIL written in BCPL on an Alto at PARC in 1976 and went to write his own in Modula-2 on a PDP-11, which grew gradually into the Oberon graphics editor.

On p. 385 we have the viewer-broadcast update mechanism from p. 48 explained again.

On p. 388 we have the 1980s view of object-orientation: its virtue is that it allows you to dynamically load machine code you don't have the source code to, as long as it implements a calling interface you do, by means of "the extensible record type and the procedure variable". Yuck.

On p. 407 we find that they encountered the object-graph serialization problem ("pickle") in the graphics editor, solving it with an object table. Later on pp. 435–436 we see that in the ensuing years they generalized this approach to arbitrary object graphs, using it for the repertoire of objects in a text as well.

There is a screenshot from 1995-09-21 on p. 440, showing the state of the Oberon system at that time, with desktop icons, overlapping windows, over 1000 messages in a mailbox, and still regrettable non-antialiased pixel fonts.

Laser printer oscilloscope

Kragen Javier Sitaker, 2017-04-18 (updated 2017-06-20) (2 minutes)

I've been trying to figure out if there's a way, using salvaged electronics, to store a series of high-speed analog waveforms long enough to digitize them with a low-speed ADC, in order to make a cheap DSO. To be more specific, I want to digitize a channel or two with signals at and above 20MHz, and thus a 40MHz Nyquist frequency, with perhaps 1000 samples, with at least 8 bits of precision, stored following an analog detection of a trigger signal, at varying sample rates, and then digitize them with an ADC of 6Msps or less, promptly enough to update an oscilloscope display many times per second. So those 1000 samples might be 25 microseconds, or 250 microseconds (with elements up to 2MHz), or 2.5 milliseconds (at which point you're only covering up to 200kHz).

I considered a coaxial cable delay line, but 25 microseconds is almost 4 kilometers of coaxial cable, which would impose a fatal degradation of signal-to-noise ratio. I considered driving the deflector coils of a TV tube or computer CRT with higher frequencies, but for 20MHz, the inductance involved would require such high voltages that the coils would almost certainly fail (see TV oscilloscope (p. 1253)). I considered recording the analogue waveform on a hard disk (see Disk oscilloscope (p. 713)) and then digitizing it during succeeding revolutions, which might work, but I don't know enough about the linearity and SNR.

So here's another idea along those lines: use a laser-printer mechanism, electroconductive drum and all. A 10ppm A4-size 600dpi laser printer must go through 210 mm × 297 mm of paper every 6 seconds. That paper works out to almost 35 megapixels, which means that the laser has to be modulated (and successfully recorded on the drum) at 5.8 megapixels per second.

Unfortunately, this is not nearly fast enough, and of course the linearity of the system is terrible.

Maybe the 64-microsecond acoustic delay lines that 1980s PAL electronics used? Those could be hard to find.

Better: see CCD oscilloscope (p. 1861).

Precisely how is 3 “optimal” for one-hot state machines, sparse FIR kernels, etc.?

Kragen Javier Sitaker, 2014-04-24 (8 minutes)

If you have a state machine with one-hot encoding, perhaps because you're computing your state transitions with non-inverting a logic family such as diode logic, then with two bits of output you have two states; with three bits of output you have three states, with four bits of output you have four states; and with five bits of output you can either have five states, or if you split your state into a two-bit output and a three-bit output, six states. With six bits of output you can have six states, or three chunks of two bits giving you eight states, or two chunks of three bits giving you nine.

This is an interesting thing; by using ternary instead of binary, your state machine gets the power to representation an extra state. It's not much, but it's something. And it compounds: with 24 lines of output split into 8 groups of 3, you get $3^8 = 6561$ states, while if you split it into 12 groups of 2, you get only $2^{12} = 4096$. It's about 5.7% extra information per bit: instead of getting 0.5 bits per bit, you get 0.53 bits per bit.

That is, the optimal number of states per state-machine variable is three.

Suppose you're trying to factor a target finite-length comb FIR kernel into a set of sparse FIR kernels that convolve to produce your target kernel; you want to minimize the number of multiply-accumulates per sample. If you convolve a comb with three unit impulses separated by eight empty points (zero samples) with another comb with three unit impulses separated by two, you get a comb with nine unit impulses separated by eight intervals of two empty points, at a cost of six multiply-accumulates. By contrast, if you convolve three combs with two unit impulses each, separated by two, five, and seven empty samples, you do the same number of multiply-accumulates and get a comb with unit impulses separated by two empty points --- but only eight of them rather than nine. The same is true if you replace two of those two-impulse combs with a four-impulse comb. Things get worse as you move to less-sparse kernels with five, six, or more nonzero points.

That is, the optimal number of impulses per kernel, in some sense, is three.

If you're building a balanced search tree and you want to minimize the number of keys you have to compare your probe key against, binary is the best branching factor: each comparison result gives you exactly one bit of information. But consider, instead, a menu system user interface for an idealized user who makes no errors but must read each menu item before deciding, correctly, whether to select it or not, but who may be seeking an operation not present in the menu tree. How do you minimize the number of menu items the user must read when successfully navigating the system?

If there are two items in each menu, the user must read, on

average, one of them before making a successful selection, so she will need to select lg N menu items to reach her final destination; say, 20 items if there are 1048576 total possibilities. If there are four, she must read on average two items, but need only make half as many selections: 10, while reading 20, just as before. If there are three, she must read on average 1.5, while selecting about $\log_3 N$ times --- in this case, 12.6 selections, reading 1.5 items each time, for a total of about 18.9 menu items read.

So it turns out that the optimal number of menu items, in some sense, is three.

(Real menu systems, of course, have to deal with other cognitive issues: how do you organize hundreds or thousands of things in such a way that users can guess or even remember which category each thing is in?)

Suppose you want to make a program as debuggable as possible. How big should your functions be?

To be a little more concrete, suppose you're trying to track down an incorrect result from the execution of a program that runs for a hundred billion instructions, or about a minute. If the program is built out of functions that call other functions and combine their results, and you can tell from looking at each result whether it's correct or not, maybe you can navigate to the result you want by expanding the execution history as an outline.

If each function calls three other functions, then within 24 clicks, you can make your way from the top-level result to the particular incorrect result; at each step, you have to examine on average 1.5 intermediate results, so you need to look at about 35 results.

If each function calls only two other functions, you have to look at about 37 results, which is slightly worse; and the same is true if each function calls four other functions.

So, in some simplified sense, the optimum branching factor for function-call graphs is three.

The number of nodes you have to traverse to reach one of N nodes with branching factor B is ceil(log N / log B), and if you're examining each of the B branches in the node to figure out which one to follow, you end up examining B ceil(log N / log B) branches. If we remove the discretization, we get log N (B / log B), and it turns out that B / log B has a minimum at B = e, so in practice the optimal branching factor is 3.

That's the phenomenon underlying the above simplified problems. But, as you can see, B/log B is pretty flat over the 2 to 4 region. It jumps up to infinity as you approach 1, and from e on, it grows slowly. It's only 0.4% worse than optimal at B = 3, 6% worse (as seen above) at B = 2 or 4, 15% worse than optimal at B = 5, 60% worse at B = 10, twice as bad at B = 15, and 3.2 times as bad at B = 30. So it's easy for the optimal factor in the real world to be anywhere between 2 and 10, depending on what other things you're trying to optimize.

For example:

- in the case of the state machine, your state-transition logic might be simpler with one-hot encoding among six output lines rather than some kind of conjunction over a group of two and a group of three, and that might pay the cost of the extra line;
- in the factored FIR filter, you might be trying to produce a comb

with eight or ten impulses, in which case convolving two impulses with four or five works, and nothing involving three will;
• in a menu system, you have to make the menu items reasonably comprehensible, which usually requires a larger branching factor.
• while debugging a program, changing stack frames has a cognitive cost, where you have to orient yourself in your new surroundings, and it can be practically very difficult to make a program in which each function calls only three others. The optimum for this is maybe somewhere between 5 and 18.

DReX and "regular string transformations": would an RPN DSL work well?

Kragen Javier Sitaker, 2016-09-19 (3 minutes)

I found this paper from last year on a thing called DReX, which claims to be "a declarative language for efficiently evaluating regular string transformations". Apparently a "regular string transformation" is a kind of transformational equivalent to a regular expression, and they came up with a linear-time evaluation algorithm for it; "regular string transformations" seem to be a thing they invented more or less for the paper before this one.

I think their notation could use some work though.

One of their examples is a program to delete one-line comments from a (C++) program; here's the original version from DReX paper:

```
del_slashes = split(del('/'), del('/')),
del_non_nl = iterate(del(x ≠ '\n')),
del_comm = split(del_slashes, del_non_nl),
del_comm_line = split(del_comm, del('\n')).
```

Here's an inlined version:

```
split(split(split(del('/'), del('/')), iterate(del(x ≠ '\n'))), del('\n'))
```

Here's an RPN version:

```
'/' del '/' del split x '\n' ≠ del iterate split '\n' del split
```

Here's an infix/postfix version:

```
'/' del, '/' del, x ≠ '\n' del*, '\n' del
```

How is this different from sed or whatever? Would this maybe work as an editor user interface?

They say:

…regular string transformations is a… class that strikes a balance between decidability and expressiveness. In particular this class captures transformations that involve reordering of input chunks, it is closed under composition, it has decidable equivalence…

So DReX is a combinator-based DSL that covers exactly this class with a prototype linear-time implementation (polynomial-time in program size, linear-time in input size).

The DReX combinators are:

- φ → d, where φ is a predicate and d is a function: maps any character a that satisfies φ(a) to d(a);
- split(f, g), which is unambiguous concatenation;
- iterate(f), which is unambiguous Kleene closure;
- combine(f, g), which applies both f and g to the same string and

concatenates their results (unambiguous intersection);
• f else g, which falls back to g if f fails (unambiguous union); and
• chain(f, R), where R is a regexp for tokenizing, which applies f to pairs of tokens.

Split, iterate, and chain also

have a left-additive version in which the outputs computed on each split of the string are concatenated in reverse order.

Apparently the domains of DReX functions are in some sense inspectable and don't include the whole universe of strings. Their only primitive combinator is the → combinator, whose domain I guess is the set of characters for which φ returns true.

They come up with this definition for "consistent" that allows fast (linear-time) evaluation and argue that it "does not sacrifice expressiveness". Interestingly, even though regular string transformations are closed under composition, they don't include composition because it makes the evaluation-problem PSPACE-complete, so their definition of "does not sacrifice expressiveness" may be counterintuitive.

Fast geographical maps on Android

Kragen Javier Sitaker, 2015-10-16 (9 minutes)

I'm fed up with the terribly slow performance of OsmAnd~ on my phone. But how can I get access to OSM data to reformat in different formats?

Formats and getting geodata

OsmAnd~ uses its own .obf format, and decoding that data seems to involve using their precompiled jar files, since I can't figure out how to get their code to compile.

OSM has two principal formats, an XML format called .osm, and a ProtoBuf format called .pbf, which is a few times smaller, which is documented at http://wiki.openstreetmap.org/wiki/PBF_Format#File_format and implemented in, among other things, Osmosis http://wiki.openstreetmap.org/wiki/Osmosis, which is in Debian. http://wiki.openstreetmap.org/wiki/Osmosis/Detailed_Usage_0.44o#--read-pbf_.28--rb.29 sort of explains how to use it. `osmosis --read-pbf foo.pbf --write-xml` creates a `dump.osm` file full of XML; adding a `-` argument to the end spews the XML out on stdout as Ghod intended. The XML format is documented in http://wiki.openstreetmap.org/wiki/OSM_XML.

For better or worse, the XML format has all the nodes first, followed by all the ways, then all the relations.

GDAL/OGR has support for these formats http://www.gdal.org/drv_osm.html but only from 1.10 on. GDAL in the Debian I'm running is 1.9.

A current PBF of Argentina is only 103MB: http://download.geofabrik.de/south-america/. Planet.osm is 29.3GB http://wiki.openstreetmap.org/wiki/Planet.osm so maybe the 300× smaller Argentina file is better. http://openstreetmapdata.com/ has "generalized" OSM data (sadly, in shapefiles) including coarse coastlines, land polygons, and water polygons (30 MB each).

https://github.com/scrosby/OSM-binary is a PBF library for C.

Arranging data for rapid access

The PBF data is apparently not arranged for rapid access, even though it's divided into independently decompressable PrimitiveBlocks.

My basic thought is that you can fit maybe 20 × 40 roads on my phone display before it becomes too crowded to read, so we ought to be able to produce level-of-detail summaries of the data that allow us to read some constant factor more than those 800 paths when we're drawing a display.

Like, if the display is only 2km tall and 4km wide, or less, we should be able to draw *all* the data in that region, but only access data that is actually in or near that region. If you break the full-resolution data up into 1km×1km tiles, each of which is stored contiguously, then you might need to access 8 to 15 of these tiles, which is probably

okay even on spinning rust, especially if you use Z-ordering or Hilbert curve ordering for those tiles.

Each such tile might have 200 line segments in it, mostly sharing endpoints with other line segments, with 7 decimal places of accuracy in each of lat and lon, and maybe a bit more metadata, like street names. That's probably about one endpoint per segment, and probably about 56 bits (7 bytes) of coordinates, although maybe delta-encoding can shorten that to about 32. $7 \times 200 = 1400$, so each such tile might be 2 to 4 kilobytes. Most will be smaller, a few might be bigger.

If you zoom out to almost 4km tall and 8km wide, then you may have as many as $5 \times 9 = 45$ such tiles in view, and need to access as much as 180 kilobytes of data. This is still doable in a small fraction of a second, even on my cellphone, but for zooms this large and larger, we can do better by making "summary tiles" that include the large-scale-visible features from 16 smaller tiles, but only about 200 line segments in the summary tile; so the summary tiles will also be only 2 to 4 kilobytes each.

The summary tiles should only include the most important ways; the importance ranking for "highway" ways goes something like motorway, trunk, primary, secondary, tertiary, unclassified, residential, service, living_street, pedestrian, track, footway, bridleway, raceway. Perhaps "road" should be near "residential", as should the various "_link" types.

In most areas, data will be so sparse that these 4×4 summary tiles will be able to include all the data.

The summary-tile process should be recursive, so you have metasummary tiles that cover 4×4 summary tiles, and third-level summary tiles that cover 4×4 metasummary tiles, and so on. There will be some duplication of data, but the summary tiles will never add more than a sixteenth (6¼%) to the size of the base tiles, and even an infinite pyramid of such things would only add a fifteenth (6⅔%). But Argentina is only 2.7 million km², so you only need six levels of summary tiles.

In this way, no view will *ever* need to access more than 180 kilobytes of data, plus the bounds as it walks down the tree to find the tiles it needs.

Build process

I feel like even on my netbook the 103 megabytes of Argentina data should fit in my 2 gibibytes of RAM, especially since I don't care about the users, versions, timestamps, or changesets of nodes, just their lat, lon, id, and tags. Generating the XML file on disk, at 150+ bytes per node, is probably not an ultra great idea; it would be about a gig.

For estimating sizes from the XML:

```
perl -lne '$tag{$1}++ while /<(\w+) /g; END { for my $tag (keys %tag) { print "$to
ag $tag{$tag}" }}'
```

```
  <relation id="56688" user="kmvar" uid="56190" visible="true" version="28" chan
   <member type="node" ref="294942404" role=""/>
   ...
```

```
<member type="node" ref="364933006" role=""/>
<member type="way" ref="4579143" role=""/>
...
<member type="node" ref="249673494" role=""/>
<tag k="name" v="Küstenbus Linie 123"/>
<tag k="network" v="VVW
```

Results:

entity	2014 count	est. 2015 count	actual 2015 count
byte	65M		103M
relation	10,913	17,292	24,878
member	228,594	362,233	482,756
way	621,045	984,117	1,169,064
tag	1,666,072	2,640,083	4,468,399
node	6,597,342	10,454,249	10,697,272
nd	8,139,986	12,898,747	12,791,230

So this suggests that the average node participates in ("nd") about 1.2 different ways and thus about 2.2 different line segments; it's almost cheaper to store the nodes redundantly, using an extra 10% (6 bits), rather than indirect node access through some kind of ID, which is necessarily bigger than 24 bits each. The high tag count is a surprise to me, and I assume that it's because ways have a lot of tags, but I should look.

The 65-megabyte 2014 Argentina PBF I downloaded by mistake has only 8.1 million "nd"s in it and takes Osmosis about 5 to 7 minutes to decode into XML. This would put my estimated-8-bytes-per-node optimized binary format at 65 megabytes, or about 103 megabytes for the current dataset, consisting of about 32k to 128k tiles.

The 2015 dataset took Osmosis 11 minutes to decode.

I should be able to do at least the initial build process in Python rather than C, despite it being in-RAM on this netbook, because a dict entry in Python only weighs about 128 bytes; so 10 million nodes will only weigh about 1.3 gigs. I should probably test on some smaller data first. If that doesn't work out, I can probably hack together something in C, or I guess I could put the node data into files and use an external sort, or maybe use SQLite or Postgres.

Reducing the ways to sequences of (lat,lon) tuples, plus a bit of metadata, as a sort-merge job, would involve these steps:

- Reduce the ways to 13 million (nodeid, wayid, seqno) tuples in 325 megabytes. Sort.
- Reduce the nodes to 10 million (nodeid, lat, lon) tuples in 400 megabytes. Sort.
- Merge the two into 13 million (wayid, seqno, lat, lon) tuples in 600 megabytes. Sort.
- Coalesce runs with the same wayid into (wayid, [(lat, lon) ...]) structures.

An alternative multipass strategy would involve decoding the PBF

file several times, each time computing the tiles in a particular geographical area and ignoring the other data. This is a more or less linear time-space tradeoff: I can use 10% of the memory in exchange for running the job in 2 hours instead of 12 minutes.

Bootstrapping instruction set

Kragen Javier Sitaker, 2018-11-06 (updated 2019-05-03) (19 minutes)

Chifir is inspirational. It's the first archival virtual machine good enough to criticize. You can implement the CPU in a page of C (my version is 71 lines and took me 32 minutes to write), and then all you need is screen emulation, which took me another 40 lines and 28 minutes.†

Archival virtual machines have applications beyond archival. Independent implementations of the virtual machine defeat Karger–Thompson attacks at the virtual machine level and potentially the hardware level as well. And a stable deterministic virtual machine enables the publication of reference implementations of other virtual machines and deterministic rebuilds of derived files, such as compiler output, database indices, or raw pixels output from an image codec.

Alas, Chifir is not good enough to actually use as a *general-purpose* archival virtual machine, which of course is not its intended purpose. Any of the following problems would by itself be a fatal flaw (for a general-purpose archival virtual machine):

• The specification does not include test cases, so there is no way to debug a candidate implementation, and in particular to easily disambiguate the natural-language specification of the instruction set. In fact, as far as I can tell, not even the Smalltalk-72 image described in the paper has been released. This is important because when I added screen output to my implementation of Chifir, my first test program was a single-instruction infinite loop, which had a bug and also found a bug in my implementation of Chifir.
• Also, the instruction set contains unspecified behavior, including access to out-of-bounds memory addresses, execution of any of the 4294967280 undefined opcodes, division by zero, the appearance of pixels that aren't all-zeroes or all-ones, and arguably the rounding direction of division. Unspecified behavior is a much worse problem for archival virtual machines than for the systems we're more familiar with, because presumably the archaeologist implementing the virtual machine specification has no working implementation to compare to.

• The straightforward implementation of the instruction set using `for (;;) { ... switch(load(pc)) {...} }` is unavoidably going to be pretty slow, because the instructions only manipulate 32-bit quantities. Getting reasonable performance would require a JIT-compiler implementation, which is complicated by the need to invalidate and recompile self-modifying code.
• Input is blocking; it is impossible to read keyboard input, which is the only kind of input, without blocking. That means that Chifir will, at any given time, be either unresponsive to the user or unable to execute any code until the user types a key.
• The instruction set has absurdly low code density, requiring 128 bits per instruction. This is a big problem for archival virtual machines because archival media are many orders of magnitude lower density than media customarily used for software interchange.

• Although the specification specifies the bit order of the image when stored as individual bits (as in their proposed physical medium), it does not specify an image file format as a series of bytes. In my implementation, I chose to represent the image in binary big-endian format, with the most significant byte first, but a different implementor might make a different choice, such as representing the image in a sequence of the ASCII digits "0" and "1". Such differences would produce unnecessary incompatibility at the file level between implementations, if not at the micro-engraved disc level.
• Chifir has no provision for access to storage media; the only I/O is the screen and keyboard.
• Because Chifir has no clock, no timer interrupts, and no keyboard interrupts, there is no way within the Chifir system to regain control from an accidentally-executed infinite loop.

However, it's worth pointing out some things Chifir got right:

• Unlike Lorie's UVC, the Chifir virtual machine has well-defined arbitrary implementation limits and overflow behavior, so it should be straightforward for all implementations to have the same arbitrary limits. This will avoid incompatibilities where a virtual machine image works on one implementation of the virtual machine (perhaps the one used by an archivist) but fails for obscure reasons on another (perhaps the one written by an archaeologist.)
• Like BF, and unlike most virtual machines, Chifir does succeed in being implementable in an afternoon, being a "fun afternoon's hack". In fact, it vastly overshoots this goal: an afternoon is three to eight hours, depending on your definition, and it took me 32 minutes to implement Chifir without a display and an hour to implement Chifir with a display. (The COCOMO model used by David A. Wheeler's 'SLOCCount' instead estimates it would take a week, but it's usually wrong in such a way for such small programs.) Chifir could be about three times more complicated without overshooting the one-afternoon budget, especially if the implementor has known-good test programs to work with instead of having to concurrently write and debug their own. Maybe a complexity budget of 512 lines of C, a bit under eight pages, would be a reasonable absolute maximum.
• Chifir's CPU lacks many edge-case-rich features present in other CPUs, which are common compatibility stumbling blocks. For example, it doesn't have floating point, flag bits, signed multiplication and division, different memory access modes, different instruction formats, different addressing modes, for that matter any general-purpose registers, memory protection, virtual memory, interrupts, different memory spaces (as in modified Harvard architectures like the Hack CPU). Similarly, its I/O specifications are ruthlessly simple, leaving little room for compatibility problems. It's very likely that a straightforward implementation of the specification will be, if not absolutely right, at least almost right.
• In part because Chifir lacks such corner cases, nothing stops you from writing a multithreaded program or JIT compiler in Chifir code.

† My implementation of Chifir is available via `git clone http://canonical.org/~kragen/sw/dev3`. It requires the following files:

http://canonical.org/~kragen/sw/dev3/Makefile

http://canonical.org/~kragen/sw/dev3/chifir.c
http://canonical.org/~kragen/sw/dev3/chifir.h
http://canonical.org/~kragen/sw/dev3/chifir_xshmu.c
http://canonical.org/~kragen/sw/dev3/xshmu.c
http://canonical.org/~kragen/sw/dev3/xshmu.h

I'm not counting xshmu.c and xshmu.h as part of the Chifir implementation because I wrote them separately.

Some approaches to a possibly viable archival virtual machine design

How should we design an archival virtual machine to make it easy to write correct and sufficiently fast emulators for existing systems we want to preserve?

Use a register-based instruction set

Register virtual machines are faster than stack machines or belt machines (like the Mill) when all three are implemented in a straightforward way; typically the benefit is about a factor of 2. Register virtual machines have a small instruction density penalty, and their assembly code doesn't factor as nicely as stack machines' and isn't as easy to generate as stack machines'. But I find it easier to write by hand, and in any case, reasonable register allocation can be fairly simple.

Register virtual machines can also, in theory, eliminate the need for jump instructions if the PC is as accessible as any other register, though the overhead on this mechanism is a bit high to use it as a calling mechanism as well.

Look to Thumb (and the curiously similar Cray-1 instruction set) for code density tricks.

Other things we've considered include: MOV machines ("transport-triggered architectures") like my "dontmove"; stack machines like the MuP21; and RTL designs where the only operation was producing new bitvectors from the NAND of slices of existing bitvectors.

Focus the instruction set design on video with SIMD instructions

The most performance-critical part of computers with graphical displays has always been the graphical display. This was true in 1963 when Ivan Sutherland wrote SKETCHPAD; it was true in 1974 when the Alto implemented bitblt in microcode; it was true in 1980 when 6502-based microcomputers competed to provide more hardware sprites on the display at once; it was true in 1996 when Andy Glew designed MMX for the Pentium MMX; it's true today in 2018 when we're using GPUs instead of CPUs to mine Ethereum, crack passwords, and train neural nets.

If updating the screen is slow, everything will feel slow. If updating the screen is fast, probably the other parts of the system's code will be fast enough too.

So probably wide SIMD registers, like SSE, NEON, or AVX, are a good model to follow. Unlike SSE (but like GPUs) it's probably better to have *only* wide SIMD registers. You can always ignore the rest of the vector if you only care about a scalar operation!

GCC offers a particularly simple and reasonably effective way to apply such facilities, documented in its manual in the section "Using Vector Instructions through Built-in Functions". Briefly, it provides only "vertical" operations (those that operate on corresponding vector items), except that you can subscript vector values to fetch individual items, you can broadcast scalars across vectors, and there's a `__builtin_shuffle` function which can rearrange vector items. And of course each operation can operate on any vector type. (Heterogeneous operations, e.g. 4 floats with 4 uint32s, are not supported.) This is mupch simpler than the irregular zoo of 600+ vector instructions provided by Intel, and if it's at times somewhat less efficient, it's still dramatically more efficient than just writing scalar code.

(In C++, GCC also offers `?:`, `!`, `&&`, and `||` for these vector values.)

SIMD instructions provide the opportunity for a naïve for-switch loop to get reasonable performance, because each instruction is doing enough work to pay for the heavy interpretation overhead. This can also helps with the cost of bounds-checking, at least if you don't have scatter-gather — a bounds-check every 16 or 32 bytes is less costly than a bounds-check every byte.

Originally I thought you could get by with only 32-bit unsigned math, like Chifir, and that might actually be true. But then I got a tiny bit of experience writing SSE code, and it sure is nice when you can get 16 byte additions in an instruction instead of 4.

(However, I don't think the saturating arithmetic mode is worth it.)

Or use vector instructions as an alternative to SIMD

"Vector instructions" here is referring to Cray-style or NEC-SX-style vector instructions. I don't think this is a good idea for archival because it's far too easy for implementation optimizations to leak through to the visible semantics, but see A simple virtual machine for vector math? (p. 986) for more details.

Forget about floating point

Floating-point math is profoundly important and very tempting to support, but even with near-universal adherence to the IEEE-754 standard, which requires that the basic arithmetic operations produce results accurate to within half an ulp (which means that all conforming implementations will produce bit-identical results), it's impossible to argue that floating point is easy to get right. Even in the last few years, the introduction of the FMA facility in Intel processors has introduced divergence from bit-identical results in expressions as simple as `a+b*c`, which may produce results differing by an ulp depending on whether your compiler compiles it to use FMA or not.

Aside from that, getting gradual underflow, rounding modes, and NaN handling right requires lots of special cases, and it is often omitted for the sake of performance.

Don't have unspecified behavior

This means no undefined instructions, no undefined video results, no undefined results of out-of-bounds memory, no race conditions, nothing.

Have nonblocking I/O

It's absolutely essential to be able to run code while periodically checking whether the user has provided any input. It may not be necessary to make the input interrupt-driven — modern machines are fast enough to poll a keyboard at 100Hz without producing undue CPU load, even in emulation. A "hardware" input event ring buffer is probably the right mechanism here.

Have a timer interrupt

Without a timer interrupt, you can't do preemptive multitasking, and without either a timer interrupt or a pollable system clock, you can't do animation at a correct speed, because you have no way to tell what speed you're doing it at. The timer interrupt should be able to run at a high enough frequency that you can poll the keyboard at over 100Hz. A fixed 1000Hz is probably fine, but it's possible that it may need to be configurable by the program, like the Unix alarm(2) system call or JS's `setTimeout` and `setInterval`.

This thought is scary because it inevitably introduces nondeterminism into the system, because it potentially provides side-channel communication into the virtual machine, and because bugs in interrupt handlers are hard to debug. But the cost of not having it is just too high.

(With respect to nondeterminism — consider possible implementations in which timer interrupts are handled at the end of each instruction, at the end of each basic block, and at backward jumps or calls. How likely is it that a program that is tested and working in one of the later cases will turn out to have previously undetected heisenbugs when run on a simulator with more possible interruption points?)

For non-interactive tasks or those in which determinism is paramount, this facility can be disabled.

As an alternative sufficient for animation timing, a purely deterministic facility could freeze the virtual machine's execution until a given timestamp had passed, but provide no way for the program to determine the current timestamp. (Waiting for a time in the past would simply return immediately.) Since the program cannot execute any instructions while frozen, it cannot observe whether any time has passed or not. However, this doesn't enable you to implement a preemptively multitasking operating system.

Write a comprehensive set of test cases

You don't need any testing hooks in the virtual machine definition for this, just a breakpoint facility and the ability to look at memory when a breakpoint is hit, which are entirely external to the VM as seen by the program — they are a *deus ex machina* from the program's point of view.

For math operations with up to 32 bits of input, such as 16-bit binary operations and 32-bit unary operations, there's no reason not to exhaustively test them.

Specify a file format

That means a concrete representation as a sequence of 8-bit bytes, not just glyphs engraved on a disk. Provide the test cases in this format.

Don't have memory protection

Memory protection is probably not worth the complexity it would add to the virtual machine.

Minimal set of ALU operations

BF only provides increment and decrement ALU operations, which is insufficient. Chifir provides +, -, ×, ÷ (presumably floor division), modulo, <, and NAND. C provides +, -, *, / (usually floor division), %, ?:, <, !=, ==, >, <=, >=, |, ^, &, ~, <<, >>, and unary -. Golang adds abjunction, &^, which is also in AVX2, PDP-10, and (IIRC) ARM; Java adds >>>, unsigned right shift, as a separate operation, while in C the choice between logical and arithmetic right shift is based on the declared data type. The F18A offers 2*, 2/, +, and ~ (spelled -), &, ^, and +*, which executes an 18-bit multiply if you run it 18 times. Various kinds of vector instruction sets (for example, SSE and APL) also offer min and max; many languages support exponentiation; and lerp, a sort of continuous generalization of ?:, is often offered as a fundamental operation. I saw somewhere an instruction set whose > operation was actually unary; it was just `x > 0 ? x : 0`, so applying it to the result of a subtraction would give you a nonzero value precisely when the result had been positive. CPU instruction sets traditionally have rotation instructions as well as shift instructions, but I find them useful very rarely.

You also have really out-there stuff like CLMUL, AES, CRC32, and the like, the abominable children of the dark-silicon age.

So how much do you really need? For an archival virtual machine, probably the F18A's seven operations (three of them unary) is too minimal, since it means that (in the absence of a sufficiently smart compiler, which is not an afternoon hack) a CPU or FPGA with hardware multipliers must emulate the very common operation of multiplication through an arduous sequence of simulated instructions, and similarly for barrel shifters and multi-bit shifts. On the other hand, the cost of emulating > given < is generally nil, and the cost of emulating >= given < is small. Where it comes to bitwise operations, abjunction (with constants) or NAND alone is sufficient to produce all the others, but producing XOR with either of these alone requires five operations, which seems excessive (thus the F18A's three bitwise operations).

I suggest the following set:

- Unsigned binary integer +.
- Two's-complement unary integer -.
- Unsigned integer *, producing a double-width result.
- Unsigned integer divmod, taking a double-width dividend but producing two single-width results.
- Unsigned integer << and >>> with arbitrary shifts.
- Signed integer >>.
- Bitwise &, ^, |, and ~. (See Performance properties of sets of bitwise operations (p. 636) for the exploration of this.)
- Two's-complement signed integer max, i.e. λ(x, y).(x > y ? x : y).
- ==.
- The ternary operator ?:, which is particularly important with vector registers, since you can't implement it the traditional way using control flow.

This is 14 operations, considerably more than the F18A's 7 but

substantially less than C's 19; they are chosen with the intention that the missing 7 operations, plus many other useful ones, can be constructed in two operations:

- `a - b` = `a + -b`
- `a > b` = `max(0, a - b)`
- `a < b` = `max(0, b - a)`
- `a >= b` = `0 == max(0, b - a)`
- `a <= b` = `0 == max(0, a - b)`
- `a &^ b` = `a & ~b` (or `a ^ (a & b)`)
- `a NAND b` = `~(a & b)`
- `a NOR b` = `~(a | b)`
- `a != b` = `0 == (a == b)`

It's arguable that maybe we shouldn't include both ~ and unary -, since you can get from one to the other with a simple +1 or -1.

Topics

3-D printing by flux deposition

Kragen Javier Sitaker, 2017-02-24 (updated 2019-07-27) (21 minutes)

We've been doing some experiments in 3-D printing of glass parts. It's a classic powder-bed binder-deposition process, except that the binder is another solid powder, and the postprocessing is different — rather than removing a fragile greenware part from the powder bed and then possibly baking, curing, or soaking it, we fire the whole powder bed to activate the binder, which acts as a flux to sinter or even dissolve the surfaces of the powder grains; the binder itself may or may not melt.

We've had success so far with a quartz powder bed and fluxes of soda-lime glass frit and a commercial pottery glaze, both baked at 1020°, in air, at atmospheric pressure. We also expect success with fluxes of potassic feldspar and lead oxide. In all of these cases, the final product is either a glass or a glass with a quartz filler.

However, this process is much more widely applicable.

Unique advantages

The flux-deposition process, unlike most binder-deposition powder-bed processes, involves no extra step of handling delicate greenware extracted from the powder bed. This extra step is labor-intensive and often involves extra equipment such as sandblasting cabinets to remove extra unused powder without damaging the greenware part.

Aside from the reduction in human effort, this should improve the resolution. Typical binder-deposition processes as offered by service bureaus like Shapeways cannot reliably produce walls and wires under about 1000 microns in thickness. By contrast, flux deposition powder bed printing should offer very high resolution — 3D Systems's direct-metal selective laser melting machines can, as of 2015, produce parts with 100-micron wall thickness because they, too, have no greenware-handling step, so the articles are already at their full strength when they are removed from the powder. We think flux-deposition printing can offer the same or better resolution, but without the long build times and inert atmospheres needed for direct metal SLM or SLS.

While we do not expect flux deposition to be able to avoid the issue of dimensional change during sintering, which is a plague for sintering manufacturing processes in general, there is good reason to expect the distortion introduced by the process to be very small compared to fused deposition modeling, selective laser melting, selective laser sintering, or machining of green ceramics before firing them. The binder is deposited when the powder bed is at room temperature, so the average expected final expansion is zero; the article is supported by unused binder throughout the process, limiting forces that could produce deformations; and the process need not involve any strong thermal gradients.

Immediately after sintering, the boundaries between the original powder grains will be enriched in the flux, while their cores will contain none of it; but if the flux and the bulk material are miscible in solid solution as well as liquid, then diffusion annealing can remove

these inhomogeneities. This process can allow the article thus produced to withstand higher temperatures than those used to make it in the first place.

Aside from the microscale inhomogeneities stemming from the union of different materials in powder form, it's possible to use this process to create macroscale inhomogeneities; for example, by smoothly varying the concentration of lead oxide in a glass article, it should be possible to fabricate an article whose refractive index is not constant, but has some controllable gradient. If the microscale inhomogeneities can be eliminated, such graded-index optics can constitute monolithic refractive optical systems that approach diffraction-limited performance arbitrarily closely, lacking as they will refractive index discontinuities to reflect stray light.

Steel and iron alloys

Iron melts at 1538°; due to alloying with 0.18% of carbon, AISI 1018 steel, the most common steel, melts around 1520°. AISI 1070 steel is popular for harder goods such as knives; it contains 0.70% carbon and melts at 1479°. The iron-carbon phase diagram shows a eutectic point at 4.3% carbon at about 1175°, and some cast irons approach that content of carbon, typically replacing some with silicon.

This process is already used industrially to produce sintered steels; for example, Höganäs offers a range of "pure iron powders" for this purpose, which all range from 20–200 μm in particle size, with little variation in that dimension.

As of 1997, iron-powder metallurgy normally takes place at 1120°–1150° for 20'–30' because this allow mesh-belt furnaces to survive, although some processes supposedly may require a sintering temperature between 1100° and 1300°. Even 1120° is enough to sinter plain iron. Carbon is added as graphite; endogas avoids removing the carbon, though we think mere carbon dioxide should be adequate.

Apparently it is common to include up to 2.5% powdered copper in the iron in order to fill pores and produce precipitation-hardenable alloys. So copper is a possible alternative to carbon for this purpose; copper and carbon are usually used together to avoid thermal expansion induced by the copper.

The biggest difference with the process being considered here is that iron powder is normally compacted into a mold at 200 to 800 megapascals before being sintered.

Iron phosphide, though hazardous to handle, is another alternative flux which is known to form a eutectic with iron at 10% phosphorus that melts at only 1050°. The resulting iron-phosphorus alloy is similar to a steel, with final phosphorus concentrations of up to 0.6% being beneficial. (Phosphorus is considered a contaminant in normal steelmaking for reasons that are not relevant here.)

Aluminum is probably not a good bet; it forms no eutectic with iron, its miscibility is low, and the intermetallics are brittle and weak, although there has been promising work by Hansoo Kim in Korea to fix this with manganese, nickel, and carbon.

This makes us optimistic that even a very small amount of carbon, copper, or iron phosphide could work effectively to flux a powder bed of pure iron heated to somewhere below 1120° so as not to sinter the iron itself. If the carbon particles are small enough relative to the

firing time, they will dissolve entirely into the iron particles; further diffusion while hot should gradually eliminate the lowest-melting-point liquid regions. Depending on the size of the iron particles, the result should be either a pure steel article, or an article composed of grains of pure iron cemented together with steel or cast iron, in a bed of loose iron powder.

We don't know if there is a way to get the articles to be fully dense; this would require that the steel or cast iron have greater volume than the iron and carbon that went into them. This seems unlikely, as steels are usually slightly denser than iron.

Korol'kov & Kibak report that iron sinters more easily with 100–250 ppm boron; they mention that the eutectic liquid phase Fe_2B + Fe melts at 1160° to 1180°, and they sintered at 1160°. Also, their 100ppm boron-doped pressed iron powder began to shrink at 450°–500°, suggesting that sintering was already beginning, and hit a discontinuity at about 900°. They suggest that this initial shrinkage was due to cementation of iron grains with liquid oxides of boron.

Aluminum

Aluminum natively melts at 660°, but for casting, it is normally alloyed with silicon, with which forms a eutectic at 12.2% Si, melting at 577°. Silicon itself melts at 1414°. Aluminum-alloy powders are commonly sintered at 590–620°, which is hotter than the melting point of the eutectic. It seems that it should thus be possible to flux an aluminum powder bed with small amounts of silicon, bake the result somewhere between 500° and 590°, and get good "cast" aluminum articles out without sintering the aluminum powder.

Sapphire

Sapphire, Al_2O_3, also known as corundum, aluminum oxide, or ruby, doesn't melt until 2044° or so. It's an extremely hard and refractory material widely used for engineering ceramics as well as bulk refractories.

In 1957, Cutler, Bradshaw, Christensen, and Hyatt showed that the addition of about 4% (wt%) of appropriate fluxes could lower the sintering temperature of finely divided sapphire to 1300° to 1400°. Specifically, they added oxides of manganese, titanium, and copper as fluxes. 2% of either MnO or Cu_2O and 2% of TiO_2 were successful at getting very nearly full sintering to 3.8 g/cc at 1300°. Furthermore, they reported "bleeding" of a black liquid from their pressed pellet specimens onto the coarse sand below, suggesting that the mixture didn't merely sinter — it partly melted. This suggests that sintering should be possible at even lower temperatures, although they did not attempt this.

Indeed, Xue and Chen successfully sintered alumina at 1070° in 1991 with 0.9% CuO (mol%), 0.9% TiO_2, 0.1% B_2O_3, and 0.1% MgO. Full sintering took an hour at 1070°, but only about 15' at 1200°; their result had even higher fracture toughness than undoped alumina. (They also mention as an aside that 1500° to 1700° is adequate to sinter high-purity alumina, and that there's a known 1096° eutectic between Al_2O_3, CuO, and Cu_2O.)

A perhaps even more effective flux for sapphire may be the $MgCl_2$-NaCl mixture in US patent 7,988,763, although this is a flux in the metallurgical sense — it fulfills various functions, including

scavenging contaminants from the metal and preventing oxidation of the molten metal, but also including liquefying metal oxides. The patent mentions that $MgCl_2$ mixes with other salts are already in use to keep the melting point of the flux in the 400–500° range. Unfortunately, the patent doesn't quantify how low it reduces the melting point of the aluminum oxide; it does mention that the mixture was prepared at 550° in an alumina crucible which it apparently did not dissolve in 45 minutes, and that variants of it were used to purify molten aluminum at 850°, 720°, and 700°, but it does not affirm that it liquefied the sapphire dross at these temperatures.

NaCl boils at 1413°, so using it in a pottery kiln salt-glazes both the pottery and the kiln and releases chlorine gas. And that would also be true, and very objectionable, if you heated up sapphire to its normal sintering temperature of 1500–1700°. But if it's possible to use small amounts of these salts to flux alumina at temperatures more like 400° to 900°, no significant amount of salt should boil off.

By far the most famous flux for sapphire, however, is cryolite (Na_3AlF_6, melting point 1009°) with an excess of aluminum fluoride, which is used in the Hall-Héroult process to dissolve sapphire at 950–980° so that aluminum can be electrolytically produced from it. The binary eutectic melts at 962.7° and contains about 22% alumina, and apparently there is no solid solubility between the compounds, so cryolite may not in fact be very suitable for facilitating the sintering of granular sapphire.

Viridian

Chromium(III) oxide, the rare mineral eskolaite, also known as chromia, is the surface film that makes chromed bumpers and common stainless steels stainless. It's a green pigment ("viridian" or "chrome green") and harder than quartz, though slightly softer than sapphire. It's sold for pigment use at about US$25/kg.

Viridian is super fucking refractory, not melting until 2435° or sintering until 1600° in pure form, but you can sinter it at 1280° by adding 1% TiO_2 by weight, according to Callister, Johnson, Cutler (the sapphire dude), and Ure 1979. A tricky problem is that under low pressures it tends to smelt to chromium at temperatures above 1600°, and if exposed to oxygen it tends to not sinter, so the sintering has to be done in a non-oxidizing (endogas or argon) atmosphere. The rutile also may serve to stabilize the oxidation state of the viridian.

Viridian is miscible with alumina in all proportions.

According to Nagai and Ohbayashi (1989), viridian is a P-type semiconductor, but the addition of over 2% rutile makes it N-type.

Rutile

Rutile, titanium dioxide, is commonly used as a white pigment, including in food. In fact, 70% of worldwide pigment production is synthetic rutile. It's a medium-hard mineral, in the same Mohs 6–6.5 range as orthoclase, a bit softer than quartz. It melts at 1800° and costs about US$20/kg on eBay.

Likely fluxes include oxides of iron (FeO), magnesium, and manganese; more improbable candidates include alkali halides and oxides of zinc and vanadium. The spinel group consists of solid solutions of oxides of titanium, magnesium, zinc, iron, manganese,

aluminum, chromium, and silicon crystallized in a cubic close-packed lattice, but titanium spinels are rare, naturally occurring only as ulvite, iron titanium oxide.

Cho and Biswas did find that doping rutile (actually its polymorph anatase) with 1.3% (mol%) vanadium sped up its sintering dramatically, but none of their tests were at a low enough temperature to see if the doping lowered the sintering temperature; their coolest test was at 900°. They do predict theoretically that their "V-TiO_2" should sinter at 800°, while pure TiO_2 basically won't.

PZT

PZT by far the best piezoelectric material, the best high-capacity dielectric, and the best ferroelectric material. It is normally sintered above 1250° but can be sintered at 1000° by doping it with bismuth oxide and carbonates of sodium or lithium (e.g. 0.375% wt% of lithium carbonate and "an equal mole fraction of Bi_2O_3"); this according to Cheng, Fu, and Wei, 1989. Corker, Whatmore, Ringgaard, and Wolny reported in 2000 being able to sinter it at 800° with a "sintering aid" of 5% liquid oxides of lead and copper; the eutectic mixture of PbO (litharge or massicot) and Cu_2O (cuprous oxide or cuprite), which is 80% PbO, melts around 680°, while PbO alone doesn't melt until 888°, and Cu_2O doesn't melt until 1235°. (Given PbO's well-known use as a flux and thinner for glasses and pottery glazes, I suspect this mixture would also work well as a "sintering aid" for quartz, and might result in a transparent article, though Cu_2O alone is so red it's commonly used as a pigment, and might precipitate out as lead silicate forms.)

Corker et al. also briefly survey the overall use of such sintering-temperature-reducing additives in ceramics, typically metal oxides, citing a pair of papers by Kingery in 1959.

Table salt

While probably not useful for any practical use, sodium and potassium chlorides may provide an inexpensive way to test and debug apparatus. The NaCl-KCl system has a eutectic point at about 670° at about 50% KCl; NaCl by itself melts at 801°, while KCl by itself melts at about 770°.

This is not an ideal test system from the point of view of the relative concentrations, the relatively low freezing point depression of the eutectic, the hygroscopic and corrosive nature of the powder, and the purely ionic nature of the bonding in the powder; however, we can easily build a "furnace" that reaches 700°, and the two feedstocks are very cheap, nontoxic, and readily available. Potassium chloride costs US$25 for 10 pounds on eBay (US$5.50/kg); on Mercadolibre sodium chloride costs AR$285 (US$18) for 50kg (US$0.36/kg).

According to US Patent 7,988,763, the ternary $MgCl_2$-KCl-NaCl system has a eutectic point of only 383°, where all three components are equal, and a binary eutectic between $MgCl_2$ and NaCl at 45% wt% NaCl melting at 439°. Magnesium chloride, which melts at 714°, is even easier to obtain than KCl, and on Mercadolibre it costs AR$400 (US$25) for 5 kg (US$5/kg).

Titanium

Amalgams

Applying small amounts of mercury to many different metals can produce stable amalgams.

Brass and bronze

Could you use a powder of some other metal to flux copper powder?

Pure copper, though somewhat expensive, is easily obtained in the modern economy (or from electrical scrap) and does not melt until 1084°; sometimes it occurs naturally allied with arsenic ("bronze"), which both fluxes it so that it can melt at much lower temperatures and hardens it greatly. The humans started using natural bronze some 5300 years ago and synthetic bronze made by mixing separately-occurring tin, rather than arsenic, with copper about 6500 years ago, at first in Thailand and later in the Middle East. Other elements are also widely alloyed with copper, notably aluminum ("aluminum bronze"), zinc ("brass"), zinc and nickel ("nickel silver"), and silicon ("silicon bronze"), with much the same results.

Beryllium forms a precipitation-hardenable alloy with copper that can be harder and stronger than most steels (an ultimate tensile strength of some 1150 MPa at 2% Be), but is little used because of the toxicity of beryllium and beryllia; I do not think it lowers copper's melting point much in the tiny quantities (0.2%–3%) required to make precipitation-hardenable beryllium copper. XXX yes it fucking does

According to 2001 edition of the ASM Specialty Handbook *Copper and Copper Alloys*, the solubility limits of these elements in copper at 20° are 6.5% for arsenic, 1.2% for tin, 9.4% for aluminum, 30% for zinc, 0.2% for beryllium, and 2% for silicon, all by weight; it's miscible in all proportions with gold, nickel, and platinum.

Arsenic is somewhat dangerous, vaporizing at 615° and producing deadly arsenous oxide gas; this may be a significant reason for the switch from arsenical bronze to tin bronze in the early Bronze Age.

Typical bronze is around 12% tin (the rest being copper) and melts around 950°, while tin itself melts at 232°, but remains liquid until 2600°. The tin–copper system is not very friendly for this kind of thing; its eutectic composition is I think Indalloy 244, melting at 227°, which is 0.7% copper, with the rest being tin; the copper is present as a small amount of the brittle intermetallic Cu_6Sn_5 rather than forming an alloy. This suggests that you'd really just be kind of just soldering the copper particles together with the tin, rather than dissolving them fully to make a homogeneous alloy.

Brass — copper fluxed with zinc — melts at 900° to 940°. Zinc melts at 420° and boils at 907°, producing a serious danger of zinc oxide fumes — mixed with air, the zinc vapor burns immediately, and the oxide solidifies as particles with a diameter of around a nanometer, since the oxide is solid until 1975°. So Roman brass was made by the "cementation" process of heating calamine (zinc carbonate or silicate) with copper and charcoal (presumably to scavenge the oxygen), rather than from metallic zinc; or by heating zinc oxide together with copper. This works by producing zinc vapor directly from the calamine, which is taken up by the solid copper, but the reaction is slow; it typically takes several hours. Roman brass is typically 20% to 28% zinc, but some modern brasses have even higher levels, up to 40%.

So, again, the likely outcome of trying to flux copper powder with zinc metal would be just sort of soldering the copper particles together with zinc.

Brasses and bronzes increase in strength as the degree of copper is reduced; when 60% cold-reduced, 8%-tin bronze has an ultimate tensile strength of some 750 MPa, and 30%-zinc brass is nearly as strong at 600 MPa, compared to some 400 MPa for pure copper or 225 MPa for pure annealed copper. But the objects produced by this flux-deposition process would be fully annealed, so their strength would be more like 350 to 400 MPa even at those high alloying levels

Debokehfication

Kragen Javier Sitaker, 2019-09-01 (updated 2019-09-12) (4 minutes)

Bokeh preserves sharp edges; it just spreads them out. The circularly-symmetric boxcar filter of an ideal bokeh has a circularly-symmetric sinc frequency response in two-dimensional frequency space, and sinc's falloff is pretty slow, just 6 dB per octave. So even a 32-pixel-wide bokeh is only attenuating single-pixel detail by about 30 dB.

(Of course, boosting single-pixel noise by 30 dB will add nontrivial graininess; that's 5 bits of precision lost, after all. But some photos have that degree of precision.)

Indeed, as suggested in Starfield servo (p. 1709), under some circumstances such a bokeh can actually *enhance* sensor precision, and it might be preferable to use a large pinhole in front of a sensor rather than a lens on a camera, both because it gives you a more precise reading on the position of bright impulses in the visual field, and because it does a better job of taking advantage of the limited dynamic range of common image sensors. The principle is the same as how R's default graphic for plotted points is a circle, not just a point, and in fact a disc in the center of the pinhole would probably work even better for extending the sensor dynamic range and precision. A more elaborate shadow mask such as a Hadamard matrix could improve this further.

Real camera bokehs tend to not be perfectly flat, even at small scales; although they don't include Hadamard-matrix shadow masks, in addition to spherical aberrations, they do include tiny imperfections on the lens and lens filters that only add a tiny amount of stray light to a focused image, but are easily visible in unfocused images of (near) point source lights.

N.B.: This effect might be useful for getting lensless optical transmission microscopy out of commonplace digital cameras without taking the lenses off of them: put the slide reasonably close to the camera, illuminate with one or more out-of-focus point sources, ideally with some non-overlapping or mostly non-overlapping images on the focal plane.

These imperfections provide additional high-frequency information that could permit improved estimates of the unblurred image; moreover, in images that contain at least some bright points, they can provide much tighter estimates of the defocus of a particular region of the image. Also, if they are sufficiently strong, they can disambiguate behind-focal-plane defocus from in-front-of-focal-plane defocus. (Any kind of half-turn asymmetry in the bokeh can provide such disambiguation, including the common feature of approximate polygonality with an odd number of sides.)

Aside from the obvious approach of removing bokeh by applying Wiener filters selectively to parts of the image, it might be worthwhile to try not only convolution with an estimated bokeh shape but also morphological erosion with it, to identify candidate bright points — both to improve the estimate of bokeh shape and to measure the scale of the bokeh in different parts of the image.

Image-processing tricks on the bokeh are not limited to removing it and doing microscopy with it; you can also do camera

identification (from the lens imperfections) and depth estimation. You might be able to correct chromatic aberration.

Bokeh can vary over the focal plane due to, for example, occlusion from a shroud extending in front of the lens. If this is recognizable it should be relatively easy to correct, but more general occlusion effects cannot be corrected in general — you might have a single light that's half-covered by a finger halfway between the camera and the light, giving a sort of partially-eclipsed-moon bokeh not shared with much else in the scene.

Dercuano backlinks

Kragen Javier Sitaker, 2019-05-22 (7 minutes)

I want to add backlinks to Dercuano articles.

Backlinks

Backlinks are the Wiki feature which shows you all the pages that link to a page; they make links in some sense bidirectional, and they allowed us to categorize pages on Wiki years before Wikipedia — you would just create a page called CategoryWhatever and then link to it from whatever pages you thought should belong to it, and look at its backlinks page.

I think having backlinks will improve Dercuano's navigability dramatically.

Desired implementation in Dercuano

In Dercuano I'd like to display the backlinks on the same page as the rest of the article, maybe at the end, and ideally with a bit of context. This is especially helpful when I have a later note that essentially obsoletes an earlier one.

Implementation techniques

Dercuano goes to some amount of trouble to avoid rerendering notes unnecessarily, because rerendering all the notes takes 28 seconds on my laptop, while just regenerating the categories and the index page takes only 6.3 seconds. A more detailed timing breakdown (as of dercuano-20190522):

	sec
rerendering all the notes	28
just regenerating categories and index	6.3
instantiating Bundle and all Notes	0.5
reading `triples`	0.065
bundle.generate_index()	2.0
bundle.generate_categories()	2.9

Actually about a quarter of this time to generate categories and indices is finding note titles, and another 10% is finding the notes in a category; most of the rest is generating HTML, though some of it is querying the unnecessarily inefficient triple store, which is also a factor in the note titles being slow. But 77% of the execution time is rendering notes, which is mostly a matter of running Markdown, though it actually spends about 25% of its time finding the notes in a category too.

So Dercuano is a lot more usable when it doesn't rerender notes when it doesn't have to, although it produces incorrect results when it fails to rerender notes whose titles and categories have changed. The trouble is, the point at which we learn about the backlinks is when we render the bodies of the notes. (At present, repl() on line 469 inside `replace_links` is getting called 3095 times, some of which it finds a backlink.)

One of the things I'd like to do is do the actual rendering in

subprocesses, so that I can run four or so of them; ideally, this should speed up the 22 seconds of rendering to 5.5 seconds, although lazy memoization may result in some duplication of work between the subprocesses.

Without caching, the minimal-work way of handling the unknown-backlinks problem would be to do it in two phases: one phase where we render all the bodies, and a second phase where we render all the backlinks. However, this adds complication if we want to farm the rendering out to subprocesses, since they would then need to deliver both the backlinks and the bodies back to the main process, probably via the firesystem.

A different approach would be to store the relevant backlinks in the filesystem somehow, in the output directory probably, and rerender the page when its backlinks change. Most of the time, they wouldn't change even when some other note that links to it changes, but when they do, this could require you to render the same note twice in the same run. In particular this results in rendering nearly all the notes twice when starting from a missing output directory, since at first each note is rendered with no backlinks, and then later it will be rendered with backlinks.

…this suggests I should optimize the triple store a bit and profile my execution times again. So I did. Upon adding code to index the triple store on startup, the Bundle instantiation time ballooned from 0.50 s to 0.55 s; upon using it, the build-from-scratch time went down from 28 s to 18 s, and the just-rebuild-index-and-categories time went from 6.3 s to 2.5 s. Now the top time consumers are all Markdown rendering functions, except for 650 ms waiting for tar to finish.

This in some sense makes the case for avoiding and parallelizing Markdown rerendering more urgent than before: previously Markdown took 75% of the runtime, and now it takes 85%.

So, my thought is to do the following:

• At program startup, read all the backlinks.
• For each note:

• Generate a glob of metadata for a note from the triple store (for example, the titles and note counts of categories) and the backlinks.
• Compare the glob of metadata to the previous glob of metadata for that note, stored on disk. If it's the same and the note source file hasn't changed, continue to the next note.
• Render the note and generate backlinks.
• Store the glob of metadata and the backlinks.
• Update the backlinks store and do #2 a second time. A second time should be sufficient to reach a fixed point. This should be done automatically, rather than requiring the user to do it as L^AT_EX does.

This requires separate stores for the glob of inputs for a note and the glob of outputs (including backlinks). I'm thinking this can be in places like .meta/cheap-frequency-detection.inputs and .meta/cheap-frequency-detection.outputs for the note notes/cheap-frequency-detection.html.

The code path actually needs to be a little bit more complicated, because the set of other notes' titles that the note HTML depends on is a function of the note source file's contents, and finding out what

that set is presently would require us to rerender the Markdown, which is what we're trying to avoid. But we don't actually need to go that far — if the source file has changed, we need to rerender it anyway.

We could imagine storing the titles of notes parsed from the HTML in the same store as the backlinks (thus the filename .output rather than .backlinks) in order to avoid opening and parsing the same files multiple times.

This is of course very much the kind of thing discussed in A minimal dependency processing system (p. 911), Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870), Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257), and Dehydrating processes and other interaction models (p. 3208), and to a lesser extent Simple dependencies in software (p. 2447). I haven't written any of the systems described therein, so I need to do it by hand.

Reducing nighttime bedroom CO_2 levels

Kragen Javier Sitaker, 2019-07-08 (updated 2019-07-09) (14 minutes)

My girlfriend's bedroom is cold in winter, so we sleep with the door closed and the electric heater turned on, which pretty much eliminates air circulation. But sometimes we wake up out of breath, perhaps because so much CO_2 has accumulated in the air. Recent research suggests that this is a problem for a lot of modern sleeping arrangements, but it doesn't usually rise to levels that cause perceptible discomfort. This note explores the possibilities for solving this problem.

(See Notes and calculations on building luxury underground arcologies for whoever wants them (p. 1566) for more information on the air changes per hour needed for clean air.)

The CO_2 level can get really fricking high without ventilation

The bedroom is 3 m × 3 m × 4 m, and pretty much at sea level, where the density of air is 1.2 g/ℓ (at STP, according to Millikiln (p. 2581)), so it contains about 43 kg of air. The window seals pretty well. We are two people, and we commonly spend 12 hours straight in there; at 2000 kcal/day/person that's 4000 kcal/day or 2000 kcal without opening the door.

Carbohydrates, our normal energy source, are about 5 kcal/g (21 MJ/kg), and carbohydrates all have the empirical formula CH_2O, thus the name. (Glucose, for example, is $C_6H_{12}O_6$.) Multiplying by the atomic weights, that's 12 parts carbon, 2 parts hydrogen, and 16 parts oxygen, so carbohydrate is 12/30 carbon by mass. (Protein is similar; fat is about twice as high in carbon and also about twice as high in energy, so the result is approximately the same.) So that's about 12.5 kcal per gram of carbon (52 MJ/kg). CO_2 is 12 parts carbon to 32 parts oxygen, so that's about 3.4 kcal per gram of CO_2 (14.3 MJ/kg).

So 2000 kcal is 590 g of CO_2, which would amount to 14000 ppm by mass, 1.4% of the air, 35 times the concentration in the outside air. No wonder we get uncomfortable!

If we wanted to use ventilation to limit the CO_2 to only 2½ times the 400 ppm in the outside air, we'd need to have only an extra 600 ppm in the air, or 26 g CO_2, or 370 kJ, or, in archaic units, 88 kcal, which our two human bodies emit every half-hour. This would require roughly two or three air changes per hour.

You can suck it up with succulents, if your house doesn't suck

If you put houseplants in your bedroom to keep the CO_2 levels down when you sleep, you may be disappointed if you are one of those people who sleep at night, rather than during the day. Plants convert CO_2 to oxygen (and sugar) through photosynthesis, which

only happens when the sun is shining on them. At night, plants oxidize sugar to survive, just like the humans do.

Plants using crassulacean acid metabolism are commonly recommended to help with this; these are typically succulent desert plants. Normal land plants keep their pores ("stomata", literally "mouths") open during the day, allowing water to evaporate from their leaves and keeping the plants cool. CAM plants instead tolerate the high temperatures, keeping their stomata tightly closed during the day. But, like normal plants, they need sunlight and CO_2 for photosynthesis. So the motherfuckers open their stomata *at night*, releasing the excess oxygen from photosynthesis, and store the CO_2 as malic acid until daylight comes around.

Cacti, aloe, and pineapples are among the crassulacean acid metabolism plants, although none of those are actually Crassulacea. Because most CAM plants are specialized to very dry climates, they grow very slowly, prioritizing surviving over thriving. This means, I suspect, that they tend to photosynthesize very slowly. Aloe vera might be the best choice of CAM plant for this kind of thing.

The amount of CO_2 consumed is dependent on the amount of sunlight and the photosynthetic efficiency of the plant. Typical photosynthetic efficiency is 3%–6% at 114 kcal per mole of CO_2, which is to say, it instead takes 1900–3800 kcal of sunlight (8–16 MJ in SI units) falling on typical plants to reduce a mole of CO_2 (44 g).

So how much aloe do you need, or how much sunlight do your aloes need to soak up during the day, in order to suck up 590 g of CO_2 per night? Well, 590 g · 12 MJ/44 g = 161 MJ, and divided by a day, that's 1900 W. But how much sunlight is that?

Let's figure that the "capacity factor" of photosynthesis is close to the capacity factor for utility-scale solar photovoltaic energy in the US, which is about 25% — that is, for every 100 watts peak of installed solar photovoltaic generation capacity, you get on average 25 watts, due to things like the sun being on the wrong side of the Earth half the time, and clouds, and a suboptimal sunlight angle on your panels. Or leaves.

The "solar constant" against which those theoretical numbers are calibrated is 1000 W/m², which is about how much sunlight gets to the bottom of Earth's atmosphere where the humans live. At a 25% capacity factor, this is 250 W/m². So you need almost 8 square meters of aloe plants. (And 8 square meters of sunlight to put them in. You might want to put them in some Radio-Flyer-style wagons so you can trundle them out onto the patio in the daytime.)

So basically this approach can work, but it requires on the order of 4 m² of sunlit leaves per person, so you kind of have to design your house around it. I can't do it here in my apartment (not enough sunlit area) and neither can she.

If we had that much sunlight available, we might be able to store much of its energy thermally (see Household thermal stores (p. 1533)) which would reduce our desire to keep the door closed.

Scrubbers

I've written previously in Notes on a possible household air filter (p. 1961) and House scrubber (p. 248) about mechanical means of removing CO_2 from the air in your house; I will not go into more details here except to mention that it does seem feasible, and could be

retrofitted to existing sun-poor housing.

A heat exchanger — a nose for the house

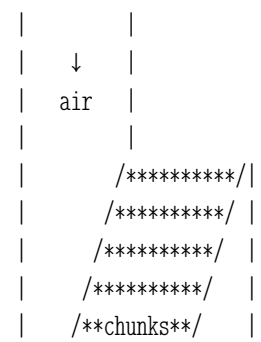
As David MacKay (RIP) pointed out in Without Hot Air, Section III, chapter E, the humans' nose is a heat exchanger which reduces heat and humidity losses to your breath, and they can install a countercurrent heat exchanger on their houses, with the same purpose of transporting air in and out without transporting the precious heat along with it. (Or, in the summer, the odious heat.)

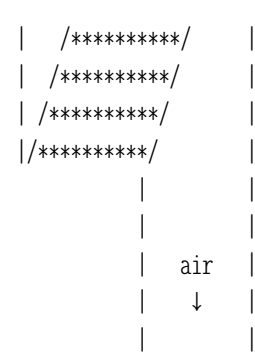
Countercurrent heat exchangers ("recuperators") have a couple of major differences from the "regenerator" design used in Stirling engines and the noses of the humans. One is that, for the same efficiency, they must be much larger, because the two working fluids in a recuperator are in much less intimate contact than the fluid and reservoir in a regenerator. (However, see Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) for a design that fixes this.) The other is that regenerators transfer not only heat but also material between the two directions of flow. For example, water condenses in your nose as you exhale, then evaporates again as you inhale. For some applications, such as your nose, this mass transport is essential; for others, such as transferring heat from a sodium coolant loop to a steam coolant loop, mass transport would be fatal. (Regenerators also have a third difference, which is that their flow is unidirectional and alternating rather than continuous, which is somewhat awkward for rigid structures such as most human bedrooms; often they are used in pairs to compensate for this.)

Ventilating your house is an intermediate case: it's not essential for the water vapor that condenses from the outgoing air to be infused into the incoming air, but it would be desirable, because otherwise an aqueous human is going to want a humidifier in the bedroom. (Maybe hundreds of kilograms of aloes would solve this problem as well.) This suggests that regenerators would be a better choice for this application than recuperators.

Suppose we want to achieve 10 air changes per hour, a relatively normal number of air changes for spaces designed for the humans, and one which in this case would exceed the two or three air changes per hour computed above. This is 100 liters per second in the bedroom I described. If we want to keep air speeds below about 10 m/s to avoid thunderous wind noise, we need to use a duct of at least about 100 mm × 100 mm in each direction.

This presumably means that the regenerators themselves, the pebble beds, will be somewhat wider than 100 mm in order to have comparable air resistance despite being full of chunks, but perhaps not much wider:





To prevent infestations like Legionnaires' Disease, some kind of anti-bacterial and anti-fungal treatment might need to be applied to the chunks. For example, you could use steel ball bearings plated with nickel and then with copper, or (at the risk of deliquescence) rock salt. Some kind of gravel — say, non-clumping clay kitty litter — that's been somehow copper-plated or infused with blue vitriol would also work. Maybe chunks of portland cement would be natively sufficiently alkaline to keep mold or bacteria from growing. (The specific heat of portland cement is 0.880 J/kg/K. Probably the specific heat of clay kitty litter is the same as brick: 0.84 J/kg/K.)

(Shah and Sekulić tell me that paper, wool, hygroscopic nylon, and polypropylene are common materials for such regenerators in HVAC applications, and that the cycle time is frequently measured in seconds.)

How small could we make the pebble beds?

The total thermal mass of each regenerator needs to be much larger than the thermal mass of the air sent through it between reversals of direction. The amount of air sent between reversals of direction needs to be much larger than the amount in the duct, which can be reduced to just over the amount of air in the regenerator pebble beds themselves by doing the reversals of direction close to those beds. This way, if the air ducts from the regenerator to the bedroom has to run a long distance through the house, the air in those ducts can continue moving in the same direction.

Air's specific heat of 1.01 kJ/kg/K is a bit higher than steel's specific heat of 0.47 kJ/kg/K, but steel's density of 7.9 g/cc is much higher than air's 0.0012 g/cc. So if the volumes of air and steel in the pebble bed were equal, the thermal mass of the steel would be about 3100 times greater.

So, presumably, whatever their size, you could send air through them in one direction until you had sent through 150 times their volume of air, then reverse. So far this isn't getting me any closer to conclusions about how big or small the pebble beds have to be if they're just serving to transfer heat and humidity from outgoing air to incoming air.

To take a particular size, suppose one pebble bed is 100 mm × 400 mm in cross-section and 400 mm long, and it's mostly full of steel shot plated as above, close-packed as spheres, which means the spheres occupy $\pi/(3\sqrt{2})$ or 74% of the space. This is 11.9 ℓ of steel, weighing 94 kg, and holding 44 kJ/K, the same thermal mass as 44 kg of air, roughly the entire bedroomfull. If $\Delta T = 22° - 10° = 12$ K, this is 530 kJ, equivalent to running the 2 kW electric heater for four or five minutes. So this is probably overkill, by at least one and possibly three orders of magnitude.

Making the regenerator matrix finer increases airflow resistance but also increases heat conduction between the mass of the matrix and the air passing through. Probably using parallel fins, as in corrugated cardboard, improves this tradeoff. Actual corrugated cardboard itself may be a reasonable material; its specific heat should be close to that of wood, 1–3 kJ/kg/K.

Adapting a regenerator to temperature changes

Sometimes we might have the heater turned off, for example because we're not there, and then want to turn it on.

Topics

Recurrent comb cascade

Kragen Javier Sitaker, 2018-11-09 (updated 2018-11-10) (2 minutes)

A cascade of recursive (i.e. feedback) comb filters at subharmonics of a desired frequency should be able to provide a high-Q bandpass filter at very low computational cost. For example, to isolate a 256-Hz signal with a sampling rate of 1024 Hz, you can subtract the sample 2, 6, 10, 14, 18, or 22 samples ago. Suppose you start by subtracting the sample X[i-14] 14 samples ago, which is 3½ cycles; this produces a new signal A. Now add the sample 16 samples ago from that new signal A[i] + A[i-16]; this produces a new signal B. Now subtract the sample 18 samples ago from that new signal B[i] - B[i-18]. This produces a new signal C. Now add the sample 20 samples ago C[i] + C[i-20], producing a new signal D.

This signal C is the input signal filtered with the product of the frequency responses of the three component filters; that filter has exact nulls at every place any one of the filters had an exact null, including DC, and it has peaks at multiples of the least common multiple of their periods, which I think is well above the Nyquist frequency in this case.

Wait, I'm confusing feedforward and feedback implementations.

Hmm, with unit impulse amplitude this ends up being a linearly growing signal if you make it feedback. You probably need to apply some kind of Hogenauer-style limit thing to keep its amplitude below a limit.

Topics

Notes on local file browsing

Kragen Javier Sitaker, 2019-09-15 (updated 2019-09-28) (4 minutes)

I've been struggling with local-files WWW browsing in Dercuano since its inception, and I've learned a few things in the process.

Android, the special shitty snowflake

As described in How to make Dercuano work on hand computers? (p. 1371), I think that probably PDF is a more feasible solution for *delivery to* hand computers, but I also want to do *development on* hand computers.

I can build Dercuano on Android in Termux with no difficulty, especially now that I've spent the hour to port it to Python 3. However, browsing the built HTML tree is more difficult.

Firefox Lite on Android can't browse local files at all. Chrome on Android can, using the normal file:///sdcard/whatever URLs, but not the entire filesystem. So it's necessary to put the files you're browsing in /sdcard, even if it's "emulated", so that the browser has access to them.

Opening HTML files in Android from Termux with `termux-open-url` does not work well, because it doesn't use the file:// but rather a content:// URL which could perhaps in theory export the whole tree of HTML files (and CSS, and JS) but in practice doesn't. It's rather fiddly to get the correct directory in Termux if you got there via symlinks; I've resorted to `termux-open-url "file://$(readlink -f "$(pwd)")/index.html"`, though maybe there's an easier way.

Chrome on Android is capable of saving HTML files you're viewing, which it does in a MIME multipart/related document. Firefox Lite does not deign to permit mere users such abilities.

Same-domain problems in filesystem browsing

Normal Firefox of course can browse local file URLs; however, it has some rather strange restrictions. dercuano-20190915/index.html (p. 1) can successfully load dercuano-20190915/liabilities/style.css, which can then successfully load, for example, dercuano-20190915/liabilities/et-book-roman-old-style-figures.ttf, and if you click from dercuano-20190915/index.html to, for example, dercuano-20190915/notes/notes-on-local-file-browsing.html, it can also load these files. Similarly, both can load addtoc.js from the liabilities directory. However, if you open dercuano-20190915/notes/notes-on-local-file-browsing.html directly (for example, by pasting the URL, launching it from the command line, or clicking a bookmark), it can load the CSS and the JS but not the TTF, which gets an error message about cross-origin requests in the JS console. So as long as you're clicking around from the top level, you're fine, but entering through another path will result in a mysterious font failure.

Chromium also fails to load the fonts under similar but not identical circumstances.

Whatever concept of "origin" the browsers are using isn't exported

to JS as `window.origin` or `document.domain`, which are consistently `"null"` (a string) and `""`, respectively.

localStorage

Somewhat surprisingly, both Firefox and Chromium support localStorage from local files; Firefox, for one, seems to use the same notion of "origin" that sometimes prevents it from loading the fonts. In both cases localStorage survives browser restarts. This suggests that it should be possible to use localStorage as a persistent cache, but it's not safe as the only way to store important data.

data: URLs

Data URLs such as data:text/html,hello are apparently not supported by Firefox Lite, but they are supported by Android Chrome, and they support JS and base64. Unfortunately I don't think there's a way to get them to be gzipped. This is maybe a useful delivery mechanism for apps that can be encoded in a single QR code (size limit: 2953 bytes without chaining multiple QR codes, which is maybe enough for a decompressor).

Topics

A proposal to support hypertext links in ANSI terminals

Kragen Javier Sitaker, 2013-05-17 (updated 2019-12-26) (13 minutes)

We should totally have a way to render HTML-style links in terminal emulators.

Why this is a good idea

Lots of terminal emulators already have a way to recognize URLs in free text so that you can visit them (ctrl-click in gnome-terminal, an option on the dropdown menu in both gnome-terminal and Konsole), which is useful. But if you're chatting over XMPP with someone who's using HTML (like HipChat), they're probably going to embed links from time to time. And they expect that when they say:

> We'll go from my house to Facebook at around 10:00.

where "my house" is linked to http://maps.google.com/maps?client=ubuntu&channel=fs&oe=utf-8&q=1456+Edgewood+Dr.,+Palo+Alto,+CA&um=1&ie=UTF-8&hq=&hnear=0x808fbb0d745a65e9:0xfde4b05151805922,1456+Edgewood+Dr,+Palo+Alto,+CA+94301&gl=us&sa=X&ei=bZNCUbbuI62g4AOPyYDQDw&ved=0CDAQ8gEwAA and "Facebook" is linked to http://maps.google.com/maps?q=facebook&hl=en&sll=37.45392,-122.13933&sspn=0.007495,0.013797&gl=us&hq=facebook&t=m&z=16, then you will see something like

> We'll go from *my house* to *Facebook* at around 10:00.

and not

> We'll go from http://maps.google.com/maps?client=ubuntu&channel=fs&oe=utf-8&q=1456+Edgewood+Dr.,+Palo+Alto,+CA&um=1&ie=UTF-8&hq=&hnear=0x808fbb0d745a65e9:0xfde4b05151805922,1456+Edgewood+Dr,+Palo+Alto,+CA+94301&gl=us&sa=X&ei=bZNCUbbuI62g4AOPyYDQDw&ved=0CDAQ8gEwAA my house to http://maps.google.com/maps?q=facebook&hl=en&sll=37.45392,-122.13933&sspn=0.007495,0.013797&gl=us&hq=facebook&t=m&z=16 Facebook at around 10:00.

which is pretty annoying and hard to read.

The proposed solution: `ESC [ _` and `ESC [ U < url >`

We define two new ANSI-compatible escape sequences, which ought to be proposed for the next version of ECMA-48 and the corresponding ISO standard:

- `CSI _`, or `ESC [ _`, "LNK": to indicate the beginning of a hyperlink to an URL. All characters produced before the next URL sequence form part of the link.
- `CSI U`, or `ESC [ U`, "URL": to indicate the end of the link text begun by LNK. This sequence is followed by the unencoded text of the

URL to which clicking the link should take the user, preceded by "<" and terminating before the next ">" or " ", which is part of the escape sequence and not displayed.

As an example, a link labeled "Canonical Hackers" linking to http://canonical.org/ could be represented as follows, with `ESC` representing the ASCII escape character:

```
ESC[_Canonical HackersESC[U<http://canonical.org/>
```

Rationale for the design of the escape sequence

Above and beyond the typographical possibilities of whitespace, we already have boldface, underlining, and different colors in our terminal emulators. These are produced by "escape sequences", invisible sequences of characters typically beginning with the ESC character (character 27) followed by a "[", which change the state of the terminal so that subsequently displayed characters will have a different effect. The `ESC[` sequence is called "CSI", "Control Sequence Introducer".

So I think we should define an escape sequence to make the following (or preceding?) sequence of characters into a clickable link to a given URL.

It would be desirable if the escape sequence degraded into something that was human-readable when displayed on terminals that didn't support it. This is only possible to a limited extent, since programs that try to be aware of screen layout will necessarily be confused about where the text is on the screen, but it is still somewhat possible.

ANSI escape sequences can't contain sequences of arbitrary characters, while URLs can contain most characters. Consequently the escape sequences for setting the terminal title aren't ANSI escape sequences: `ESC]0;new title^G`, where `^G` is the BEL character control-G (character 7) and can also be `ESC\`, and `0` can be replaced with `1` or `2`. The `ESC]` sequence is known as "OSC" or "Operating System Command".

xterm's parsing of the above sequence seems to consume anything following `ESC]` until the next `^G` or `ESC\`, even if it doesn't start with a digit, which is pretty unfriendly. This suggests that if we wanted to use the same `ESC]` introduction sequence, incompatible xterm implementations would eat the URL if we terminated it with the same `^G`, and other things as well if we used a different terminator. Even if most people are now using other terminal emulators, this seems like a compatibility trap.

Putting the link escape sequence *after* rather than *before* the text to be marked up offers a certain kind of safety; it's quite easy for an unterminated color escape sequence to set the next few pages of output to white on white, or flashing, or underlined, or whatnot. It also probably improves matters on terminals that don't yet understand the escape sequence, as they could see "Canonical http://canonical.org/" rather than "http://canonical.orgCanonical". Since you presumably need two escape sequences anyway to indicate the boundary of the link, you might as well put the URL in the final

one. So you have one escape sequence to indicate "beginning of link" and another one to indicate "end of link; URL is xyz".

For reasons of tradition and URL-safety, I would like the delimiters (particularly in the gracefully degraded form) to be <>. Ideally the beginning and ending sequences would also have a pleasing visual and memorable symmetry, and would disappear from view entirely in old terminals.

(In the following, ESC means the ASCII character 27, escape.)

This suggests using one of the ASCII matching delimiter pairs []()<>{}``. [] are right out, since they're already in use. ESC( and ESC) cause rxvt to swallow the following character; I'm not sure what their meaning is, but they seem to be used. Treating `` as a matched pair is sadly out of style, due to the unfortunate but now nearly universal adoption from Microsoft Windows fonts of a vertical '.

ESC{ and ESC} disappear in rxvt and xterm, render as literal ESC character glyphs in gnome-terminal, overlaid on top of the {} in my font, and disappear in konsole while producing warning messages on its stderr. ESC< and ESC> disappear in rxvt; the second disappears in gnome-terminal, while the first renders as a literal ESC character glyph; they disappear in konsole. This suggests that perhaps ESC< and ESC> are already taken.

A little looking around suggests that ESC> is "set numeric keypad mode" aka DECKPNM on VT100s, ESC< is "exit ANSI mode" on VT52s, while ESC(and ESC) are used by VT100s to change character sets (setaltg0, setaltg1, etc.)

ESC} on VT100s is "invoke the G2 character set", according to http://rtfm.etla.org/xterm/ctlseq.html, although that's ignored in xterm and probably all other modern terminal emulators.

So this suggests the following syntax:

```
ESC{Canonical.ESC}<http://canonical.org/>
```

Actually, though, you could use valid ANSI escape sequences instead of ESC{ and ESC}. I wanted to use ESC[a for the "begin link" sequence (like <a>), but rxvt already uses it for a nonstandard "move right" sequence, an alternative spelling of ESC[C. (See rxvt-2.6.4/src/command.c:2652, inside process_csi_seq.) The full set of CSI-ending codes handled by rxvt seems to be iAeBCaDEFG`dHfIZJK@LMXPT^Scmnrshltg^W, which is to say, @ABCDEFGHIJKLMPSTWXZ^``acdefghilmnrst.

Argh, so what to use for the other escape sequence? Wikipedia says:

> For two character sequences, the second character is in the range ASCII 64 to 95 (@ to _). However, most of the sequences are more than two characters, and start with the characters ESC and [(left bracket). This sequence is called CSI for Control Sequence Introducer (or Control Sequence Initiator). The final character of these sequences is in the range ASCII 64 to 126 (@ to ~).

This suggests that we could use "ESC[*", which konsole reports as an "Undecodable sequence" and drops, rxvt apparently drops (and isn't in rxvt's list of CSI codes), xterm and screen drop, and gnome-terminal displays literally. "ESC[*" is nice and mnemonic: links are normally underlined.

ESC[U would work for the "end link, begin URL" sequence, which could be followed by the URL wrapped in <>. If the URL is specified

to end at the next space or >, then this sequence would be unlikely to inadvertently gobble up a large quantity of text when random data is sent to the terminal that randomly happens to include ESC[U. So that would give us:

```
ESC[_Canonical.ESC[U<http://canonical.org/>
```

Implementing the escape sequence

You could write your own terminal emulator to support links, but it probably makes more sense to implement the feature in existing terminal-emulation software. The popular free-software terminal emulators are tmux, screen, gnome-terminal, konsole, rxvt, xterm, Emacs, and whatever Apple ships, plus perhaps implementation in ncurses is necessary for much application software to use it.

I looked through the available file on my Ubuntu box to see what other terminal emulators there are. The relevant popularity metrics from http://popcon.debian.org/main/by_vote are:

```
 #rank name                      inst  vote   old recent no-files (maintainer)

```

(I thought Text::CharWidth might be relevant, but it doesn't seem to handle escape sequences anyway.)

Now, libvte9 or libvte-2.90-9 is the actual terminal emulator library that powers a number of the above terminal emulators, at least gnome-terminal, sakura, xfce4-terminal, vala-terminal, tilda, lxterminal, gtkterm, and evilvte. But from looking at the code of gnome-terminal and xfce4-terminal, each separate application built on top of libvte would probably have to write some code to handle clicks on link regions.

It seems that once you add the feature to libncurses5 (in the termcap, at least), libvte9, and gnome-terminal, it's available to 20% of users of Debian and similar systems; if you add it to xterm, you get another 12%, although it's perhaps dubious whether upstream xterm will accept such a patch; adding the feature to screen makes it available to another 9%, although some of them will still be using other terminals (such as MacOS X terminal) to connect to their screen; konsole gets another 6%; emacs ansi-color.el 4%; xfce4-terminal 3%; and tmux 1.6%.

Security

Some escape sequences of the past have been disabled for security

reasons in modern software. However, in general, it's safe to launch arbitrary URLs in a normal browser at the moment, or so we believe; so this should be safe. It may, however, result in terminal users getting rickrolled. It would be useful to have a way to see what the linked URL is before you click on it.

Radiant heating

Kragen Javier Sitaker, 2018-05-20 (3 minutes)

Humans are most comfortable when the air they are breathing is substantially cooler than the radiant temperature of their environment. If both are at 19–24°, humans can be reasonably comfortable, but it's better to have the radiant temperature at some 40° and the air temperature closer to 20°.

This, of course, implies some kind of continuous energy input — supplied by the sun in our natural environment, whose "solar constant" is 1000 W/m². If the radiant temperature is 40°, without any cooling, things will gradually heat up to 40°, and humans will feel like shit. The air inside a building itself doesn't absorb a substantial amount of radiant energy at thermal IR wavelengths, but surfaces will — even with low-emissivity coatings, they will absorb at least 10% of the incident radiation, which is the radiation they would be emitting at 40° — that's 545 W/m² for a black body, 54.5 W/m² for one whose emissivity at the relevant wavelengths is 0.1. And the 1000 W/m² of the solar constant works out to a radiant temperature of some 91°.

54 W/m² is a relatively reasonable amount of heat to remove through airflow and air conditioning, especially compared to the 1000 W/m² supplied by the sun shining through an open window. What does it look like to supply it through radiant heaters?

Note that you have to have the whole 545 W/m² incident on your body for the radiant temperature to be 40°. But only some of it has to come directly from the radiant heaters; other parts can be reflected, or even emitted, by other materials in your environment. So let's consider what it takes to reach 150 W/m² on the floor directly from ceiling-mounted radiant heaters radiating down.

High-emissivity heating elements that can reach 900° without damage are commonplace. Higher-temperature materials, like the Kanthals, are somewhat expensive. 900° is 107 kW/m², while 1400° (about as high as any Kanthal goes) is 440 kW/m². So each cm² of 900° heater radiator can cover 720 cm² of floor with 150 W/m². To cover a whole 40m² efficiency apartment, you need 560 cm² of 900° heating elements to emit the requisite 6 kW (requiring 25 A at 240 V to produce it through Joule heating).

If you instead use coolant from a phase-change reservoir at, say, 500° (not sure what material melts at 500°, but I'm sure there's something), it only emits 20 kW/m², so you need 3000 cm² (0.3 m²) of emitting panels.

A note on meditation

Kragen Javier Sitaker, 2019-04-20 (1 minute)

From *The Mind Illuminated*, p. 117:

Meditation is a series of simple tasks, easy to perform, that only need to be repeated until they bear fruit. So where is the sense of difficulty and exertion coming from? We usually describe a task as difficult because we're dissatisfied with our performance, which means we've started judging. Your expectations haven't been met, and maybe you're starting to doubt whether you'll ever succeed, which can sap your motivation. You're not actually struggling with meditating, you're struggling with unrealistic expectations and an idealized image of what you think "should" be happening. As a result, it feels like you're forcing yourself to do something you think you aren't very good at. If you believe those feelings, the ego-Self naturally wants to avoid blame. If you can convince yourself that you've been trying really hard, then the ego-Self doesn't feel guilty for not meeting its own self-imposed expectations. You can blame the teacher, the method, or concoct a story about how meditation isn't right for you. The real issue isn't that meditation takes too much effort, or that something is innately wrong with you, it's your judgment and expectations.

Useful to keep in mind.

Dercuano formula display

Kragen Javier Sitaker, 2019-04-30 (5 minutes)

Dercuano contains a bunch of text, which can be more readable and comprehensible and navigable if properly formatted (see Dercuano stylesheet notes (p. 374)), but a lot of that text also contains mathematical formulae, things like ½LI² or k (2 cos θ_0 cos² ω - cos θ_0 - 2 sin θ_0 sin ω cos ω) or log cos x ≈ -x²/2 - x^4/12 - x^6/45 - 17x^8/2520 - … when $x^2 < \pi^2/4$. One problem is that Unicode's ability to represent mathematical formulae is pretty limited; you can do x^i but not vice versa, you can't do simultaneous subscripts and superscripts (for things like $\int$), and any kind of two-dimensional layout is pretty limited. Another problem is that the spacing and fonts are all wrong; that last formula, for example, should look more like

$$\log\cos x \approx -\frac{x^2}{2} - \frac{x^4}{12} \ldots$$

only with better fonts and no misalignment between the minus signs and fraction bars. (That'll depend on your fonts.)

The standard approach to solving this problem on the web is MathJax, which scans your HTML after page load for TEX formulas tagged with \(\) and renders them into nice readable formulas. I downloaded a copy, and it doesn't look like it sends the formulas to a server for rendering (the way Wikipedia's alternative does) but it's 33MB. And it looks like a big chunk of that 33MB is necessary to use MathJax in the usual way.

MathJax can generate SVG and HTML with CSS, though, so maybe I could somehow get it to compile my formulas to HTML or SVG at build time. Although, to bring up problems reminiscent of those in Dercuano drawings (p. 64), here's the bletcherous markup it spat out for `$\sim\bigoplus_{i=0}^7b_{n,i}$`, generating screen output which looks absolutely gorgeous:

```

id="MathJax-Span-26" style="font-size: 70.7%; font-family:
MathJax_Math; font-style: italic;">i<span
style="display: inline-block; width: 0px; height:
4.014em;"><span style="display:
inline-block; width: 0px; height:
2.302em;"><span style="display: inline-block;
overflow: hidden; vertical-align: -0.436em; border-left: 0px
solid; width: 0px; height: 1.662em;">

That gzips to 643 bytes. Without using the MathJax fonts or `position:`, you might try doing something like

$$\sim\oplus \quad 7 \quad b_{n,i}$$
$$i=0$$

Markdown won't let me treat a `<table>` as an inline element, but CSS will, and the idea would be to hack the math stuff in further down the processing chain anyway. The source code to that looks like this, reformatted:

```
<table cellspacing=0 cellpadding=0>
    <tr><td rowspan=2 style="font-size: 2em">~⊕</td>
        <td style="font-size: .71em">7</td>
        <td style="padding-left: 3px" rowspan=2><i>b<sub>n,i</sub></i></td>
    </tr><tr>
        <td style="font-size: .71em"><i>i</i>=0</td>
    </tr>
</table>
```

It's 253 bytes, gzipping to 180 bytes — more than the 50 bytes of the original formula, but not the 3 kilobytes gzipping to 643 bytes (not counting the fonts!) generated by MathJax.

So one alternative, which also might be reasonably okay for some

things, is to hack together some kind of thing to spit out some HTML. It won't look as good as MathJax or real T_EX, but it's potentially a lot more capable than raw Unicode, and it should be able to express most of what I want to express.

Certainly when I'm *editing* formulas I want to see them with MathJax, though. And if someone is online and willing to take advantage of MathJax, they should be able to.

Sorting in logic

Kragen Javier Sitaker, 2019-12-28 (2 minutes)

I was thinking about Prolog as I lay in bed last night, and I came up with this:

```
%% Sorting a sequence of numbers: a constructive definition.

%% Choosing an element from a nonempty sequence:
choose([X|Xs], X, Xs).
choose([X|Xs], Y, [X|Ys]) :- choose(Xs, Y, Ys).

%% Permutations of sequences.
perm([], []).
perm([X|Xs], [A|As]) :- choose([X|Xs], A, B), perm(B, As).

%% Ordering of sequences.
ordered([]).
ordered([_]).
ordered([X, Y | Xs]) :- X =< Y, ordered([Y | Xs]).

%% Sorting.
sorted(Xs, Sorted) :- perm(Xs, Sorted), ordered(Sorted).
```

This can, in fact, be used in an ordinary Prolog system to sort a sequence of numbers:

```
?- sorted([5, 1, 3, 7, 8, 9, 2, 6, 4], X).
X = [1, 2, 3, 4, 5, 6, 7, 8, 9] ;
false.
```

However, Prolog's standard evaluation order makes this a ridiculously inefficient way to sort, taking a factorial number of steps.

What would you do if you wanted to evaluate this definition efficiently? `perm/2` with its first argument instantiated generates its permutations left to right, and `ordered/1` inspects permutations left to right; it is clear that no sequence of the form `[2, 1 | As]` can ever pass `ordered/1`, so there is no need for `perm/2` to recurse to generate alternatives for `As` in that case. Suppose you could propagate that nogood set from one branch of the program to the other; would that give you an $O(N^2)$ sorting algorithm?

I don't think so, because in the example above, there is only one correct initial sequence of 2 items, and 35 other pairs of 2 items that must be tried and rejected --- but rejecting them involves trying everything that can follow them. I'm not totally sure.

This is a reasonably efficient insertion sort with Prolog's usual semantics, but I think it's still $O(N^3)$:

```
isort([], []).
isort([X | Xs], Ys) :- isort(Xs, Sx), choose(Ys, X, Sx), ordered(Ys).
```

This is vaguely related to Generic programming with proofs, specification, refinement, and specialization (p. 958).

Studies in Simplicity

Kragen Javier Sitaker, 2007 to 2009 (5 minutes)

In the last year or so, without quite knowing what I was doing, I've been constructing a series of "studies in simplicity". I've been inspired by apostles of simplicity such as Niklaus Wirth and Chuck Moore; by friends from whom I've learned a lot such as Dave Long, Darius Bacon, Norm Hardy, and Aristotle Pagaltzis; and by current projects such as VPRI's "Reinvention of Computing" effort and the "NAND to Tetris" or "The Elements of Computing Systems" course.

I've been doing this to construct working, useful systems with small amounts of code, with the functionality of the aspects of computers that used to scare me, or seem magical, or seem impossible to understand. For a long time, I've known that there aren't *really* magic elves in the computer, but I've always felt pretty uncomfortable with the handwaving I have to do to explain how, say, a compiler works.

Part of my objective has been to enable other people to share my newfound fearlessness. I haven't gotten much feedback, so I can only assume I haven't succeeded in that yet.

To a great extent, this stuff is nothing special; I think it's stuff that any computer science undergraduate does, or should do, in a compilers or operating-systems class, and indeed the "TECS" course covers most of it in a single semester.

Tinylisp (2007–09)

Tokthr (2007–11)

An interactive Forth interpreter under 2kiB; 1000 lines of code; unfinished.

One of the first things I tried was implementing a tiny token-threaded interactive Forth system. I worked on this for about a week, in November 2007. It's not quite complete, and it's 1534 bytes in size when compiled, from about 1000 lines of assembly.

The primary objective is to see if it's possible to build a usable interactive development environment in two kilobytes or so, so that software development doesn't have to be limited to the wealthy and the fortunate. I'm pretty confident that this shows that it's possible, at least for people who like Forth. Here's my basic rationale, quoted from the source:

> There are still a lot of computers out there that have tens of kilobytes of memory or less, and they cost a lot less than, say, a cellphone. Cellphones are apparently still too expensive for half the world's population. I want to see how close I can get to having a comfortable programming environment in a smaller device.
>
> Some smallish microcontroller chips from five different manufacturers, with current Digi-Key prices:
>
> Name bytes RAM bytes ROM MHz price
> ATtiny2313 128 2048 20 US$1.38
> ATMega48-20AU 512 4096 20 US$1.62
> MSP430F1111AIPW 128 2264 8 US$2.43
> LPC2101 2048 8192 70 US$2.52
> H8/300H Tiny 1536 8192 12 US$3.58
> M16C/R8C/Tiny/1B 1024 16384 12 US$3.54
> SX28AC/SS 136 3072 50 US$2.79

In a sense it's a fairly slow interpreter; it needs about 100ns per

bytecode on my 700MHz laptop, about 70 clock cycles per bytecode. That's about as slow as Python 2.4's bytecode interpreter, but the bytecodes are much lower-level, so it's actually slower than Python.

If I (or somebody else) should finish Tokthr, it will be one of the smallest Forths, and indeed the smallest interactive interpreters, ever created; it should provide an interactive development environment in under 2kiB of program with a few hundred bytes of RAM.

Tokthr draws on, among other things:

- My cheap electronics dissection project, where I found out that you could buy a variety of electronic devices for under US$10, some with enough space and computational power to be usefully programmable, but none that were actually programmable (2006);
- Richard W. M. Jones' JONESFORTH, a Forth implementation in x86 assembly language (2007);
- C. H. Ting and Bill Muench's public-domain eForth Model 1.0, which shows that you can build a practical Forth in very little space and very little code (1992?).
- The inspiration of Chuck Moore, obviously, and Jeff Fox's evangelical and sometimes slightly unhinged zeal in telling the rest of us what Chuck had achieved.

Ur-Scheme (2008-02)

Compiler from a subset of Scheme to x86 assembly, written in itself; 1600 lines of code; finished.

This was my first real compiler. It compiles a subset of R5RS Scheme big enough to write a compiler in, which I know because I wrote it in that subset.

Although it takes a very naïve approach to code generation, the code it produces runs surprisingly fast, only about a factor of 5 slower than C compiled with GCC. In part this is due to its omission of first-class continuations and garbage collection.

It does implement closures, and the assembly it generates compiles to statically-linked, standalone executables.

Ur-Scheme draws on many inspirations, which are listed on its home page.

Amnesic hash tables for stochastically LRU memoization

Kragen Javier Sitaker, 2017-04-03 (1 minute)

A policy rarely used for handling collisions in hash tables: discard the old colliding entry! This is appropriate for using a hash table as a cache, e.g. for memoization. Or push the oldest, or one of the older, entries out of a small bucket, of four or eight items, like a 4-way or 8-way set-associative CPU cache.

If you hash the key twice, so that it hashes into two separate buckets — rather like cuckoo hashing — then the chance of survival goes up significantly. You check both buckets before declaring that it's not found. In this case, you should probably rewrite the entry into both buckets when read-accessing it, so that more-often-read entries will be erased with lower probability. This is an alternative to using 4-way or 8-way set-associative caches; I suspect it will turn out to be more efficient.

Topics

Matrix memory

Kragen Javier Sitaker, 2016-07-27 (1 minute)

If you want 4096 bytes of memory as a minimum, and you're somehow storing the data in some kind of cheap (or even homogeneous) passive elements activated by intersections of wires, and you want to minimize the number of wires, you need ⌈√(4096*8)⌉ = 182 wires in each direction, a total of 364 wires. If you do it in the more usual way, you need 128 wires in one direction and 256 in the other, for a total of 384 wires.

Ferrite cores are the most typical way of storing data in such a memory, but there are other possibilities as well, even at the ferrite-core macroscale. For example, you could imagine a ferroelectric material sandwiched between two layers of indium tin oxide electrodes, one vertical and one horizontal, like an LCD but with PZT or whatever replacing the liquid crystals; or an e-ink (electrochromic) display.

Topics

the oversold-as-low-power Renesas RL78 microcontroller line

Kragen Javier Sitaker, 2019-08-27 (10 minutes)

The RL78/G12 datasheet describes a low-power 16-bit 31-MIPS 24 MHz microcontroller, supported by GCC. At first glance, **it appears to run under 100 pJ per instruction, but this is not true**; my calculations from inspecting the datasheet and the Hardware User's Manual suggest more like 450 pJ per instruction, nearly twice the 230 pJ/insn that excited me about the STM32L0 in Notes on the STM32 microcontroller family (p. 3176) — and the STM32's instructions are 32-bit instructions!

These are my notes from reading the datasheet and some other sources.

Wikipedia tells me it descends from the NEC 78K0R, which descends from the 8-bit 78K/0, which NEC launched in 1986. The "G" in "RL78/G12" is "general-purpose" as opposed to LCDs, industrial, or automotive use.

The R5F10278ANA#W5 member of the family costs US$2.01 in quantity 1, US$0.986 in quantity 1000, at Digi-Key, with almost 5000 in stock. This is the version with 24 pins, 8 KiB of program Flash, 2 KiB of data Flash, and 768 bytes of RAM.

Supporting hardware

It runs on a single power supply, which can be 1.8 to 5.5 V, and includes a ±1% on-chip oscillator, which can do up to 24 MHz. So you don't need a ceramic resonator; you need a crystal if you need tighter timing than that. (The lower-end R5F103 line is ±5%.)

If you do use an external crystal, you're limited to 20 MHz, or 8 MHz if you're under 2.7 V. I don't see anything about being able to use a 32.768 kHz crystal, which would be ideal for precisely timed sleeps.

CPU

It's a 16-bit architecture with a 1-megabyte address space, 2–16 KiB of program Flash (rewritable 1000 times), in some cases 2 KiB of data Flash (rewritable 1,000,000 times if you only care about 1-year data retention, or 10,000 times for 20 years), and 0.25 to 2 KiB of on-chip RAM, and 8 8-bit general-purpose registers — comparable to an AVR in power and the 8086 in convenience, so programming it in C seems like a reasonable thing to do. (And there are four register banks, presumably like the Z80, for interrupt handling and other task switching.) It says it's CISC, but also that it has a 3-stage pipeline.

Oh geez. The registers are "AX", "BC", "DE", and "HL". Then it has ES, CS, 8-bit registers "A", "X", "B", "C", "D", "E", "H", and "L", a carry flag, an auxiliary carry flag (!), a PC, and an SP. The memory map starts with interrupt vectors. This thing is damn close to being an 8080. There's an "ES:" instruction prefix (a la 8086 segment overrides) and a register bank select (a la Z80). Unlike the 8080, it has indexed addressing modes (no Z80-style IX and IY, though). And, yes, there are instruction timings — mostly 1 or 2

clocks, or 4 or 5 clocks if you're accessing Flash.

It's maybe not totally surprising NEC copied Intel; I had an NEC V20 IBM-compatible once.

Unlike the 8086, the ES and CS registers are shifted by *8* bits before forming the effective address, not *4*.

The INC and DEC operations don't affect the carry flag, but they do affect the zero flag.

The instruction set listing (without opcodes) takes 17 pages, but mostly that's because they listed the large number of addressing modes separately (since they vary by instruction), so MOV takes up 2½ pages. Seems like it's probably on the order of a Z80 in complexity.

The general-purpose registers (all four banks!) are mapped into memory. Also, code and data are in the same memory space — no AVR-style Harvardry here.

It includes a 32×32→32-bit multiplier but no floating-point. It's mapped into memory as a device. (All the devices are memory-mapped; there are no IN and OUT instructions.)

The smallest chips in the family, the ones with only 2 KiB of program Flash, can't reprogram their own Flash under program control. The others can.

The interrupt system has multiple priorities, four hardware and one software.

There's a *separate* "RL78 Family User's Manual: Software", which I haven't read; it has instruction maps in it.

Power usage

This is the main attraction! But it turns out to be false. It's actually specified to be worse than an STM32L0!

It says "basic operation" at 24 MHz is 1.5 mA, but "normal operation" is 3.3–5.0 mA; these numbers do not depend on voltage, except that running at 24 MHz at all requires you to be at 2.7 V or more. 3.3 mA ÷ 24 MHz is 138 µA/MHz, twice the 63 µA/MHz touted on the datasheet's front page, but maybe they were talking about "basic operation", which is not defined, but apparently only possible at 24 MHz. Lower-speed numbers do not use lower currents per MHz, but they do use lower voltages; low-speed 8-MHz mode is 1.2–1.8 mA, at either 2 V or 3 V. This is slightly worse — 150–230 µA/MHz — but uses less power (300 pJ/cycle rather than 370) because of the lower voltage.

Moreover, the "31 DMIPS at 24 MHz" on the front page is also misleading. **This is not a superscalar chip**; at best it can run one instruction per cycle, and many instructions take 2 cycles. It might really manage 16 million instructions per second.

That means those 300 pJ/cycle are really 450 pJ/insn! That's almost *twice* what the STM32L0 claims in its datasheet. (I probably ought to verify its claims.)

They also have modes HALT (110–1210 µA, leaves clocks running) and STOP (0.19–2.20 µA, doesn't leave clocks running). Restarting the clock after STOP can take a while.

These power numbers generally don't include peripherals, including the timers needed to wake up. The low-speed on-chip oscillator uses 0.20 µA, the interval timer 0.02 µA, and the watchdog timer 0.22 µA. The ADC uses 500–1700 µA.

Leakage current is specified as ±1 µA per pin, which is enough to be worrisome. (Presumably you could use external multi-megohm resistors to cut down on that.)

"RL78/G12 User's Manual" documents SNOOZE mode, which, using the on-chip oscillator, makes it possible to trigger ADC conversions from a timer without waking the CPU, or to receive UART or SPI data.

In STOP mode you can use the interval time and watchdog timer, but not the PWM-generating timer array. Ports remain latched.

As for "Basic operation"? Not documented anywhere. Maybe they're running a NOP loop or something.

Peripherals

It has three timers (an interval timer, a timer array with 4–8 channels, and one that is a watchdog), I²C, a 4Mbps UART, 12Mbps "CSI" (which appears to be Renesas's name for SPI), and a rather sad ADC. The timers can run from a low-speed 15-kHz (±15%) on-chip clock, which I assume is to save power while sleeping for an interval. Some of its pins are N-channel open-drain for 5-volt tolerant I/O.

There's a DMA controller that can be used for the ADC, SPI, and even GPIO ports.

The ADC has 11 channels, but only 10 bits, and it needs 39 µs to complete a conversion (except in low-voltage mode, when it needs 95). The internal voltage reference is specified as 1.38–1.50 V, which is I guess ±9%, and it has a temperature sensor that's 3.6 mV/°C, which I guess you can select as an ADC input, with 25° being 1.05 V. It seems like this means that measuring the temperature against the internal reference has an error of ±24°, which is unusable except for emergency shutdown.

It has a lot of interrupt lines, like, 15 or so. Presumably this is also to facilitate waking from sleep.

It can source 20 mA or sink 10 mA per pin (40 mA absolute maximum), up to a maximum of sourcing 140 mA or sinking 100 mA (170 mA absolute maximum), plus some other minor restrictions. Also it has loosely specified pullups (10–100 kΩ) on chip.

The timers can be clocked from off-chip data.

Development tools

FreeRTOS and ChibiOS/RT run on it.

GCC supports the R78 line. There's a note in the datasheet about an "on-chip debug function" in the datasheet but it just says it's "provided"; I don't know if it's provided with free software.

There is some documentation of programming waveforms. It has a "TOOL0" pin with a dedicated UART which can be used to reprogram the device via serial data at 115,200 baud, 250 kbaud, 500 kbaud, or 1 Mbaud. The hardware user's manual refers me to "RL78 Microcontrollers (RL78 Protocol A) Programmer Edition Application Note (R01AN0815)," which presumably means that the programming protocol is public and so probably someone has implemented it.

Conclusions

The RL78/G12 looks like a reasonable 16-bit microcontroller, if a bit anemic; it's broadly comparable to an AVR, but faster, and uses

much less power than an AVR does. In a lot of ways it looks like "the 8088 done right", and if there's a version of the chip with more RAM, it might be reasonable to do a self-hosting development environment on it.

However, in the usual cross-compilation context, it seems hard to justify choosing an RL78 over an ARM Cortex-M chip like the STM32L0, which uses half the power, runs more than twice as fast, has first-class debugging support in free software (maybe the RL78 has that too?), and has more pins and an ADC that runs 110 times as fast.

Topics

Interactive geometry

Kragen Javier Sitaker, 2018-04-26 (1 minute)

To make an interactive geometry application, maybe when a point or line or arc or whatever is selected, then the things you can construct from there should be immediately visible and selectable, with a little pushbutton to create each one. Maybe things like midpoints and intersections should be created as soon as segments and lines are, as in Laszlo Pandy's (and Bret Victor's?) dynamic drawing application.

To clean up clutter, you might want to have some constructions that are a little more at arm's length; given a library of them, you could choose one to instantiate a cartoon of it with a little pushbutton on each of its inputs. Then you can constrain it to objects in your scene one by one.

Additionally, you may want to put some things in another layer, then hide that layer. In multitouch, this can be done with a layer quasimode.

(See Two-thumb quasimodal multitouch interaction techniques (p. 1765) for more details.)

Topics

Transmission line computer

Kragen Javier Sitaker, 2016-07-11 (updated 2019-07-23) (7 minutes)

Reading *The Art of Electronics* I was reminded of a rumored unpublished result I vaguely recall from somebody at Bell Labs in the 1990s to the effect that you can build a universal computer if you have a single NAND gate. Could you do something like this in practice using a big coil of coax?

(Coaxial and fiber-optic delay lines are an existing commercial product.)

Table 2.1, on p.74 (the 107th page) of the current edition of *The Art of Electronics* is labeled, "Representative Bipolar Transistors". Almost all of them can switch at 100 MHz; the 2N3904/2N3906 "jellybean" is 300MHz. But at c, an oscillation at 300MHz is 999mm. Typical coax propagates signals almost nondispersively (is this close enough?) at about half of c, so each meter of it could hold about four bits of storage. My 32768-bit benchmark for a practical computer would then require about 16 kilometers of cable. At 2.95mm (the diameter of RG58 instrumentation cables) that's 109 liters of cable, which is a completely reasonable amount of cable to manage, but somewhat costly.

(Some RF-amplifier transistors in the table reach up to 4GHz, reducing all of this by an order of magnitude.)

(With magnetostrictive torsion delay lines, you could reduce the size of all this stuff by many orders of magnitude; if your wire transmits shear waves at 2km/s, which I think is a reasonable ballpark, and is 0.3mm wide, each bit takes up about 300µm×300µm×3.33µm, so 32767 bits is 109mm instead of 16km, nearly a milliliter of wire instead of nearly a cubic meter. It should be practical to have megabytes of memory. But nondispersive magnetostrictive delay lines require special stress-relieved spring wire and magnetostrictive transducers, both of which sound tricky to me.)

http://www.digikey.com/product-detail/en/tpi-test-products-int/508-1200-1M/290-1020-ND/268032 is a hundred-foot (30.5 m) length of 50Ω 30V RG58 coaxial cable with BNC connectors on the ends. They sell it for US$57.49, which would set the price of the above quantity of cable at US$30200. I hope it's cheaper in bulk!

http://articulo.mercadolibre.com.ar/MLA-610317920-cable-rg-58-cuerda-foam-nuevos-_JM is a roll of 100m of 50Ω RG58 coaxial cable without connectors for AR$1583, which is just over US$100, so the cost would be about half of what I said above.

If all of this cable were in a single length, the bit-circulation latency would be about 55 µs (32768 bits of 1.67 ns each), but in practice you would probably want to have at least some modest amount of parallelism; some sort of ideal compromise would be to have something like 128 cables each containing 256 bits with a circulation time of about 427 ns. You probably also want to have some diversity of cable lengths; for example, if the main cycle time is 256 bits, you might want some cables of 255, 254, 252, 248, 240, 224, 192, 160, 96, and 32 bits delay times, allowing nonlocal interaction.

Another reason for wanting shorter delay lines is that the lines are lossy; the cable I linked above is specced to attenuate at 138dB/km at 100MHz. That means that the 100-foot (200ns, say) cable attenuates by about 4.2dB. Your jellybean transistor might have a β between 25 and 150, which means that a single one of them can recover from over 30dB of signal loss and maybe up to 44dB. So 200ns or 400ns of delay line at a time is fine, but if you get up over about 200 meters (700 ns) you might start to need a repeater. At some point you're going to start having SNR problems.

What would the logic design for such a machine look like? I'm thinking of the delay line as containing a number of separate state machines (something like 128 to 4096 of them), each of whose has a state represented in a set of parallel bits in the different cables, one bit per cable; each of them goes through a single state transition every time it cycles through the state-transition active circuitry that they all share. The circuitry is entirely capable of latching some amount of state from one machine to the next; this constitutes an output from the previous machine, and an input to the next.

By itself, this is adequate to implement simple machines like the rule-33 or rule-110 cellular automata. But we can surely build a machine that's easier to program and more efficient than those are. The "nonlocal communication" strange-length links I mentioned above are one useful enhancement: they link these virtual state machines into a much more densely connected topology than the ring topology inherent in the temporal sequence of the delay lines. (If you could only pick a single extra length, rather than the eight I suggested, it should be the square root of the total number; for example, if there are 1024 state machines, each with 32 bits of state, this extra network link should have a delay time of 32 or 992, enabling a message to be routed from any machine to any other in at most 64 hops with an average of 32. The logarithmic network would cut this to a maximum of 10, at the cost of needing ten odd-sized links instead of one.)

(I should read about what Turing's Pilot Ace and the LGP-30 were like, since they had some of this nature.)

On the Pilot Ace:

> The main store of the machine used ten delay lines each holding 32 words of 32 bits. There were also six temporary stores implemented as short delay lines each capable of holding a 32-bit number.
>
> The operations of the Pilot ACE allowed the programmer to specify move operations from one delay line to another. This was achieved by waiting for the number to come round and then "gating" it into the data flow of another delay line. Because it was arranged so that the numbers emerged from the delay lines at the same moment you could only move the nth number in a delay line to become the nth number in another delay line.
>
> If you wanted to change the order of numbers in the long delay lines you had to first transfer the number to a short delay line and then wait for the position in the destination to come round. This made programming more like juggling.

(
http://www.i-programmer.info/history/9-machines/11-an-ace-of-a00-machine.html?start=1)

32 to 128 bits is not enough space to program a very complicated state transition function.

Differential spiral cam

Kragen Javier Sitaker, 2017-07-19 (9 minutes)

To make an automaton like the Jaquet-Droz artist, you need to program a relatively extensive series of paths.

One mechanically very simple way to do this is with a differential spiral cam gantry, like a couple of Chinese windlasses driving a vertical plotter.

The first step is to wind a couple of threads — one for X, one for Y — around eccentric spools mounted rigidly to a common shaft. The rates at which the threads are taken up by the spools will vary depending on the rotational position of the spools, which can be out of phase. If you hook up the threads to a pen in X and Y, as you wind, the pen will trace a wavy line across the paper as the phases vary.

This is kind of lame, though, because not only does the motion repeat on every turn, but also, in a given direction of windings, the pen is limited to a fairly small range of directions: up, left, or somewhere in between. Moving it right or down is impossible.

The solution to the direction limitation is to make the motion differential: instead of directly driving the pen with the thread, run the thread around a pulley on a long loop between a supply spool and a takeup spool mounted rigidly to the same shaft. Each of the spools can be eccentric or oddly shaped. The difference between their radii at the tangent points of the thread at a particular rotational position results in a net lengthening or shortening of the loop, and thus extension or retraction of the pulley. If they have different overall circumferences, the loop will have a net extension or retraction for each revolution.

Now we have four spools mounted on the same axis and two pulleys connected to the pen; each revolution of the spools moves the pen through a fixed pattern, which may not end where it began, and so repeating the rotation will draw the pattern repeatedly at slightly different positions.

Suppose that we don't want to simply repeat the pattern, though. Then instead of simple drum-shaped spools, we can use spools with helical grooves to entrain the thread; perhaps a 140-µm thread (Dyneema 10-pound fishing line, say) could run in the bottom of a 2mm-deep wide. Now, each rotation of the spool can vary its radius independently of previous and subsequent rotations, as long as you can confidently shape the 2mm-wide groove "above" or "below" the previous and following windings of the groove. You're still limited in how quickly you can increase or decrease the radius — you need a quarter turn to ramp all the way up from or down to zero — but hopefully the differential principle keeps that from being a huge problem.

Now let's suppose we have a reasonable-sized RepRap-printed version of such a doohickey. Let's say, four spools with 2mm grooves, max 100mm radius, and 200mm allocated among the four, 50mm each, printed at 100-µm precision. 50mm of a 2mm-pitch spiral gives you 25 turns, a total of 7.9 meters at the maximal 100mm radius. It probably makes sense to think of the actual motion as being

half of that: about 4 meters. I'm not quite sure how quickly we can change speed, but if we figure that we can control more or less each 100μm unit separately, then we have about 40 000 line segments here to draw with, which is plenty for encoding a Jaquet-Droz-Artist-like picture.

Some final details and variations:

• It might make sense to "gear up" the output so that the detail is rougher than 100μm, but the total line length is more than the 6 or 8 meters you get with this design. For example, you might use an extra pulley or two so that the pen moves 2mm or 4mm every time the thread difference changes by 1mm.
• Rather than a gantry system (like what you see in a construction crane), you could use the standard vertical-plotter configuration, where the two dimensions are the distances from two reference points.
• By using three pairs of spools instead of two, you could overconstrain the pen, keeping it under tighter control; and you could selectively relax that constraint for when, for example, you'd like to lift the pen from the paper. Indeed, this gives you a deltabot, with its attendant three degrees of freedom.
• You could print each spool as two separate prints, instead of all as one piece, so that you have four times the length. And you could probably space the grooves closer than 2mm, though 1mm might be pushing it.
• Instead of using the threads under tension as linear actuators, you could use them to rotate things. I kind of feel like cords under tension eliminate most of the usual problems with linear motion, though, except for lack of precision.
• You could use it to position things other than pens. Markus Kayser used a vaguely similar system in his SunCutter to control the MDF-burning effect of a magnifying glass, although he was using timing-belt-linked big acrylic cams pushing on cam followers on a linear slide gantry moving a table around. You could position machine tools, position squirting nozzles of various materials, trace lines in wet sand, trace lines in wet frosting or other plastic material, move an electro-etching or electrodeposition head around to selectively etch or deposit metal, cut foam with hot wires, cut things with lasers or cutting torches or sparks, etc.
• You could use thicker thread. 140-micron Dyneema fishing line is capable of supporting loads of a few kg; if you were to go up to 1500-micron Dyneema braid, that would hold loads of up to 400 kg or more, 800 kg in each dimension considering it's going around the differential pulley twice. This would also provide greater rigidity, but probably much greater than is necessary; if we want 1mm positioning precision over a 1-meter distance, and our pen or whatever weighs 500g and accelerates at 1 gee, we need to have less than 1 millistrain of deformation at 4.9 N. Doubled-up 140-micron Dyneema with a Young's modulus of 100 GPa would hit a millistrain at about 3 N, so it's already close. Doubled-up 1500-micron Dyneema doesn't stretch a whole millistrain until 350 N; at 5 newtons over a meter, it stretches 28 microns.
• The Grail, of course, is to make the device programmable at run-time, instead of requiring a new set of spools for every new

picture. This can be accomplished by making the spools cylindrical and not eccentric, with a constant radius, but no longer rigidly fixed to the same axis; instead, their axes should be linked with some kind of continuously variable transmission, probably one of the positive-displacement ratchet-controlled types rather than one of the friction-controlled types. The setting of the CVT then determines whether the thread is being extended or retracted.

You could imagine using a lightly angled cone spool instead of a cylinder, then controlling where along the cone the thread winds onto it. This might work, but I fear that the thread might slip too easily along the cone after being wound; maybe a sufficiently bumpy cone surface would prevent that problem, at the cost of less precise positioning.

Eventually, with any of these variations, you run out of thread in one direction and have to change directions. If you're driving the spools with a powerful motor, this may require slowing down and stopping before you hit the end and break the thread. In fact, this is likely to be a showstopper unless you have several hundred meters of thread.

• By threading the thread through various kinds of paths, we can actuate things other than just a pen floating around in space. For example, three threads running through a universal joint are sufficient to pull the joint into any position.

String cutting cardboard

Kragen Javier Sitaker, 2016-06-30 (5 minutes)

Recently I bought some Dyneema (UHMWPE) fishing line, a 0.5 mm diameter four-strand braid rated for 50kg; there are thinner grades down to about 0.2mm. Among the first things I did with it were to cut my hands a bit (accidentally) and neatly cut some sandwiches (on purpose).

This Saturday I visited the Mini Maker Faire Buenos Aires and talked with a designer who makes cardboard furniture. She gave me a little laser-cut and laser-engraved heart magnet made from cardboard.

I'm interested in self-replicating machinery fed from cheap materials, and in particular fabrication by planar cutting. It occurred to me that you could almost certainly cut cardboard with this string, although I haven't tried yet.

In particular, I think that you can make a kind of string bandsaw out of this string that will cut cardboard with a precision of about a third of its diameter, which would be about 60µm with the 200µm braid. Laser cutters typically manage about 100µm, but cannot be made out of cardboard themselves.

The pressure of the string along the edge of the cardboard needs to be high enough to cut into it rather than just drag over the edge. But the crucial feature here is the pressure, not the force; the pressure is determined by the force and the string's bending radius. In the other parts of the machine where cutting is not desired, the string can be run around a large-radius pulley made from the same cardboard without cutting it, because the larger radius reduces the pressure on the pulley proportionally.

Thinner strings at the same stress will produce less pressure on the edge at a given bend radius, directly proportional to the diameter ratio; if their bend radius is proportionally smaller, they will produce the same pressure. This suggests that using thicker string will provide a larger margin between the pressure needed to cut into the cardboard and the tension the string can withstand, at the cost of less precise cuts and larger radii. Laser cutters are typically capable of 100µm-wide kerfs, which will be difficult to achieve with off-the-shelf Dyneema.

(A 490-newton force reaches the rated stress of 2.4 GPa in this 500µm braid; such a string wrapped around a 3mm-radius half turn will be exerting 980N net on it, spread over 6mm diameter and 500µm diameter, for a final pressure of 330 MPa. By contrast, a 200µm-diameter braid stressed at 2.4 GPa bears only 79 N; wrapped around the same 3mm-radius half turn, it exerts 130 MPa. But if instead it is wrapped around a proportionally smaller half turn with a 1.2mm radius — the thickness of a sheet of cardboard — it exerts 330 MPa again.)

However, the cardboard, too, is experiencing bend radii that depend on the string used to cut it. I don't know enough to know whether this will matter in practice.

The 500µm-diameter braid is comprised of four tows braided together, each of some hundreds of fibers, so each fiber might be 10µm or 20µm across. Rebraiding the braid into smaller braids should

make it possible to get sub-100μm kerfs, at least if the resulting string is still capable of cutting cardboard — the analysis above suggests it may not be.

The same kind of string bandsaw could melt through PVC pipe and perhaps plastic sheets, but it may be better not to use UHMWPE for this. UHMWPE is commonly listed as having a softening point or maximum service temperature of about 82° to 90°, barely above PVC's temperature of 54° to 80°. Spun nylon is the standard string used for friction-melting through PVC in construction; I find different sources giving its softening temperature as 75° or 180° (for nylon 6, polycaprolactam, which is not polycaprolactone) and as 76°, 110°, or 230° (for nylon 6,6), so I don't really have any idea.

Tying knots in the string might help to provide enough irregularity to ensure cutting rather than just sliding.

It should be possible to achieve tight radius turns by rotating the workpiece around the place where the string runs through it.

With the addition of abrasive, this bandsaw could also cut other materials, like metal and glass, but the string won't last long.

Typical lightweight cardboard box material can withstand an edge crush test of 32 pounds per inch ("32ECT"); over 500 microns, that would be only 2.8 N, while this string is capable of withstanding 490 N on each side, almost 400 times as much. This bodes well for the ability to cut cardboard cleanly by this method. Note that by this measure, thicker string is better in proportion to its diameter; halving the diameter halves the force needed to crush the edge, but cuts the strength of the string by four. The longitudinal motion of the string should reduce the effective strength of the paper further.

Approximate optimization

Kragen Javier Sitaker, 2019-11-13 (3 minutes)

Many successive-approximation algorithms for mathematical optimization --- including the variants of gradient descent that are currently fashionable for training ANNs, but especially things like Newton-Raphson iteration, the method of secants, and the method of Halley --- are quick to converge to a global optimum once they are close to it, but can take a long time to get anywhere close to that optimum.

This suggests that it may be advantageous to do the first iterations of these algorithms using relatively imprecise but cheap means, then do only the last few iterations using higher precision. What kinds of imprecise means might work for the early iterations?

Analog computation

Differential analyzers and similar analog "computers" are commonly accurate to 2% or so, although it depends on the computation, since errors in numerical integration of ODEs, for example, can grow exponentially with time (and this applies equally to analog "computers", even though no actual numbers are involved). Successive-approximation algorithms are something of a best case, though, since rather than growing over time, errors tend to die out over time.

So it seems likely that a properly configured analog computation circuit could approximate the solution within the limit of whatever its signal-to-noise ratio is; commonly 60dB (0.1%) to 80dB (0.01%) is reached. You could imagine some kind of crossbar interconnect made out of CMOS analog switches --- multiplexor/demultiplexors --- to interconnect op-amps, resistors, capacitors, OTAs, and entire analog processing blocks.

0.01% is close enough that two further iterations of a quadratic-convergence method such as Newton-Raphson iteration would reach the precision limits of double-precision floating point.

One difficulty is that, with the exception of integration over time provided by capacitors and differentiation over time provided by inductors or gyrators or the like, analog circuits normally have no memory --- their output is a function of their input, not a function of all their past inputs. This means that you need separate circuits for each scalar variable in your problem state; a single vector equation like $a = b + c$ might require hundreds or thousands of op-amps, unless you can arrange for those vector variables to be indexed by time.

Analog delay lines of various kinds can improve this situation considerably; the old standards for slow signals were thermostatically-controlled piezoelectric mercury delay lines and later torsional magnetostrictive delay lines, with Pupin-like cascades of inductors and capacitors or coaxial transmission lines for faster signals. The approach of using a CCD or similar camera sensor described in CCD oscilloscope (p. 1861) is a potential pure-analog solution that permits some degree of out-of-order access.

In this context, though, it may not be necessary; maybe we can offload the problem of memory onto digital circuitry and feed it

through a DAC feeding the analog circuitry, then digitize the result with an ADC to store it again.

Low-precision floating-point and fixed-point

"Half-precision" 16-bit floating-point is commonly available in GPUs, "TPUs", and modern SIMD instructions; typically it runs at the same cycle time as double-precision floating point, but four times the parallelism. So it's an obvious candidate.

Even lower precisions may be useful for computing initial approximation. Some kind of 8-bit floating-point format, for example, or 8-bit saturating fixed point.

A quintuple-acting vacuum cascade to recycle heat for more efficient distillation and desalination

Kragen Javier Sitaker, 2017-06-21 (updated 2019-12-27) (3 minutes)

I previously calculated (in Fast sea salt evaporator (p. 1087)) that the enthalpy of vaporization of water (2.26 MJ/kg) and terrestrial mean insolation (180–280 W/m² at temperate latitudes) make solar evaporation a relatively inefficient method of desalination: 80–120 mg/m²/s of water. This also makes sea salt production relatively inefficient. Indeed, these efficiencies are so low that even normally abundant solar thermal energy only permits their use in niche cases.

By comparison, the Sorek reverse-osmosis desalination plant forces water through semipermeable membranes at 7.1 MPa, producing drinking water at a total cost of US$0.58/kℓ. 7.1 MPa × 1 kg/ℓ is 7.1 kJ/kg, or 0.0071 MJ/kg, about 320 times less energy than the enthalpy of vaporization. 7.1 kJ/ℓ works out to 2.0 kWh per kiloliter, which costs between US$0.08 and US$0.24 at 4¢ to 12¢ per kWh, current US electrical prices. By contrast, 2.26 MJ/kg works out to 630 kWh/kℓ, which would be US$25 to US$75 per kiloliter, compared to Sorek's US$0.58. (The reason solar desalination happens at all is that you don't have to buy the energy.)

However, vaporizing water once with solar energy is a silly way to do things. When that water condenses, it releases its enthalpy of vaporization again. If you could harness that heat released in condensation to vaporize more water, even a few stages of the process would improve the efficiency of the system dramatically, although 17 stages would be needed to bring it closer to Sorek's consumption. However, 5 stages would reduce the energy consumption to 450 kJ/ℓ, or, say, increase to 500 mg/m²/s.

A tricky problem is that you need to deliver this condensation heat into water that is cooler than the condensing steam or water vapor, for example by running the steam through coils cooled by water that is evaporating. It would be sufficient, if perhaps not necessary, for the coolant water to be boiling — but at a lower temperature. This approach requires that each successsive stage of the desalination apparatus operate at a successively lower pressure — exponentially lower: 85 kPa for 95°, 70 kPa for 90°, 58 kPa for 85°, 47 kPa for 80°, 39 kPa for 75°. The water thus produced needs to be pumped out of these partial-vacuum chambers against this pressure — 62 kPa for the 75° chamber. While this is less than 1% of the pressure used in the Sorek reverse osmosis plant, and therefore will not add a significant *energy* cost, it still represents machinery that adds significant complexity to the apparatus.

I suspect that this quintuple-acting vacuum cascade approach will make solar water distillation sufficiently more inexpensive to permit its use in a wide variety of settings where it is currently too expensive.

Update: this method is called "multi-stage flash distillation" and is currently in widespread use; reverse osmosis typically uses less energy, as described above, so few new MSF plants are being built. The margin is sufficiently large that you can desalinate a larger amount of water per sunlight joule even by powering a reverse-osmosis plant from photovoltaic panels.

Intermittent fluid flow for heat transport

Kragen Javier Sitaker, 2019-07-10 (4 minutes)

As mentioned briefly in Heating my apartment with a plastic tub of hot water (p. 1310), intermittent fluid flow can transport heat better than continuous fluid flow with the same average speed. The case there is that heating my apartment with the shared hot-water heater would require 19 mℓ/s, but drawing that continuously would just heat up the pipes in the wall, not the apartment. If, instead, I draw 300 mℓ/s for two minutes, I can put 36 liters of hot water into a bucket or radiator, which can then release the heat into the apartment over the next half hour. This eliminates more than 85% of the heat loss — although the half-liter or so of water left in the pipe for that half hour will lose nearly all of its heat, that's only 3% of the total heat.

This is a general property of heat transport through thin, lossy tubes: if the amount of time the transport fluid spends in the lossy tube is pushed to extremes by using pulsing flow, the overall system efficiency improves, sometimes dramatically. I speculate that, in the mass-transport realm, this might be a reason vertebrate hearts use the shocking, violent pulsing motion that they do, incurring an obvious waste of energy from unnecessary viscous energy losses, rather than the peristaltic motion used by earthworm hearts and insect hearts: that way, most of the blood can spend more of its time in the capillaries and less of its time uselessly losing oxygen in large vessels, and furthermore even the venous part of the non-pulmonary capillaries gets fully-oxygenated blood, and even the venous part of the pulmonary capillaries gets fully-deoxygenated blood to oxygenate and decarbonate.

This has a direct application to ice vest design (see Ice pants (p. 298).) Here you have a substantial amount of coolant (salt water, say) sitting in tubing inside the vest, absorbing heat from your body, and a substantial amount of coolant sitting in tubing inside an ice pack, releasing heat into the melting ice. If you use a continuous slow flow, all the coolant passing through the transitional tubing between these two points is going to lose an unnecessarily large amount of heat, and additionally, part of the vest will be ice cold, while another part will barely be cold at all, decreasing heat transfer; an analogous phenomenon will impede heat transfer within the ice pack, where the coolant near the exit is already too cold to release much additional heat. If, instead, you use periodic sudden pulses that replace most of the vest coolant at once, the whole vest will be a spatially uniform (but temporally oscillating) temperature, increasing heat transfer substantially.

Probably the way to do this electrically is to use a small electric motor to wind up a spring, then release a brake on the spring to drive the pump. This avoids the need for a large electric motor.

I think I hadn't noticed this previously because of an aesthetic or philosophical inclination toward symmetrical, steady-state solutions, which are easier to analyze, rather than oscillatory or asymmetric

solutions: wheels rather than legs, turbines rather than pistons, linearity rather than nonlinearity, flat rather than curved walls, continuous rather than crenellated or fractal webs. I speculate that this inclination is shared by much of modern science and engineering and represents a significant blind spot.

Microprint visor

Kragen Javier Sitaker, 2016-09-07 (2 minutes)

I'm trying to figure out how to do a paper microprint system for my notebook.

If I print text out at a line height of six 600dpi pixels, it's like uh 100 lines per inch so 0.72 point. For text to be comfortably readable with the naked eye it needs to be 12-point, which is the standard line-printer 6 lines per inch; that's 16⅔× bigger. So a head-mounted magnifying apparatus of between 16× and 30× is probably adequate to make it comfortably readable.

The column width shouldn't be more than about 0.3 radians in order to be comfortably readable. At 30×, an apparent 0.3 radian image is something that was originally 0.01 radians; this means that if it's at a distance of 500mm (from the lens), the column width is then 5mm, which is 118 pixels at 600dpi; at 3.5 pixels per character, that's only 33 characters, about 6 words. So being towards the lower end of that range is probably desirable for ergonomic reasons.

4.8× handsfree magnifying visors are readily available, but 15× and 30× are harder. I did find a 20× one with LED illuminators and a 10× monocle one each for about US$27.

If we stick to 10×, we want 1.2-point fonts, which are 10 pixels high on a laser printer, or maybe 8 or 9 pixels with 1 or 2 pixels of leading. If the glyphs occupy 5 pixels horizontally, then a 600×600 pixel square inch can contain 7200 characters of text, or about 1440 words; a 4×5 inch A6-size page with some margins can hold twenty times that, 144 kilobytes, 28800 words or about 27 standard line-printer pages. Call it 32, then 16 pages (8 sheets of paper) holds 512 standard pages.

(There's still the unknown of whether I can properly align the pixel grids and fully exploit the 600dpi theoretical capability of the printer, or whether I have to stick to Nyquist, taking a 4× areal density hit.)

Some ideas of what to put in it:

Storing CSV records in minimal memory in Java

Kragen Javier Sitaker, 2015-09-03 (6 minutes)

Objective: store CSV records in minimal memory in Java. Main sub-objective: minimize number of heap allocations without costing too much runtime.

Brief overview

A class per CSV format, with field types defined and fields named. Private booleans to indicate whether the fields have been parsed. Store CSV line in a char array. Store comma offsets in int array. Actually, use the same array for both. Loop over the line in getters to set the requested field when it's unknown. Weakly reference String fields to avoid either retaining no-longer-used Strings on the heap or multiplying a String on the heap because it's gotten many times. Optionally intern the Strings in a (possibly weak) hash table to handle the common case where many lines have the same value for a string field.

In more detail

From a list of CSV fields and their types, we generate a class automatically with a getter method for each field. Instantiating this class with a line from the file leaves behind only two heap allocations: one for the instance, and one for an array containing the line's characters and the offsets into them where each field starts.

We could find the field boundaries lazily; in that case, the method template code looks something like:

```
boolean hasQuarter = false;
int quarter = -4242;
int getQuarter() {
    if (hasQuarter) return quarter;
if (knownOffsets < 4) findFieldOffsetsUpTo(4);  // ensure offsets[3] ok
int q = quarter = parseInt(data[3]);
hasQuarter = true;
return q;
}
```

Thus when you invoke getQuarter() the usual case will be to check the boolean, find that it's true, fetch the field, and return it. The next most common case will be to fetch `knownOffsets`, compare it to 4, find that it's not less, and jump ahead to the call to `parseInt`, which iterates over the characters from the relevant point in the character array; hopefully that will get inlined.

It might make more sense to always find the field offsets when the object is created (i.e. not find them lazily, but rather eagerly), because that would avoid storing knownOffsets and conditionally testing it every time a field is parsed.

Laziness

Most of the time that I'm processing CSV files, I don't process all the fields. I might just want the maximum value of a single field, for example.

(I'd actually like to be able to avoid doing even character set conversion, since it's both potentially lossy and also uses up CPU time for no good reason on fields that I'm not parsing. Just keep the data in byte arrays. This is inconvenient to do in Java.)

Strings

Strings are a little more difficult than primitive types like floats and doubles, because strings are heap-allocated, so if we're not careful, they can eat up a lot of memory and also put pressure on the garbage collector. There are two strategies to deal with this:

• Weak references. A weak reference doesn't prevent an object from being collected by the garbage collector, but if the object hasn't been garbage-collected yet, it allows you to avoid recreating the object. So the idea is that when we lazily parse a string field, we store a weak reference to the created String value, and return a strong reference to it. As long as the client program holds on to that String, we can keep returning references to it, but if it releases it, it becomes fair game for the garbage collector, and then we may have to recreate it if the program asks for it again.

• Interning. Consider this CSV data from the R distribution:

```
Name,Country,City,OK,CountryCode
"Argentina (La Plata)",Argentina,"La Plata",1,ar
"Argentina (Mendoza)",Argentina,Mendoza,1,ar
"Australia (Canberra)",Australia,Canberra,1,au
"Australia (Melbourne)",Australia,Melbourne,1,au
```

Some of its text columns contain data that will occur only once, but other columns are drawn from a small set of alternatives, like the world's countries. The most effective way to reduce memory usage for those other columns is to ensure that every CSV object returning the string "Argentina" from `getCountry()` is returning a reference to *the same* String object, so that it only has to exist once on the heap. To achieve this, we'd maintain a hash table of existing "interned" strings, and when we want to parse out a field, we check to see if it's already in the table before we allocate it.

This is a little bit tricky because using the standard Java HashMap or even Hashtable objects requires that we have already allocated the String, but a custom hash table implementation avoids that problem.

The potential problem with interning is that if you intern values in a unique field, your hash table retains and eventually tenures strings that will never occur again and do not need to be retained.

These two strategies can be combined to get the best of both worlds: a custom hash table containing weak references to Strings both avoids duplicate allocation and avoids retaining data that doesn't need to be retained.

Weak references are a little less efficient than strong references. I don't yet know enough about Java's implementation of them to know whether they impose an extra cost on the garbage collector (push notifications) or on the mutator (pull notifications) or both.

Line parsing

One very common CSV format, Excel's, allows newlines inside of fields as long as they are inside of double quotes. This implies that you cannot simply walk into Mordor by reading a line and turning it into a CSV object; you need to involve the CSV-parsing stakeholder earlier in the process so that it can tell you when you're done parsing a record. And, as long as it's doing that, it might as well remember where the fucking commas are.

External buffers

Going a little bit further to reducing allocations, copying, and bounds-checking, we could avoid creating a separate char array for each CSV object.

Illuminating yourself with 10 kilolux of LEDs to combat seasonal affective disorder

Kragen Javier Sitaker, 2013-05-17 (5 minutes)

Lots of people suffer from "seasonal affective disorder", or just think they'd function better, because they spend a lot of their awake time in environments illuminated at 50–500 lux, which is hundreds of times dimmer than full daylight. 10klux is the low end of full daylight; 32klux is the low end of direct sunlight; 130klux is the high end.

What's the minimal amount of equipment I'd need to illuminate my body (including eyes, but other things just in case) at 10klux?

A lux is a lumen per square meter. At 555nm, the most efficient wavelength, a lux is 1.5 mW/m², so 10klux would be 15W/m². I might have a surface area of about 2m², so I'd need about 30W of light, or 20klm. The most efficient light source is probably an LED; red-orange and green LEDs are around 95 lumens per watt, which means I'd need (20klm/(95 lm/W)) = 210 watts of LED power to reach that. Common LEDs are closer to a third of that efficiency, so I'd need about 630 watts, and about US$600 worth of LEDs. Cree Inc. supposedly has 200lm/W white-light room-temperature LEDs available, but Digi-Key only has up to 153lm/W.

Cree's CXA2530-0000-000N00S40E7 ("Cree XLamp CXA2530 19mm white") LED array, in stock at Digi-Key, costs US$25.50 in quantity 1 and delivers 4643 lm at 1.5 amps at 37 volts, for 84 lm/W; it gets above 100 lm/W at half the current. (That's about 15% efficiency: 150mW/W.) Getting 20klm out of these guys would require five of them, costing US$127.50; they could then deliver 23klm at max current (278W), or 15.5klm at optimal efficiency (148W). Linearly interpolating, that gives you 20klm at 226 watts (+ 148 (/ (- 20000 15500) (/ 1 (/ (- 278 148) (- 23000 15500.0))))).

So you could probably cure seasonal affective disorder for the cost of US$130 plus a three-hundred-watt 37-volt power supply (say, US$50), plus 226 watts. You make a chamber of mirrors with all-transparent furniture, stick the brilliant lightbulbs into it (maybe with some frosted glass to make them less harsh), and go sit in it, naked, for some 16 hours a day. (You could imagine that this might cause some other kinds of disorders related to social interaction, though.) 226 watts for 16 hours a day is 151 watts or 1320 kWh/year, or US$132 per year, assuming a 100% efficent power supply.

Given the high power cost, so it probably makes sense to use six of the Cree 19mm LED arrays instead of five to improve efficiency: the cost for the LEDs jumps from US$127.50 to US$153, but the necessary power drops: if the output light from a single array in the 0.8 to 1.5 amp range is 3095lm plus (/ (- 4643 3095) (- 1.5 0.8)) = 2211 lumens per amp, and 20klm is 2860lm per array, we can interpolate to (+ 0.8 (/ (- (/ 20000 6.0) 3095) 2211)) = 0.91 A per array, or (* 37 6 0.91) = 202 W. That means we can get by with a two-hundred-watt power supply and also reduces our power usage by more than 10%, to

1180 kWh/year, US$14 less. The extra array pays for itself in energy savings in less than two years, not even taking into account the likely parts savings from the smaller power supply, the increased resilience to part failure from having more redundant LEDs, and the lower junction temperature.

From the datasheet, it doesn't look like you can significantly improve efficiency by lowering the current further.

20%-efficient photovoltaic panels covering the roof of a 10-meter by 10-meter house in a zone with 300W/m² average day/night insolation would give you 6kW average. If you were powering your LEDs with photovoltaic panels, you could provide light for about 40 people. Of course, during summer daylight hours, it would be more efficient to just put the daylight inside the house directly; then, instead of 20% efficiency at the panels times 15% efficiency at the LEDs, for a total of 3% efficiency, you'd have more like 80% efficiency. Too bad that only works a small amount of the time.

If you only want to illuminate your eye pupils at 10klux, well, your pupils are about 4mm in diameter, so they have a total area of about 25 millionths of a square meter; a quarter of a lumen would suffice to illuminate them to 10klux. You could get that out of 2.5 milliwatts, a hundred thousand times less than what I'm proposing above.

Vectorized prefix sum

Kragen Javier Sitaker, 2017-07-19 (5 minutes)

You can apply the parallel prefix sum algorithm in a serial, vectorized way using a logarithmic number of Numpy's vector operations. The parallel prefix sum algorithm puts the vector elements into the leaves of a complete N-ary tree (here I use N=2) and propagates partial prefix sums first up and then back down this tree.

Here you have the sum of 16 numbers in four elementwise-parallel operations using strided arrays:

```
>>> import numpy
>>> x = numpy.array([1,2,3,4,5,6,7,8,1,2,3,4,5,6,7,8])
>>> a = x[::2] + x[1::2]
>>> a
array([ 3,  7, 11, 15,  3,  7, 11, 15])
>>> b = a[::2] + a[1::2]
>>> b
array([10, 26, 10, 26])
>>> c = b[::2] + b[1::2]
>>> c
array([36, 36])
>>> d = c[::2] + c[1::2]
>>> d
array([72])
```

You can then use reverse the ordering to propagate the prefix sum back down to the leaves. The 72 in `d` is of course the prefix sum at the end of the right half of the tree, and `c` already contains the prefix sum of the left half of the tree. For reasons that will become somewhat less obscure below, we can transpose and ravel to perfect-shuffle them into the right order:

```
>>> cp = numpy.array((c[::2] + numpy.concatenate(([0], d))[:-1], d)).T.ravel()
>>> cp
array([36, 72])
```

The corresponding full prefix sums at the points represented by `b` are half elements of this `cp` and the other half composed from the even-indexed elements of `b` added to the previous element, or 0 if none.

```
>>> bp = numpy.array((b[::2] + numpy.concatenate(([0], cp))[:-1], cp)).T.ravel()
>>> bp
array([10, 36, 46, 72])
```

Then we can do the same trick to get an expanded version of `a`:

```
>>> ap = numpy.array((a[::2] + numpy.concatenate(([0], bp))[:-1], bp)).T.ravel()
>>> ap
array([ 3, 10, 21, 36, 39, 46, 57, 72])
```

And similarly to get the whole prefix sum:

```
>>> xp = numpy.array((x[::2] + numpy.concatenate(([0], ap))[:-1], ap)).T.ravel()
>>> xp
array([ 1,  3,  6, 10, 15, 21, 28, 36, 37, 39, 42, 46, 51, 57, 64, 72])
```

A thing to note about this expression is that it has only two O(N) operations in it: the prepending of the 0 and the addition. The stride-indexing, transposition, and raveling operators are all constant-time.

In a sense, this is not very interesting, because numpy already has a prefix-sum operator:

```
>>> numpy.cumsum(x)
array([ 1,  3,  6, 10, 15, 21, 28, 36, 37, 39, 42, 46, 51, 57, 64, 72])
```

But the above transformation can be generalized to any monoid, not just integer addition, and in particular to function composition, which means it can in theory be used to generate the sequence produced by any definite loop that can be expressed with these operations. It's a little bit tricky in that the monoid elements are functions representing the action of an iteration of the loop and their composition takes the place of addition in the above calculations. If you're going to represent them with numpy array elements, they need to be in some sense constant-space, and you may need many arrays.

As a useless and less trivial but still comprehensible example, consider the action taken by a loop decoding a digit string in some base b:

```
result = 0
for i in range(k):
    result = b * result + digits[i]
```

The action taken by any n iterations of the loop is to multiply the previous result by b^n and add some number m to it. To compose two such actions, (n_0, m_0) followed by (n_1, m_1), we compute $(n_0 + n_1, m_0 \cdot b^{n_1} + m_1)$; processing a number m merely produces (1, m). So we need one array (at each level) for n and one for m. Moving up the tree:

```
>>> na = numpy.ones(len(x))
>>> ma = x
>>> nb = na[::2] + na[1::2]
>>> nb
array([ 2.,  2.,  2.,  2.,  2.,  2.,  2.,  2.])
>>> mb = ma[::2] * 10**na[1::2] + ma[1::2]
>>> mb
array([ 12.,  34.,  56.,  78.,  12.,  34.,  56.,  78.])
>>> nc = nb[::2] + nb[1::2]
>>> mc = mb[::2] * 10**nb[1::2] + mb[1::2]
>>> nc, mc
(array([ 4.,  4.,  4.,  4.]), array([ 1234.,  5678.,  1234.,  5678.]))
>>> nd = nc[::2] + nc[1::2]
>>> md = mc[::2] * 10**nc[1::2] + mc[1::2]
>>> nd, md
```

```
(array([ 8.,  8.]), array([ 12345678.,  12345678.]))
>>> ne = nd[::2] + nd[1::2]
>>> me = md[::2] * 10**nd[1::2] + md[1::2]
>>> me
array([  1.23456781e+15])
```

If we move back down the tree, we get all the intermediate results. This is somewhat tricky, though conceptually straightforward, and is left as an exercise to the reader, or to me at a later date maybe.

Note that everything in the above has used only the monoid operation and the identity element 0. But we don't actually need the 0; the algorithm is still applicable to semigroups lacking an identity element. A practical example of this is finding the minimum or maximum of the elements seen so far.

Absurd household materials

Kragen Javier Sitaker, 2018-04-26 (updated 2018-05-18) (8 minutes)

Suppose we wanted to take advantage of modern materials, manufacturing, and pricing to make high-quality household goods. What would that be like?

How about a copper bowl? A 2mm thick copper bowl, maybe alloyed with a bit of some cheap metal to harden it, would be quite solid. Luxurious, even. What if it were a 300mm hemisphere? That's 570 mℓ of copper. Copper's density is almost 9 g/cc, so this would be 5 kg of copper, which would make it a rather heavy bowl. But copper only costs about US$2.20 per pound, according to the USGS (US$4.85/kg), so this is about US$25 of copper. Not a terribly cheap bowl, but that's like US$25 for your entire life.

Even if US$25 and 5 kg is too much for a bowl, maybe it would be reasonable to copper-plate other things. Copper-plating is very cheap, and reduces infection risk, because copper kills germs. Bathtubs in particular ought to be ideal.

How about making your glasses from synthetic sapphire instead of soda-lime glass? High-purity fused aluminum oxide costs US$1440 per ton (US$1.59/kg), and about 140,000 tons of it are consumed by the US each year (as abrasives), a fraction of the worldwide use. So price and supply are not problems, but of course processing requires high temperatures and/or hard cutting tools. But the glasses would be very difficult to break or scratch and would have a totally different ring to them. Granular aluminum oxide would make a nice powder-coat enamel for materials that can resist the temperature — much like the alumina ceramic we use for spark plugs.

High temperatures probably call for molybdenum, of which the world mines some 200,000 tons per year at a price of US$14.50/kg. This leads me to believe that refractory molybdenum crucibles for growing synthetic sapphire crystals would probably only contain US$100 or so of molybdenum. However, the only sources of molybdenum I can find locally sell small reels of 110-micron molybdenum wire for manual cutting of cellphone glue, at prices like AR$35 (US$2) per meter — that's about 100 mg (molybdenum weighs 10.3 g/cc), working out to about US$20000/kg.

(This molybdenum wire might be useful for heating elements? Molybdenum doesn't melt until 2623°. But it oxidizes at much lower temperatures with a volatile oxide, which I suppose is to say that it catches fire.)

Pyrolytic graphite has a nice sheen to it, and although it's brittle, it could probably be deployed advantageously to substitute for metals in many places.

Dichroic iridescent surface coatings would be a nice addition to many materials, and indeed iridescent coatings are widely available in decorations, but are currently treated as a sign of poor taste. Titanium dioxide makes the brightest colors, due to its high index of refraction.

Aerogel would be a nice substitute for fiberglass in many applications, and allows transparent high-value insulation. You could imagine the glass in the front of your oven, for example, being a silica aerogel sandwich between two plates of monocrystalline synthetic

sapphire. But silica aerogel is brittle, and the powder is irritating to human skin. (It ought to be safe from silicosis by virtue of being amorphous, though.) Aerogels made from other materials, such as gelatin, might also be useful for transparent high-value insulation, even if they don't resist such high temperatures.

Near-microscopic flexures ought to be able to make comfortable cushions, with tailored stress-strain curves, from heat-resistant, water-resistant materials — and, unlike glass fiber or ceramic fiber, it should be feasible to make them safe for human skin contact. Even a silicone or Teflon layer would aid greatly in making it possible to clean waterproof cushions.

An annoying problem I'm confronting at the moment is that available floor materials are either combustible or uncomfortably hard. An aluminum honeycomb sandwich, perhaps with aluminum mesh on the surface, could perhaps solve this problem. The aluminum has enough compliance to bounce like a wood floor, without being combustible like a wood floor. And then you can paint it with a surface treatment that reduces slipperiness and changes the color without adding too much combustibility — perhaps some kind of sand in a sodium-silicate or portland-cement binder, although that itself might suffer from cracking and flaking (perhaps with sharp, glassy edges!) if the surface is as flexible as a wood floor. Alternatively, a thin layer of plaster might work — either plaster of Paris, sand in plaster of Paris, or sand in lime. Gypsum is comfortingly soft to sit on, porous to absorb sweat, and cool without the coldness of glazed ceramics.

A bit of mica would be a nice addition to many surfaces.

Doorknobs have no need to be hollow or have sharp edges. This is not so much an issue of materials as it is of shaping. Carved soapstone would be fine.

Polycarbonate, or perhaps polycarbonate with a harder surface to resist scratching, would be a nice alternative to glass for tabletops. Candidate harder surface materials might include potassium-nitrate-hardened soda-lime glass, fused quartz, synthetic quartz crystal, and synthetic sapphire.

Garbage cans should have nonstick coatings: Teflon or silicone, for example. Moreover, organic garbage should be shredded and desiccated before it has a chance to decay, rather than dumped into a garbage can to potentially decay anaerobically. (You can add water to compost it later if you like.)

Teflon coatings would also dramatically improve zirconia kitchen knives.

There's a lot we can do for soundproofing: isolating walls from small vibrations with the same kind of path-lengthening tricks we use for high-efficiency window frames, filling walls with fibers and foams, angling walls and ceiling to reduce standing waves, punctuating sound-absorbing walls with many small holes, and so on. None of these are novel, but they are rarely used in the home.

Sometimes it is nice to have lighting coming from small pointlike sources — when you want to bring out the sparkle of water drops or a gem, for example, or emphasize the surface profile of a sculpture you're working on. Other times, it's nicer to have ambient light, a desire incandescent lights were poorly fitted for. However, with LEDs, light diffuser panels, and electroluminescent materials, it's

relatively easy to put light in as many different places as you like: inside the cabinets and drawers when you open them, in a reproduction of the constellations all over your ceiling, in light diffuser panels covering the whole ceiling, inside your tabletop. Moreover, you can make the lights of whatever color you like, even changing them from moment to moment.

Teflon fabric is a really remarkable material. It cannot be stained, is undamaged by sunlight, does not decay, and is nontoxic, being entirely biologically inert.

UHMWPE is also a really remarkable material. It nearly cannot be stained, does not currently decay, and is nontoxic, but additionally it's as strong as steel, and only slightly more compliant. This offers a number of possibilities for lightweight, free structures in furniture and the like.

Minimum hardware and software to get a flexible notetaking device running

Kragen Javier Sitaker, 2017-04-28 (4 minutes)

I was thinking about the minimum hardware and software needed to get a flexible notetaking device working on an AVR microcontroller or something similar. There are a variety of old Nokia cellphone displays out there that can be accessed via SPI, such as http://articulo.mercadolibre.com.ar/MLA-647101617-lcd-nokia-5110-_JM (84×48 pixels, monochrome, SPI, AR$99). PS/2 keyboards (http://articulo.mercadolibre.com.ar/MLA-624534188-teclado-everte-c-kb-12u-bk-ps2-teclas-resistentes-compacto-_JM AR$59, a few blocks from my house) are easy to interface. Supposedly 4GB MicroSD cards are easy to interface via SPI (http://articulo.mercadolibre.com.ar/MLA-648833744-memoria-micro-sd-4gb-micro-sdhc-nueva-sandisk-micro-hc-_JM $49). And the ATMega328 is readily available (http://articulo.mercadolibre.com.ar/MLA-609412290-atmega328-atmega328p-pu-dip28-bootloader-arduino-nubbeo-_JM#D[S:ADV,L:VQCATCORE_LST,V:3] $70).

So the basic hardware costs (+ 99 59 49 70) = AR$277 = (/ 277 15.8) = US$17.53. Plus batteries I guess. And the result has 105 full-sized keys, (* 84 48) = 4032 pixels (8 lines of 24 4×6 characters, say, although originally it was used for 4 lines of 13 characters), and 4 gigabytes of permanent storage — storage you can remove and read and write elsewhere!

I actually already have an old PS/2 keyboard lying around, reducing the cost to AR$218. It weighs about 800 g, and there's a space containing the LEDs with no keys of about 85×45mm where maybe the LCD could be mounted. The Nokia 3110 from 1997, featuring the display I mentioned above, is only 45 mm wide, so the screen must be about 40×25 mm.

But what do you do about the software? At a minimum you need a font, some screen update logic, editor buffer update logic, search, and probably some kind of snapshotting, ideally using the firesystem other machines will expect on the SD card.

The ATMega328 has 32K of Flash and 4K of RAM. You could probably fit all the code necessary for the editor and the LCD, filesystem, and keyboard drivers into that 32K. Ant's Editor, a simple buffer-gap vi clone written for the IOCCC around 1993, is a bit under 3K compiled to amd64 machine code. But you probably want to do paging from the SD card as much as possible; in particular you don't want the 4K of RAM to have to contain the whole document you're editing.

None of these three devices requires extremely tight timing. The LCD is clocked from the microcontroller (its five lines are reset, chip select, clock, data, and "data/command", of which I think the last three can be multiplexed with other things as long as chip-select is

held high), the SD card in SPI mode is also clocked from the microcontroller (ideally at 20 megabits per second, 2.5 megabytes per second, using four lines: clock, data in, data out, and chip select, so again it only needs one dedicated pin), and the keyboard generates its own clock but only clocks at 10–16.7 kHz, which means that each phase of the clock lasts 30–50 µs (according to http://www.computer-engineering.org/ps2protocol/). That means that, although there is a deadline, the deadline is very generous: 10 or 20 microseconds, which is 160 to 320 clock cycles at 16MHz, 200 to 400 at 20MHz, or 80 to 160 at 8MHz if I want to save myself a crystal. And all we have to do at that time is sample the DATA line.

Also, if we miss the deadline, all that happens is that we miss a keystroke.

The whole microcontroller interface needs eight pins: the LCD reset line (maybe optional), two chip select lines for the LCD and SD card, three clock and data lines shared between the LCD and SD card, and two lines for the keyboard. That leaves the other 15 GPIO pins of the ATMega328 free.

Topics

How to get 6 volts out of a 7805, and why you shouldn't

Kragen Javier Sitaker, 2019-06-08 (updated 2019-06-10) (8 minutes)

Lots of discarded electronics has things like 7805s and white LEDs in it. White LEDs need about 3 volts to light, and the bright illumination ones have a substantially less exponential V–I curve than ordinary indicator LEDs (because of a larger ohmic resistance component and special magic I don't understand to prevent thermal runaway) so it's typical to hook two of them in series up to a 6-volt power supply. But they're not *so* ohmic that it's a good idea to hook them up to, say, a 9-volt or 12-volt supply, or that they'll work on a 5-volt supply. (8 volts — 4 volts per LED — does seem to work with the 6-volt lighting panels I picked up off the sidewalk. At 12 volts — 6 volts per LED — my 12-volt 500-mA switching power supply detects an overload and turns off before burning out any LEDs.)

There *is* a 7806 6-volt voltage regulator, but it's much less common than the 7805 and the 7812. But it's not actually that hard to get a regulated 6 volts out of a 7805.

The 7805

The 7805 is a three-pin regulator which reduces, according to Fairchild's datasheet, 7–35 Vdc to 5 Vdc ±4% at up to 1 A (1.5 A from TI) as long as it's below 125° (150° from TI), with 5°/W of thermal resistance from the junction to the case (3°/W from TI), and so with adequate heatsinking it can dissipate 20 watts or more. It regulates its output pin to 5 V above its ground pin, which sources up to 8 mA. Bypassing with 0.33µF on input and 0.1µF on output is suggested but not generally needed.

The hack

The idea is that you float the 7805's "ground" pin 1 V above the real ground, using a 5:1 voltage divider. This is shown on p. 23 of Fairchild's datasheet. If we're satisfied for the 8 mA regulator current through the voltage divider to produce an error of 0.2 V, which is comparable to the 4% error of the regulator itself, the divider circuit needs to be fairly low resistance: 25 Ω down to real ground and 125 Ω up to the output pin. The 125-Ω resistor will be dissipating 200 mW, so you need to use at least a ¼-watt resistor. (Alternatively, you can use an op-amp buffer to set the "ground" voltage for lower power consumption and error, as shown on p. 24.)

In this case, though, you could probably tolerate a larger error and use, say, a 100-Ω resistor and a 330-Ω resistor. 15 mA through the 330-Ω resistor plus 4–8 mA of bias current through the ground pin put 19–23 mA and thus 1.9–2.3 V of offset on the 100-Ω resistor, giving 6.9–7.3 V on the output, or 6.7–7.5 V if we include the 7805's own error too.

Power dissipation

If 500 mA (a guess) is running through the 6-volt LED strings,

they'll be dissipating 3 watts, which is not a big problem since they're spread out over a large area. If the 7805 is dropping 12 volts (–1) down to 5 volts, it will also be dissipating 3 watts. Though it's specced to operate at 125°, I'd kind of want to keep it below 70° so it will last longer and I'm not at risk of burning my hand on it, and in environmental temperatures up to 35° here in Buenos Aires, that only leaves $\Delta T = 35°$, so we only have a thermal resistance budget of 11.7°/W, of which the junction-to-case resistance already eats up 5°/W. So we need 6.7°/W or less between the heatsink and its coupling to the TO-220 case.

The heatsink tab is, for better or for worse, connected to the package's ground pin, since that's the most negative voltage in the circuit.

In 2019, you should probably just use PWM for multi-watt loads, though

A transistor switch (maybe controlled with a second transistor), a small inductor and a small capacitor for an LC filter, a microcontroller, and possibly a resistor or two for analog feedback from the output is a better solution. You can totally run the microcontroller off your 7805, and you get 95+% efficiency (instead of the 50% described here). The ±4% precision of the 7805 may or may not be available from a microcontroller without trimming, but it's plenty good enough for this. For example, the ATMega328P datasheet specifies its internal bandgap voltage reference as 1 V ±10%, and its ADC contributes about an additional ±1% error; the STM32F103xx is specified to be better with only ±3% error on its reference and ±0.3% ADC error.

Additionally, this gives you programmability and dimming up to a few hundred kHz for free. The dimming is only voltage dimming, and so highly nonlinear for LED illumination.

The downside of this is that you lose the overheating, current-limiting, and foldback protections built into the "virtually indestructible" 7805.

LEDs can general tolerate higher pulsed power than constant power, so the LC filter might seem unnecessary. But if you're running off a 12-volt or 19-volt DC supply, I'm not confident that even short current pulses through the LEDs won't destroy the LEDs or the switching transistor, and of course the shortness of the pulses is a function of the microcontroller software.

Power dissipated by PWM

If you're dimming at 200 kHz via a IRLML6402 (a 40¢ P-channel power MOSFET rated for 20 V and 3.7 A; see My attempt to learn about jellybean electronic components (p. 1974)), you're dumping 12 nC from its gate to ground every time you turn it on; that might be about 12 volts. That's 2.4 mA of gate switching losses at 12 V: 30 mW, about 100× less than the linear 7805. Its 65 mΩ on-resistance will dissipate another 16 mW at 500 mA. So you don't gain much from using a substantially lower frequency like 20 kHz, right?

No, wait — the datasheet also lists a 48 ns rise time and a 381 ns fall time, so each 5-µs-period pulse includes an 0.43-µs transition time during which the on-resistance is significant. If we simplify its

behavior to a linear ramp up of current from 0 to 500 mA during that time, while its drain–source voltage linearly drops from 12 V to 0, its linear power consumption follows a parabola from 0 to 0 during that time, with a peak at 1.5 W in the middle. So it might also have some 90 mW or so of switching losses just from being slow. (Its real behavior is somewhat more complex, but that toy model is probably adequate for our purposes here.)

So, although power consumption is acceptable at around 125 mW, you actually might improve it substantially by dropping to 100 kHz or 50 kHz or something, or using a beefier MOSFET.

Low-carbohydrate diets are ecologically sustainable

Kragen Javier Sitaker, 2018-04-27 (2 minutes)

Quite aside from the question of whether low-carbohydrate diets are good for people, bad for people, or good for some people and bad for others, there's the question of whether they're economically sustainable — agriculture produces much more energy stored as carbohydrate than in other forms. So, some people have claimed that there isn't enough land in the world for everyone to survive on a low-carbohydrate diet.

Soybean yields average 2.93 metric tons per hectare per year; world arable land is currently a bit over 48 million km², which is 4.8 billion hectares, about 11% of the world's land area. Dry soybeans are 37% protein by weight. Multiplying these three figures together, if all current arable land were continuously planted in soybeans at current average soy yields, the world would produce 1.4×10^{13} kg of soybeans per year, containing 5.2×10^{12} kg of protein, 680 kg of protein per person, or 1.87 kg per person per day — about 7500 kcal of protein per person per day.

However, soybeans are also 18% fat by weight, which would add another 910 g of fat per day per person, 8200 kcal, for a total carbohydrate-free yield of 15700 kcal. This is about six or seven times the human daily caloric requirement.

It seems likely that the yields from other arable land not currently cultivated in soy would be lower than current average soy yields, and also that sustainable farming practices would reduce yields modestly further. However, it seems unlikely that this would reduce yields by the factor of six that would be needed to make a zero-carbohydrate diet economically unsustainable.

Of course, soybeans also contain carbohydrates (30% by weight), but you can remove those before you eat them.

The reason that agriculturally produced food appears scarce is that most of it is fed to livestock, which converts most of it into manure. There are more efficient ways of removing carbohydrates from soybeans than feeding it to chickens or cows.

There may be a way to produce more protein per hectare than growing soybeans, but I don't know of it; the reason soybeans are currently such an important crop is that they are the favored protein source for fattening up livestock.

Notes on reading eForth 1.0 for the 8086

Kragen Javier Sitaker, 2007 to 2009 (5 minutes)

These are notes on the original 8086 eForth model, eForth 1.0 by Bill Muench and C. H. Ting, 1990.

The assembly-language parts of eForth are:

- the colon header on each colon word: NOP; CALL DOLST
- the $NEXT macro: LODSW; JMP AX
- the boot code ORIG, 14 instructions
- The following 31 primitive FORTH words; their instruction counts include $NEXT where applicable:

```
;   BYE     ( -- )
;       Exit eForth.
        1 instruction.

;   ?RX     ( -- c T | F )
;       Return input character and true, or a false if
;       no input.
        16 instructions.

;   TX!     ( c -- )
;       Send character c to the output device.
        8 instructions.

;   !IO     ( -- )
;       Initialize the serial I/O devices.
        2 instructions.

;   doLIT   ( -- w )
;       Push an inline literal.
        4 instructions.

;   doLIST  ( a -- )
;       Process colon list.
        6 instructions.

;   EXIT    ( -- )
;       Terminate a colon definition.
        5 instructions.

;   EXECUTE ( ca -- )
;       Execute the word at ca.
        2 instructions.

;   next    ( -- )
;       Run time code for the single index loop.
;               i.e. FOR-NEXT, usually known as DO-LOOP.
        9 instructions.
```

```
;   ?branch ( f -- )
;       Branch if flag is zero, sometimes called _IF or
;       (IF)
        9 instructions.

;   branch  ( -- )
;       Branch to an inline address, sometimes called
;       _ELSE or (ELSE).
        3 instructions.

;   !       ( w a -- )
;       Pop the data stack to memory.
        4 instructions.

;   @       ( a -- w )
;       Push memory location to the data stack.
        4 instructions.

;   C!      ( c b -- )
;       Pop the data stack to byte memory.
        5 instructions.

;   C@      ( b -- c )
;       Push byte memory location to the data stack.
        6 instructions.

;   RP@     ( -- a )
;       Push the current RP to the data stack.
        3 instructions.

;   RP!     ( a -- )
;       Set the return stack pointer.
        3 instructions.

;   R>      ( -- w )
;       Pop the return stack to the data stack.
        4 instructions.

;   R@      ( -- w )
;       Copy top of return stack to the data stack.
        3 instructions.

;   >R      ( w -- )
;       Push the data stack to the return stack.
        4 instructions.

;   SP@     ( -- a )
;       Push the current data stack pointer.
        4 instructions.

;   SP!     ( a -- )
;       Set the data stack pointer.
        3 instructions.

;   DROP    ( w -- )
```

```
;       Discard top stack item.
        3 instructions.

;   DUP     ( w -- w w )
;       Duplicate the top stack item.
        4 instructions.

;   SWAP    ( w1 w2 -- w2 w1 )
;       Exchange top two stack items.
        6 instructions.

;   OVER    ( w1 w2 -- w1 w2 w1 )
;       Copy second stack item to top.
        4 instructions.

;   0<      ( n -- t )
;       Return true if n is negative.
        5 instructions.

;   AND     ( w w -- w )
;       Bitwise AND.
        6 instructions.

;   OR      ( w w -- w )
;       Bitwise inclusive OR.
        6 instructions.

;   XOR     ( w w -- w )
;       Bitwise exclusive OR.
        6 instructions.

;   UM+     ( w w -- w cy )
;       Add two numbers, return the sum and carry flag.
        9 instructions.
```

That's 157 instructions worth of primitives in all, in 31 primitives, plus 14 more instructions in the boot code. The rest of the system is written in Forth. It would be about 31 fewer instructions if there were a central NEXT instead of an indirect jump on the end of each word.

I don't have an assembler that can assemble it or a disassembler that can disassemble the compiled version, but if it's similar to Bill Muench's updated "8086 eForth ITC16i 971014.1", there should be about 4.3 bytes per instruction, which would make this a 675-byte kernel of an interpreter. (That later Forth also has CHAR+, CHAR-, CHARS, CELL+, CELL-, CELLS, and REDIRECT as primitives, but omits lower-case next.)

The 161 high-level FORTH colon definitions in EFORTH.SRC are another 3078 words of text (according to wc) and so are probably about another 6000 bytes. There's an 8814-character span of NULLs in the middle of the .COM file, which totals 15600 bytes, leaving 6786 bytes that might be meaningful; this is pretty close to my estimate of 6675 bytes. (Which leaves out the user variables and so on.)

If we use token threading, 3078 words of text are probably closer to

3000 bytes, but the token table is another 1024 bytes.

To implement the I/O stuff on Forth on Linux, we'd probably want to implement a "syscall" word in machine language taking up to 6 arguments (because we need select() for ?RX, and it takes five arguments) that makes an up-to-5-argument system call. Apparently the parameters go into %ebx, %ecx, %edx, %esi, and %edi, in that order, according to my disassembly of select.o from my libc.a.

In a direct-threaded system, there's a few bytes extra penalty for colon definitions --- probably five.

"unnecessary" primitives here include: "next" (the lowercase looping one) R> 1- >R I 0= (IF) R@ R> DUP >R or : R@ R> R> TUCK >R >R ; over : over >R DUP R> SWAP ;

That is, it would be possible to avoid defining them as primitives.

The 24 different instructions used are NOP, CALL, LODSW, JMP, MOV, CLI, STI, INT, CLD, IRET, XOR, JZ, OR, JNZ, PUSH, POP, CMP, XCHG, JC, SUB, ADD, CWD, AND, and RCL.

Fast secure pubsub

Kragen Javier Sitaker, 2019-02-04 (updated 2019-12-03) (2 minutes)

Suppose you want to implement a fast, secure publish-subscribe ("pub-sub") service. What if you package your message transformation and filtering code into individual processes that run and produce a result?

The idea is that Turing-complete rules provided by the sender, the receiver, and possibly intermediate routing entities run in very-short-lived ephemeral processes which have relevant information mapped into their memory space. Even on Linux, it's possible to spawn off 7000 processes per second; we should be able to do better with a custom kernel, and for example Fastly's Lucet WebAssembly runtime "can instantiate WebAssembly modules in under 50 microseconds", thus potentially permitting the creation of some 20,000 "processes" per second per core. Processes that exceed their CPU allocation are ruthlessly killed.

Processes running sender-supplied code can be run with access to information about potential recipients to prevent insensitive recipients from seeing sensitive information, and then they can be killed to prevent them leaking information about the potential recipients either to the sender or to other recipients. Processes running receiver-supplied code can inspect relevant aspects of the message to decide whether or not to pass the message along — either whole or in some summarized form.

If access to the message is provided not via memory-mapping but via some kind of recordable API, a recipient-provided Turing-complete selection function that is careful not to inspect more message fields than needed can implicitly produce a memoized filter rule in a supervisory process. For example, if the filter function inspects a "newsgroup" field, finds that its value is "alt.sex", and then rejects the message without inspecting further fields, then the supervisory process can memoize a filter rule: `[{"newsgroup": "alt.sex"}, "reject"]`. Perhaps it can construct a trie on known values of "newsgroup" and only actually invoke filter functions whose results are not already recorded in the trie — perhaps they inspected an additional field, for example, or perhaps there are values of "newsgroup" that have not previously been seen.

This is very similar to how transactional memory observes the reads being executed by the code in a transaction in order to be able to safely detect update conflicts.

I think this is a particular application of Umut Acar's "self-adjusting computation".

Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels

Kragen Javier Sitaker, 2019-08-31 (updated 2019-09-08)
(28 minutes)

On the bus, thinking about vision, there occurred to me a simple way to convolve an image with a fairly precisely approximated (real) Gabor filter or Morlet wavelet, in fixed point, with no multipliers, and a cascade of a small number of sparse FIR and IIR filters. This is probably known, but not to me.

Gabor filters

The general form of a Gabor wavelet in two dimensions has five parameters: an angle θ, a wavelength λ, a phase ψ, a radius σ, and an aspect ratio γ.

WIKIPEDIA SAY

$$g(x, y;\ \lambda, \theta, \psi, \sigma, \gamma) = \exp(-(x'^2 + \gamma^2 y'^2)/(2\sigma^2)) \exp(i(2\pi x'/\lambda + \psi))$$

where

$$x' = x \cos\theta + y \sin\theta$$
$$y' = -x \sin\theta + y \cos\theta$$

Here the first exp gives you the Gaussian envelope and the second exp gives you the oscillation. As you might or might not guess, its Fourier transform is *also* a Gabor wavelet.

You convolve this thing with an image and it detects edges at its given angle at or near its given frequency, in the area selected by its Gaussian window, which is nearly zero when you reach displacements of several times σ, or σ/γ^2 in the y' direction.

Sparse approximations

As mentioned in Sparse filters (p. 834), I'm looking for ways to get good approximations of convolution filters using networks of small, sparse kernels, to reduce the total amount of computation. In particular I'm interested in Hogenauer filters, which is discussed in Some speculative thoughts on DSP algorithms (p. 2590), Recurrent comb cascade (p. 483), and Cheap frequency detection (p. 3026), The Bleep ultrasonic modem for local data communication (p. 966), and similar things. In Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679) I describe how you can use precise resonators that are not only non-FIR but non-BIBO to very efficiently compute precise finite infinite response filters, and I'll use that here.

I think a sparse Gabor-filter approximation is particularly interesting because of the filter's importance and because of its relatively great computational cost. (But maybe someone already knows this algorithm.)

Overview

The filter is a composition or pipeline of five major stages, each composed of a cascade of small, sparse linear filters. Because of the convenient properties of convolution, the order of all of the individual pieces can be reordered as desired, and in particular if you're computing several different Gabor filters over the same image with some parameters in common, it may be desirable to move stages that are in common between them to the beginning of the processing pipeline.

The stages are a resonating feedback comb to create the oscillations, an oscillation window to confine them to a Gaussian along the direction of oscillation, a low-pass filter along the direction of oscillation to remove frequencies higher than the desired frequency, an antialiasing filter to deal with pixels a fraction of a sample off the oscillation axis, and a transverse window blur to spread the impulse response along a Gaussian at right angles to the direction of resonation.

In what follows, I will suppose that the angle θ can be adequately approximated as a ratio of small integers, as examples of which I will use 3 and 4: we are looking for waves whose phase varies not at all in the direction $(x+3, y-4)$, and varies fastest in the direction $(x+4, y+3)$. Below I will refer to this (4, 3) displacement as the "stride". And I will suppose that the wavelength λ we're looking for can be adequately approximated as an integer multiple of *twice* that displacement; that is, at some integer n, $(x+8n, y+6n)$ has a phase precisely 2π advanced from the phase at (x, y). There are some tricks to handle waves of other wavelengths, but they are not as well developed.

The resonating feedback comb and oscillation window

To window the resonance over a given distance, we first use a feedback comb filter whose impulse response is an infinite non-decaying oscillation:

$$y[i, j] = x[i, j] - y[i-4n, j-3n]$$

That is, the pixel (i, j) of the output y is the corresponding pixel $x[i, j]$ of the input, minus a *previous output pixel* positioned exactly half an oscillation away along the line of oscillation, at $(i-4n, j-3n)$. You can easily verify that the impulse response of this filter is an alternating sequence of positive and negative impulses leading away from the impulse in the desired direction of oscillation.

To tame this wildly unstable filter, we simply use a window over some finite number m of oscillations, a *feedforward* comb filter; here our x input is the y output of the previous filter:

$$y[i, j] = x[i, j] - x[i - 8nm, j - 6nm]$$

When using exact arithmetic, the composition of these two filters has a finite impulse response; in its impulse response, the alternating positive and negative impulses generated by the first filter continue on for m oscillations, then are canceled completely and precisely by the subtraction.

This alternating impulse train contains our desired spatial frequency as well as all of its odd harmonics, and the second filter just brutally windows it with a rectangular window after some integer number of oscillations. The first, feedback, comb filter plays the role

of the integrator in a Hogenauer downsampling CIC filter, while the second, feedforward, comb plays the role of the comb in the Hogenauer filter.

Unlike the integrator in a Hogenauer filter, the response of the feedback comb at DC is identically 0, and its amplification factor for frequencies that don't precisely align with its resonant frequency is finite; it only fails to act BIBO if the input data actually does contain nonzero energy at precisely the resonant frequency (necessarily over infinite space, at least in one direction). So you might be able to get reasonable results using floating point, but there are no guarantees there.

That window doesn't look very Gaussian yet, so to fix that, we repeat the process two or three more times, for a total of six to eight atomic kernels each consisting of a single subtraction. The window will have the most Gaussian shape if m remains the same in all of the stages, but this trades off against undesirable quantization in the available window sizes.

This is one of the places where you have a little flexibility to go beyond the limitations of the basic method; you can use resonators in slightly different directions and frequencies to get an intermediate overall direction and frequency of oscillation. But the windowing functions must be matched to those precise strides to prevent the overall system impulse response from becoming infinite.

The oscillation-axis low-pass filter

The above is not yet satisfactory for two reasons. First, we still have the odd harmonics to deal with — the third, fifth, seventh, and so on — which are exactly the same amplitude as the fundamental, since it's an impulse train. Second, aside from those harmonics, looked at precisely along the oscillation axis, the two stages described above give us a very nice Gabor wavelet, but at any other angle it looks like an impulse — all frequencies pass unchanged.

For these two purposes, we need to do some low-pass filtering, some of which is transverse to the oscillation axis and is what gives us the roundness or ellipticity of our two-dimensional Gaussian window, and some of which is parallel to it. And in particular, if it's possible, we may want to use another feedforward comb filter to stab the third harmonic in the heart precisely, because it's going to be the most troublesome harmonic to handle with general-purpose low-pass filtering, since it's only 1.58 octaves above the fundamental, and a filter with its first precise zero at that harmonic will suppress it completely, as well as most of its spectral leakage. The fifth harmonic is 2.3 octaves above the fundamental, so a generic low-pass filter can separate it from the fundamental pretty easily.

Our fundamental has a period $(8n, 6n)$, so our third harmonic has a period $(⅓8n, ⅓6n)$. We can either subtract pixels at this displacement or add pixels at half this displacement $(¼4n, ⅓3n)$ to completely suppress the third harmonic. If these offsets are not precise, for example because $4n$ isn't divisible by 3, the suppression won't be precise either, and a lot more of the third harmonic will survive to be dealt with by the other more generic low-pass filtering. (But we'll get a little bit of bonus transverse low-pass filtering.)

So the simplest form of our heart-stabbing filter would look like this:

$y[i, j] = x[i, j] + x[i - \frac{1}{34}n, j - \frac{1}{33}n]$

That taken care of, we can proceed to the oscillation-axis low-pass filter, which is mostly important if n is larger than 2 or 3. Suppose $n = 5$; now a period of the full oscillation is (40, 30). We can use an orthodox Hogenauer filter along the axis of oscillation to suppress harmonics higher than the third; first an integrator (calculating a prefix sum along each strided diagonal, also known as a sum table, scan, or integral image):

$y[i, j] = x[i, j] + y[i - 4, j - 3]$

and then a feedforward comb of, for example, two strides:

$y[i, j] = x[i, j] - x[i - 8, j - 6]$

This amounts to a rectangular window, whose frequency response is a sinc; its first null is where a full oscillation fits precisely into the window, which in this case would be a period of (12, 9). It has a 6 dB per octave frequency rolloff.

We probably want a better rolloff than that; if we repeat it two more times, we get 18 dB per octave, which attenuates the fifth harmonic by almost 42 dB, and higher harmonics by more.

The usual CIC-filter concerns about passband flatness don't apply here, since we are only trying to select a single frequency and frequencies very close to it.

At higher spatial frequencies, as long as the stride is a pair of integer number of pixels, the higher harmonics disappear because they alias harmlessly back down into the lower harmonics.

So the oscillation-axis low pass filters end up being seven more filter stages each consisting of a single addition or subtraction. But, as we see in the next section, we will reduce this to five.

The antialiasing filter

So far, pixels have only ever been combined with other pixels at a multiple of the basic stride (4, 3) from them. This means that every pixel in the first three lines of an image is in a separate, noninteracting signal, so far; even very high-frequency components will survive and may be aliased down. We'd like to sort of "fill in" the other pixels, at least along the axis of oscillation, rather than skipping over them completely as if they belonged to an entirely different image.

There are a variety of different ways this can be achieved. For example, we could use a couple of simple feedforward combs to get reasonably good fill-in without widening the line of the OTF much:

$y[i, j] = x[i, j] + x[i-1, j-1]$
$y[i, j] = x[i, j] + x[i-2, j-1]$

But let's not do that; we can perhaps get a bit more mileage out of the antialiasing filter in the case where the oscillation wavelength and both dimensions of the Gaussian window and are much larger than this; we could use, for example, a simple Gaussian blur, which also takes some of the load off the low-pass filter along the oscillation axis. Again, this can be done as an orthodox Hogenauer or CIC or box filter, but this time on the usual pixel rows and columns:

$y[i, j] = x[i, j] + y[i-1, j]$
$y[i, j] = x[i, j] - x[i-8, j]$
$y[i, j] = x[i, j] + y[i, j-1]$
$y[i, j] = x[i, j] - x[i, j-6]$

The cascade of those four filters has an impulse response of an 8x6

constant-1 rectangle, and in particular it has the same low-pass effect along the axis of oscillation as the $-x[i - 8, j - 6]$ filter proposed in the section above, as well as providing antialiasing fill-in along the axis of oscillation and some amount of transverse window. If you were to iterate this filter two more times you would have a second-order approximation to a squished Gaussian, but let's not — let's just run it once more and be satisfied, and reduce the high-pass filtering from the previous section by one filtering stage.

So this stage is a cascade of eight tiny kernels, each consisting of a single addition or subtraction.

Since this, in effect, reduces the resolution of the image, it might be wise to do it early on in the pipeline and then decimate the image so that later stages can run much faster, operating on a reduced-resolution image.

The transverse window blur

So at this point our impulse response is a fairly precise sinusoidal oscillation along the correct axis, with a fairly precise Gaussian envelope along that axis, and some sort of relatively crude smooth falloff about 10 pixels to either side of that axis. Now we want to widen out that transverse axis into a Gaussian envelope, either round or elliptical; the existing falloff may help us a bit, but we still need to widen it out considerably.

We can do this with, again, a strided CIC filter, consisting of a cascade of an integrator and a feedforward comb, but this time along the transverse axis, using a stride rotated 90 degrees:

$$y[i, j] = x[i, j] + y[i - 3, j + 4]$$
$$y[i, j] = x[i, j] - x[i - 3p, j + 4p]$$

Here p gives the number of strides in the width of (one stage of) our window, as nm gave the dimension of the Gaussian window in the perpendicular direction.

Because of the existing falloff, we may be able to get away with one more stage of this CIC filter at this point, but we'll probably need two more.

The direction of blurring can be chosen as either (-3, 4) or (3, -4); I chose the first here in order to use previous scan lines rather than previous columns, in the interest of making pipelining possible (see below.)

So implementing the transverse window requires another six stages, each consisting of an addition or subtraction.

Summary

The overall Gabor filter, then, requires a cascade of around $8 + 5 + 8 + 6 = 26$ stages, each performing a single integer addition or subtraction, followed by some final scaling by a constant. This is quite small compared to the millions of pixels in the support of the approximate Gabor wavelet that is the system's finite impulse response, although downsampling the image on its way into the pipeline would reduce this disparity somewhat.

Python smoke test of the algorithm

I did try it in IPython tonight (notebook viewer), and got a pretty round-looking kernel with $n = 5$, $m = 3$, $p = 30$, and the (4, 3) stride suggested above. In plots it looks just fine, but of course that's not

strong evidence. I haven't calculated its error (that would require figuring out the diameters of the Gaussians), but I estimate that in essentially this form it should be able to deliver worst-case errors of less than 1% (-40 dB) and average-case errors that are smaller still.

The code in the notebook boils down to something like this very crude code, with all but the last plot stripped out:

```
from numpy import zeros, dtype
from matplotlib import imshow, colorbar

n = 5
m = 3
p = 30

impulse = zeros((700, 700), dtype=dtype('float16'))
impulse[300, 100] = 1.0
ir1 = impulse.copy()
for i in range(4*n, len(ir1)):
    ir1[i, 3*n:] -= ir1[i-4*n, :-3*n]
fr1 = ir1.copy()
for i in range(8*n*m, len(fr1)):
    fr1[i, 6*n*m:] -= ir1[i-8*n*m, :-6*n*m]
ir2 = fr1.copy()
for i in range(4*n, len(ir2)):
    ir2[i, 3*n:] -= ir2[i-4*n, :-3*n]
fr2 = ir2.copy()
for i in range(8*n*m, len(fr2)):
    fr2[i, 6*n*m:] -= ir2[i-8*n*m, :-6*n*m]
ir3 = fr2.copy()
for i in range(4*n, len(ir3)):
    ir3[i, 3*n:] -= ir3[i-4*n, :-3*n]
fr3 = ir3.copy()
for i in range(8*n*m, len(fr3)):
    fr3[i, 6*n*m:] -= ir3[i-8*n*m, :-6*n*m]
hs = fr3.copy()
for i in range(int(4*n/3), len(hs)):
    hs[i, 3*n/3:] += fr3[i-int(4*n/3), :-3*n/3]
ai1 = hs.copy()
for i in range(4, len(ai1)):
    ai1[i, 3:] += ai1[i-4, :-3]
ff1 = ai1.copy()
ff1[8:, 6:] -= ai1[:-8, :-6]
ai2 = ff1.copy()
for i in range(4, len(ai2)):
    ai2[i, 3:] += ai2[i-4, :-3]
ff2 = ai2.copy()
ff2[8:, 6:] -= ai2[:-8, :-6]
bf1i = ff2.copy()
for j in range(1, len(bf1i[0])):
    bf1i[:, j] += bf1i[:, j-1]
bf1c = bf1i.copy()
bf1c[:, 8:] -= bf1i[:, :-8]
bf2i = bf1c.copy()
for j in range(1, len(bf2i[0])):
    bf2i[:, j] += bf2i[:, j-1]
```

```
bf2c = bf2i.copy()
bf2c[:, 8:] -= bf2i[:, :-8]
bf3i = bf2c.copy()
for i in range(1, len(bf3i)):
    bf3i[i] += bf3i[i-1]
bf3c = bf3i.copy()
bf3c[6:] -= bf3i[:-6]
bf4i = bf3c.copy()
for i in range(1, len(bf4i)):
    bf4i[i] += bf4i[i-1]
bf4c = bf4i.copy()
bf4c[6:] -= bf4i[:-6]
tvi1 = bf4c.copy()
for j in range(4, len(tvi1[0])):
    tvi1[:-3, j] += tvi1[3:, j-4]
tvc1 = tvi1.copy()
tvc1[:-3*p, 4*p:] -= tvi1[3*p:, :-4*p]
tvi2 = tvc1 / 256
for j in range(4, len(tvi2[0])):
    tvi2[:-3, j] += tvi2[3:, j-4]
tvc2 = tvi2.copy()
tvc2[:-3*p, 4*p:] -= tvi2[3*p:, :-4*p]
tvi3 = tvc2 / 256
for j in range(4, len(tvi3[0])):
    tvi3[:-3, j] += tvi3[3:, j-4]
tvc3 = tvi3.copy()
tvc3[:-3*p, 4*p:] -= tvi3[3*p:, :-4*p]
imshow(tvc3[200:500, 300:600], origin='lower'); colorbar()
```

Reducing memory usage

As is standard practice, you can pipeline these stages (see Evaluating DSP operations in minimal buffer space by pipelining (p. 321)) so that you don't need 26 modified copies of the entire image floating around in memory (some at increased precision). But doing this in the straightforward way, scan line by scan line, you still need a pretty big buffer to do this in, because some of the 26 stages need to look pretty far back into the past. If we suppose $n = 5$, $m = 3$, and $p = 60$, for example, the number of scan lines of memory needed is as follows:

stage	scan lines	$y[i, j] = x[i, j] +$
resonator 1	15	$-y[i - 4n, j - 3n]$
oscillation window 1	90	$-x[i - 8nm, j - 6nm]$
resonator 2	15	
oscillation window 2	90	
resonator 3	15	
oscillation window 3	90	
resonator 4	15	
oscillation window 4	90	
heart-stabbing filter	5	$x[i - \frac{1}{34}n, j - \frac{1}{33}n]$
axis LPF integrator 1	3	$y[i - 4, j - 3]$
axis LPF comb 1	6	$-x[i - 8, j - 6]$
axis LPF integrator 2	3	

axis LPF comb 2 6
antialias filter 1 7 (4 kernels) $y[i-1,j]$; $-x[i-8,j]$; $y[i,j-1]$; $-x[i,j-6]$
antialias filter 2 7 (4 kernels)
transverse integrator 1 4 $y[i-3,j+4]$
transverse comb 1 240 $-x[i-3p,j+4p]$
transverse integrator 2 4
transverse comb 2 240
transverse integrator 3 4
transverse comb 3 240

Whew. That's 1189 scan lines of memory in total, plus some fractional scan lines I'm not considering. Is there any way to reduce this?

(Well, of course there's decimation. But I mean aside from decimation.)

I thought about tiling. It doesn't help, because you just switch from having to buffer previous scan lines to having to buffer previous rows of tiles. In fact it hurts a little because you can't discard fractional tiles. Maybe there's still a way for it to work but I don't see it.

I thought about maintaining resonator state in a different way, using per-pixel Minsky or Goertzel resonators, spatially shifted by varying integer amounts per scan line, rather than a feedback comb (which is basically a Karplus-Strong oscillator). This might help but it only saves you the memory needed by the resonator, which is relatively small compared to that needed to window the oscillations. And it makes the assertion about the precise cancellation of windowing more dubious, since I don't think there's a precise way to calculate Minsky or Goertzel resonation. (See Using the Goertzel algorithm, the Minsky algorithm, PLLs, and prefix sums for frequency detection (p. 2679).)

I thought about using more stages for the transverse window. That will give you a more precise Gaussian but uses more memory, not less.

If you try to use exponential blur for the transverse blur instead of an honest Gaussian blur, you completely lose not only finite impulse response but also zero-phase behavior. To get zero-phase behavior back you need to do a second pass backwards, which requires keeping the whole result image in memory instead of just part of it.

Multiple Gabor sharing

So, if you're going to do a bunch of Gabor convolutions on the same image, what parts of the pipeline should you share between them?

The most computationally intensive (heh) parts of the pipeline are those dependent on the frequency and the angle: the resonating feedback comb, the oscillation-axis low-pass filter, and (more loosely) the antialiasing filter. These depend on λ and θ, but not σ or γ. It might make sense to move these stages, as well as the transverse blur's integrators, to the beginning of the pipeline so that they can be shared between different window sizes and shapes, running the oscillation window and the transverse blur window later, which are only six of the 26 stages. This probably is not practical to do in floating-point because of the large magnitudes needed to feed the Hogenauer-style

cascade of six windowing combs.

The antialiasing filter is applicable over an octave or so of frequencies at any angle (although in the above example it's a bit longer in one direction than the other), and the transverse-blur integrators are applicable for any frequency at a given angle. They can't both go first, though; putting the antialiasing filter first is probably better because it allows you to decimate the image immediately.

Dealing with invalid pixels ("NA")

Sometimes we can identify certain pixels as containing invalid data — for example, they don't work on the sensor, or they're suffering salt-and-pepper noise in this frame, or they're saturated (perhaps due to a lens flare). Some numerical-computation environments have special facilities for such situations; Octave and R have "NA", while Numpy has "masked arrays" which support most of the same operations as ordinary arrays.

Dealing with such invalid pixels is a particularly tricky problem for FFT-based convolution algorithms, since the structure of the FFT doesn't have a reasonable way to incorporate validity information. R's `fft` function, for example, will simply return an array of NA values if asked to transform an array with a single NA value in it. Octave, by contrast, returns an array whose values are NA only in the phase or phases affected by the NA value — so they may have a NA real magnitude, a NA imaginary magnitude, or both. In either case, you can't use FFT convolution on a signal containing even a single invalid pixel; the signal comes back entirely NA.

By contrast, a direct implementation of convolution has three straightforward ways to handle NA values: it can propagate them to the affected neighborhood, turning each single NA pixel into a giant NA hole in the result; it can omit the NA pixels from the weighted sum, increasing the weights on the other pixels to compensate, unless all pixels with nonzero weight are NA; or it can switch between these two strategies at some threshold of invalidity, such as 50%. (Both Octave's `conv` and R's `filter(method='convolution')` take the first approach.)

This kind of sparse filtering using two-input kernels could take any of these three approaches, but in the recursive case (integrators) any of them would lead rapidly to disaster. Probably in that case the least bad approach is to treat NA pixels as 0 in recursive filters.

Conclusions

Well, really, beginnings... but it seems like this approach to approximating convolution with a Gabor wavelet probably works and probably is efficient (although my IPython notebook prototype certainly is not). It provides obvious ways to set five of the six parameters, but not ψ, the phase offset. This is a little alarming because without the phase offset there's no way to get the *complex* Gabor wavelet. It would be surprising if there turned out to be no way to do this, but none is obvious to me at the moment.

(The issue is that you want to phase-shift the oscillation by a quarter cycle, but without moving the Gaussian window along with it. Maybe the solution could be something as simple as a differentiator in the direction of oscillation, perhaps by a half cycle,

and a compensating constant factor.)

Among the possible applications are approximating an arbitrary convolution kernel as a sum of Gabor wavelets. One possible approach to this is analyzing it in different directions and at different scales using the Gabor transform or the one-dimensional wavelet transform with the Morlet wavelet, choosing a sparse subset of these basis functions that could possibly approximate the target kernel well, then optimizing the weights of that sparse subset further, under a loss function that drives small weights toward zero.

Moreover, there's no particular reason to limit yourself entirely to Gabor wavelets when optimizing that approximation; you can include other kernels that can be computed efficiently using such sparse cascades, such as separable kernels (see The miraculous low-rank SVD approximate convolution algorithm (p. 747)), flat and especially polygonal kernels (see Real-time bokeh algorithms, and other convolution tricks (p. 2661)), and, using the techniques used above to propagate the Gabor's oscillation along a line, line segments.

Another possible application is the design of transmission-line RF filters, including stripline/microstrip transmission lines built into printed circuit boards, and waveguide filters — though I'm not sure how much that will buy you, given the need for matching networks to interconnect the signal paths. An open-ended transmission line spur is in some sense a unity-positive-weight feedforward comb filter whose lag is twice the length of the line, while a closed-ended one amounts to a unity-negative-weight feedforward comb filter, similarly.

Replicating education

Kragen Javier Sitaker, 2017-07-19 (7 minutes)

Education is broken; people don't learn much, it takes them a very long time to learn it, they forget most of it, and then they don't generalize. It's tempting to attribute this to people being stupid, and clearly that's a condition of the problem space, but it's no excuse for not solving the problem.

Lectures are terrible

The medieval lecture model we use is partly to blame. It originated as a kind of mass production for books: the reader reads from one copy of the book while the audience notes down verbatim everything they say. As manual methods of making many copies of a text go, this is quite efficient, but once the number of copies goes past 500 or so, the printing press is far more efficient.

Sadly, this model survived the introduction of the printing press and even the xerox, continuing to this day in many classes, in which the pupils waste precious attention they could spend assimilating the material on copying it instead, as if they didn't have smartphones in their pockets capable of copying documents over Bluetooth at hundreds of pages per second.

Nowadays the goal of lectures is not really making copies of written material, but transferring knowledge from the mind of the lecturer into the minds of the students, at its best leavened with some entertainment or practical demonstrations to clarify the abstract concepts. But it is a terribly inefficient way of achieving this kind of knowledge transfer; it's roughly as effective as reading a textbook [citation needed] but consumes the time of the lecturer as well as imposing expensive coordination costs on the lecturer and students, who must not only arrive at the lecture hall together but also pause to think together if they are to have a chance of understanding the material.

(In British universities, the rank below Professor, equivalent to US "professor", is in fact "Reader", followed by "Lecturer", which is a mangled French word that also means "reader".)

As a means of inspiring enthusiasm, however, lectures are almost unmatched; only music, movies, sports, and blood rituals seem to be able to compete, and of these all except music are much more costly. So lecturers often opt for lectures in order to manipulate their audiences emotionally, usually to further the interests of the lecturer (for example, persuade colleagues that their research interests are worthwhile, or to whip up political sentiment) but occasionally in the interests of the audience.

Sadly, nowadays our lectures are quite often afflicted with slide decks full of text. While these are of some communicational benefit when a language barrier separates the lecturer from their audience, far more often, they further reduce the bandwidth of information transfer while vitiating the lecture's most signal virtue, that of inflaming the passions.

Knowledge transfer

Learning depends, of course, on many other factors beyond knowledge transfer. For example, you need problem sets to guide students to construct their knowledge, you need some kind of feedback loop to make sure that the students aren't learning errors as fact, you need spaced practice to prevent the loss of knowledge to disuse, and you need motivation to interest the students in the knowledge. But in what follows I'm focusing on purely the knowledge-transfer component of the education process.

Bligh's book *What's the Use of Lectures?* and Armstrong's Natural Learning in Higher Education go into more detail on what lectures are good for and how to promote better lectures. But I come not to praise lectures but to damn them, to damn them to Hell forever.

This is because reading a textbook and attending a lecture are far from the fastest or most thorough means of learning. In numerous controlled studies students progress about two standard deviations faster with a dedicated one-on-one tutor than with traditional classes. (I think this means about 30% faster.)

You could argue, though, that one-on-one tutoring is too expensive, and can only be justified when the goal of knowledge distribution is light (i.e. it is desired for a small number of students to learn the material) or the benefits of transferring the knowledge are so great that it justifies occupying the time of a large number of skilled tutors who could be practicing the knowledge rather than transferring it. Bloom does in fact argue this: "...more practical and realistic conditions than the one-to-one tutoring, which is too costly for most societies to bear on a large scale."

However, this is not in fact the case. Most lecture classes only lecture to about 24 listeners, the majority of whom (let's say ⅔) do not learn the material well enough to teach it. Of those who do, almost none are allowed to teach the material for some three or four years.

If we track the number of people to whom the knowledge has been transferred over time, it can grow exponentially in this model, but it works out to a doubling time of a year or a bit more.

By contrast, in the "one-room schoolhouse" model, the teacher mostly teaches the most advanced students, who teach the less advanced students, who teach those who are less advanced still. The process of teaching what you have recently learned serves both as a check to unmask the pernicious fluency illusion and as additional practice time. Typically in the schoolhouse, according to rumor, this also achieved a doubling time of around a year.

But we could do much better; the crucial question is how short a time you have between mastering a lesson and having to teach it to someone else. If, for example, you study a lesson one week, balanced half-and-half between working with a tutor and doing exercises on your own, and act as a tutor in that lesson to two other people in the next week, then the doubling time could be under a week. (During the first week you were presumably teaching the previous lesson to two other people during the hours that you weren't studying the new lesson.)

Even if one-on-one tutoring were only as effective as attending lectures, this model would still defeat it; only four weeks after tutoring the two initial students, you'd have $2+4+8+16 = 30$ students already up to speed on it.

Other Benefits of Tutoring

Bloom points out (in his paper on the "2 Sigma Problem" I mentioned above) that tutoring also helps with focus (students spent 90% of time on task instead of 65%) and with positive attitude.

What's wrong with CoAP

Kragen Javier Sitaker, 2017-06-15 (3 minutes)

I've just read through a bunch of the CoAP RFCs (RFC 7252, say), and although it sounds like a workable protocol (and I know people are using it), it seems pretty suboptimal.

I may be coming at this from a kind of bad position given that I've written an HTTP server that's under 2K of code (albeit on top of Linux's TCP/IP stack), so I'm maybe a bit unsympathetic to arguments claiming that a more constrained protocol is needed for more constrained devices.

You're going to use X.509 certificates on devices with 10 kilobytes of RAM? You're mandating the secp256r1 curve? You're mandating AES? That's feasible, but AES is bigger than my entire web server, and let's hope none of your devices are unconstrained enough to have cache timing attacks on the S-boxes.

You have ETags, great — but If-None-Match can't accept one, so there's no way to revalidate your ETag-indexed cache with a conditional GET? No, wait, you just send an ETag option in your request, and it works like If-None-Match with an ETag does in HTTP.

The minimal CoAP packet size is pretty great, though.

Every path segment of up to 13 bytes needs only a single option-header byte with a 0 option-delta nybble, except for the first one, which will have an option-delta nybble of 11. That's pretty reasonable. And they're guaranteed to occur together in sequence. So actually you can get things pretty compact; here's a 16-byte request:

```
>>> m = aiocoap.Message(code=aiocoap.GET, mtype=aiocoap.CON, mid=1234)
>>> m.opt.uri_path = ('temperature',)
>>> m.encode()
b'@\x01\x04\xd2\xbbtemperature'
>>> len(_)
16
```

`\xbb` there is the pair of "11" nybbles, one of which is the length of "temperature". And the rest of the packet is just the four-byte header, whose first byte encodes version 1, type 0 (CONfirmable), and 0 bytes of token length TKL, and whose second byte is GET (0.01); the request for CONfirmation, and the message id (0x04d2). This packet (with a different message ID) is the first example in Appendix A.

Here's an encoding of `GET /~kragen/sw/dev3/zmqhello.c`:

```
>>> m.opt.uri_path = ('~kragen', 'sw', 'dev3', 'zmqhello.c')
>>> m.encode()
b'@\x01}4\xb7~kragen\x02sw\x04dev3\nzmqhello.c'
>>> len(_)
31
```

I mean, that's not too bad, is it? 31 bytes.

There are no byte-ranges. So you can't use it for partial retrieval. But that's probably just as well.

All the multicast stuff seems kind of poorly thought out, as well as all the security stuff. The "resource discovery" stuff makes it sound like they didn't really understand REST, but its application/link-format content-type is the only format that has a content-format number assigned that can reasonably contain links (assuming we discount XML XLink).

Allowing content-type sniffing even in the presence of an explicit content-format is a terrible idea.

I suspect that the duplicate-transaction problems that RFC 1644 T/TCP had due to lacking the three-way handshake may also afflict CoAP, although of course REST cuts down tremendously on such problems.

HTML is terser and more robust than S-expressions

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

HTML is more succinct for things in its intended domain than S-expressions, but still has better error-detection and correction capabilities.

S-expression fans like to say that HTML, SGML, and XML are just bastardized S-expression languages. SGML partisans often respond that matching end-tags allow for better error-reporting and correction. But for typical HTML content --- mostly running text with a little bit of interspersed markup --- S-expressions are not only harder to correct, but also more verbose.

Consider this partial paragraph from the Ur-Scheme web page http://pobox.com/~kragen/sw/urscheme:

```
<li><b>Reasonably fast.</b> It <b>generates reasonably fast
code</b> &mdash; when compiled with itself, it runs 2½ times
faster (in user CPU time) than when it's compiled with <a
href="http://www.call-with-current-continuation.org/"
>Chicken</a>, 1½ times faster than when it's compiled with...</li>
```

Now, in traditional HTML, I could have left out the quotes around the URL and the ending tag. Consider this S-expression version:

```
(li (b "Reasonably fast.") " It " (b "generates reasonably fast
code") " " mdash " when compiled with itself, it runs 2½ times
faster (in user CPU time) than when it's compiled with "
(a :href "http://www.call-with-current-continuation.org/"
"Chicken") ", 1½ times faster than when it's compiled with...")
```

Most of the markup constructs take up more characters here:

```
LI: '<li></li>'    (end tag could be omitted in traditional HTML)
    '(li "")'
B:  '<b></b>'
    '(b "") '
B:  '<b></b>'      (the second one)
    '" (b "") "'
--- '&mdash;'
    '" mdash "'
A:  '<a href=""></a>'  (quotes could traditionally be omitted)
    '" (a :href "" "") "'
```

If you look at this in a fixed-width font, you'll see that the number of markup characters is detectably smaller in the S-expression serialization of the structure, with the exception of the first two. I maintain that this is typical of the bulk of HTML, especially if you weight it by how often people write it instead of how often it gets sent to browsers. You can come up with examples where that is not the case:

```
<html><head> <title>...</title>
             <link rel="stylesheet" href="../../style.css" />
             <meta http-equiv="Content-Type" content="..." />
             <style type="text/css">...</style></head>...</html>
```

vs.

```
(html (head (title "...") (link :rel "stylesheet" :href "../../style.css")
            (meta :http-equiv "Content-Type" :content "...")
            (style :type "text/css" "...")))
```

but those structure-heavy, text-light examples with long-winded tag names are relatively rare for people to read and write.

Of course, the cost of terser syntax is often that errors are hard to diagnose. Ada's `end loop`, `end if`, `end record`, and so on mean that if you leave out an `end` delimiter, the compiler will usually be able to tell you which one you left out. At the opposite end of the spectrum, S-expression languages in which all the various kinds of `end` are spelled as `)` can only tell you when they get to the end of the program or to something that doesn't make sense in the current context.

This is not a phenomenon limited to end-delimiters. In programming languages, there are many other examples of verbosity that helps to diagnose errors; for example, explicit type declarations, mandatory delimiter characters (in cases where the syntax would be no more ambiguous if they were removed from the grammar), sequences of single-line comments, and the conventional parenthesization of the arguments of fixed-arity functions ("ratio square sin x square sin y" is perfectly unambiguous, after all, and Forth, PostScript, Logo, and REBOL use more or less that syntax.).

However, in the case of HTML, the terser syntax does not make errors harder to diagnose; in fact, the HTML syntax permits better error-detection and even error-correction, because all of the end-tags are explicitly labeled. (It differs from SGML in this regard; in SGML, you can write `<li><b/Reasonably fast./ It ...</>` and eliminate the redundant end-tags altogether.)

Entry-C: a Simula-like backwards-compatible object-oriented C

Kragen Javier Sitaker, 2015-04-05 (updated 2017-04-03) (24 minutes)

Entry-C is a Golang- and SIMULA-67-inspired design for adding object-orientation to C in a backwards-compatible fashion, unlike C++, while adding only a small amount of extra syntax. As with C++, it doesn't require garbage collection, it can be used to write allocation-free programs to ensure constant space usage, and only the language facilities you use will cost you anything at run-time. However, it is more flexible and potentially more efficient than C++.

Semantic overloading of existing language features can make it harder to report compiler errors usefully, because it increases the space of valid programs.

The mysterious `entry` keyword explained

The C language has a set of reserved words that cannot be used for identifiers (such as names for variables, fields, or types), such as `struct` and `if`, which are generally used as syntactic elements of the language. Among these, we find the curiosity `entry`, which is not used for anything; it's simply illegal in valid C programs, like a stray `@` or `` ` ``.

Presumably this was intended for defining functions with multiple entry points, which is an easy enough thing to do in assembly. For example, maybe you'd like to make an argument optional:

```
printf:  push $stdin
fprintf: ...
```

In general, multiple entry points give you a way to make a tail call to another function at a cost of zero instructions in code space and zero execution time. Here's an example tail call from http://canonical.org/~kragen/sw/netbook-misc-devel/nand.c:

```
int inputs_for_pattern(char *pattern) {
  char *s;

  for (s = pattern; *s; s++)
    if ((*s != '0') && (*s != '1') && (*s != 'x')) return 0;
  return log2_int(s - pattern);
}

int log2_int(int n) {
  int rv = 0;
  while (n > 1) {
    if (n & 1) return 0;        /* lousy error reporting, but whatever */
    rv++;
    n >>= 1;
  }
```

```
  return rv;
}
```

Presumably what the `entry` keyword was contemplated for was being able to write the above code more like this:

```
int inputs_for_pattern(pattern)
char *pattern;
{
  char *s;
  int n;

  for (s = pattern; *s; s++)
    if ((*s != '0') && (*s != '1') && (*s != 'x')) return 0;
  n = s - pattern;

  entry int log2_int(n);

  int rv = 0;
  while (n > 1) {
    if (n & 1) return 0;        /* lousy error reporting, but whatever */
    rv++;
    n >>= 1;
  }
  return rv;
}
```

If you remove the `entry` statement in the middle, this is valid C already; but presumably the idea of the `entry` statement is that you could, in a sense, enter in the middle of the function; the tail end of the function is a function in its own right.

This is a relatively minor micro-optimization in most contexts, and error-prone; and making the compiler smart enough that it's actually a win is kind of hard.

Activation-record objects: unifying structs with functions

SIMULA 67's big insight was that, in a way, a function call has a lot in common with an object. It has a set of variables and some code to run with access to those variables. The difference is that a function call has very strict sequencing constraints: first the space for the variables is allocated (and some of the variables are initialized), then the code is executed, and when it returns, the space is deallocated. A C++ object is, in some sense, the union of the features of a struct and a function call.

Nesting constructor code

Suppose we simply relax this constraint and blur the distinction between structs and functions. Then, instead of writing this code (adapted from http://canonical.org/~kragen/sw/inexorable-misc/simpleproxy.c):

```
struct pipe {
    struct pipe *next;
```

```
    struct pipe *partner;
    struct bufferevent *buf;
    int marked_for_deletion;
    int fd;
    char *error;
};

static struct pipe *
new_pipe(int fd)
{
    struct pipe *p = malloc(sizeof(*p));
    if (!p) {
        log_msg("malloc failed (%s)", strerror(errno));
        return NULL;
    }

    p->next = NULL;
    p->marked_for_deletion = 0;
    p->fd = fd;
    p->error = NULL;

    p->buf = bufferevent_new(fd, read_callback, NULL, error_callback, p);
    if (!p->buf) {
       p->error = "bufferevent_new failed";
       return NULL;
    }

    if (-1 == bufferevent_enable(p->buf, EV_READ | EV_WRITE)) {
        p->err = "bufferevent_enable failed";
        bufferevent_free(p->buf);
        return NULL;
    }

    return p;
}

static void
error_callback(struct bufferevent *bufev, short what, void *arg)
{
    struct pipe *p = arg;
    log_msg("error %d on conn %d", what, p->fd);
    mark_for_deletion(p);
}
```

we could write

```
struct pipe(int fd)
{
    struct pipe *next = NULL;
    struct pipe *partner;
    char *error = NULL;
    int marked_for_deletion = 0;
    struct bufferevent *buf = bufferevent_new(fd, read_callback, NULL,
                                              error_callback, &fd);
    if (!buf) {
```

```
        error = "bufferevent_new failed";
    } else if (-1 == bufferevent_enable(buf, EV_READ | EV_WRITE)) {
        error = "bufferevent_enable failed";
        bufferevent_free(buf);
        buf = NULL;
    }
};

static void
error_callback(struct bufferevent *bufev, short what, void *arg)
{
    struct pipe *p = arg;
    log_msg("error %d on conn %d", what, p->fd);
    mark_for_deletion(p);
}

static void
mark_for_deletion(struct pipe *p)
{
    /* ... */
}
```

This puts the initialization code for the struct inside the struct itself, leaving the allocation or deallocation up to the caller. It's clearly a win in terms of avoiding code duplication, but it has a few drawbacks.

It doesn't have a convenient way to report initialization errors, since it doesn't have a return value, and it also doesn't have convenient syntax like C++'s `this` to take the address of the object it's initializing, for use in registering the callback `error_callback` with libevent. Instead, it type-puns a pointer to the first parameter, which is implicitly stored in the struct, into a pointer to the struct as a whole — which will break with no compiler warnings if someone inserts a new parameter before `fd`.

Pointers to nested functions with trampolines

GCC implements Pascal-like nested functions, with access to the outer function's stack frame, using a small amount of runtime code generation, putting a small trampoline that pushes a pointer to the stack frame and then jumps to the function, into the stack frame itself. If we use that feature, we could simplify the above to the following:

```
struct pipe(int fd) {
    struct pipe *next = NULL;
    struct pipe *partner;
    char *error = NULL;
    int marked_for_deletion = 0;

    void error_callback(struct bufferevent *bufev, short what, void *arg)
    {
        log_msg("error %d on conn %d", what, fd);
        mark_for_deletion();
    }

    void mark_for_deletion()
```

```
    {
        /* ... */
    }

    struct bufferevent *buf = bufferevent_new(fd, read_callback, NULL,
                                              error_callback, NULL);
    if (!buf) {
        error = "bufferevent_new failed";
    } else if (-1 == bufferevent_enable(buf, EV_READ | EV_WRITE)) {
        error = "bufferevent_enable failed";
        bufferevent_free(buf);
        buf = NULL;
    }
};
```

Now, `error_callback` no longer needs an explicit pointer passed in, and indeed if libevent were written to require you to use runtime code generation to use basic functionality, `bufferevent_new` could take three parameters instead of five. This expands `struct pipe`'s space by the space needed to hold the trampolines.

GCC's regular nested function support generates functions that are only safely callable until the outer function returns, because both the outer function variables and the trampoline itself are stored on the stack. This design avoids that restriction, because the trampoline can be stored within the struct itself.

Invoking nested functions without trampolines

The only reason for the trampolines, though, is that we're converting nested-function pointers into regular function pointers, and then, instead of calling them immediately, we are passing them to a function that takes regular function pointers as parameters. The call to `mark_for_deletion` in the above code needs no such trampoline; neither does a call such as the following:

```
void invoke_error(struct pipe *p) {
    p->error_callback(NULL, 37, NULL);
}
```

The underlying `error_callback` function takes an extra hidden parameter that is a `struct pipe *`, and in this case we're passing that parameter explicitly.

If we adopt a rule that only code lexically within the struct declaration is permitted to convert nested-function pointers to regular C function pointers, then we can statically compute the set of nested functions that need trampolines generated for them, which will usually be empty.

Initializing objects

Normally you can initialize a statically-allocated or stack-allocated struct with an initializer list (from http://canonical.org/~kragen/sw/netbook-misc-devel/hanoitri.c:

```
typedef struct { int num, denom; } ratio;
static const ratio sin_60 = { 56755, 65535 };
```

It makes sense that you'd repurpose that same syntax to supply initializer arguments to struct types like `pipe` above that have declared constructor arguments. Also, as in C++, it seems convenient to allow you to just say `= x;` rather than `= { x };` in the case where there's just one argument.

But what about dynamically-allocated objects on the heap, or in an array or whatever?

I think the most harmonious approach is to define an additional coercion rule from lvalues that are structs with constructors, or pointers to structs with constructors, to function pointers. If you invoke such an lvalue as if it were a function, then it decays to a pointer to the constructor code, which has a void return value.

Thus, this will initialize element 5 of the array of pipes with the `fd` argument `fd0`, and element 6 with `fd1`, and give a compile error about a missing constructor argument on element 7:

```
struct pipe pipes[10];
pipes[5](fd0);
struct pipe *p = &pipes[6];
p(fd1);
pipes[7]();
```

The following will also give a compile error, because you're trying to invoke a constructor on a `struct pipe` rvalue, which is generally a useless thing to do:

```
struct pipe pipes[10];
struct pipe f() { return pipes[5]; }
f()(fd0);
```

This seems compatible with considering structs and functions merely slightly different versions of the same thing.

Temporary objects

In C++, if you have a `Rational` class, you can say

```
Rational seven_sixths = Rational(2, 3) + Rational(1, 2);
```

which (given the existence of the relevant constructors and overloads) constructs two or three temporary `Rational` objects and then destroys them (you might say "on the stack", although of course that's just one possible implementation). This is pretty handy, but the rules about the lifetimes of those objects are very tricky, and the syntax creates a conflict between the namespace of classes and the namespace of functions and variables. The interaction of this feature in C++ with the absence of sequence points between the constructors created a bug in most C++ programs where one constructor may be partly complete when the other throws an exception.

So, for the moment, I'm not adding temporary objects to Entry-C.

Ad-hoc polymorphism with dynamic dispatch with Golang-like interfaces

I've been claiming Entry-C was a "backwards-compatible object-oriented C", but so far all I've given is a way to avoid writing

a separate initialization function for your structs and a little syntactic sugar to define functions that operates on them more conveniently. Object-orientation is usually described as consisting of encapsulation, (ad hoc) polymorphism, and inheritance, [and something else?] none of which have made an appearance so far. Also, I haven't used the `entry` keyboard I spent so many bytes bloviating about at the beginning.

So let's steal Golang's approach to polymorphism wholesale. Golang uses these things called interfaces to get polymorphism. Golang interfaces at runtime are basically three-tuples: a pointer to an object, a pointer to a vtable, and a pointer to the underlying type of the object for the sake of further interface conversions. Any method can be invoked polymorphically, via an interface, or monomorphically, via some concrete type; and you can attempt to convert anything to any interface type. Conversions from a concrete type to an interface type use a vtable for that interface type computed at compile time, and give a compile-time error if that conversion is impossible. Conversions from one interface type to another use a vtable generated at runtime, and if the new interface type is not simply a subset of the old one, they can yield a runtime error.

We can add the same mechanism to C by using the `entry` keyword for a totally unintended purpose — declaring an interface type, with a syntax exactly analogous to `struct` or `union`:

```
entry callback_handler {
    void error_callback(struct bufferevent *, short, void *);
    void read_callback(struct bufferevent *, void *);
};
```

Now we can cast a `struct pipe` to an `entry callback_handler`, which will use a pointer to a compile-time-generated vtable, as with Golang; and we can also attempt to cast an `entry {}` to an `entry callback_handler`, which may succeed (constructing a new vtable at runtime, or finding a cached one) or may fail.

And that's polymorphism in Entry-C: both more efficient and more flexible than in C++. It's more efficient because you only use polymorphism where it's needed; it's more flexible because the caller, not the callee, decides when polymorphism is needed.

Encapsulation

Encapsulation might be a good idea, but Entry-C doesn't have it, or even a good way to approximate it.

You can make some of your methods "private" by declaring them `static`, which will also keep them from being called polymorphically via an `entry`. But usually the things you would most like to make private are variables, and you can't make variables private by declaring them `static`, because static variables are something else.

The best you can do is only a little better than in standard C: you can put an `entry` type in your .h file and keep the actual implementation type inside your .c file. Then, because the callers can't allocate space for your implementation type, you probably need to provide a function to allocate new instances of it and return `entry`s to them, and a function (perhaps in the `entry`) to deallocate instances.

This is better than the "pimpl" idiom in standard C or C++

because it doesn't have that disgusting name.

Inheritance

Traditional inheritance is a terrible idea:

• Subtyping gives rise to questions of covariance and contravariance, which make your programming language an unnecessarily confusing user interface.
• The possibility of inheritance typically makes every variable run-time polymorphic, which makes reading the code more challenging. As a consequence, things that ought to be compile-time errors (e.g. casting from a type that doesn't define `foo()` to an interface that requires it) become runtime errors (because some subclass might define `foo()`). Also, things that ought to be trivially easy for the compiler to optimize become difficult. You can't inline a callee if you don't know which callee is going to be called.
• Classes that are not designed to be subclassed often can't be subclassed to do what you want, although the language won't stop you from trying.
• Classes that *are* designed to be subclassed have no way in the language to define the interface between themselves and their subclasses, and it's very common for new versions of library classes to break existing subclasses; for example, it's trivially easy to accidentally get recursion this way, creating the danger of not just infinite recursive loops but also problems with re-entrancy.
• Everything that you can do with inheritance, you can do better with delegation.

So Entry-C doesn't have traditional inheritance.

However, as in Plan 9 C and consequently as in Golang, you can import the names defined in a nested struct into your own namespace by simply not naming the struct:

```
struct pipe;
```

The names in the inner anonymous struct (both inner functions and data fields) will be visible wherever your own names would be visible. If you define conflicting names, that's a compile error. This enables you to share implementations of certain methods across multiple classes in a convenient way, without the problems introduced by standard inheritance, but it's purely syntactic sugar for a bunch of one-line delegation methods. The "inherited" methods can't implicitly call methods you define.

At file scope, this allows you to incrementally refactor from global data to local data; you can start by collecting the global data into an anonymous struct, then move functions into it one or a few at a time.

Error reporting

There's a big problem with error reporting in C, and adding constructors to structs just makes it worse, because you might want to do things in a constructor that could fail, and as in C++, the constructor doesn't really have a way to return that failure value. This is, I think, why Golang doesn't have constructors.

The standard C++ answer is to use exceptions, but exceptions have their own problems, especially in the absence of garbage collection

and in the presence of the kind of things that make code non-reentrant.

The Golang answer is to use multiple return values for everything that might fail. Entry-C doesn't have multiple return values, although clearly C should have had them.

The standard C answer is for your initializer function to either take the address of the struct as an argument and return an int, or to return the address of a newly allocated struct or NULL. Entry-C constructors don't have return values.

You can do what I did in the example above: define an "error" field in the object, indicating whether construction failed. Alternatively, you can move things that could fail out of the constructor, and return a success or failure code:

```
struct pipe() {
    struct pipe *next = NULL;
    struct pipe *partner;
    struct bufferevent *buf = NULL;
    int fd;
    int marked_for_deletion = 0;

    void error_callback(struct bufferevent *bufev, short what, void *arg) {
        log_msg("error %d on conn %d", what, fd);
        mark_for_deletion();
    }

    void mark_for_deletion() {
        /* ... */
    }

    char *open(int new_fd) {
        fd = new_fd;
        buf = bufferevent_new(fd, read_callback, NULL,
                              error_callback, NULL);
        if (!buf) {
            return "bufferevent_new failed";
        }

        if (-1 == bufferevent_enable(buf, EV_READ | EV_WRITE)) {
            bufferevent_free(buf);
            buf = NULL;
            return "bufferevent_enable failed";
        }
        return NULL;
    }
};
```

However, Entry-C also adds a new kind of error condition: casting one entry type to another that isn't a superset could produce a runtime error. XXX I need a design for how to handle that operation and the resulting error.

Function overloading

No. *Fuck* no.

Operator overloading

This might be a good idea, especially for arithmetic. I'm not sure how to do it, especially without constructing temporary objects or throwing exceptions.

Example: integer DSP pipelines set up at runtime

Here we have a bunch of DSP filters that can be connected to each other at runtime, including a software phase-locked loop, using no heap allocation and no casts. The final paragraph sets up an example.

This code is adapted from http://canonical.org/~kragen/sw/netbook-misc-devel/pll.c.

A "crad" is a made-up unit of angular measure designed to avoid multiplication and division in the main loop of the PLL algorithm. (You could argue that it's at least as bad to do polymorphic method dispatch, but probably only if you're on a computer so big that memory references are slower than division.)

```
enum {
    pi = 0x400,     /* Crads per pi radians. must be a power of 2 for & */
    iir_shift = 9,  /* >> for low-pass rolloff at 512 samples (16Hz). */
};

/* Every struct defined below can be cast to this type. */
entry sink {
    void consume(int sample);
};

/* om0 is const base angular frequency, omega, in crads/sample. */
struct pll(int om0) {
    int pha;         /* Current phase in crads. */
    int err;         /* Accumulated low-pass-filtered phase error. */
    int amp;         /* Accumulated low-pass-filtered amplitude. */

    /* Compute the actual current angular frequency of a PLL. The bit
       shift "10", which determines how much frequency shift we get, was
       determined by trial and error because I am ignorant of theory. */
    static int current_om() { return om0 + (err >> 10); }

    /* Update PLL state for a new input sample. */
    void consume(int cc) {
        pha += current_om();
        iir_low_pass(&err, (pha       ) & pi ? cc : -cc);
        iir_low_pass(&amp, (pha - pi/2) & pi ? cc : -cc);
    }
};

static void iir_low_pass(int *out, int in) {
    *out += in - (*out >> iir_shift);
}

struct pll_amp_filter(struct pll *p, entry sink s) {
    void consume(int cc) {
        p->consume(cc);
```

```
        s.consume(p.amp);
    }
};

struct pll_freq_filter(struct pll *p, entry sink s) {
    void consume(int cc) {
        p->consume(cc);
        s.consume(p.current_om());
    }
};

struct low_pass_filter(int current_value, entry sink s) {
    void consume(int sample) {
        iir_low_pass(&current_value, sample);
        s.consume(current_value);
    }
};

struct freq_to_squarewave(entry sink s) {
    int ph = 0;
    void consume(int omega) {
        ph += omega;
        s.consume(ph & pi ? -1 : 1);
    }
};

struct hold(int val) {
    void consume(int new_val) {
        val = new_val;
    }
};

struct multiplier(entry sink s, struct hold volume) {
    void consume(int sample) {
        s.consume(volume.val * sample);
    }
};

struct putchar_sink {
    void consume(int sample) {
        putchar(sample);
    }
};

struct example {
    struct pll p = 110 * pi * 2;
    void consume(int sample) {
        p.consume(sample);
    }
    struct putchar_sink s;
    struct hold volume = 255;
    struct multiplier m = { s, volume };
    struct pll_freq_filter f = { &p, m };
```

/// XXX missing square wave generator struct pll_amp_filter a =

```
{ &p, volume };  };
```

Example: some of Lisp

This example suffers from the lack of a way to write `this`, and it probably needs garbage collection, which will really benefit a great deal from being able to write `this`.

```
entry value {
    entry value car();
    entry value cdr();
    int is_null();
    struct symbol *as_symbol();
    void visit(entry collector gc);
};

entry collector {
    void recurse(entry value child);
    void found(void *data);
};

struct pair(entry value car_, entry value cdr_) {
    entry value car() { return car_; }
    entry value cdr() { return cdr_; }
    int is_null() { return 0; }
    struct symbol *as_symbol() { return NULL; }
    void visit(entry collector gc) {
        gc.found(&car_);  /* XXX this means "this" */
        gc.visit(car_);
        gc.visit(cdr_);
    }
};

struct symbol(const char *name, struct symbol *next) {
    entry value car() { return err("car of a symbol"); }
    entry value cdr() { return err("cdr of a symbol"); }
    int is_null() { return 0; }

    struct symbol *as_symbol() {
        return (symbol*)&name;
    }
    void visit(entry collector gc) { gc.found(&name); }
} *symbol_table[256] = {0};

void *allocate(size_t size) {
    void *rv = malloc(size);
    if (!rv) abort();
    return rv;
}

struct symbol *intern(const char *name) {
    /* This hash function is almost as silly as PHP using strlen */
    struct symbol *b = &symbol_table[(int)name[0] & 255];
    struct symbol *s = b;
    while (s) {
        if (0 == strcmp(name, s->name)) return s;
```

```
        s = s->next;
    }

    s = allocate(sizeof(*s));
    s(name, b);
    *b = s;
    return s;
}

struct _nil_type {
    entry value car() { return err("car of nil"); }
    entry value cdr() { return err("cdr of nil"); }
    int is_null() { return 1; }
    struct symbol *as_symbol() { return NULL; }
    void visit(entry collector gc) { }
} nil;

struct pair *cons(entry value car, entry value cdr) {
    struct pair *rv = allocate(sizeof(*rv));
    rv(car, cdr);
    return rv;
}

int length(entry value v) {
    return v.is_null() ? 0 : 1 + length(v.cdr());
}

entry value assq(entry value alist, symbol *key) {
    if (alist.is_null()) return nil;
    entry value item = alist.car();
    if (item.car().as_symbol() == key) return item;
    return assq(alist.cdr(), key);
}

entry value reverse(entry value list) {
    static entry value reverse_with(entry value list, entry value tail) {
        if (list.is_null()) return tail;
        return reverse_with(list.cdr(), cons(list.car(), tail));
    }
    return reverse_with(list, nil);
}
```

Nothing surprising so far, except maybe that I didn't make a `typedef` for `entry value`. Now let's amp up the weird with a lazy mapcar:

```
struct mapcar *mapcar(entry value *f(entry value), entry value items) {
    struct mapcar *rv = allocate(sizeof(*rv));
    rv(f, items);
    return rv;
}

struct mapcar(entry value *f(entry value), entry value items) {
    entry value car() { return f(items.car()); }
    entry value cdr() { return mapcar(f, items.cdr()); }
    int is_null() { return items.is_null(); }
```

```
    struct symbol *as_symbol() { return items.as_symbol(); }
    void visit(entry collector gc) { gc.found(&f); gc.visit(items); }
};
```

Heap-allocation here is necessary because the caller of `cdr()` doesn't know they're receiving a `struct mapcar`; the declared return type of `cdr()` is just `entry value`. Consequently, they can't allocate space for a `struct mapcar` return value; so, that needs to be allocated on the heap. That's one reason this needs garbage collection, but of course Lisp in general kind of needs it.

This is the kind of situation where "virtual destructors", which is to say a run-time polymorphic method to recursively deallocate child resources, are helpful, although in this particular case they aren't enough, because some objects in the object graph may be referenced more than once.

Oscilloscope screens

Kragen Javier Sitaker, 2018-06-05 (2 minutes)

I was thinking it would be pretty nifty to rig up something like the displays in Brazil using a big Fresnel lens and an old analog oscilloscope tube. The benchmark here is maybe the TX-2 display used to develop Sketchpad and GENESYS in the 1960s: 1024×1024 with a single brightness, a limited range of color (blue initially, yellow afterglow), typically less than 32768 points lit, and I think 100 000 points per second (?).

If we were to drive a 20MHz oscilloscope with the analog VGA signal from a modern video card, we could probably actually do better than that. The video card can produce about 72 *million* points per second, about 720 times greater than the TX-2, and has memory for a bit over a million of them, about 32 times greater. The tube becomes the limiting factor — if we figure that it can be persuaded to go to an arbitrary spot on the display 40 million times a second, perhaps with a bit of filtering to compensate for the 3dB attenuation and phase shift at that point, that's one limitation. But that still means we could paint every point on the display 40 times a second — the slow phosphor becomes an even bigger limitation. And it probably doesn't have 1024×1024 faceplate resolution, maybe more like 512×512 if we're lucky.

A possibly more entertaining approach is to allocate, say, 100k points to each of many oscilloscopes, and refresh them each at, say, 10 Hz — with a fast enough switch you could multiplex one pixel to each display and thus drive 72 oscilloscopes off a single video card, but it's probably easier to switch a 20MHz signal to each display for the requisite 2.5 milliseconds out of every 100, limiting you to 40 oscilloscopes but allowing you to use a 4kHz multiplexing switch.

If you wanted to drive them all from a single frame — so you didn't have to synchronize your page flips with the switch — you could still drive about 10 oscilloscopes.

India rubber memory

Kragen Javier Sitaker, 2019-03-19 (4 minutes)

I watched Tony Hoare's 2009 talk about how null pointers were a billion-dollar mistake today. One of the things he mentioned was that, often, pointers are used because computer memory doesn't stretch — you want to logically include some child object into a parent object, but the child object has a potentially variable size, so you're stuck using a pointer to it (a Box, in Rust parlance). If you had "India-rubber memory" that could expand without invalidating later pointers, you could just include the child object inside the parent, as we traditionally represent syntax trees in text using nested brackets.

This is an appealing idea, and I wonder if you actually could make it work in practice, using some kind of flexible buffer scheme to hold all your data — like Emacs buffers with markers pointing into them, except that the buffers can contain not only characters but also references to markers. To the extent that you can make your data immutable, you can avoid the need to update the positions of markers from inserting and deleting data in the middle of the buffer. You need the markers in order to be able to rapidly jump over variable-length child objects and reach later children.

For example, suppose you have these definitions (from the FlatBuffers tutorial):

```
struct Vec3 {
  x:float;
  y:float;
  z:float;
}

table Monster {
  pos:Vec3; // Struct.
  mana:short = 150;
  hp:short = 100;
  name:string;
  friendly:bool = false;
  inventory:[ubyte];  // Vector of scalars.
}
```

Now, if you know the starting byte position of a `Monster`, you can easily find the starting byte position of its `pos`, `mana`, `hp`, or `name`, since those are all at fixed offsets. But `friendly` comes after `name`, and `name` is variable-length, so somewhere we must store a marker to find `friendly` with — a marker which will continue to point to `friendly` even if some characters are inserted or deleted in `name`. From that marker we can find the byte position of `inventory`, since `friendly` itself is fixed-size. We don't need a second marker to find the end of the object, but since the variable-length `name` and `inventory` fields make `Monster` as a whole variable-length, we would need an array of markers to organize an array of `Monsters`, and if `Monster` were embedded in some other object, we'd need a marker to find the field following the `Monster`.

At least, that's one possible set of implementation decisions. You

could also imagine storing the markers at the end of the `Monster`, and using the end position rather than the start position to identify the `Monster`, which would have the advantage that you could write out the representation in a purely sequential fashion with no backpatching, which in turn would allow you to use variable-length representations for the markers, such as variable-length byte counts. In that case, you'd need a marker to find the beginning of `inventory` (and the end of `friendly`) and a marker to find the beginning of `name` (the end of `hp`). In this case, this "trailers" representation requires more markers than a "headers" representation would, but that's only because the last field is variable-length; more usually both would require the same number of markers.

You could also imagine representing the markers in such a way that an update to them was needed under different circumstances. For example, you could represent a marker as a sequence of indices into B-tree blocks walking down from some root, and only an insertion into a B-tree block before the marker would require an update to that marker; or you could represent it as something like a BASIC line number, in the sense that the marker destinations would be physically present in the buffer along with characters, in a lexicographically ordered fashion, and might occasionally need a "renum" operation to redistribute them over the index space, which could be carried out somewhat lazily.

Hot lye granite cutting

Kragen Javier Sitaker, 2019-11-01 (2 minutes)

Granite and similar materials are commonly cut to shape with diamond saws. This has a few disadvantages: even abrasive-grade diamonds are still somewhat expensive, the process produces carcinogenic dust of crystalline silica, and, with the usual circular-saw blades, the cuts are necessarily fairly straight and not very precise.

Granite, as I understand it, gets most of its strength from the interlocking quartz crystals that make up a significant part of its bulk. Other major constituents such as feldspar and mica are mostly much softer and less chemically inert, so they are easier to cut. (Zircon is an exception, but it typically constitutes only a small part of granite.)

Quartz can be converted to water-soluble sodium silicate waterglass with an aqueous solution of sodium hydroxide heated a bit above room temperature, ideally to 100 degrees. So a plausible approach to these problems is to cut preheated granite with a wire saw flood-lubricated with hot lye. For the wire, you'd need a metal that was adequately stable in the strongly reducing, warm, wet, and alkaline conditions we're talking about; I think ordinary steel wire would work fine, but if not, surely some kind of brass or bronze would be adequate, in an argon chamber if all else fails. Using a wire made of a hardened tool steel would increase the risk of wire cracking but reduce the abrasive wear on the wire. Some saw-tooth-like surface treatment (perhaps a helical ridge) might be effective at increasing swarf clearance and concentrating abrasive wear on a non-structural part of the wire.

The side forces on the "sawing" wire would be much smaller than the forces on a diamond saw or even an abrasive-sawing wire, and it could cut paths through the stone with tight curves and corners, enabling the fabrication of a much wider array of shapes than a circular saw can, perhaps at higher precision, and certainly with much smaller side forces on the machine guiding it.

This approach could also work for cutting other troublesome materials that are vulnerable to lye, in particular including glasses such as soda-lime glass and borosilicate, but also some other silicate minerals and metal sulfides.

Bicicleta maps

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

It should be relatively straightforward to implement Bicicleta with Self-style "maps" --- where each "map" contains a bunch of constant things inherited from somewhere (in Self, cloned from somewhere) and a few variable things.

Many objects in Bicicleta seem to inherit directly from some widely-used global constant (prog.if, prog.sys.nil, and so on) and then override a small number of things. Objects that inherit directly from a particular other object and override the same set of things can share the same "map", just as if they were members of a Self clone family.

If you take outer-self references into account as if they were overridden slots, you can cover a larger number of cases. For example, prog.sys.rational.coerce:

```
coerce = {op: arg1 = 2
    '()' = prog.if(
        op.arg1.denom.is_ok -> op.arg1,
        op.arg1.as_integer.is_ok -> self.new(op.arg1.as_integer, 1),
        else = prog.error(\"could not coerce {arg1} to rational\" % op)
    )
}
```

The 'coerce' methods in different 'rational' objects differ only in their binding of 'self', and their children differ only in that and in their binding of 'arg1'. Ideally you could put most of this stuff into a prog.sys.rational.coerce "map" object.

This brings up a bit of a problem --- ideally you'd have one map object for all the (ordinary) coerce activation records, and those activation records would just have slots for self and arg1. As proposed above, each rational object's coerce method would have only a slot for self; but the activation records of a particular rational object's coerce method would have a map of their own, corresponding to that rational object.

Gradient rendering

Kragen Javier Sitaker, 2016-09-24 (11 minutes)

From https://news.ycombinator.com/item?id=12223616

Raph wrote:

Another serious potential win in SVG is that you might be able to interleave the area integration with alpha compositing / masking. Could end up pretty darned fast.

I responded:

I was thinking about using your prefix-sum approach for exactly that almost all of last night. I don't have an attack on the problem that I'm satisfied with yet:

• Render each path to a fresh pixel buffer, alpha-compositing it down onto the final canvas. Advantage: straightforward, works for sure. Disadvantage: you need a lot of multiplies per pixel.
• Partition paths into "layers" of nonoverlapping paths, render each layer as a unit, and composite each new layer down onto the final canvas. Overlapping opaque paths can be incorporated into the same layer as whatever is below them by cutting an overlap-shaped hole in what's below before adding in the new path; although that involves some intersection tests to know where to stop, my intuition is that it will be a big win. Advantages: straightforward, probably faster than the previous one. Disadvantages: the partitioning is a potentially costly extra step (one of those things that makes me wonder if it's NP-complete to do it optimally), and there are still potentially many multiplies per pixel.
• Separately accumulate a numerator (total premultiplied color) and denominator (total alpha) for each pixel, then divide in the end. Advantages: You avoid doing lots of work per pixel. Disadvantages: This is a weighted sum, not alpha blending. Alpha blending is a different thing. So the result is wrong. Also, an honest division per pixel is more expensive than quite a number of multiplications, although maybe you could cheat on the final division with a table of approximate multiplicative inverses or something. So this would probably be super slow.
• Find a different group other than $\mathbb{Z}/256\mathbb{Z}$ in which to do prefix-sum that somehow gives you the right results. Then you can just render all the edges into the same buffer and do a single vectorizable prefix-sum operation over it.

Advantages: This sounds super fast.

Disadvantages: It seems clear that this group is going to have to be able to represent the entire Z-ordered stack of colors at every pixel, because if I'm looking at some translucent green on top of translucent red on top of opaque black on top of pale blue, and I reach the right (negative) edge of the opaque black path, somehow I have to have remembered the blue thing underneath in order for it to peek through, which suggests to me that I need an unbounded number of bits per pixel to implement this scheme, which probably is not going to admit an actually fast implementation. In effect it has to reduce to the second approach, except that the software has to deal with the stack of layers once for every pixel. Or is there some magical way around this, at least for a fast-path case?

This part is probably obvious to you, Raph, but you can do SVG linear gradients with two prefix-sum passes instead of one, where the first pass just runs over signed gradient stops and gradient clipping boundaries, and then you draw the signed path boundaries into the buffer before the second prefix-sum pass. (Is that clear? I suspect it may be too abbreviated.)

I suspect that with three prefix-sum passes you could do a decent quadratic-spline† approximation of arbitrary gradients, including the weird skew cone gradients SVG calls "radial gradients". But I haven't worked out the details.

I know you don't have a lot of time to hack on this stuff right now, but would you have time to provide feedback if I were to hack on it a bit? I imagine that I'd run into any number of places where talking to you about it for half an hour could save me days of wasted effort.

† here I'm talking about what Carl de Boor calls "splines", which I know disagrees with your usage of "splines". I think you called them "B-splines" in your dissertation.

Then I wrote this:

You might have seen Raph's recent article on font-rs, where he observes that the color of a pixel in an antialiased painted polygon is the prefix sum of the signed edge coverages, and prefix sum is a thing you can do super fast with SSE.

Dan Amelang's work with Gezira and Nile is pretty inspiring to me, and the idea that you could get enough performance out of modern hardware to not have to worry about precaching font glyphs or really anything else is pretty neat. And hey, AAA games rerender each frame more or less from scratch, right? And in 3D at that.

I've had pretty good experiences hacking together stuff in SVG, especially with the little bit of data binding provided by D3 — you end up with a buttload of code, but you have a lot of control over how things look, and you seem to have pretty good composability, even if there's a large constant factor. It's just kind of like writing stuff in assembly, but less error-prone. (So maybe the verbosity problem of D3 is a shallow problem that could be solved with a better surface notation, like BLISS or Thompson's B instead of assembly?)

Amelang's Gezira, as I understand it, uses a single graphical primitive: a path made of quadratic Bézier curves, filled with a single solid alpha-blended color. SVG primitively supports filling with multi-stop linear RGBA gradients as well as solid RGBA colors, and if you were going to pick a single kind of fill, gradients include solid colors as a special case. And linear gradients are powerful enough that you can Gouraud-shade projected triangles with them, although I never took advantage of that when I did that long-ago 3-D torus.

It may have occurred to you by now that linear gradients can also be rendered by the prefix-sum method; it just requires two passes instead of one. First you fill the polygon with the ∂color/∂x of the fill (which is constant for a linear gradient, regardless of its orientation, until you hit a stop) using a first pass of the prefix sum; then, to that, you add the signed edge coverages at the borders of the polygon before doing a second pass of prefix sum.

I haven't yet figured out how to do overlapping alpha-blended filled paths with this method. Nonoverlapping paths can be done simply by rendering all their signed edges into a single buffer before the prefix-sum step or steps, and overlapping opaque paths can be done by cutting holes in the paths on the bottom, removing the hidden parts of their original edges (which nearly requires the property Levien calls *extensionality* in his dissertation) and adding extra edges to route them around the intruding space. But overlapping alpha-blended paths seem like they could be arbitrarily expensive.

So, I was thinking that it might be reasonable to make a UI out of nothing but a collection of closed Bézier polylines filled with linear RGBA gradients. Maybe? Texture maps would be hard to fit into that model, and textures are pretty important, I don't know.

Dave Long pointed out that two overlapped alpha-blended linear gradient regions still add up to a linear gradient:

> Is that really true? After reading, I'd guess you'd calculate stops at every path vertex *and* path intersection[0]. At each stop, the color layers are known and because gradients are linear, the combination of gradients from all layers ought to also be linear.
>
> [0] these could be expensive, up to n**2

More recently, it occurs to me that there is a potential problem with precision here, but it can be overcome. If we want to be able to make a linear gradient from any given 24-bit color to any other given 24-bit color across some horizontal distance, then we need to support a change of a single count across that distance. If our intermediate results are only 48 bits (16 bits per color plane), then the furthest we can reach without missing is 256 pixels horizontally. (In a sense, the other 8 bits per pixel hold a fractional color or error accumulator.)

This suggests that the optimal way to do this thing is to render things in 256×1 chunks, with the buffer occupying 1536 bytes. Alternatively, you could do it a scan line at a time with 32-bit ints, which would work properly as long as the scan lines were shorter than 2^{24} pixels, but this requires more buffer space and also runs half as fast with optimal SIMD instructions. For example, a 2048-pixel scan line would require 12288 bytes of buffer space, big enough to put serious

pressure on the L1D cache. (I'm writing this on an Atom with a 24 KB 6-way set associative write-back L1D cache, for example.)

It might turn out to be work more effectively with current SIMD instruction sets to render a band of several scan lines at a time, because the vertical SIMD instructions have better coverage of the available space. For example, using AVX-512 instructions, you could maybe handle 32 scan lines in each instruction, or maybe one color plane for each of 10 scan lines, thus rendering a 256×10 or 256×32 band. I think that with AVX-512 and four-way loop unrolling, the inner loop of the critical prefix sum there will take probably 320 cycles; if it's 256×10, that would be 8 pixels per cycle, or 4 pixels per cycle if you do it twice. Repainting a 2048×1536 screen that way will take about 786432 cycles, plus whatever overhead is needed to set up the gradient stops and copy the finished pixels into the framebuffer and whatnot.

(AVX2 and AVX-512 support gather load with the VGATHERDPS, VGATHERDPD, etc., instructions, as well as permuting stuff within a register with VPERMPS, VPERMD, PSHUFB, etc., so copying the finished pixels into the framebuffer might not be the horrible performance nightmare you might expect. AVX-512F also has scatter store.)

Queueing messages to amortize dynamic dispatch and take advantage of hardware heterogeneity

Kragen Javier Sitaker, 2016-09-17 (13 minutes)

I've been thinking about a new computational model to eliminate the runtime costs of dynamic dispatch and take better advantage of modern heterogeneous hardware.

Background

The Tera MTA

The Tera MTA was a computer that achieved consistently high performance despite a high-latency main memory and no cache hierarchy by hiding the latency with multithreading — its heavily-multibanked RAM system could hold a lot of requests in flight, each one being routed to an autonomous memory unit, and the CPU's hardware context switching with multiple hardware register sets meant that whenever some data arrived from a memory unit, it would probably wake up a thread that could do work on it. In this way, the MTA was able to achieve very high performance not only on cache-friendly tasks like dense linear algebra but also on cache-unfriendly tasks like traversing linked lists.

The Actor model

The Actor model unifies objects, threads, and activation records into a single "actor" abstraction, which reacts to an incoming message by sending some set of other messages and changing its internal state. Erlang is probably the language most directly based on this model, but its evolution was intimately intertwined with that of Smalltalk, in which an object that "receives" a "message" will "answer" it.

You could imagine an implementation of the Actor model in which each actor is a physically separate piece of hardware, communicating with other actors through some kind of bus or packet-switching network that carries the messages; but it's much more typical for a single CPU to sockpuppet the actors one by one, first executing the code of one actor, then the code of another. Although the Actor model easily accommodates an actor sending several messages without waiting for responses, or receiving a message and not responding to it, the traditional approach is for the CPU to implement nearly all message sends by subroutine calls or returns.

Dynamic dispatch is slow

One of the key difficulties in efficiently implementing Smalltalk and similar object-oriented languages has been the overhead of dynamic dispatch. In theory, in Smalltalk, not just every function call, but every arithmetic operation and every conditional, is performed by sending a message to an object. Conditionals are performed by sending messages like #ifTrue:ifFalse: to a boolean

object; arithmetic is performed by sending messages like #+ to a number object. The lack of static type information in Smalltalk and descendant languages like JS, Python, Objective-C, and Ruby means that in general the dispatch of these messages requires some pointer indirections and a hash-table search with the method selector. This has led to performance in optimized versions of these languages typically about an order of magnitude worse than optimized C; Objective-C, like C++, avoids this by reserving such dynamic method calls for special occasions. (C++ additionally uses extra static type information to reduce the cost of method lookup.)

There are two efficiency difficulties with this. One is that the dynamic dispatch itself requires a certain amount of computational work — comparing a class identifier to the class identifier in an inline cache, for example, or comparing method selectors found in a hash table to the selector for the method being called. The other is that it necessarily involves a certain amount of pointer-chasing, which implies random memory access patterns. On a large memory, this inevitably results in higher latency. The single-threaded programming model we use turns that high latency into low throughput.

Actor message queues

Some versions of the Actor model, like the one implemented in Erlang, associate a message queue with each actor — rather than running the actor's code immediately when a message is sent, the message is added to a queue, and the actor's code can run later to process the queue. In Erlang, the process's code can actually select particular messages from the queue to process out of order, which is used to support a call-response pattern in which a client sends a message to a server process and then blocks until the reply is available.

Such queuing is a general-purpose system design pattern for maintaining throughput in the face of large or highly variable latency.

Fast dynamic allocation with good locality

Generational copying garbage collectors typically require only about two or three machine instructions to allocate memory in the nursery: one to save the old value of a register, another to add an immediate constant to it, and a third to compare its value against the end of the nursery to see if the allocation succeeded. In theory, if the nursery is large enough, the work to iterate over the root set and fish the few surviving objects out of the nursery will be amortized over enough objects that the garbage collection work per object is also very small.

This is still a great deal more work than is needed to allocate and deallocate an object on the stack in C or C++, which is typically zero, because the compiler can determine upon entry to the function how much space its local variables will consume and subtract the total from the stack pointer in a single operation.

However, maybe you can do the same thing for generational heap allocation — check upon entry to a function to see whether the nursery is big enough for everything you're going to allocate, do a minor GC if necessary, then preallocate all the objects you're possibly going to allocate in the function. If the collector happens to run

while you're still on the stack, it can relocate your entire "heap frame" out of the nursery, consulting a liveness map to see which objects in the heap frame have been initialized thus far in the function.

This should have the benefit that the objects you allocate in your function remain close together in memory until after the function returns.

Mergesort converts random memory-access patterns to near-sequential

This is how people did compilers and databases in the days when they only had a few kilobytes of RAM: they used multiple tape drives to store data for the different passes of the compiler and to sort the database into an order that allowed a single sequential pass over it to produce the answers for all the queries (called "reports", more or less).

Consider the basic problem of a linker: after concatenating its input files, it needs to combine a potentially large amount of object code full of relocations with symbols providing definitions for those relocations. One way to do this is to take the list of relocations, sort it in symbol order, and then merge it with the sorted list of symbols to produce a list of instructions roughly of the form "add 382 to location 10078". Then, sort this list of instructions by location, and then merge it with the object code.

If you have 100 megabytes of object code, 3 million relocations (totaling 36 megabytes), 300,000 symbols (totaling 4 megabytes), 64 kilobytes of RAM, and eight "tapes", then sorting the symbols requires three passes totaling 24 megabytes of sequential I/O (one to break them into 128-kilobyte sorted chunks, a second to merge those into 896-kilobyte sorted chunks, and a third to merge the five chunks); sorting the relocations requires five passes, merging them with the symbols requires one pass, and sorting them again requires five more passes, for a total of 796 megabytes of sequential I/O; and then you need a final pass to generate the linked object code.

Using actor queues to hide dynamic dispatch latency and increase locality

What if we use message queues instead of a call stack?

When you start running a function, it allocates a heap frame and starts processing its incoming message queue. While it's running, it can send many, many messages to other actors, but it can't get responses from them; it can allocate new objects in its heap frame that will later handle responses, if need be. It doesn't need to actually be able to access any information of those other actors; all of its outgoing messages could even be accumulated in an outgoing-queue buffer, which is perhaps part of that heap frame.

This requires that all of its loops be statically bounded from the time you enter the function. It's okay if they iterate some dynamically-determined number of times, but that number has to be determined up front, because it affects how much to allocate. This means that the function is guaranteed to terminate. This unforgivable incursion upon Turing-completeness is not really a problem, since the function can send messages to itself if need be. In the worst case, this

reduces to continuation-passing style.

Once it exits, perhaps it is time to sort the outgoing messages by destination. Then we can select a next function to run, ideally one with at least one message in its message queue. Maybe we select the function with the most messages in its message queue.

If the function's input data and computational structure are sufficiently regular, we can vectorize it, so that in fact it is processing many input messages in a single instruction. Perhaps eventually those many input messages will result in response messages going to many different destinations.

If the messages are like Smalltalk messages, consisting of a selector, a "receiver" (in Smalltalk terms) on whose class the selector is dispatched, and arguments, there are a few different ways the dispatching could be amortized. If the routing system can identify the method, it can have a single queue for that method, with messages for many different receivers mixed in it.

Note that in this model, unlike in Erlang, we can guarantee in-order message delivery between a given pair of actors, even though there's a great deal of nondeterminism about sequencing otherwise. But taking advantage of that requires state to exist in the actor, unlike the actor-per-method approach suggested in the previous paragraph, where the actor is a stateless method. (And it seems like with this amount of nondeterminism in ordering, you really want to keep local state to a minimum; maybe only a kind of barrier-synchronization primitive, which aggregates two or more expected messages from different sources, should be allowed to have any mutable state.)

Alternatively, you could have queues per selector, per object, or per class. The function handling the per-selector queue would forward the message, somehow, to the appropriate method; the per-object or per-class function could perhaps contain the code for all the methods.

This approach, despite its obvious drawbacks in nondeterministic ordering of operations and potential to be slower rather than faster, has some potential advantages:

- You can, obviously, replicate and distribute the actors across a network for (ha) performance.
- You can take advantage of heterogeneous hardware by running different actors on different hardware — some might run much faster, for example, on a GPU or an FPGA.
- You can distribute actors across *time* rather than *space* in cases where memory is limited — you need only have one actor in RAM at a time, as each message contains everything that is needed to process it. This could allow you to run large late-bound systems on very minimal hardware. (This is really just another way of looking at the benefits of running in the CPU cache on a modern big CPU.)
- Even very large setup and teardown costs could potentially be amortized over a large number of messages. For example, reprogramming an FPGA with a bitstream that implements a particular actor might take milliseconds — maybe seconds if you have to run project IceStorm to generate the bitstream — but if it's processing a million queued messages, that's likely okay.
- The ordering nondeterminism I moaned about over and over again amounts to separating the scheduling concerns about latency vs. throughput vs. memory usage from the algorithmic concerns about

what to compute. Perhaps being able to change your scheduling policy separately from the code will empower you to choose a better one.

Arduino curve tracer

Kragen Javier Sitaker, 2018-06-17 (10 minutes)

I was thinking about diode logic (see Diode logic (p. 272)) and I realized that I really need a curve tracer in order to theorize sanely about diodes and whatnot. But an off-the-shelf curve tracer is pricey.

You could generate carefully controlled ramps using PWM and filtering, but you don't need to; if you're willing to take the voltages that show up, you can just measure voltages at different points in a test circuit and see what happens. A simple test circuit would have a capacitor, an inductor, a resistor, and the device under test, in that order, and you'd apply voltages (5V or 0V) at the ends of the circuit and measure the voltages at the two ends of the resistor.

The idea is that the capacitor and inductor and so on turn your step-function voltage changes into a smoothly changing voltage, so you can see what the DUT does at a bunch of different voltages. The inductor also serves to limit current, as well as permitting variation of dV/dt at a given voltage, and the capacitor serves to limit the total charge you can put through the device, thus the energy dissipated, thus the damage done. The resistor also limits the current and additionally provides a way to measure currents.

An Arduino's built-in ADC can sample at 200 ksps, and you probably only really need 1000 samples to draw an adequate curve, which ends up being about 10ms if you're sampling two separate points. If you'd like this to be a single ramp, you probably want the resonant frequency $1/(2\pi\sqrt{(LC)})$ to have less than a single cycle in 10ms, i.e. to be less than 250Hz, but it's probably okay for it to be three or four or even ten cycles. And the resistor will probably slow it down further.

The ADC is most accurate when measuring against the 1.1 V bandgap reference, but of course we will potentially have voltages to the 5V rail and beyond — if the DUT is a piece of wire, then the voltage at that end of the resistor will be 5V all the time. So we should probably use the 5V reference and merely calibrate it against the bandgap reference periodically.

If we figure on currents up to about 2 mA, then a 2.2 kΩ resistor would scale those currents to be within the same 0–5V range. If we use a much smaller resistor, we start losing precision on the current measurements. Then if we want our RC time constant to be around, say, 2ms, then we need something like a 1 μF capacitor. Then, if we want $2\pi\sqrt{(LC)}$ to be something like 1ms, we need a honking 22 millihenry inductor. Maybe a better balance is to use a 1 kΩ resistor, a 3.3 μF capacitor, and a 4.7 mH inductor.

ω_0 = 8000 radians/sec, $Q = \omega_0 L/R \approx 0.04$. This suggests that with such low inductance this is going to behave basically like an RC circuit. You don't even get ringing until Q = 0.5, I think. So to get the potential benefits of inductance here, you really would need a bigger inductor, which is surprising to me, since I think of millihenries as largish.

The maximum energy stored in the capacitor at 5 V is 41 μJ, which seems comfortingly small. The 100-pF 1.5 kΩ Human Body Model

reaches that energy level at only 900 volts, so hopefully any device that is ESD-rated should be able to handle this without breaking down. Maybe even back-biased tantalum capacitors. This should be gentler than the HBM, because its initial current spike into a 1.5 kΩ load is 300 mA and 135 watts, while this circuit should be closer to 5 mA and 25 mW, or maybe twice that.

I wish I could use a smaller resistor, too, because I'd like to trace curves well beyond 5 mA.

So, next iteration of design: 220 Ω resistor, 1 μF capacitor, 47 mH inductor, resonant frequency 734 Hz, ω_0 = 4600 radians/sec, Q = 1.0, maximum current should be in the ballpark of 20 mA (the maximum on the datasheet for an AVR pin), 12 μJ in the capacitor when charged to 5 V, but we should be able to get a bit of overshoot from Q = 1.0; RC = 220 μs, which is about 44 samples from the ADC, so we probably have to do a few cycles to get good coverage of the curve.

If we were naughty we could perhaps get rather higher voltages out of the inductor by switching the pin on the other end of the DUT from its low-impedance "output" state to a high-impedance "input, no pullup" state.

With a low-impedance DUT, when voltage is initially applied, all of it will be across the inductor. This will result in a dI/dt of 5 V / 47 mH = 106 A/s or 106 μA/μs. Every 10 microseconds we will take a sample of voltage and a sample of current, with the current ramping up about 1.06 mA per sample at first, which works out to 230 mV across the resistor (about 48 counts out of 1024). This seems like it will give poor coverage of the originally planned 0–2 mA range, but we could use a short pulse to start a current through the inductor, then turn the output back off to allow the inductor current to decay under the influence of the DUT, the resistor, and the capacitor. If the current is at 5 mA, the capacitor is empty, and the DUT is low impedance, then the sense resistor will oppose with 1.1 V, which will cause the inductor current to decay more slowly at 23 A/s (23 μA/μs, 0.23 mA per sampling interval).

Also, though, for many kinds of DUTs, we should have plenty of time at low currents when the capacitor is almost charged.

I hacked together a shitty simulation (using difference equations to approximate the differential equations, with a timestep of 200 ns) and observe the following:

• The capacitor voltage overshoots the 5V rail by almost exactly a diode drop, 5.79 volts. In a sense that's about the best we can hope for — it'll start to hit the AVR's input-clamping action there.
• The simulation sees the current continuing to ring down for 9 full oscillations before it dies from roundoff error, but only the first two full oscillations are above 5 mV, which is one count on the AVR's ADC when it's using 5V as the reference. Also they are negative half the time, although they never reach a full diode drop below ground.
• Those 9 full oscillations reach about 15 ms, which would be about 600 Hz, suggesting that either my simulation is crappy or my calculation of the resonant frequency is not a good way to calculate the intervals between zero-crossings during ringdown. Lowering the resistance to 47 Ω shortens that to about 12 ms, which would be about 820 Hz, which seems right.

• The peak current is a bit over 12 mA, which is better than 5 mA, but still leaves out a lot of interesting territory for many devices.

Slow devices — over a millisecond or two — may be hard to test in this circuit.

(Discarded idea: how about if we use 220 Ω, 47 mH, but 4.7 μF? This eliminates the overshoot entirely (and thus presumably the possibility of doing much interesting with the inductor) but does give us slower ramps — we have like 6 ms of V_R being over 5 mV. I didn't expect that adding more capacitance would make it stop ringing entirely, but I guess it lowers the resonant frequency, and consequently Q if you don't change R and L.)

I tried driving this (simulated) circuit with a squarewave chirp and got peaks of current up to 15 mA where the period was about 3.6 ms. However, this also resulted in inductor voltages down to -6 volts. Better make sure that inductor-capacitor point isn't connected to an AVR pin! Worse, though, even the resistor voltage got down to about -3 volts, and that point *does* have to be connected to a pin. We can perhaps raise the whole RLC circuit bodily to Vcc by raising the pins at each end to 5V, thus allowing us to measure these reverse currents and avoiding clamping.

(You do want to make sure you have pins connected separately on both sides of the DUT and both sides of the capacitor, which amounts to three of the four pins you need to make this work at all. Otherwise you have no way to discharge the capacitor in a reasonable amount of time if the DUT is diodish.)

Topics

Recuperator heat storage

Kragen Javier Sitaker, 2016-11-01 (updated 2019-08-21) (4 minutes)

Stirling engines and adiabatic compressed-air energy storage both depend for their efficiency on a regenerator, which can be something as simple as a pebble bed or packed column, or as elaborate as a ceramic honeycomb.

I think regenerators have some significant tradeoffs, though. In particular they tend to impose a fairly large pressure loss on the air (or other fluid) passing through them, and they cool off significantly if left to sit, just through the diffusion of heat through the regenerator itself. And I think — though I'm not sure — that the thermal mass of the regenerator itself slows down the ramp time of Stirling engines.

You can cut a regenerator's head loss by making it shorter, so the air travels less distance while constricted by it, but this puts a low ceiling on the total amount of thermal energy that can be stored, and also worsens the diffusion problem.

A countercurrent heat exchanger with a different, probably liquid, coolant — a recuperator — could solve these problems. This allows you to keep separate superinsulated hot and cold reservoirs, connected to the heat exchanger with long, thin pipes, and pump the coolant either direction through the pipes to keep the heat exchanger at a constant temperature.

Countercurrent heat exchangers with very low pressure drops and very high heat fluxes are feasible — in biology they are called "retia mirabilia" and were discovered 1800 years ago. They intertwine two fractal branching structures in such a way that they come in contact throughout a surface with a large fractal dimension vaguely resembling the surface of a piece of broccoli. As far as I know, nobody has ever built an artificial rete mirabile, although there have been a number of papers and books on process intensification that come close. It will be best to build them from a solid material with low thermal conductivity such as a glass or ceramic, since if you can get the fluid passages below 100µm in diameter, the distance between them is very small and the surface area between them is very large, so it's probably more important to slow lengthwise heat diffusion than to promote transverse heat diffusion.

(See Heat exchangers modeled on retia mirabilia might reach 4 TW/m³ (p. 1487) for more about such heat exchangers.)

If the secondary coolant is a liquid, it may be necessary to use more than one liquid, because most liquids have a narrow usable temperature range. For example, ethanol spans -120° to about +100°, propylene glycol spans -59° to +188°, and glycerol spans about 0° to +290°, but organic liquids in general start not merely to boil but to break down chemically somewhere between 200° and 300°. Molten nitrate salts span a somewhat larger temperature range but are solid anywhere near room temperature. Liquid metals cover the 200° to 1000° range reasonably well, but most of them are also solid at room temperature, potentially posing difficulties for a cold start.

I think this is important because Carnot efficiency is $1 - T_k/T_h$, where T_k is the temperature of the kold reservoir and T_h the temperature of the hot one, so a wide temperature swing is crucial for

heat engine efficiency; this clearly applies to Stirling engines, but I'm not yet clear on whether it's necessary for adiabatic compressed air energy storage.

Applying FM synthesis to natural sounds such as voices

Kragen Javier Sitaker, 2019-11-12 (2 minutes)

A common technique in modern music (going back to the Beatles) is to sweep a comb filter over the frequencies. One variant of this is for no particularly good reason called "flanging", but there are others.

Another common technique is to use FM synthesis, in which the time axis is distorted according to a modulator waveform. Typically this differs from the kind of FM used in FM radio in that, in FM radio, the modulator is many octaves lower than the carrier, while in FM synthesis, typically they are the same frequency or an octave or two apart, so the waveform repeats with the same period as the carrier — so the FM distortion merely produces harmonic distortion, rather than inharmonic sidebands. A typical technique is to gradually reduce the "depth of modulation" down to zero, thus causing the harmonics thus produced to die away, just as the overtones of a string or a bell do.

An interesting thing about FM synthesis is that the carrier wave being distorted is almost invariably a simple sinewave. It would be interesting to use some kind of frequency and phase tracking to apply the same kind of "FM" periodic time-domain distortion to a wave from some other source, such as a singer's voice.

Most children in the rich world have done something similar by talking or singing through the blades of a spinning box fan to make a "robot voice", which provides a sawtooth "FM" distortion of time at frequencies somewhat lower than voice frequencies, perhaps 50–100 Hz, and without phase tracking of them.

Topics

Heliogen

Kragen Javier Sitaker, 2019-11-19 (6 minutes)

From a comment on the orange website.

Solar furnaces have been useful for reaching especially high temperatures since at least Trombe's 1949 furnace, which can hit 3500°, without computer vision or even closed-loop control. So why is a 1500° solar furnace being touted as a groundbreaking innovation and a new high-temperature landmark?

A friend asked me what I thought about this earlier, based on a somewhat better reprinting of their press release.

Scroll back to 2010, when Bill Gross started working on this. That's when he got funded by that dude whose futurism book about the Information Superhighway, *The Road Ahead*, didn't mention *the internet*. In 1995. In 2010, photovoltaic modules cost €1.62 per watt. Concentrating solar power was a promising alternative; it uses the same steam engines used by coal and nuclear power plants, so at scale it should be just as cheap as they are, as long as you can get the cost of the heliostats under control somehow and scale up. It also didn't have that pesky intermittency problem PV modules have: you can store the heat overnight.

Since then, though, heat engines have become economically uncompetitive relative to PV, because PV modules now cost €0.19 per watt, where they've been stuck all year. And steam turbines, almost a century and a half old, aren't improving or getting cheaper rapidly the way PV has been. Being just as cheap as coal isn't a blessing anymore; it's a handicap.

So, if you've been working on CSP and filing patents for a decade before getting your pilot plant up and running, a decade during which the PV market has left your product's price in the dust, what do you do? You look for a possible use where CSP is still viable, such as process heat; you hire a good PR firm; you announce that you won't be building any plants, but you're "willing to partner with" companies that want to build your design; and you hope to God nobody says "Solyndra".

But what's the actual invention? It seems like the actual news is that Bill Gross has patented some aspect of his closed-loop control system using webcams and GPU-accelerated CV to figure out where the mirrors are pointing to improve your concentration factor. The key improvement that made it possible was better GPUs, according to the press release, anyway.

So what happened, from the point of view of anyone outside Idealab, is that now Idealab and Intellectual Ventures will sue you if you do this fairly obvious thing of using high-resolution webcams for precise heliostat control.

So, when would this be a sensible thing to do?

Trombe's solar furnace and similar devices are able to compete quite effectively in the "market" for process heat at the 2500–3500° level, since, as I said, 1949. (I guess Bill's PR firm didn't know this, or hopes you don't.) That's a level almost impossible to achieve using fire (oxy-acetylene burns at 3500° under ideal conditions), and difficult even with arc furnaces. But Bill's thing is designed for a more prosaic

1000–1500° level, where it's competing not only with fire but also Kanthal or SiC fed from PV, wind, hydro, and nukes, as well as induction, dielectric heating, and microwave heating.

The potential advantage of CSP for process heat at these lower temperatures is that it's cheap and abundant. If you fill a field with mirrors, they can harvest 6× as much power than PV modules covering the same field can. But if land area is your limiting factor, your cement plant or steel mill or whatever probably isn't in the middle of a big field; it's using a lot more energy than your land receives in sunlight. In that case, you probably want to pull your power from someplace further off, whether in the form of coal, oil, gas, biomass, or electricity. Probably electricity from PV panels if we're talking about anything post-2030.

But suppose you *can* put your factory in the field where the mirrors are, and the limiting resource isn't land but money. In that case, it might be a reasonable approach. PV modules cost €30 a square meter now. That's probably more expensive than mirrors, if you take into account that mirrors give you 6x as much energy: €180 per square meter is the price mirrors have to beat, and that seems doable.

But now you are on notice: if you do that, make sure it's in a country where Intellectual Ventures's shell companies haven't gotten a patent on it, or you have to deal with patent trolls. The press release reprinted above is clear: as with IV's laser mosquito swatter, they aren't going to make it happen themselves, but they'll definitely "partner with" you if you try.

I think we're about to see a giant boom in shitty "do well-known thing X, but with computer vision" patents similar to the shitty "do well-known thing X, but on a computer/on the internet" patents that plagued us in the early 2000s. The availability of massive GPU power means that many things that used to be impractical to do with video data have become possible.

Offline datasets

Kragen Javier Sitaker, 2014-04-24 (15 minutes)

What currently existing datasets would most effectively use the capacity of a modern laptop disk, if it was going to be disconnected from the internet? What would most powerfully augment its possessor?

8.4 GiB: Project Gutenberg 2010 DVD, 29,500 ebooks, most pre-1921 English lit

12.5 GiB: Debian 7.0.0 amd64 DVD images, all free software in Debian, compiled

34.1 GiB: Debian 7.0.0 source DVD images, the source for the same software

9.7 GiB: the articles in the English Wikipedia, an overview of all knowledge

13.2 GiB: StackExchange dumps, all common technical questions with answers

19.9 GiB: Planet.osm, a map of most of the streets and rail lines in the world

6.8 GiB: Open Library latest dump, bibliographic data on all published books

15.0?GiB: Freebase in Turtle RDF, a unified database about everything known

20.0 GiB: wikileaks-files-20100612.tar, Wikileaks Full Archive, including cables

139.6GiB: total

http://aws.amazon.com/datasets lists a number of freely-available datasets on Amazon S3; not only can you download them directly from there, but you can also fire up an EC2 machine with gratis network access to them in order to analyze them, extract relevant parts, and summarize and compress. For example, the 2.2 terabyte Google N-Grams corpus is available, and you could quite reasonably fire up a machine to fetch all the 3-grams that occurred more than 5 times and return them in a compressed format. (A particularly interesting free dataset is the 81-terabyte Common Crawl Corpus, containing 5 billion crawled web pages.)

http://arxiv.org/help/oa/index describes the arXiv Open Archives Initiative interface, which is suitable for bulk-downloading of all abstracts of the 850 000 papers in the arXiv (essentially all significant current math and physics papers, and a smaller but still significant fraction of other academic papers.) In 2010, the papers totaled 200GiB , but there was no bulk download interface publicly available. Later, http://arxiv.org/help/bulk_data_s3 explains that they are now available in S3, including both the source LaTeX and the rendered PDF versions.

Citeseer has a bibliographic record for the majority of scientific publications in any field, including pointers to online versions of the articles where available. They, like the arXiv, support the OAI for bulk downloading of this data. There seems to be a dump from 2010 in http://www.cs.purdue.edu/commugrate/data/citeseer/, which looks like it might be around a hundred megs compressed. http://www.hrstc.org/node/33 explains how to do an OAI bulk download and reports that, as of 2009, it ended up as about 500MB of

uncompressed XML.

IMDB has bulk downloads available, and I guess movies are pretty popular: http://www.imdb.com/interfaces. The data isn't free, but it's available for some uses. It looks like it's a gigabyte or two.

Project Gutenberg has gone from 30 000 titles to 43 000 since 2010, and many of the new titles and versions include illustrations, but I don't know where to do a bulk download of all of this data. It has a substantial number of non-English books these days, too.

http://datahub.io/, organized by the Open Knowledge Foundation, has a collection of already-structured datasets, but most of them are small and they are somewhat spammy. http://www.infochimps.com/datasets is another similar, but apparently somewhat better, collection.

http://dbpedia.org/About is an effort to extract structured data from Wikipedia, which has substantial overlap with Freebase. Shallow discussion of the relationships between the two projects can be found at http://wiki.freebase.com/wiki/DBPedia and http://www.google.com/url?sa=t&rct=j&q=dbpedia%20freebase&so
ource=web&cd=3&ved=0CD0QFjAC&url=http%3A%2F%2Fblog.db
pedia.org%2Fcategory%2Finter-linkage%2F&ei=mU_aUZqYF6iXi
QKJwoCoDw&usg=AFQjCNHcf8Bti6uQcqv-aDUjwG4lg_YY7A
&bvm=bv.48705608,d.cGE&cad=rja. Among the interesting sub-datasets in DBpedia are "bijective inter-language links", "short abstracts", and "geographic coordinates". I can't tell how big the whole DBpedia dataset is, but it looks like it should be a few gigabytes. It also sort of looks like the project is faltering, since the latest DBpedia release is at http://downloads.dbpedia.org/3.8/en/?C=S;O=A, and it's a year old, despite their quarterly release schedule.

http://www.clearbits.net/torrents/680-california-learning-resource-
network-textbooks is among the interesting things on ClearBits other than StackExchange; it's 0.8 gigabytes of supposedly high-quality secondary-school textbooks in English, called the California Learning Resource Network Textbooks, from the California Free Digital Textbook Initiative. Another 0.3 gigabytes at http://www.clearbits.net/torrents/158-physics-textbooks covers secondary-school physics.

There's a couple of attempts to put the Khan Academy in an offline-accessible form. One is Khan Academy on a Stick, which is just a 16GiB selection of 2000 English video lectures, and a similar set of 800 in Spanish. A much more ambitious project is KA-Lite, which includes exercises, progress tracking, multilingual subtitles, and the ability to make your own selection of videos; I don't have a clue how much space this stuff takes up, aside from the videos, but I imagine not much on the scale we're talking about here.

http://www.clearbits.net/torrents/571-fsi-mandarin-chinese---comp
lete-course is a public-domain Mandarin Chinese course in 1.6 GiB.

GenBank is the NIH's annotated collection of all publicly available DNA sequences. A 200GiB 2009 snapshot of GenBank is on S3.

http://earthobservatory.nasa.gov/Features/BlueMarble/ has a 500-meter-resolution true-color map of the earth made from MODIS satellite data, with month-by-month composites. This could

be a nice supplement to OpenStreetMap data, but I'm having a bit of a hard time downloading it. Calculations suggest that in JPEG form it should be about 9 gibibytes, since each world coverage should be about 0.7 gibibytes. Now that Landsat data is open-access, and even available in pre-downsampled form, it should be straightforward to produce a higher-resolution version; if we budget 20 GiB, to be comparable in weight to the OpenStreetMap planet.osm data, we could manage about 100-meter resolution. If you were more judicious, you could skip the 100-meter resolution on open water and use data down to Landsat's 15-meter resolution limit in areas the OSM data shows to be dense.

http://geonames.org/ is a CC-BY collection of eight million place names, with coordinates, which is a lot more than you can get from Wikipedia. I think it's about a gigabyte.

Not all the software in Debian is adequately documented within Debian itself. In particular, Debian includes no tutorial for C, as far as I know, although I am pleasantly surprised to find that the `c++-annotations` package contains a tutorial for C++ for people who already know C; and the RFCs that document much of what you need to know about networking are relegated to the "non-free" Debian repository, which is not included on the DVD images. I have no idea how big non-free is.

I think the WikiLeaks snapshot (from 2010, when they were having a hard time keeping the site up in the face of censorship attempts from the USG) includes the full Cablegate file only in encrypted form. After David Leigh negligently published the encryption key in a book, WikiLeaks re-released the full, but censored, Cablegate archive (only 0.6 GiB) at . These leaked US diplomatidc cables have been a major primary source for journalists writing new articles over the last few years, as well as a major source of civil unrest in US "allies".

A similarly important set of primary sources may be WikiSource. The English Wikisource dump is currently 1.3GiB http://dumps.wikimedia.org/enwikisource/20130629/ but doesn't include images, because Wikimedia dumps never include images. But that's probably okay in this case, because most of Wikisource seems to be transcriptions rather than scans.

What about music?

• The Archive Team archive of all the MIDI files they found on GeoCities, which probably covers most 20th-century US popular music and a fair bit of other music (albeit in low quality), is fairly tiny and contains some fifty thousand songs. It's very likely illegal, though.
• http://www.infochimps.com/tags/music?page=4 has some other related datasets.
• http://cantorion.org/ has a large collection of scanned public-domain sheet music, mostly classical, and collections of it have been uploaded to the Internet Archive.
• http://discogs.com/ has a public-domain database of metadata on 35 million recorded tracks, with dumps at http://www.discogs.com/data/, which are some 0.2GiB.
• http://freesound.org/ has a mixed CC-sampling-plus and CC0 database of samples for making music with, which may or may not be

bulk-downloadable.
• However, there's an 8.5GB chunk of sound samples released under CC-BY for OLPC at http://wiki.laptop.org/go/Sound_samples.
• http://imslp.org/ has 220 000 musical scores, mostly of public-domain music, which may or may not be bulk-downloadable; there's a very old torrent backup from 2008.
• Musicbrainz I think is already incorporated in Freebase, but it has rich metadata on some 12 million recorded tracks.
• The MOD Archive had some 120 000 songs in MOD and related formats as of 2007, totaling 31.2 GiB; these are somewhere in between MP3 and MIDI in their level, since they include the samples. But the MOD Archive is also probably almost entirely illegal, because the samples come from all over the place and were frequently copied from one MOD musician to another without consent.
• Mutopia has some 1600 public-domain musical scores which can be played with MIDI or typeset with LilyPond. I assume these can be bulk-downloaded, but they're tiny.
• Musopen has a collection of public-domain music recordings, but no bulk download as far as I can tell.

Some very valuable kinds of information that may not be present in any of the above:

• Transport schedules, e.g. bus and train schedules, not to mention route information (OSM has some route information);
• Contact information for people and businesses (i.e. phone books; available from, say, Yelp or Foursquare).
• Reputation information for people and businesses (i.e. Yelp), or even for pages (e.g. the freely-available page hits data for Wikipedia articles, for use in ranking search results.)
• In-depth engineering data, e.g. Machinery's Handbook, the CRC Handbook, Organic Syntheses, electronics datasheets, and so on. US military MILSPECs may provide some useful data here.
• Pricing information about pretty much anything: minerals, chemicals, electronic parts, commodities, stocks, forex, household appliances, foods.
• Social graph information. Presumably any number of spy agencies have a full crawl of the social graph from Facebook, including everybody's profile photos, but Facebook's terms of service forbid doing this, so nobody admits to it. But this is in the terabytes, anyway, since you have at least thousands of bytes for the profile picture times about a billion accounts. If you just wanted uncompressed names and graph links, without geographic or photo info, it's probably on the order of 64 links (of 4 bytes each) per person, total 256 bytes, plus their name, so about 200 to 300 GB.
• Travel information, like WikiTravel: what to see when you get to Córdoba, how to get there, what neighborhoods to avoid, how the local taxi system works, where to stay. WikiTravel is licensed under a CC-BY-SA license that would permit this in theory, but I'm not sure how to download a snapshot dump of it in practice; they seem to be trying to make it difficult. Hitchwiki might be an alternative, but it seems nascent — its dump is only 15MB.
• Cooking recipes, other than the very old ones from Project Gutenberg.
• Guides to identifying natural things, such as plants, animals, rocks,

and diseases.
• Much in the way of modern how-tos. en.wikibooks has almost 2700 books at the moment, and might help some; but if you want to know how to fix your 1997 Ford Taurus, how to incorporate a company in Argentina, how to upgrade the hard disk in your Dell Mini 9, etc., you're out of luck. A fair bit of this kind of information may be available in the public domain from the US Military, but finding and organizing it will be difficult.
• Nutritional information.
• Public records information, such as land titles, lawsuit records, invention patents, EDGAR filings, trademark filings, marriage records, statute law, caselaw, or international treaties.

A much smaller-scale version of this problem is: what should I put in my next paper notebook? I'd like to print some things out: obviously my friends' phone numbers and other contact information, a map of the city and surrounding areas, and so on. I can print them in reduced size, as long as I can still read them; I think I can distinguish 600 pixels per inch with a magnifying glass, and ordinary laser printers can print that. My current notebook is 288 pages, which is to say 144 leaves, or 72 sheets of paper, which are roughly A5-size,

one thirty-second of a square meter, so 2¼ square meters of paper in total, or 4½ square meters of paper surface. The smallest reasonable ASCII font is about 6×4 pixels, which works out to 23.25 million characters per square meter, or about 105 megabytes of text. If we use the traditional 80×66 unit for a "page", that's 19 815 pages.

Now, I only want to fill a fraction of the notebook with text. So what are the most useful, say, ten to thirty megabytes I could print out and bind into my new notebook? The Wikipedia Vital 100 articles at http://en.wikipedia.org/wiki/Wikipedia:Vital_100 might be a reasonable thing to include, for example. Ten articles chosen from there by random clicking are Fire (12 pages), Crime (16 pages), Biology (18 pages), Human sexuality (38 pages), Earth (32 pages), History of the World (27 pages), History of art (16 pages), Philosophy (33 pages), Mathematics (12 pages), and Energy (19 pages). These sum up to 223 pages, suggesting that the Vital 100 in total will be about 2230 pages. This would be a fairly straightforward thing to include in the notebook in its reduced form; if we figure 56 reduced pages per notebook page, it would occupy about 40 pages.

You might be able to do something similar with

Constant current switching capacitor charging

Kragen Javier Sitaker, 2017-07-19 (1 minute)

Lots of energy-harvesting devices use capacitors for energy storage. The simplest way to do this, given a somewhat unpredictable AC voltage source, is with a diode or bridge rectifier. This has a couple of big problems, though: the diodes dissipate more than half of the energy you're trying to harvest, and without any significant linear resistance, the capacitor gets fully charged during the first quarter-cycle, so if the capacitor is large, they're dissipating it very rapidly and will explode.

(A reason you might not see this happen in practice is that your energy source isn't actually a voltage source, i.e. negligible impedance; more on that later.)

If you have a diode or resistor or some other passive element in series with the capacitor, it's going to take up whatever the voltage difference is between the capacitor's current state of charge and the voltage source. Ideally you would like that to be just enough to push the right amount of current through the passives to charge the capacitor, so that almost all the energy gets harvested instead of dissipated.

You could maybe do it literally like that using a buck regulator: instead of regulating the duty cycle of the PWM signal in the buck regulator to seek a fixed goal voltage, regulate it to seek a fixed goal current.

Topics

Practically decodable random error correction codes with popcount

Kragen Javier Sitaker, 2015-07-01 (updated 2015-09-03) (6 minutes)

I tried designing a super-simple holographic ECC scheme, and although it does work, it bloats the message by an order of magnitude before it stops being an error-introduction code instead of an error-correction code. The scheme is described below, in case someone wants to try to rescue it.

RESCUE: MAKE THE MATRIX SPARSE AND COMPARE POPCOUNTS OF ZERO-DERIVED AND ONE-DERIVED CODEWORDS! popcount(num & row) > popcount(~num & row).

To encode a block of N (preferably N is odd) bits into a block of M bits, where normally M>N, use a M×N matrix of random bits defining the code. Invert (NOT) each of the N columns that corresponds to a 1 bit, which is to say, XOR each of the M rows with the N bits you are attempting to encode. The M-bit codeword is then the majority-rule of each of the M rows of the output matrix: if it contains more 1 bits than 0 bits, then the output is 1, and otherwise 0. To decode, you apply the same process, but with the original matrix transposed.

Why should we expect this to work? The output bits are a holographic representation of the input bits. Each bit in the matrix represents a coupling between the probability that a given output bit is 1 and the input. If a column happened to be all 1s, then it would slightly increase the probability for each output bit to be 0 when the corresponding input bit was 1, or 1 when the corresponding input bit was zero. If there are enough output bits, and the other columns are uncorrelated, then this will probably flip a few of them — enough that the majority of output bits will correctly reconstruct the original input bit.

This can be implemented with somewhat reasonable efficiency (a few machine instructions per bit) on normal CPUs now that the NSA has finally pushed a POPCOUNT instruction into them; or at extremely high speed in hardware.

This Python code, encoding and decoding a message, shows that this works in practice if M is large enough. However, it seems that M needs to be almost always 8× and often 16× larger than N for it to work, so in practice this code is dramatically worse not only than Reed-Solomon codes, but in fact worse even than just repeating the message several times.

```
#!/usr/bin/python
from __future__ import division

import random

def main(N, M, message='This is a test message'):
    print 'N =', N, 'M =', M
    r = random.SystemRandom()
```

```
    key = [r.randrange(2**N) for ii in range(M)]
    print 'key', key
    unkey = transpose(key, N)
    print 'unkey', unkey
    # If this fails, it means transposing has a bug, so nothing can
    # work.
    assert key == transpose(unkey, len(key))
    print 'message', `message`
    message_digits = to_base(2**N, bytestring_to_int(message))
    print 'digits in base', 2**N, message_digits
    encoded = [encode(digit, key, len(unkey)) for digit in message_digits]
    print 'encoded', `encoded`
    decoded = [encode(item, unkey, len(key)) for item in encoded]
    print 'decoded', `decoded`
    decoded_bytes = int_to_bytestring(from_base(2**N, decoded))
    print 'decoded bytes', `decoded_bytes`
    print 'matched' if decoded_bytes == message else 'mismatch', (
        'N =', N, 'M =', M, '+%.2f%%' % (100*(M/N-1))
    corrupted = [item ^ (1 << r.randrange(128)) for item in encoded]
    print 'corrupted', `corrupted`
    decodedc = from_base(2**N, [encode(item, unkey, len(key))
                                for item in corrupted])
    print 'corrected bytes', `int_to_bytestring(decodedc)`

def bytestring_to_int(s):
    return from_base(256, (ord(b) for b in s))

def from_base(base, digits):
    "Expects digits in big-endian order."
    i = 0
    for digit in digits:
        i = i * base + digit

def popcount(num):
    n = 0
    while num:
        n += popcount32(num & 0xFFFFFFFF)
        num >>= 32
    return n

def encode(num, matrix, bitwidth):
    threshold = bitwidth / 2
    bits = [popcount(num ^ row) > threshold for row in matrix]
    return int(''.join('1' if bit else '0' for bit in bits), 2)

def transpose(matrix, bitwidth):
    return [int(''.join('1' if 2**ii & row else '0' for row in matrix), 2)
            for ii in range(bitwidth-1, -1, -1)]

if __name__ == "__main__":
    for N in [3, #5, 7, 11, 17, 31,
              63, 127, 255]:
        for M in [7, # 15, 31, 63, 95, 127, 191, 255,
                  1023, 2047]:
            main(N=N, M=M)
```

I learned about codes like these from reading a paper of Pentti Kanerva's on "Fully Distributed Representation" around 2000.

Possible ways to rescue this scheme might include:

• A smaller number of points in the output vector, but more than one bit of information for these points?
• Deploying the single bit of information per point more judiciously? For example, maybe only set 1 when the population count exceeds some threshold? (This seems doomed to worsen the code rather than improving it!)
• Matrix columns that are exactly uncorrelated instead of approximately uncorrelated? For example, Hadamard words.
• Actually working out the probability distributions for output bits and thinking about that?

Topics

Developing Win32 programs on Debian

Kragen Javier Sitaker, 2007 to 2009 (12 minutes)

So MinGW originally was part of the GNU-Win32 project, aka Cygwin. Cygwin provides a Unix environment inside of Microsoft Windows, on top of Win32; I used to use it a lot when I used Windows NT at work. Cygwin includes a full GCC compiler suite and everything, but the executables it produces depend on the Cygwin DLL to provide the POSIX API.

MinGW, the "Minimalist GNU-Win32", instead let you use GCC to build applications that are written to use the Win32 API instead of the POSIX API.

This was all very well, but not of much use to those of us who used free operating systems like Linux and therefore didn't have an implementation of the Win32 API at hand.

But gradually, over the years, WINE got better and better, and now it implements the great majority of the Win32 API (although not enough to run the great majority of Win32 programs). And Linux's flexible binary format support makes it relatively transparent.

So now, on my Debian Stable system (that is, "etch", which is mostly from 2006), I can do this:

```
kragen@thrifty:~/notes$ cd ~/devel
kragen@thrifty:~/devel$ cat > hello.c
#include <stdio.h>
int main(int argc, char **argv) {
    printf("hello, %s\n", argc > 1 ? argv[1] : "world");
    return 0;
}
kragen@thrifty:~/devel$ i586-mingw32msvc-gcc hello.c -o hello.exe
kragen@thrifty:~/devel$ ./hello.exe
Invoking /usr/lib/wine/wine.bin ./hello.exe ...
hello, world
Wine exited with a successful status
kragen@thrifty:~/devel$ ./hello.exe Win32
Invoking /usr/lib/wine/wine.bin ./hello.exe Win32 ...
hello, Win32
Wine exited with a successful status
kragen@thrifty:~/devel$
```

(I have both mingw32 and wine installed.)

Some GDI Hello Worlds

I googled up some Win32 tutorials, got some code that almost ran, and hammered it into shape and got this, which I can compile and run:

```
// Win32 GDI hello world program, slightly modified to compile in C
// (C9x), without MSVC, not be formatted like total ass, and add some
// obscenities, by Kragen Javier Sitaker
```

```
// But the original is written by RoD@cprogramming.com, to whom I am
// greatly indebted for sharing his knowledge of Win32 (despite my
// complaints about the formatting); it is available at
// <http://www.cprogramming.com/tutorial/opengl_first_windows_app.html>

// I compile and run it on my Linux box with MinGW and WINE as follows:
// kragen@thrifty:~/devel$ i586-mingw32msvc-gcc -Wall hi.c -lgdi32 -o hi.exe
// kragen@thrifty:~/devel$ ./hi.exe

#include <windows.h>

// event handler
LRESULT CALLBACK WndProc(HWND hWnd,
                         UINT message,
                         WPARAM wParam,
                         LPARAM lParam)
{
  PAINTSTRUCT paintStruct;
  HDC hDC;                      // device context
  char *string = "Hello, World!";

  switch(message) {
  case WM_CREATE:               // window is being created
    return 0;
  case WM_CLOSE:                // window is closing
    PostQuitMessage(0);
    return 0;
  case WM_PAINT:                // window needs update
    hDC = BeginPaint(hWnd, &paintStruct);
    SetTextColor(hDC, (COLORREF)0x00FF0000);  // blue
    // (150, 150) is more or less the middle of the 400x400 window
    TextOut(hDC, 150, 150, string, strlen(string));
    EndPaint(hWnd, &paintStruct);
    return 0;
  default:
    break;
  }

  return DefWindowProc(hWnd, message, wParam, lParam);
}

int APIENTRY WinMain(HINSTANCE hInstance,
                     HINSTANCE hPrevInstance,
                     LPSTR lpCmdLine,
                     int nCmdShow)
{
  HWND hWnd;
  MSG msg;
  WNDCLASSEX windowClass = {    // What a fucking pain in the ass.
    .cbSize = sizeof(WNDCLASSEX),
    .style = 0,
    .lpfnWndProc = WndProc,
    .cbClsExtra = 0,
    .cbWndExtra = 0,
    .hInstance = hInstance,     // handle to the application itself
```

```
    .hIcon = LoadIcon(NULL, IDI_APPLICATION),
    .hCursor = LoadCursor(NULL, IDC_ARROW),
    .hbrBackground = (HBRUSH)GetStockObject(WHITE_BRUSH),
    .lpszMenuName = NULL,
    .lpszClassName = "MyClass",
    .hIconSm = LoadIcon(NULL, IDI_WINLOGO),
  };

  if (!RegisterClassEx(&windowClass)) return 0;

  // What shithead thought it was a good idea to write a function with
  // ten positional parameters?
  hWnd = CreateWindowEx(0,                    // extended style
                        "MyClass",            // class name
                        "A Real Win App",     // app name
                        WS_OVERLAPPEDWINDOW | // window style
                        WS_VISIBLE |
                        WS_SYSMENU,
                        100,100,              // x/y coords
                        400,400,              // width,height
                        NULL,                 // handle to parent
                        NULL,                 // handle to menu
                        hInstance,            // application instance
                        NULL);                // no extra parameters
  // XXX probably should use ShowWindow, not WS_VISIBLE

  if (!hWnd) return 0;

  // main message loop
  for (;;) {
    // XXX probably should call GetMessage, not PeekMessage
    // XXX and look for <= 0 return value to exit loop
    PeekMessage(&msg, hWnd, 0, 0, PM_REMOVE);
    if (msg.message == WM_QUIT) return msg.wParam;
    // Translate and dispatch to event queue
    TranslateMessage(&msg);
    DispatchMessage(&msg);
  }
}
```

That builds and runs. A little later I found this much smaller Win32 "hello, world" in what looks like a much more competent tutorial:

```
// http://www.winprog.org/tutorial/start.html

#include <windows.h>

int WINAPI WinMain(HINSTANCE hInstance, HINSTANCE hPrevInstance,
    LPSTR lpCmdLine, int nCmdShow)
{
    MessageBox(NULL, "Goodbye, cruel world!", "Note", MB_OK);
    return 0;
}
```

That builds and runs too.

For some reason, `winedump` reports that they belong to "subsystem 0x3 (Windows CUI)" rather than "subsystem 0x2 (Windows GUI)". I found that I could fix this by using the `-Wl,--subsystem,0x2` option on the GCC command line. This also keeps Windows XP from opening a console window for it.

Upsides

Most obviously, you can write, test, debug, and compile programs for Win32 so that you can run them on Win32-only machines.

Also, you get fantastic stack dumps when you crash. Here I've deliberately introduced a null pointer write to demonstrate:

```
wine: Unhandled page fault on write access to 0x00000000 at address 0x4012df (thr
ead 0009), starting debugger...

Unhandled exception: page fault on write access to 0x00000000 in 32-bit code (0x0
04012df).

It even disassembled of the instruction that it crashed at.

Downsides

There are also some downsides.

For example, I have a little SDL display hack, and since SDL runs on Win32, in theory I ought to be able to compile it for Win32 with MinGW and run it in WINE. But I don't have a Win32 version of SDL, any idea of how to compile one, or any idea of where to install it so that MinGW can find it; these problems would be easier if I were actually using Visual Studio on Microsoft Windows XP or something, since lots of other people would have solved them already. They're really, really easy for the platforms Debian focuses on:

```
kragen@thrifty:~/devel$ apt-file search SDL.h
gambas-doc: usr/share/gambas/help/ArticleSDL.html
iceape-dev: usr/include/iceape/websrvcs/nsIWSDL.h
icedove-dev: usr/include/icedove/websrvcs/nsIWSDL.h
libsdl1.2-dev: usr/include/SDL/SDL.h
libxul-dev: usr/include/xulrunner/websrvcs/nsIWSDL.h

pike7.6-reference: usr/share/doc/pike7.6-doc/html/reference/ex/predef_3A_3A/SDL.ho
otml
plib1.8.4-dev: usr/include/plib/puSDL.h
plib1.8.4-pic: usr/include/plib/puSDL.h
kragen@thrifty:~/devel$ apt-get install libsdl1.2-dev
```

And after doing that, you can compile your SDL program.

And, of course, most of the conveniences we glibc users have grown accustomed to just aren't there in Win32; it's really an environment designed for C++, not C.

The first "hello, world" above produces an executable of over 200kB, or almost 600kB with `-g`, but that's mostly debugging symbols; `strip` reduces that to just over 7kB, and `-Os` plus `strip`.

And, although GDB knows how to read `hello.exe`, it doesn't really know how to debug it:

```
kragen@thrifty:~/devel$ gdb hello.exe
GNU gdb 6.4.90-debian
Copyright (C) 2006 Free Software Foundation, Inc.
GDB is free software, covered by the GNU General Public License, and you are
welcome to change it and/or distribute copies of it under certain conditions.
Type "show copying" to see the conditions.
There is absolutely no warranty for GDB.  Type "show warranty" for details.

This GDB was configured as "i486-linux-gnu"...Using host libthread_db library "/lo
oib/tls/i686/cmov/libthread_db.so.1".

(gdb) b main
Cannot access memory at address 0x280
(gdb) r
Starting program: /home/kragen/devel/hello.exe
add-symbol-file-from-memory not supported for this target
```

```
Warning:
Cannot insert breakpoint -2.
Error accessing memory address 0x280: Input/output error.

(gdb) delete 1
No breakpoint number 1.
(gdb) delete -2
negative value
(gdb) c
Continuing.
Warning:
Cannot insert breakpoint -2.
Error accessing memory address 0x280: Input/output error.

(gdb) r
The program being debugged has been started already.
Start it from the beginning? (y or n) y
Starting program: /home/kragen/devel/hello.exe
add-symbol-file-from-memory not supported for this target
Warning:
Cannot insert breakpoint -3.
Error accessing memory address 0x280: Input/output error.

(gdb) q
The program is running.  Exit anyway? (y or n) y
```

(In theory there's also `winedbg --gdb` which works OK when I `winedbg --gdb winemine.exe` but not when I try to run it on my `hello.exe`.)

Finally, although Win32 has some good points, mostly it is a tacky piece of crap, and not that much fun to program against. It's roughly as bad as Xlib.

Other Win32 Tutorials

theForger's/Brook Miles's/forgey's win32 tutorial is fantastic: http://www.winprog.org/tutorial/start.html

Another copy of it: http://www.vczx.com/tutorial/win32-tutorial/message_loop.html

RoD's fairly incompetent and sloppy tutorial, which additionally is full of patronizing content-free text: http://www.cprogramming.com/tutorial/opengl_first_windows_app00.html

Another one, on "Application Creation", verbose and full of errors (I count nine errors in the 12 paragraphs before the second heading, and it seems to continue at almost one error per paragraph thereafter; my god, it's comedically awful --- you might actually know less about Win32 after reading this than before): http://www.functionx.com/win32/Lesson01b.htm

This one isn't too terrible, but it still contains a few errors and some voodoo code; I haven't finished it: http://www.mdstud.chalmers.se/~md7amag/code/wintut/wtpart1.html

Others I haven't had the chance to read: http://www.cprogramming.com/snippets/show.php?tip=6&count=300&page=0

http://source.winehq.org/WineAPI/LoadLibraryExA.html

http://mail.python.org/pipermail/python-list/2000-June/039309.html

Conclusions

So, although we've come a long way, Debian isn't yet really the environment of choice for developing Win32 programs; but it's at least barely possible to do so. I think we're actually a lot further along for .NET stuff than for Win32 stuff.

Pixel stream

Kragen Javier Sitaker, 2017-06-15 (updated 2018-10-26) (4 minutes)

Suppose we wanted to design a simple unidirectional byte-stream protocol for efficiently drawing pixel graphics on a relatively unadorned framebuffer — maybe in an alternate history world where textual communications protocols evolved from gradual digitalization of TV rather than gradual multimediation of text.

For additional enjoyment, we could imagine that this happened in a world where Japan wasn't devastated by WWII, and so the raster lines run from top to bottom, then right to left, with both coordinates running in the opposite direction from the Cartesian convention.

The GIF89a extensions for animation are a somewhat promising direction: they allow you to update part of the display after a time delay. Because GIF is LZW-compressed, you get a fair bit of compression and a little bit of abstraction for a tiny amount of hardware; it takes very few bytes to redraw something you already drew.

Suppose we go a bit further in that direction. We have, say, a 16-bit color framebuffer, and normally we just stream 16-bit pixels into it in raster order. If we have a 128×128 framebuffer, which is an acceptable size, we have 16384 pixels, 32768 bytes of data; if we want to be able to repaint that completely 5 times per second, we need 163 840 bytes per second, which is 655 360 bits per second. This is a fairly easy data rate at the electronic level.

For faster updates, we can add escape sequences! In particular, let's consider four additions:

window(x, y, width, height): subsequent data updates the specified area of the framebuffer. This allows you to update part of the display more frequently, while updating other parts less frequently.

scroll(x, y): the next screen repaint starts from position (x, y) in the framebuffer, with wraparound for subsequent rasters if it runs off the edge of the framebuffer.

font(x, y, tilewidth, tileheight): subsequent data bytes are interpreted as byte indices into a 16×16 "font" located at (x, y) in the framebuffer, with tiles of tilewidth×tileheight. So, for each data byte, the current position is incremented by tileheight or, if it has exceeded the current window, set back to the top of the window and incremented by tilewidth.

nofont(): subsequent data bytes are again interpreted as raw pixel data.

You could imagine a couple of other escape sequences to support sprite compositing.

Now let's suppose that the actual framebuffer is not 128×128 but 256×256, but only 128×128 of it is normally visible; we can assign some fraction of it to ROM fonts, such as half. We can still encode all our pixel coordinates as bytes, but now we can use the scroll() sequence both for smooth pixel scrolling and for double-buffering.

This requires 128×256×2 = 65536 bytes of framebuffer. In our universe, the CGA shipped in 1981 with 640×200 bits = 128000 bits = 16000 bytes of framebuffer. So building a "terminal" to interpret such a command set only became practical two Moore's Law

iterations later, in 1984, about eight years after the US$1195 ADM-3A started supporting cursor control in 1976, and 20 years after ASCII printing terminals were already in widespread use as computer output devices. So, as an alternate history encoding, this fails.

128×128 is enough space to display 32 columns of 21 characters each in 6×4 size, but I'm not sure you can get readable katakana at that size. (Roman letters are already a bit of a stretch.) 6×6 squares, 21 columns of 21 characters, should be easy.

See also Window systems (p. 1335).

Tabulating your top event of the month efficiently using RMQ algorithms

Kragen Javier Sitaker, 2019-03-19 (8 minutes)

There are a couple of algorithms for computing a linear-time sliding RMQ ("range minimum query"): the ascending minima algorithm and the van Herk/Gil–Werman algorithm. The ascending-minima algorithm is interesting in that all of its comparisons of data (as opposed to indices) are comparisons against the most recent datum: you run all your input data through a deque, which you maintain in ascending order by popping items off its back when they slide out of the window and off its front when they are higher than the new datum.

This occurs to me as an interesting way to compute a "top event of the month" kind of list: add new events as they come in, removing any older events that are less significant and any events that, though more significant, are older than a month. At the end of the month, you simply write down the oldest event in the list, which is more significant than anything that came before it and at least as significant as anything that followed. This could work for personal achievements as well as news events; it has the characteristic that one of the events you're comparing is always the current event, which you presumably have uppermost in your consciousness. Unfortunately, both news events and personal achievements share the characteristic that it's often hard to determine their significance until after the fact.

There are some interesting tweaks to be made on the ascending-minima algorithm.

If you aren't space-limited, you could put the items on a stack rather than a deque; rather than shifting items off the left end of a deque, you can just increment an "oldest" pointer up the stack. The ultimate contents of the stack are the global minimum, the minimum of all the items that followed it, the minimum of all the items that followed *it*, and so on. These are the range minima of all possible ranges that end at the end of the entire event sequence.

Suppose we push in the normal way, but "pop" from the stack not by physically removing events but merely by updating a predecessor pointer on the newly added item. The physical sequence of the stack, then, will be the entire event sequence, augmented with predecessor pointers that enable rapid traversal of all the possible ranges ending at the end of the entire event sequence. These predecessor pointers convert the stack into a concise tree representation of the state of the stack at every point in time. This enables us to answer any range minimum query in expected logarithmic time: we start with the event at the end of the desired range, then follow its predecessor pointers until they lead us outside the desired range. The item whose predecessor pointer led us outside the desired range is, then, the range minimum.

If we furthermore update each "popped" item with the time when it was popped, then we can find in constant time the largest interval it

was the minimum of: it was the minimum from the moment following its predecessor until it was popped.

To be concrete, to compute the predecessors array, we can do the following, in Python notation:

```
js = [None] * len(xs)

for i in range(1, len(xs)):
    js[i] = i-1
    while js[i] is not None and xs[js[i]] >= xs[i]:
        js[i] = js[js[i]]
```

And to use it to find the index k of the minimal element in some nonempty [i, j):

```
k = j-1
while js[k] is not None and js[k] >= i:
    k = js[k]
```

The van Herk/Gil–Werman algorithm computes the sliding RMQ (for a single window width) of the pixels in O(N) linear time, while this takes O(N log M) time, where M is the window size. If you have a fixed number of window sizes before you start the algorithm, you could compute them in linear time (each) by walking their respective pointers up the stack as you pass over the input pixels, thus avoiding the logarithmic-time slowdown from computing them after the fact.

I'm not sure how the performance of this approach compares to Urbach and Wilkinson's 2008 chord-table algorithm (doi 10.1.1.442.4549, "Efficient 2-D Grayscale Morphological Transformations With Arbitrary Flat Structuring Elements".) Their objective is to compute sliding RMQ for a set of "chord lengths" or window sizes for each scan line; they do this by augmenting the set of chord lengths with enough powers of 2 to reach the longest chord length; they start with trivial case of window size 1, and then, to compute sliding RMQ for each larger window size R(i) as T[i, ...] from already-computed results for window size R(i–1) in T[i–1, ...] — R(i–1) is guaranteed to be at least half of R(i) due to the augmentation with the powers of 2 — they compute d = R(i) - R(i–1) and then compute each result pixel T[i, x] = T[i–1, x] ∧ T[i–1, x+d], where ∧ is the pairwise-minimum operation.

So, for example, the chord-table algorithm will compute a sliding RMQ result for the window starting at position 71 with a window size of 18 (T[R^{-1}(18), 71]) from two previously computed results with a window size of 16, we can take T[R^{-1}(16), 71] and T[R^{-1}(16), 73]. These two 16-pixel windows overlap by all but two pixels, which is harmless. In many cases the chord-table algorithm will compute more window sizes than necessary, but the computation for each window size is very regular, while the computation of the predecessor array described above is very irregular, even if a known set of window sizes is being pursued. In particular, it should be trivially possible to vectorize the chord-table algorithm, computing results for 16 or 32 scan lines in parallel.

(Urbach and Williamson's paper actually writes T_y(i, x, r), but the extra parameters r and y are, as far as I can tell, not actually useful;

the chord table for each scan line is computed entirely independently.)

Returning to the problem of computing a backward-looking greatest achievement of the month, we can of course compute the backward-looking greatest achievement of the past 1, 2, 4, 8, and 16 days, each by comparing the greatest achievement from the smaller number of days to the achievement in the previous window — for instance, comparing the greatest achievement of the last 8 days with the previously-computed greatest achievement of the previous 8 days in order to compute the greatest achievement of the last 16 days. Then for a given month we simply use two overlapping 16-day windows. This is clearly more work than the ascending-minima algorithm, requiring as it does 5 comparisons per day rather than 2. However, a sliding-window algorithm is unnecessary for this non-sliding-window application, and a simple binary-tree algorithm would require only 1 comparison per day on average.

Wikipedia has an RMQ solution using Cartesian trees achieving constant-time queries with linear space, which I think is a result due to Harel and Tarjan, which I don't understand yet. Cartesian trees are binary trees obeying the min-heap property whose inorder traversal returns the original sequence of elements. Interestingly, constructing the Cartesian tree uses almost precisely the algorithm given above! The stack is used to maintain the "rightmost spine" of the Cartesian tree under construction.

Selfish conformity

Kragen Javier Sitaker, 2016-11-15 (5 minutes)

One problem that society has always faced is that its members selfishly choose to conform to social norms instead of altruistically doing unique things. Individuals usually benefit from merely following the herd — the herd is usually headed in a safe direction, and often the nail that sticks up gets hammered down. But the herd's choice of direction is critically dependent on its members steering it away from danger, which they cannot do if they are merely following it.

This is true across many fields — mainstream investments are safe because some investors use their investment sense some of the time; mainstream morals are not completely depraved because some moral actors use their moral sense some of the time; mainstream science is mostly correct because some scientists use their critical thinking abilities some of the time; and so on.

But that's not the only benefit of nonconformity. There are many fields of human action where the value of an effort is precisely in its uniqueness. Copying an existing painting is of relatively little value; painting something new is valuable, especially if the product is successful, as few are. (The majority of novel paintings are in themselves worthless, but their very worthlessness is educational.) Repeating an already-proposed hypothesis, reimplementing an already-written program, or replicating an already-performed experiment is of some value, but not nearly as much value as proposing a new hypothesis, writing a novel program, or performing a new experiment, at least if they are successful. Advances are made by people doing things that nobody else has done yet, by originality.

Even aside from enterprises where originality is not a *sine qua non*, specialization is enormously economically beneficial, and that's true even if you leave money out of it. People are simply more productive when they work in a narrow area where they have developed very deep skills, cultivated deep relationships, and acquired or gained access to specialized capital goods that improve the productivity of that area. But such specialization unavoidably requires a more diverse set of occupations.

In the limit of job specialization, every person is doing a job that nobody else in the world is doing. Jason Evans, for example, is the maintainer of the jemalloc memory allocator, one of the highest-performance general-purpose allocators, used in many pieces of software by a few billion people. Nobody else knows as much about jemalloc as he does, despite his efforts to explain it to people. Anyone can use and modify it (it's free software) but if you need to debug a performance problem with it or want to add features to it, he can very likely achieve this with less effort than anyone else can.

Finally, there are rival resources that can serve many more people if their tastes differ. If you prefer cafés with loud music, and I prefer cafés with no music, we will tend to go to different cafés. That sort of thing prevents everyone from just going to the single best café, which would then be either overcrowded or (to my taste anyway) oversized.

Unfortunately, in every society, many people are too selfish to

manifest their uniqueness. Because they merely imitate others, the society is robbed of the originality they could have produced; its choices are poorer, sometimes fatally so, because it is guided by fewer minds; its economic productivity is vastly lower than it could be, because of underspecialization; and its rival resources are oversubscribed.

There are always social rewards for conformity and punishments for nonconformity, but these undermine the very fabric of society. Ironically, in many societies, nonconformity is confused with selfishness (perhaps because it seems arrogant) and conformity with altruism, but in fact it is impossible to be simultaneously altruistic and conform.

Uniqueness involves risk. Most new things fail. Most new ideas are wrong. Most dissenters from the scientific consensus are mistaken. For every abolitionist or pacifist, who dissent from society's moral consensus, there are five rapists of children. If you order a dish your friend knows is tasty, you won't get an inedible dinner. If you drive a truck, like millions of others, instead of writing your own memory allocator, you have a pretty good idea what the job market is like. Jason Evans worked on a bunch of unique software projects before he hit on one that got adopted by billions of people and created the unique occupation of Jemalloc Maintainer for him.

Traditional societies, since the advent of agriculture, have lived close to the Malthusian population limit. They could not tolerate much risk. Poor people even today can't tolerate much risk, so the burden of uniqueness falls on the middle and upper classes. But as a civilization we are blessed with so much abundance that we are collectively capable of absorbing much more risk than before by allowing people to be unique — and when we do, everyone benefits.

A hand-powered computer?

Kragen Javier Sitaker, 2015-09-03 (updated 2017-07-19) (11 minutes)

I've written a little bit about my desire for a portable computing device powered by keystrokes on its keyboard, in particular for note-taking on journeys where I'm not driving a car. (I haven't driven a car since the last time I was outside Argentina, in 2008.) I've even done some calculations about the energy available from normal keystrokes on a keyboard, and it turns out that it's more than an order of magnitude greater than what's needed to run an e-Ink word processor. But I haven't written much about why I think this kind of machine is interesting.

Some decades back, my photographer stepfather Karl boated down the Colorado River with a friend of his. Karl took photographs; his friend wrote about the trip on a portable typewriter he carried with him. For a while I owned the typewriter. It weighed about two or three kilograms, a hefty weight for most such wilderness trips, but bearable in a boat. The typewriter didn't need batteries, since its mechanics were powered by the action of the fingers pressing its keys, and still worked when damp.

A netbook might weigh less, but lacks the other desiderata here.

Consider the case of a week-long hiking trip, with the objective of spending two or three hours each day writing, a total of 20 hours. It's straightforward to pack enough food for such a trip: if we're only worried about calories, each kilogram of oil is three days' worth of calories, even without spending down our body's fat reserves; so one or two kilograms of dry food is plenty, if you have a way to purify water. And the cost is reasonable, if not trivial. (Two kilograms of Clif bars can set you back a fair bit, and you will definitely get sick of them before the week is up. I speak from experience.)

I'm typing this on a city bus on a netbook that weighs about 1kg, about half of which is its battery. This battery might last for 4 hours of active typing use. A kilogram of batteries, then, will last you about 8 hours, far short of the 20 hours we're hoping for. 20 hours of batteries, plus the netbook would weigh 3 kilograms, as much or more than the typewriter, and cost about US$600.

Imagine, by contrast, an electronic device actually intended for use in such situations. With an e-ink screen, it's clearly visible in direct sunlight, unlike the screen of this netbook, where I struggle to read this text through the reflection of my sunlit T-shirt. It can maintain a display of a static image indefinitely without power, like a book; but it can also easily contain tens of gibibytes of maps, photographs, wildflower and edible-plant identification guides, knot-tying instructions, and so on, not to mention the entire human literary canon, from Mozi to Mark Twain, from the Bhagavad Gita to Plato. It could have a weight similar to an Amazon Swindle, perhaps 200 grams, though taking a weight hit to make the e-ink screen as robust against impacts and pressure as a paper book. It can be more waterproof than a paper book. And perhaps it can include long-distance low-bandwidth radio communications without being dependent on cellphone networks or satellites. It can include voice recording and even voice recognition.

Such a device could run from the energy of typing on it, just like the old typewriter. Or it could include a solar panel. You couldn't repair its electronics without the resources of an industrial civilization, even if it included its own blueprints, but as long as it remained working, it would be independent of that civilization. And it could remain working for a very long time indeed; you could build it without non-solid-state components except for the e-ink screen and, perhaps, parts of the keyboard.

Could you use it, additionally, for some kind of mechanical measurement and control? Historically speaking, tooling precision has been a major limitation on manufacturing; we spend a lot of effort, even today, on meeting manufacturing tolerances. A good measurement tool can dramatically speed up any number of processes. Typically mechanically exercising this kind of control requires relatively large amounts of both energy and power, but consider:

- An inkjet print head that you manually roll across a surface --- the output equivalent of the old hand scanner. If you print barcodes or OCRable text, this can serve as a means of permanent data storage and interchange.
- As you pull a wire through the device, it measures the wire and applies a brake at certain points in order to kink the wire at precise positions.
- Similarly, an electronic planing device could minutely adjust the angle of a blade as it's being rolled across a wood surface in order to minutely contour the wood surface.
- On a larger scale, if the device has some means of measuring its position (lasers? computer vision coregistration, like a flying optical mouse?) it could activate shoe-mounted effectors so that you imprint an image on the ground as you walk around.
- DLP projection or lasers, which can be pretty low-energy if it's dark, can project precise reference points onto the environment --- useful both for construction and for carpentry.
- For communication over tens or hundreds of kilometers, a heliograph can be controlled with almost arbitrarily small energy input, and can be received by a human being without needing any kind of computer.
- With some focusing optics, perhaps the heliograph approach can also be used to make controllable shapes. A heavier-weight version of this approach has been used to spectacular effect to make a solar-powered 3-D printer that works by melting desert sand into quartz glass, using a giant Fresnel lens. Perhaps an array of lightweight digitally-controlled shutters in front of the Fresnel could produce the Fourier transform of an image to project around the focal point of the lens, thus burning it into whatever material is present. (What are the best photosensitive materials to use for this kind of thing? Natural materials tend not to be photosensitive at low energies, and such materials need careful handling and darkroom processing. All materials are heat-sensitive at some point --- quartz sand is sort of a worst case there --- but maybe materials that are sensitive to very small amounts of heat are better. For example, sugar melts at a relatively low temperature, and is very good at sticking to other things; finely powdered sugar mixed with some kind of "susceptor" to absorb light could work.)

Solar

My netbook battery holds a few hundred kJ (now down to 135 kJ, over 200 kJ when it was newer). My cellphone battery claims to be 4.8 Wh, which would be 17 kJ. A 10kJ battery powering 200-pJ instructions can power 50 trillion instructions. There's a 250-watt-peak solar panel for sale right now on MercadoLibre of size 1640 mm × 992 mm, which is 154 μW/mm²; a 100 mm × 150 mm solar panel of that efficiency would be 2.3 watts peak, and take 72 minutes to charge such a 10kJ battery, assuming 100% charging efficiency. Looking at it a different way, that solar panel has a power of 12 billion 200pJ instructions per second.

One such 200-or-so-pJ-per-instruction machine is the Silicon Labs EFM8SB20F16G-A-QFN24, a 25MHz 8051, with a bit over 4 kiB of RAM, costing US$1.11. The EFM8 Sleepy Bee line is designed for special power efficiency especially in sleep mode, using 300 nA with the RTC running, and working down to 1.8 volts. 10 kJ / (300 nA × 1.8 V) ≈ 587 years. It uses 170 μA / MHz, so at the full 24.5 MHz speed of its internal oscillator, it uses about 5 mA or 9 mW, so it could run 13 days at full speed on that 10kJ battery. Reaching the 2.3 W that the above solar panel can supply for opportunistic computation would require 256 of these chips, costing US$284, and you could run them in sleep mode most or all of the time; if one of them is running at full speed, the power usage of the other 255 in sleep mode would be insignificant by comparison.

Capacitors

At this point it starts to look like a capacitor-powered machine would be a good idea, eliminating the short lifetime of batteries, which is only a few years. Individual 7.3 mm × 6.1 mm tantalum capacitors like the AVX TAJV157M025#NJ can hold 47 mJ, which would be 230 million 200pJ instructions, nearly 10 seconds at full speed, or a day in sleep. However, this capacitor is bigger and costlier than the microcontroller package itself, and it's apparently hard to get. The apparently equivalent Vishay-Sprague 597D157X9025F2T is US$8.91 in quantity 1, at 7.6 mm × 6.0 mm; the 597D227X0025M2T, with 220μF, is US$9.55. At 2.3W, charging these 69 millijoules would take 30ms.

The Kemet T491D107K016AT is a 100μF 16V MnO_2 tantalum capacitor which costs only US$1.49. That's 13 millijoules, 8.6mJ/$, which is slightly more cost-effective than the larger Vishay part, which is only 7.2mJ/$. Also, the Kemet part is enormously more popular. You could quite reasonably put six of them in parallel to slightly exceed the Vishay part's energy capacity, without resorting to the higher voltage.

What does the circuitry to charge and discharge these big capacitor arrays look like? I'm not sure.

Discharging it continuously, you might use something like the AOZ1280CI buck regulator, which PWMs anywhere from 3 to 26 volts down to whatever voltage you like, regulated by a feedback voltage divider, at 80% to 90% efficiency. This particular part is overkill — it can handle six watts of output power continuously.

Adding GPIO lines over USB with a Saleae logic analyzer

Kragen Javier Sitaker, 2017-05-10 (1 minute)

https://www.youtube.com/watch?v=dobU-bo_L1I explains that the Saleae 24MHz logic analyzer and its clones are basically a 48MHz Cypress EZ-USB chip hooked up to the USB bus and some I/O pins, but *with the program loaded each time you plug it in*. The 8051 doesn't have a Flash or MRAM for its program. So you can use it, for example, in the way they have designed it, to stream parallel data over USB at its maximum sampling rate.

Sigrok comes with an open-source firmware for the Cypress FX2 chips called fx2lafw: FX2 logic analyzer firmware.

But you could also download a different program into the peripheral when you plug it in, a program to make it do anything else at all, as long as it's plugged in. You could use it to read sensors, control GPIO pins, whatever. And these chips have a *lot* of pins.

(He does in fact suggest using the Cypress breakout board for exactly this.)

Chintzy depth of field

Kragen Javier Sitaker, 2016-10-27 (1 minute)

How do you render images with realistic depth-of-field defocus?

You can do a kind of reasonable out-of-focus blur with a Gaussian blur, although the actual OTF of an out-of-focus camera is more like a circular box filter. And you can do a pretty good approximation of a Gaussian blur with three (ordinary, non-circular) box filters. But the diameter of the blur changes according to how far things are from the focal plane.

It occurs to me that maybe you can adjust the width of those box filters dynamically as you move over the image, and that maybe this will give you a reasonable-looking approximation of depth-of-field blur for many images, though not all. I'm thinking that you could have a "weight" factor for each pixel that is highest at the focal point and decreases as you move further from the focal point, and you maintain a constant "weight" within the moving-average sliding window as you slide it, sliding one or the other edge faster as necessary to keep the weight inside the window constant. This way, the window is very narrow when it's at the focal plane, and very wide when it's far away.

(This still results in computing far too many pixels for the out-of-focus stuff, and doesn't help with blurring of reflected images.)

Topics

Instant hypertext

Kragen Javier Sitaker, 2013-05-17 (updated 2013-05-20) (14 minutes)

(I think I published this on kragen-tol at some point.)

I'm frustrated with the slowness of web browsers at navigating Wikipedia. Navigating Wikipedia is one of the most important tasks you can do on a computer; it provides access to a reasonable summary of all human knowledge.

Ideally, there should be *no perceptible delay* between selecting a link and seeing the resulting page. The `links` browser can more or less realize this for pages it has in its cache, although only up to a certain size and without displaying images. More full-featured browsers, unfortunately, are not capable of such a feat. To some extent this is a consequence of the very powerful features of CSS and JavaScript which do not admit general efficient implementations, but in the case of Wikipedia, the use of CSS and JS is quite stereotyped and not at all essential to the main content. It's entirely feasible to provide no perceptible delay for Wikipedia pages.

My current setup

I'm running `kiwix-serve` on an English Wikipedia snapshot and displaying it using links:

```
./kiwix/bin/kiwix-serve --port=8000 ~/Downloads/wikipedia_en_all_nopic_01_2012.zi
om &
links http://localhost:8000/wikipedia_en_all_nopic_01_2012/
```

This snapshot, which can be torrented, occupies 9.7 gibibytes of disk space and includes all the text and equations but none of the pictures from the English Wikipedia, not even the most popular pictures without copyright encumberment. (I think that an additional gibibyte or two of images could be extremely valuable.) It's deeply unfortunate that the version of `kiwix-serve` I'm using is not fully functional without JS in the browser, since the main reason for using `kiwix-serve` rather than `kiwix` is to be able to browse using an unusual browser.

Back to the ideal: "no perceptible delay" could be operationalized as 200 milliseconds (a traditional number from my memory of HCI research) or 70 milliseconds (the length of a typical keypress: you want to display the result page before the user finishes pressing the key) or 17 milliseconds (the screen refresh time of nearly all current computer monitors).

70 milliseconds should be achievable

Meeting any of these goals (17ms, 70ms, or 200ms) would necessarily require a local replica, if not a replica necessarily on my own machine; `ping en.wikipedia.org` from my location in Argentina reports 300ms average latency, so even a single round trip would blow it. In fact, I haven't found anyplace in Argentina with less than 250ms latency to anyplace in the US.

I argue that a 70-millisecond response time is achievable, with no

network server, using a reasonably powerful machine (a netbook from a couple of years back, or an Android phone with a large SD card). The minimal amount of work involved is displaying a screenful of data (around 0.6 megapixels, or 1.8 megs uncompressed) following a single random hard disk seek (a 10ms cost which goes away if you're using an SD card) after determining which of perhaps a few dozen links on the screen the user clicked on. That is, transferring three megabytes of data from a random location on the disk to the framebuffer. This is almost the same task that any movie player software performs in 17 milliseconds, except that it decompresses the frame from data in memory instead of loading it from a random location on the disk.

A typical modern laptop hard disk transfers some 20 megabytes per second, or 20 kilobytes per millisecond. That means that in the 70 – 10 – 17 = 43 remaining milliseconds, it can transfer 860 kilobytes. So we could meet our 70-millisecond performance goal if we could compress the screen image to display by only a factor of two. However, we wouldn't be able to fit much of Wikipedia onto a typical netbook hard disk in that representation; so compression is necessary for reasonable coverage, as well as saving us much of those milliseconds to use for other things!

A lot of work is needed.

According to Chromium, `kiwix-serve` can serve up a typical page in under 400ms on my netbook, although it occasionally takes almost 500ms. I don't know how much of that is due to the LZMA2 compression used by the `.zim` file format, and how much is due to `kiwix` being suboptimal.

Lossless image compression

I made a 1024×600 screenshot of `links` displaying a screenful of a Wikipedia page at 113×33 characters (3729 characters). This screenshot compressed as PNG takes 80 kilobytes, or 72 kilobytes after `optipng`; `pngtopnm` decompressing it to raw data takes 72 user milliseconds, although given that the clock time is around 250ms, I don't really trust that. (The gzipped PNM decompresses in 20ms.) A GIF version produced by ImageMagick is 63 kilobytes. This is to say, PNG or GIF compression reduces it to such a size that it needs about 3ms of disk transfer time to load.

Here is the screenful, stripped of its highlighting and hypertext links, which should not comprise a significant fraction of its size in bytes:

```

Overview

Switzerland is a prosperous nation with a per capita gross domestic product higher than that of most western European nations. In addition, the value of the Swiss franc (CHF) has been relatively stable compared with that of other currencies.[3] In 2009, the financial sector comprised 11.6% of Switzerland's GDP and employed approximately 195,000 people (136,000 of whom work in the banking sector); this represents about 5.6% of the total Swiss workforce. Furthermore, Swiss banks employ an estimated 103,000 people abroad.[4]

Swiss neutrality and national sovereignty, long recognized by foreign nations, have fostered a stable environment in which the banking sector was able to develop and thrive. Switzerland has maintained neutrality through both World Wars, is not a member of the European Union, and was not even a member of the United Nations until 2002.[5][6]

Currently an estimated one-third of all funds held outside the country of origin (sometimes called "offshore" funds) are kept in Switzerland. In 2001 Swiss banks managed US$ 2.6 trillion. The following year they handled $400 billion USD less which has been attributed to both a bear market and stricter regulations on Swiss banking.[7] By 2007 this figure has risen to roughly 6.7 trillion Swiss francs (US$6.4 trillion).

The Bank of International Settlements, an organization that facilitates cooperation among the world's central banks, is headquartered in the city of Basel. Founded in 1930, the BIS chose to locate in Switzerland because of the country's neutrality, which was important to an organization founded by countries that had been on both sides of World War I.[8]

```
Foreign banks operating in Switzerland manage 870 billion Swiss francs worth o
of assets (as of May 2006).[9]

l#International_competition
```

This character data compresses to 1158 bytes with `gzip -9`, 3.22 times smaller, 1202 bytes with `bzip2 -9`, and 1446 bytes with `compress`.

None of these programs take a significant amount of time to decompress the data, but my measurement noise is around 4ms, so they might be taking as much as 4ms.

Conclusion: compressed images are very heavy, and to be avoided if possible.

Wikipedia size

As I mentioned, the English Wikipedia snapshot I'm using is 9.7 gibibytes. `kiwix-serve` reports that it contains "1,766,695MB (3,874,564 articles, 262,623 medias)", which is to say, 1.8 terabytes in 3.9 million articles, or 460 kilobytes per article. I seem to recall that the text of a typical article is some tens of kilobytes, and almost none are over 100 kilobytes, so I assume that the bulk of that is the "medias".

Five random Wikipedia pages (not in the snapshot) are 4, 6, 7, 7, and 10 such screenfuls in links, so I'm going to assume that 7 is a reasonable median and 20 is a reasonable guess at mean number of screenfuls. That means we have about 80 million screenfuls of text, or 300 gigabytes of text, uncompressed; perhaps it would be 93 gigabytes compressed. This seems surprisingly large, since the original Wikipedia source data is only about 9 gigabytes in bz2-compressed XML. Nevertheless, it's small enough to be feasible to store textual snapshots of this entire Wikipedia on a normal netbook, and you could retrieve any one of them with a single seek if you identified them by number.

(If you printed out these 80 million 113×33 screenfuls in a square, they would be about 800 thousand characters wide and 400 thousand tall; in a normal ten-point font, this would be about 500 feet square.)

Since lossless image compression produced files that were some 40 times larger than text compression, we probably don't have room on the disk for precomputed images of the entire Wikipedia, pre-rendered. However, it's probably perfectly adequate to layout and render the text on the fly, within limits.

Image selection

That doesn't help with things that aren't text, and in particular, math articles suffer badly from lack of diagrams. http://en.wikipedia.org/wiki/Cantor_function is rather hard to understand without the graphs, the first of which is an 8-kilobyte SVG drawn with Adobe Illustrator which gzips down to 988 bytes; the third is a 9-kilobyte PNG. If you included a single gigabyte of images, you could include a million images of the complexity of this SVG; you could include one such image per article in four gigabytes.

Presumably you want to optimize some kind of cost-benefit ratio,

perhaps using page view counts or lists of featured articles or vital articles to estimate the benefit, and the file size (perhaps with an estimate of benefit due to compression) to estimate the cost. For example, Georg Cantor is a "vital article" that is read some 700 times a day, and it uses a diagram of bijection which is 1.8 kilobytes gzipped and is also used on four other pages; perhaps the 27-kilobyte portrait of young Cantor used on no other pages does not contribute 15 times as much to your replica of Wikipedia. If a picture is one of the 3196 featured pictures it's probably better quality. http://commons.wikimedia.org/wiki/Commons:Picture_of_the_Ye
oar http://commons.wikimedia.org/wiki/Commons:Valued_images http://commons.wikimedia.org/wiki/Commons:Quality_images http://commons.wikimedia.org/wiki/Commons:Featured_pictures

Wikimedia Commons says it has 15 million files, which add up to 22.5 terabytes. This is substantially larger than any of the textual Wikipedias, by about two thousand times. The great bulk of this, about 19.6 terabytes, is JPEGs, followed by 880 gigabytes of TIFFs, 600 gigabytes of PNGs, 520 gigabytes of Ogg video, 300 gigabytes of DjVu, and so on.

These files range over a very wide range of sizes; even consulting statistics by MIME type shows that the 2597 MIDI files average 5.2 kilobytes while WebM video files average 27 megabytes, four orders of magnitude greater. That is, all the MIDI files put together are smaller than a single average WebM video, and of course within each category, there are orders of magnitude of variation.

The Commons metadata is available for bulk download, currently totaling about 2.4 gigabytes, and could be used to measure the file size distribution more precisely.

Most of the JPEGs are very large indeed, and a much smaller version would be more than adequate for initial page presentation; some random images I selected using http://commons.wikimedia.org/wiki/Special:Random/File were 0.3 megapixels, 0.3 megapixels, 3.1 megapixels, 5.9 megapixels, and a 22-kilobyte SVG. Most of the time, however, images are presented in the page at a much smaller size. For example, I clicked the "random" link above until I got a big image: http://commons.wikimedia.org/wiki/File:Ebensee1.jpg, which is 7.7 megapixels, but where it's used on http://de.wikipedia.org/wiki/Bezirk_Gmunden, it's scaled down to 150×99, or 0.015 megapixels, 500 times smaller, making it 7.5 kilobytes instead of 4.9 megabytes.

(en.wikipedia.org has its own set of uploaded files, totaling 800 thousand to Commons's 15 million. I'm not clear if Commons images used on en are included in that total.)

A quick sample of five random images finds one used on the Hebrew Wikipedia and none used in English Wikipedia. Four more finds one on nl.wikipedia; eight more finally finds one image used on en.wikipedia as well as others, one used on es.wikipedia, one used on de.wikipedia, and one more used on en.wikipedia. Naïvely, two out of 17 in the "sample" should mean that on the order of 15% of the files in Commons are used on en.wikipedia. Both of these are used at a reduced size in the articles, and have an en.wikipedia File: namespace page.

Performance properties of sets of bitwise operations

Kragen Javier Sitaker, 2018-11-06 (updated 2018-11-07) (16 minutes)

For Bootstrapping instruction set (p. 459), I did some studies of different possible sets of bitwise operations using http://canonical.org/~kragen/sw/dev3/abjsearch.py. Of the Boolean-complete sets, abjunction alone and NAND alone had nearly the worst worst case; computing `x ^ y` with them requires 5 operations, not counting the constant all-ones -1 (which it needs because it's falsehood-preserving): `-1 &^ ((-1 &^ (x &^ y)) &^ (y &^ x))` for abjunction, `(y &̄ (x &̄ x)) &̄ (x &̄ (x &̄ y))` for NAND.

Considering the case with only abjunction, which is to say, set subtraction or ANDNOT, which Golang spells `&^`.

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = 0 (truth table 0000, cost 1) = 0
r[ 3] = -1 (truth table 1111, cost 1) = -1
r[ 4] = r[0] &^ r[1] (truth table 0010, cost 1) = x &^ y
r[ 5] = r[1] &^ r[0] (truth table 0100, cost 1) = y &^ x
r[ 6] = r[3] &^ r[0] (truth table 1100, cost 2) = -1 &^ x
r[ 7] = r[3] &^ r[1] (truth table 1010, cost 2) = -1 &^ y
r[ 8] = r[0] &^ r[4] (truth table 0001, cost 2) = x &^ (x &^ y)
r[ 9] = r[3] &^ r[4] (truth table 1101, cost 3) = -1 &^ (x &^ y)
r[10] = r[3] &^ r[5] (truth table 1011, cost 3) = -1 &^ (y &^ x)
r[11] = r[6] &^ r[1] (truth table 1000, cost 3) = (-1 &^ x) &^ y
r[12] = r[3] &^ r[8] (truth table 1110, cost 4) = -1 &^ (x &^ (x &^ y))
r[13] = r[3] &^ r[11] (truth table 0111, cost 4) = -1 &^ ((-1 &^ x) &^ y)
r[14] = r[9] &^ r[5] (truth table 1001, cost 5) = (-1 &^ (x &^ y)) &^ (y &^ x)

r[15] = r[3] &^ r[14] (truth table 0110, cost 6) = -1 &^ ((-1 &^ (x &^ y)) &^ (y &^ x))
```

With only binary NAND, the situation is almost as bad, but without needing -1, and with more reuse:

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = r[0] & r[0] (truth table 1100, cost 1) = x & x
r[ 3] = r[0] & r[1] (truth table 1110, cost 1) = x & y
r[ 4] = r[1] & r[1] (truth table 1010, cost 1) = y & y
r[ 5] = r[0] & r[2] (truth table 1111, cost 2) = x & (x & x)
r[ 6] = r[0] & r[3] (truth table 1101, cost 2) = x & (x & y)
r[ 7] = r[1] & r[2] (truth table 1011, cost 2) = y & (x & x)
r[ 8] = r[2] & r[4] (truth table 0111, cost 3) = (x & x) & (y & y)
r[ 9] = r[3] & r[3] (truth table 0001, cost 2) = a & a where a = x & y
r[10] = r[3] & r[8] (truth table 1001, cost 5) = (x & y) & ((x & x) & (y & y))

r[11] = r[5] & r[5] (truth table 0000, cost 3) = a & a where a = x & b and b = x & x
```

```
r[12] = r[6] & r[6] (truth table 0010, cost 3) = a & a where a = x & b and b = x &
& y

r[13] = r[7] & r[7] (truth table 0100, cost 3) = a & a where a = y & b and b = x &
& x

r[14] = r[8] & r[8] (truth table 1000, cost 4) = a & a where a = c & b and b = y &
& y and c = x & x
r[15] = r[6] & r[7] (truth table 0110, cost 5) = (x & (x & y)) & (y & (x & x))
```

If we have 2-, 3-, and 4-input NANDs, the situation is pretty much exactly the same as with just 2-input NANDs.

Actually, though, separate `&` and `~` operations (or equivalently `|` and `~`) are even worse:

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = ~r[0] (truth table 1100, cost 1) = ~x
r[ 3] = ~r[1] (truth table 1010, cost 1) = ~y
r[ 4] = r[0] & r[1] (truth table 0001, cost 1) = x & y
r[ 5] = r[0] & r[2] (truth table 0000, cost 2) = x & (~x)
r[ 6] = r[0] & r[3] (truth table 0010, cost 2) = x & (~y)
r[ 7] = r[1] & r[2] (truth table 0100, cost 2) = y & (~x)
r[ 8] = r[2] & r[3] (truth table 1000, cost 3) = (~x) & (~y)
r[ 9] = ~r[4] (truth table 1110, cost 2) = ~(x & y)
r[10] = ~r[5] (truth table 1111, cost 3) = ~(x & (~x))
r[11] = ~r[6] (truth table 1101, cost 3) = ~(x & (~y))
r[12] = ~r[7] (truth table 1011, cost 3) = ~(y & (~x))
r[13] = ~r[8] (truth table 0111, cost 4) = ~((~x) & (~y))
r[14] = r[9] & r[13] (truth table 0110, cost 7) = (~(x & y)) & (~((~x) & (~y)))
r[15] = r[11] & r[12] (truth table 1001, cost 7) = (~(x & (~y))) & (~(y & (~x)))
```

Darius Bacon suggests considering the bitwise ternary operator `(x & y | ~x & z)` as a primitive operation.

The bitwise ternary operator is almost as universal as abjunction, which is to say that, since it's falsehood-preserving, it requires access to a constant -1 to be universal, and since it's also truth-preserving, it also requires a constant 0; but it's somewhat more efficient. It computes `x ^ y` in two operations plus a constant 0 as `x ? (y ? 0 : x) : y`, and reaching the negating operations NAND and NOR is barely more difficult. NAND is `x ? (y ? 0 : x) : -1` and NOR is `x ? 0 : y ? x : -1`.

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = 0 (truth table 0000, cost 1) = 0
r[ 3] = -1 (truth table 1111, cost 1) = -1
r[ 4] = r[0] ? r[0] : r[1] (truth table 0111, cost 1) = x ? x : y
r[ 5] = r[0] ? r[1] : r[0] (truth table 0001, cost 1) = x ? y : x
r[ 6] = r[0] ? r[1] : r[3] (truth table 1101, cost 2) = x ? y : -1
r[ 7] = r[0] ? r[2] : r[1] (truth table 0100, cost 2) = x ? 0 : y
r[ 8] = r[0] ? r[2] : r[3] (truth table 1100, cost 3) = x ? 0 : -1
r[ 9] = r[1] ? r[0] : r[3] (truth table 1011, cost 2) = y ? x : -1
r[10] = r[1] ? r[2] : r[0] (truth table 0010, cost 2) = y ? 0 : x
r[11] = r[1] ? r[2] : r[3] (truth table 1010, cost 3) = y ? 0 : -1
```

```
r[12] = r[0] ? r[1] : r[9] (truth table 1001, cost 3) = x ? y : (y ? x : -1)
r[13] = r[0] ? r[2] : r[9] (truth table 1000, cost 4) = x ? 0 : (y ? x : -1)
r[14] = r[0] ? r[10] : r[1] (truth table 0110, cost 3) = x ? (y ? 0 : x) : y
r[15] = r[0] ? r[10] : r[3] (truth table 1110, cost 4) = x ? (y ? 0 : x) : -1
```

The negated version of the bitwise ternary operator is even more expressive in this sense, as it has no need for constants; it reaches NAND, NOR, constant 0, constant -1, and the negation of either input in a single application, and needs only a single additional application to reach the rest of the binary boolean functions, including AND, OR, XOR, and XNOR. OR is `~(x ? a : a) where a = ~(x ? x : y)`, AND is `~(x ? a : a) where a = ~(x ? y : x)`, XOR is `~(x ? y : (~(x ? x : y)))`, and XNOR is `~(x ? (~(x ? y : x)) : y)`.

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = ~(r[0] ? r[0] : r[0]) (truth table 1100, cost 1) = ~(x ? x : x)
r[ 3] = ~(r[0] ? r[0] : r[1]) (truth table 1000, cost 1) = ~(x ? x : y)
r[ 4] = ~(r[0] ? r[1] : r[0]) (truth table 1110, cost 1) = ~(x ? y : x)
r[ 5] = ~(r[0] ? r[1] : r[1]) (truth table 1010, cost 1) = ~(x ? y : y)

r[ 6] = ~(r[0] ? r[0] : r[2]) (truth table 0000, cost 2) = ~(x ? x : (~(x ? x : xo
o)))

r[ 7] = ~(r[0] ? r[0] : r[3]) (truth table 0100, cost 2) = ~(x ? x : (~(x ? x : yo
o)))

r[ 8] = ~(r[0] ? r[1] : r[2]) (truth table 0010, cost 2) = ~(x ? y : (~(x ? x : xo
o)))

r[ 9] = ~(r[0] ? r[1] : r[3]) (truth table 0110, cost 2) = ~(x ? y : (~(x ? x : yo
o)))

r[10] = ~(r[0] ? r[2] : r[0]) (truth table 1111, cost 2) = ~(x ? (~(x ? x : x)) :o
o x)

r[11] = ~(r[0] ? r[2] : r[1]) (truth table 1011, cost 2) = ~(x ? (~(x ? x : x)) :o
o y)

r[12] = ~(r[0] ? r[3] : r[3]) (truth table 0111, cost 2) = ~(x ? a : a) where a =o
o ~(x ? x : y)

r[13] = ~(r[0] ? r[4] : r[0]) (truth table 1101, cost 2) = ~(x ? (~(x ? y : x)) :o
o x)

r[14] = ~(r[0] ? r[4] : r[1]) (truth table 1001, cost 2) = ~(x ? (~(x ? y : x)) :o
o y)

r[15] = ~(r[0] ? r[4] : r[4]) (truth table 0001, cost 2) = ~(x ? a : a) where a =o
o ~(x ? y : x)
```

Similarly, the closely-related AOI and-or-invert function of four bits, sometimes realized as a single gate, can also reach all of the binary boolean functions in only two applications.

```
 r[ 0] = x (truth table 0011, cost 0) = x
 r[ 1] = y (truth table 0101, cost 0) = y

 r[ 2] = ~(r[0] & r[0] | r[0] & r[0]) (truth table 1100, cost 1) = ~(x & x | x & x)

 r[ 3] = ~(r[0] & r[0] | r[1] & r[1]) (truth table 1000, cost 1) = ~(x & x | y & y)

 r[ 4] = ~(r[0] & r[1] | r[0] & r[1]) (truth table 1110, cost 1) = ~(x & y | x & y)

 r[ 5] = ~(r[0] & r[1] | r[1] & r[1]) (truth table 1010, cost 1) = ~(x & y | y & y)

 r[ 6] = ~(r[0] & r[0] | r[2] & r[2]) (truth table 0000, cost 2) = ~(x & x | a & a) where a = ~(x & x | x & x)

 r[ 7] = ~(r[0] & r[0] | r[3] & r[3]) (truth table 0100, cost 2) = ~(x & x | a & a) where a = ~(x & x | y & y)

 r[ 8] = ~(r[0] & r[1] | r[2] & r[2]) (truth table 0010, cost 2) = ~(x & y | a & a) where a = ~(x & x | x & x)

 r[ 9] = ~(r[0] & r[1] | r[3] & r[3]) (truth table 0110, cost 2) = ~(x & y | a & a) where a = ~(x & x | y & y)

 r[10] = ~(r[0] & r[2] | r[0] & r[2]) (truth table 1111, cost 2) = ~(x & a | x & a) where a = ~(x & x | x & x)

 r[11] = ~(r[0] & r[4] | r[0] & r[4]) (truth table 1101, cost 2) = ~(x & a | x & a) where a = ~(x & y | x & y)

 r[12] = ~(r[0] & r[2] | r[1] & r[2]) (truth table 1011, cost 2) = ~(x & a | y & a) where a = ~(x & x | x & x)

 r[13] = ~(r[0] & r[3] | r[3] & r[3]) (truth table 0111, cost 2) = ~(x & a | a & a) where a = ~(x & x | y & y)

 r[14] = ~(r[0] & r[4] | r[4] & r[4]) (truth table 0001, cost 2) = ~(x & a | a & a) where a = ~(x & y | x & y)

 r[15] = ~(r[0] & r[4] | r[1] & r[4]) (truth table 1001, cost 2) = ~(x & a | y & a) where a = ~(x & y | x & y)
```

These exotic three- and four-input Boolean functions, despite their attractive formal properties, are probably not ideal for a virtual machine design in practice; they are generally not provided by CPUs, so in a naïve implementation, they probably need to be emulated by a few instructions, possibly increasing register pressure.

If we limit ourselves to the full set provided by any CPU I'm familiar with — `&`, `|`, `~`, `^`, and `&^` — we never need more than two ops to reach any binary Boolean function:

```
r[ 0] = x (truth table 0011, cost 0) = x
```

```
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = r[0] & r[1] (truth table 0001, cost 1) = x & y
r[ 3] = r[0] | r[1] (truth table 0111, cost 1) = x | y
r[ 4] = ~r[0] (truth table 1100, cost 1) = ~x
r[ 5] = ~r[1] (truth table 1010, cost 1) = ~y
r[ 6] = ~r[2] (truth table 1110, cost 2) = ~(x & y)
r[ 7] = ~r[3] (truth table 1000, cost 2) = ~(x | y)
r[ 8] = r[0] ^ r[0] (truth table 0000, cost 1) = x ^ x
r[ 9] = r[0] ^ r[1] (truth table 0110, cost 1) = x ^ y
r[10] = r[0] &^ r[1] (truth table 0010, cost 1) = x &^ y
r[11] = r[1] &^ r[0] (truth table 0100, cost 1) = y &^ x
r[12] = r[0] ^ r[4] (truth table 1111, cost 2) = x ^ (~x)
r[13] = r[0] ^ r[5] (truth table 1001, cost 2) = x ^ (~y)
r[14] = r[1] | r[4] (truth table 1101, cost 2) = y | (~x)
r[15] = r[0] | r[5] (truth table 1011, cost 2) = x | (~y)
```

Removing `&^` does not worsen the situation in that sense, although `x &^ y` and `y &^ x` become two ops instead of one:

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = r[0] & r[1] (truth table 0001, cost 1) = x & y
r[ 3] = r[0] | r[1] (truth table 0111, cost 1) = x | y
r[ 4] = ~r[0] (truth table 1100, cost 1) = ~x
r[ 5] = ~r[1] (truth table 1010, cost 1) = ~y
r[ 6] = ~r[2] (truth table 1110, cost 2) = ~(x & y)
r[ 7] = ~r[3] (truth table 1000, cost 2) = ~(x | y)
r[ 8] = r[0] ^ r[0] (truth table 0000, cost 1) = x ^ x
r[ 9] = r[0] ^ r[1] (truth table 0110, cost 1) = x ^ y
r[10] = r[0] ^ r[2] (truth table 0010, cost 2) = x ^ (x & y)
r[11] = r[0] ^ r[3] (truth table 0100, cost 2) = x ^ (x | y)
r[12] = r[0] ^ r[4] (truth table 1111, cost 2) = x ^ (~x)
r[13] = r[0] ^ r[5] (truth table 1001, cost 2) = x ^ (~y)
r[14] = r[1] | r[4] (truth table 1101, cost 2) = y | (~x)
r[15] = r[0] | r[5] (truth table 1011, cost 2) = x | (~y)
```

If we leave `&^` in, it's also possible to remove `|` without the worst case getting any worse, and indeed the only impact is that we need two ops to compute `|` as `x ^ (y &^ x)`:

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = r[0] & r[1] (truth table 0001, cost 1) = x & y
r[ 3] = ~r[0] (truth table 1100, cost 1) = ~x
r[ 4] = ~r[1] (truth table 1010, cost 1) = ~y
r[ 5] = ~r[2] (truth table 1110, cost 2) = ~(x & y)
r[ 6] = r[0] ^ r[0] (truth table 0000, cost 1) = x ^ x
r[ 7] = r[0] ^ r[1] (truth table 0110, cost 1) = x ^ y
r[ 8] = r[0] &^ r[1] (truth table 0010, cost 1) = x &^ y
r[ 9] = r[0] ^ r[3] (truth table 1111, cost 2) = x ^ (~x)
r[10] = r[0] ^ r[4] (truth table 1001, cost 2) = x ^ (~y)
r[11] = ~r[8] (truth table 1101, cost 2) = ~(x &^ y)
r[12] = r[1] &^ r[0] (truth table 0100, cost 1) = y &^ x
r[13] = ~r[12] (truth table 1011, cost 2) = ~(y &^ x)
r[14] = r[3] &^ r[1] (truth table 1000, cost 2) = (~x) &^ y
```

```
r[15] = r[0] ^ r[12] (truth table 0111, cost 2) = x ^ (y &^ x)
```

This is not true of &, ~, and ^; removing any of them causes some binary Boolean functions to require three ops. If we remove both | and &^, then we also get some Boolean operations requiring three ops:

```
r[ 0] = x (truth table 0011, cost 0) = x
r[ 1] = y (truth table 0101, cost 0) = y
r[ 2] = r[0] & r[1] (truth table 0001, cost 1) = x & y
r[ 3] = ~r[0] (truth table 1100, cost 1) = ~x
r[ 4] = ~r[1] (truth table 1010, cost 1) = ~y
r[ 5] = ~r[2] (truth table 1110, cost 2) = ~(x & y)
r[ 6] = r[0] ^ r[0] (truth table 0000, cost 1) = x ^ x
r[ 7] = r[0] ^ r[1] (truth table 0110, cost 1) = x ^ y
r[ 8] = r[0] ^ r[2] (truth table 0010, cost 2) = x ^ (x & y)
r[ 9] = r[0] ^ r[3] (truth table 1111, cost 2) = x ^ (~x)
r[10] = r[0] ^ r[4] (truth table 1001, cost 2) = x ^ (~y)
r[11] = r[0] ^ r[5] (truth table 1101, cost 3) = x ^ (~(x & y))
r[12] = r[1] ^ r[2] (truth table 0100, cost 2) = y ^ (x & y)
r[13] = r[1] ^ r[5] (truth table 1011, cost 3) = y ^ (~(x & y))
r[14] = r[3] & r[4] (truth table 1000, cost 3) = (~x) & (~y)
r[15] = r[0] ^ r[12] (truth table 0111, cost 3) = x ^ (y ^ (x & y))
```

So reasonable minimal sets for implementation on existing hardware include &, ~, ^, and &^; and &, ~, ^, and |. The former is more widely supported, and it's hard to argue that the latter is even more convenient.

Current-source grid

Kragen Javier Sitaker, 2018-04-30 (updated 2018-07-05) (29 minutes)

Your wall socket is 50Hz or 60Hz, 120 or 240 volts rms ac, but most importantly it is a voltage source. That is, the voltage remains constant at, say, 235 volts, regardless of whether you're drawing 0 amps or 20 amps from it. Actually, this is a little bit of a lie; the voltage does reduce somewhat as you draw current from it. Maybe the resistance of the wire in the wall is 1Ω, so if you're drawing 20 amps, the voltage falls to 215 volts. And as your house draws more current, the voltage on the whole circuit to your house from the transformer falls a bit, though probably not as much as the voltage drop from the wires in your wall. But the voltage is *relatively* constant.

This configuration gives rise to a number of phenomena we're familiar with, not all agreeable:

• All of our unswitched outlets are wired in parallel. Switches are wired in series with the devices they control.
• If we touch the prongs of an electric plug as we plug it in or unplug it, we get a nasty shock — potentially a deadly one.
• Negative-resistance devices like fluorescent tubes and neon lights — as well as fixed-voltage devices like LEDs — require auxiliary electronics to operate at all without exploding.
• If an electrical appliance has its insulation fail inside, even if it's a low-power appliance like a VCR or LED lamp, its carcass can become electrified — resulting in either a circuit breaker tripping (if the ground wire is properly wired) or a deadly shock hazard.
• We can step voltage up for transmission and distribution using transformers, but the transformers are heavy and bulky, made from laminated electrical steel.
• Even an electrical outlet that is providing no energy to anything is potentially hazardous if a toddler sticks hairpins into it.
• 50Hz or 60Hz interference is picked up by everything; under some circumstances, many harmonics also appear. These are audible and frequently cause trouble with audio electronics.
• As little as 100 mA of this current can be fatal, and it's easy for human skin to have the <2.4kΩ resistance necessary for this to happen.
• The insulation thickness and separation between the conductors is sized for the voltage that is always present, with a healthy safety factor. But the thickness of the copper conductor itself is sized for a worst-case current that may never be present, again with a healthy safety factor.
• As at least one teenager has learned, throwing eggs into an electrical substation can cause a dangerous explosion.
• The temperature a heating element reaches depends on its length. If we reduce a heating element to half its length, we double the power it dissipates, quadrupling the power density. In addition to making calculations somewhat trickier, this means that sticking a knife in the toaster will likely melt the heating element, ruining the toaster.

• Every standard electrical cable carries this deadly voltage difference, and if cut, can easily melt the cutting tool and cause an electrical fire.
• Powering a low-voltage device (like any transistor-based electronics) requires either one of those heavy transformers mentioned above or a much more complex (and noisy and potentially unreliable) switching power supply.
• Fixed-speed single-direction electrical motors (up to 50Hz or 60Hz, i.e. 3000 or 3600 rpm) are very simple and extremely reliable, but on single-phase power, require either an inefficient shaded-pole arrangement or a large and failure-prone starter capacitor to guarantee a particular direction of rotation.
• Many switching power supplies have very large inrush currents when first plugged in, which frequently results in flying sparks from the prongs of the electrical plug.
• We protect our houses and appliances by wiring circuit breakers or fuses in series with them. When the current exceeds the rating of the safety device, it disconnects, creating an open-circuit condition and its attendant inductive voltage spikes, but cutting the current to zero. However, this generally only cuts the hot side of the supply; the problematic appliance remains connected to the neutral side, which can still carry a hazardous voltage.
• Short circuits are a bad thing which can result in electrical fires and even plasma explosions. Open circuits are innocent and totally normal, occurring whenever we unplug something or turn it off.
• If you start to receive a significant electrical shock, you lose control of your muscles, which may cause you to firmly grasp the source of the shock, increasing the danger.
• It's basically impossible to shield the extremely-low-frequency emissions and prevent them from escaping a building or penetrating a sensitive measuring instrument.

None of these are inherent to electricity in general. If we used an RF current source rather than a extremely-low-frequency voltage source, all of the above items change.

What is a current source?

First, what is a voltage source?

A voltage source is an energy source with a constant voltage across the load, regardless of the current. Its output impedance is zero. The voltage of your wall socket is a close approximation of a voltage source; its impedance is on the order of 1Ω. It has a limit to how much current it can supply — even leaving aside the fuses and circuit breakers, to draw 240 amps from your 1Ω 240V source, you would need a short-circuit load, which means that none of the power actually reaches the load, and also you cannot reduce the impedance any further in order to draw more current.

A current source, by contrast, is an energy source with a constant current, regardless of the voltage. Its output impedance is infinite. A photovoltaic cell in constant light at a voltage well below its maximum output voltage is a close approximation of a current source, because each photon it converts generates an electron-hole pair regardless of the voltage; I think its impedance is on the order of 1MΩ. Any current source has a limit to how much voltage it can supply — if you open-circuit the photovoltaic cell, its voltage will rise to about 0.7 volts and stay there. At that point you cannot reduce the

conductance any further in order to get higher voltages.

This is one of many applications of a certain duality in electronics in which we interchange serial and parallel, voltage and current, resistance and conductance, and I think capacitance and inductance, and maybe frequency and period, and everything comes out the same.

The study of electrical currents began with batteries, which are pretty close approximations to voltage sources. Current sources, on the other hand, are generally thought of as artificial or theoretical constructs. But in today's world of power electronics, our voltage sources are usually complicated circuits, and we can build current sources just as easily. Stick-welding machines and TIG welding machines are commonly designed as high-power current sources, under the name "constant-current source", or "CC", for example.

Why are RF current sources an interesting alternative?

It turns out that if you use a current source rather than a voltage source for your mains power, and run it at a higher frequency, there are a number of interesting results. In particular, all of the bullet points in the first section above become false, and there are a number of potential safety, cost, and complexity benefits — although of course we won't know if these work out in practice until we have real experience with them. Current sources defy the expectations we have built up over centuries of working with voltage sources — among other things, about what is safe and what is dangerous. To take the simplest example, short-circuiting a high-power current source is totally safe and actually the right way to turn off whatever it's powering. Open-circuiting it, by contrast, can produce a hazardous voltage.

The extremely low frequencies we're accustomed to using date from the late 19th century, when they derived from the frequencies of rotation of the steam-driven generators used to produce the power. This approach is still used today, with generators' rotation synchronized to the grid frequency before putting them online. But supplying power at higher frequencies has a number of substantial advantages in safety, electronic noise, and equipment size, cost, and complexity.

In addition to potential uses in houses and industry, this system should also be useful in spacecraft, where wiring harnesses commonly contribute an alarming amount both of very expensive mass and of very expensive power consumption.

Basics

Consider a system supplying one ampere at 32768 Hz, the frequency of a watch crystal, to every wall outlet, with current-source compliance up to 1000 VAC.

The outlets on a circuit are wired up in series — the current flows first through one appliance, then another, then another. When no appliance is plugged in, a short-circuit shunt is mechanically imposed across the two terminals of the outlet, so current flows through the outlet with no significant voltage drop. When all the outlets on a circuit are short-circuited, the total resistance of the circuit might be

1Ω, so the 1A will produce 1V of voltage drop and 1W of power consumption.

If a 10W appliance is plugged in, once its contacts have made contact with those of the outlet, its plug mechanically removes the short-circuit shunt, introducing the appliance into the circuit. The appliance's impedance of 10Ω produces a voltage drop of 10V across the plug (once the current source's output voltage rises to match), delivering 10W to the appliance.

A switched outlet or appliance has the switch in parallel to it. When the switch is closed, there is no voltage across the appliance, and consequently no current through it, or a tiny residual current due to the tiny voltage drop across the closed switch. Opening the switch forces the current to flow through the appliance instead.

A short circuit between an outlet and the neutral wire removes power from the appliances downstream from it, but causes no other problems. An open circuit, however, could cause a hazardous voltage, and therefore safety measures must be taken to shunt current past the open circuit, just as fuses or circuit breakers must create an open circuit in a voltage-source system to interrupt hazardous currents.

All the normal wires are the same tiny size, 24 AWG, 510 μm in diameter, which is enough to carry 1A without getting warm, but not so thick as to waste any significant copper due to the 400-micron skin depth in copper at 32768 Hz. Higher-current internal ac wires in some appliances need to be made of copper tape of less than 1 mm thick. The thickness of the wire does not depend on the length of the run, because the voltage drop is inconsequential; the current source will automatically raise the voltage to compensate, so that the load will receive the full 1A anyway, as long as the run isn't so long as to approach the current source's compliance limit (1000 V, thus 1000 Ω at 1 A.)

Physically, the outlets are strange. The two prongs are each 20 mm long, with their first 15 mm insulated, as in France; they are positioned a rather large 40 mm apart, with a ground prong in the middle. Behind the outlet, the attachments for the tiny wires are on strange stalks that curl back around. All of this is for high-voltage safety in the unlikely case that a single outlet is called upon to supply the full 1000 V limit of a circuit; it needs the creepage allowance not to form a conductive, but high-resistance, path between the electrodes.

Despite the possibility of using a single wire from one outlet to the next, in fact the return wire runs alongside the hot wire as a lightly twisted pair for the whole circuit in order to reduce EMI. It isn't connected to anything until the last outlet in the string.

Each circuit is fed from a separate transformer, a bit smaller than the usual circuit breaker, on a higher-voltage-compliance constant-current "bus", which is wired in series, not in parallel as usual. The transformers are center-tapped, and the center tap is grounded, so the net voltage surrounding the twisted pair of wires is zero, and of course their net current is also zero. This reduces EMI and keeps the voltage from any point to ground to a minimum. Each transformer also has a safety shunt attached to it.

Safety

First, in at least a couple of ways, the system I'm describing here is

potentially *more* dangerous than the traditional system. 240V is often not enough to kill you, depending on how dry your skin is. 120V almost never is. But one ampere through your arms is traditionally considered very likely to kill you, and the current source will happily apply 1000 volts to you if you are suddenly the only path through its circuit and that is what is needed to drive an ampere through you. 1000 watts applied to your body is also very likely to kill you.

Also, kilovolts can do surprising things that the more usual voltages do not do, jumping through air and burning tracks through dust on surfaces and whatnot.

However, there are a variety of ways this system is inherently safer, as well as a number of safety features that can be added.

First, the vast majority of circuits will not have hazardous voltages present on them at all, because they will not have hundreds of watts of load, so they won't need hundreds of ohms of impedance. And even those circuits that do have hazardous voltages will generally not have hazardous voltage differences within a single appliance.

??? I'm conflicted about whether grounding the center taps is a good idea. Without that current path to ground, there would never be any hazardous voltages relative to ground in the system, only potentially hazardous voltage differences within the circuit. But without it, grounding an enclosure will not produce a detectable ground fault if a hot wire comes in contact with the enclosure.

As explained above, short circuits are not hazardous in a current-source system — the current source will only supply its usual current to them, rather than an unbounded current, and they will dissipate no energy. Open circuits produce a hazardous voltage but no immediate fire. The real danger is near-open circuits of a few kΩ, which could potentially dissipate a few kW.

I think one amp is not enough to sustain an arc in air (???), which would eliminate the usual risk of arcing, despite the high voltages.

Using RF is a safety advantage because currents at these frequencies cannot (???) penetrate deeply into the human body, instead staying on the skin, and so they cannot cause muscular contractions (???) or cardiac fibrillation. They can still cause burns, and RF electrical burns are notorious, but that requires a lot more energy. Unfortunately, this system is capable of supplying that energy.

While it's harmless and probably useful to include traditional series overcurrent fuses in the system — if the current deviates significantly above 1 A, you have a bad problem in your current source and it would be a good idea to disconnect from it — they won't detect hazardous voltage soars or open circuits, which are the kinds of problems that could arise from electrical faults inside your house.

Grounding the cases of appliances provides a more effective safety measure against hot cases than in the traditional voltage-source system. In the standard system, a hot wire contacting the grounded case produces a ground fault, which fires the circuit breaker. In this system, by contrast, it shorts out half of the transformer and the upstream appliances, effectively dividing the circuit into two circuits of 500 mA each, joined at a shared ground point. The enclosure remains grounded and thus safe to touch; there are no sparks and no danger of electrical fire. However, nothing on the circuit will work properly until the faulty appliance is removed, because it will be getting a quarter of its usual power.

The simplest safety shunt against open circuits is just a buzzer-type SPST relay; its normally-closed contacts in series with a normally-closed pushbutton short the load, and its winding in series with the load holds those contacts open. If at some point the load goes open-circuit, the current through the load and the coil will cease, the contacts will spring closed, and the load will remain shunted out of the circuit until someone pushes the pushbutton†. This fails safe in case of coil failure and in case of power failure; it may be inconvenient to have to reset all your circuits after a power failure, but it's better than having to replace all your appliances. It may be possible to tune this circuit to reliably detect the ground-fault half-current case, too.

The other problem the above circuit has is that it doesn't actually limit the voltage; it just responds to the source's inability to sustain its current in the face of overwhelming resistance. In the case where the source is actually capable of hitting 10kV, it might fail to activate because the deadly overvoltage has burned a track across the outlet and is efficiently heating it to incandescence.

A simple truly-overvoltage-driven alternative would be a large gas tube. A fluorescent lamp tube would sort of work, but its discharge maintenance voltage is high enough (in the range of 100V) that it would probably cause major damage to the faulty load.

A fully-solid-state alternative might be a diac in series with a small inductor and a NC pushbutton, driven from a bridge rectifier in parallel with the load. If the diac goes into conduction due to overvoltage, it should crowbar the circuit rather effectively until someone presses the button; the inductor keeps it in conduction as the voltage crosses through zero 65536 times per second. This should give you under 10V across the circuit. (e.g. the Littelfuse K1400GURP SIDAC can handle an amp steady-state and will crowbar down to 1.2 volts, with a breakover voltage of 130–146V; you could use 7 of them in series, giving you a breakover of 910–1022 volts, and a voltage of 8.4 volts, plus the bridge and inductor voltages. It costs 37¢ in bulk.)

An alternative relay circuit would use a latching relay activated by current through, say, a calibrated spark gap, MOV, diac, or gas tube. It could latch either mechanically or, by virtue of energizing its own coil, electromechanically. This last has the dubious advantage of resetting automatically after power failures, including after being shunted out of the circuit by an upstream shunt.

† At which point the circuit potentially goes really open-circuit if the load still isn't repaired, thus causing further safeties to trip further upstream, so maybe this design is inadequate. Or maybe you just need two of them, maybe controlled with a make-before-break pushbutton that opens one circuit after closing the other.

Appliance design

Everything is topsy-turvy in the current-source world, but it's overall simpler. It's fine for things to short out when they fail; it's problematic and possibly dangerous for them to create open circuits, for example by breaking the filament of an incandescent lightbulb. If your lightbulb filament breaks, it will trip the safety shunt, and you will probably want to turn off all the lightbulbs on the circuit, reset the safety, and then turn them on one at a time until you figure out

which one is tripping the safety.

Resistive heating is simple. 1Ω is 1W. To get a given temperature under given cooling conditions, you use a given filament; you get the same temperature no matter how much of it you use, but more filament gives you more power. You should probably mount it on some kind of conductive backing with light insulation in between so that it becomes a short circuit if it melts, not an open circuit.

More resistance gives you more power; this is precisely backwards from the situation with voltage sources, where load resistance and power are inversely proportional.

3V 1.5W LEDs can be driven directly from the regulated 1A with no resistor. Smaller LEDs will burn out; larger LEDs will only shine 1.5W. Large fluorescent tubes of about 100W can, too, with no ballast or starter, as long as they can cold-cathode start at a low enough voltage, and fast enough to keep the safety shunt from tripping. 50W tubes should work if half-wave rectified — with one diode in series and another opposite diode shunting the combination. But most LEDs and fluorescent lights will require some kind of power supply.

Voltage-step-up transformers can be used to step down the current for some of these devices, such as small LEDs. Voltage-step-down transformers are probably useful to step up the current for larger resistive elements, so that they can use thicker wire.

Low-voltage low-power power supplies are really easy; a tiny 1A 47-microhenry inductor has an impedance of $\omega L = 4.8\Omega$ and thus a voltage across it of 4.8V (ac rms), which is 6.8V peak. Stick a silicon bridge rectifier across that, dropping 1.4V, and you can charge a capacitor to 5.4V dc at any current up to 100mA average or so (at which point the inductor voltage starts to drop because you're stealing its current). For 10% ripple at 100mA, the capacitor itself only needs to bear the 100mA for 15.3 microseconds without dropping more than 0.5V, which means 3 μF is adequate; an LC filter would allow you to use a smaller capacitor and also get better stability. If you want a regulated voltage, you might want to use a slightly larger inductor to get more like 9V peak, then drive a 7805 off it. Then it would be okay to steal more current from the inductor.

In any case, you won't have any 50Hz or 60Hz ripple. You'll have 32768Hz ripple, plus some harmonics like 65536Hz and 98304Hz, which are a lot easier to filter out.

Combining the two above, you can quite reasonably use a voltage-step-down transformer to feed a 22μH inductor 5A, then rectify, filter, and regulate, to get a 60% efficient 1A 5V regulated USB power supply in five components.

In the simplest case, of course, you can get a voltage by using a resistor rather than an inductor, but it will dissipate power. Or you could use an unpolarized capacitor of a few μF.

Inrush currents from hooking up capacitors to line voltage no longer exist. Instead you have inductive voltage spikes when you switch an inductor into the 1A circuit. You may want a snubber network to tame this, but that may be unnecessary — you aren't going to design in an inductor with more than 1kΩ of reactance, which means more than 10mH. $\frac{1}{2}LI^2 = 5$ mJ, which may not be enough energy to cause any real problems.

Switching power supplies are still a thing, despite the greatly

increased convenience of old-style transformer power supplies, and they need no inductors. If you were using dc instead of ac, a switching power supply amounts to switching between a dead short and a capacitor-diode series. You run your voltage-regulated circuit off the capacitor, and the diode keeps the capacitor from discharging during the time that the power is turned off with a short. You can do this with ac if you use a bridge rectifier or just a reverse-protection diode. For lower-power supplies, you could just use a rectifier diode to generate a voltage dissipatively and switch that voltage onto a capacitor at times.

Squirrel-cage induction motors should be barely feasible: 800 poles around the stator should give you 164 revolutions per second, which is 9840 RPM. The "squirrel cage" should probably be a millimeter-thick copper or aluminum sheet. I don't think you can use laminated electrical steel in the rotor at these frequencies. On the plus side, the starter capacitor can be quite small.

Universal motors are not feasible at all without rectification.

Wire diameter, resistance, and cost

The higher peak voltages allowed by a current-source system, as well as the automatic compensation for wiring losses, allow us to use much lower maximum currents and therefore thinner wire than in the traditional system. Instead of building the copper for the worst case and the insulation for the average case, it allows us to build the copper for the average case and the insulation for the worst case. Insulation is much cheaper than copper.

24AWG copper wire is 510μm in diameter and 84Ω/km, and it's recommended for currents up to 3.5 A. 84Ω/km means 84mΩ/m and thus, at 1A, 84 mW/m, which is not totally insignificant in terms of heating, but not really dangerous either. It means you can go over 5 km round trip with this wire before you hit the source's 1000 V compliance limit.

A bigger issue at these frequencies is likely to be stray inductance. 1Ω is only 9.7 μH. The twisted pairs should reduce this problem, but they won't eliminate it.

Copper's density of 9.0 g/cc means this works out to 1.8 grams per meter of wire, or 3.6 g if you run the neutral wire next to the hot one. But that doesn't count the insulation, which needs to be safe at 1000 V.

100 turns of this wire on an inductor work out to a coil, say, 5.1 mm long and 5.1 mm thick, for maybe 15 mm of diameter on the whole inductor. Transformers might be a little larger. None of that takes into account the insulation, though, so probably the reality will be several times that.

1000 V probably needs over 16 mm clearance between exposed conductors and 64 mm creepage distance, although I should look up the standards.

As explained in the "appliance design" section, the higher frequencies allow the use of much smaller capacitors, inductors, and transformers, which dramatically reduces cost and weight. The current-mode design allows us to get whatever voltage we want by adjusting a reactance; the use of rf ac allows us to get whatever current we want with a tiny transformer.

Etc.

are too high for humans to hear, so they cause less problems with audio equipment; and they

Dilating letterforms

Kragen Javier Sitaker, 2018-11-04 (15 minutes)

So I was thinking about how to dilate and erode letterforms, in order to generate a range of fonts from some scanned hand-drawn characters. This has a couple of applications. First, hand-drawn characters may be fairly nonuniform in line thickness, and you may want to make the line thickness more consistent; some kind of nonlinear erosion to a skeleton, followed by dilation, can give you uniform line thickness. Second, scanned data may have flecks, and various compositions of dilation and erosion are well known to eliminate flecks below a critical dimension. Third, you may want to apply calligraphic effects to letters, such as changing the pen angle or nib width, or providing a nib width to pencil-drawn characters.

Thresholded-blur-based dilation and erosion

One of the algorithms that occurred to me was to blur the characters and then threshold the blurred characters, perhaps at a much higher resolution than they were scanned at, converting each original pixel to a discrete impulse in the center of a much larger empty space before blurring. This, in a sense, provides a vectorization mechanism for a bilevel image; you can blur and threshold the characters at an arbitrarily high resolution, and thanks to Nyquist's sampling theorem and the convolution theorem, you'll always get the same results as long as your blur is the sampled approximation of whatever true analytic blur you're blurring with, and as long as it doesn't have any significant frequency components above the Nyquist frequency, whether that's a Gaussian, a sinc, or something else.

However, this contains a pitfall. What happens if we look at the contours of a blurred set of impulses like this? If we fill in the empty area with zeroes, as the theory says we should, then we'll find that the positive contours around positive impulses are convex, as are the negative contours around negative impulses, but as we cross zero going away from a positive impulse toward an adjacent negative impulse, we find our contours becoming concave. If we have a checkerboard of ±1 impulses, for example, and a circularly symmetric blur kernel, then the positive contours will be near-circles around the +1 impulses, while the negative contours will be near-circles around the -1 impulses. Only at 0 do we find the contours running in straight lines, dividing the checkerboard into positive and negative squares.

So I propose that what we should do is that, before upsampling, we should add or subtract a constant to the impulses so that our desired threshold will be, in the transformed value space, 0.

If the blur kernel has limited support, the contours in each cell or "tile" of the grid will depend only on some limited neighborhood of impulses, and of course the threshold. If the support is one pixel or less (of the original image), it will depend only on the four neighboring pixels, like Perlin noise. Like Wang tiles, the tile is guaranteed to match its neighboring tiles by virtue of shared edge colors (corner-pair colors, in this case). Even if the kernel support

takes into account a 4×4 area, for bilevel input images, it's feasible to precompute all the possible tiles. Cubic spline kernels will have continuous second derivatives, which means their contours will also have continuously changing curvature.

Furthermore, it's possible to compute points on the contours directly, without resorting to actually computing the pixels of a high-resolution upsampled image. If the blur kernel is polynomial or piecewise polynomial by tiles, then the blurred image within a given tile is a single polynomial function — bicubic in the case of splines over 4×4 neighborhoods, and in any case a linear combination of parts of the blur kernel.

This generalized erosion or dilation operation should be more capable of preserving smooth curves than the standard iterated morphological operations, but it might also lead to ink blotting at line joins.

I thought that by using an asymmetric blur kernel, it should be possible to convert strokes of uniform weight into strokes of varying width according to their angle, but I'm not sure that's actually true. It's depending on the final thresholding operator to introduce the nonlinearity where, say, vertical strokes convert into more ink than horizontal strokes. And I'm not sure simple thresholding is up to the job.

Erosion to skeletons

Erosion-to-skeletons is a nonstandard morphological operation. Standard erosion can be done on a 3×3 pixel window; if any input pixel in the window is empty, the resulting output pixel in the center of the window is empty. But this can erase lines or dots completely, and indeed such despeckling is one of the uses for standard erosion.

Suppose that instead we use a 4×4 pixel window. Now we can see whether the pixel we're about to erase is part of a line or speck that's already been reduced to a thickness of 2 or 1. In that case, we can preserve a thickness-1 line, although if we're reducing thickness 2 to thickness 1, we have to choose a bias direction in which to move the line: left, right, up, or down. My hope is that we can neutralize this bias by running successive passes of the algorithm with biases that cancel out, for example using the Thue-Morse sequence to alternate directions.

Pipelined morphological operations

In the 1970s and early 1980s, the ERIM Cytocomputer, a special-purpose parallel architecture, had the fastest implementation of the Game of Life, although it was primarily used for machine vision applications. Rather than dedicating one processor to each board region, it dedicated one processor to each time step, pipelining cells from one processor to the next. In this fashion, a Cytocomputer with a 16-stage pipeline (I don't remember if this was a normal size) could output one Life cell every clock cycle, 16 generations later than the generation that had been fed into the pipeline, with slightly over 16 rows of latency. I don't remember what the clock speed was, either, but I think it was a few megahertz.

You might think this would require a massive memory for each processor, but in fact each one only needs a couple of reasonable-sized FIFOs. To compute the cell marked O, it needs to consider the

previous-generation states of the cells marked X and the cell marked O, and needs to retain the previous-generation states of the cells marked .:

```
                  XXX.....................................
..................XOX.....................................
..................XXX
```

In a pipeline, each pipeline stage is computing one scan line plus two pixels behind the previous one; note that most of the pixels are duplicated in two different FIFOs:

```
                  XXX.....................................
..................XOXXX...................................
..................XXXOXXX.................................
....................XXXOXXX...............................
......................XXXOX.................................
........................XXX
```

The pixels were 8-bit bytes, the FIFO size was either fixed or capped at 1024 or 2048 or 4096 or something, and in addition to the Life rule, the Cytocomputer was capable of a variety of machine-vision-relevant operations such as thresholding, edge-detection (I don't remember, probably at least Canny), dilation, and erosion, which like the Game of Life can all be computed as a finite function on a 3×3 neighborhood, and of course in these applications, each stage of the pipeline could be programmed to perform a different function. You programmed it with a bletcherous scripting language on an attached general-purpose computer.

I think you can do something similar with SSE on a modern CPU, but perhaps many pixels per cycle instead of one, and maybe only one pipeline stage per instruction. The idea, though, is to stream pixel data into the L1 cache (from another cache or from main memory), apply a whole generic pipeline of such local operations to it, and then stream it back out of L1 cache with the whole set of operations applied.

Digression: tiling

Usually for this kind of processing you want to tile the pixel data to reduce the size of the necessary FIFOs, although that makes the indexing somewhat more complicated. "Tiling" means that you turn the usual two dimensions of image data into four dimensions: an X and Y to locate the tile, and an x and y to locate the pixel within the tile. For example, with 8×8 tiles, the pixels in a 16×16 image might be in this order instead of the usual one:

```
  0   1   2   3   4   5   6   7  64  65  66  67  68  69  70  71
  8   9  10  11  12  13  14  15  72  73  74  75  76  77  78  79
 16  17  18  19  20  21  22  23  80  81  82  83  84  85  86  87
 24  25  26  27  28  29  30  31  88  89  90  91  92  93  94  95
 32  33  34  35  36  37  38  39  96  97  98  99 100 101 102 103
 40  41  42  43  44  45  46  47 104 105 106 107 108 109 110 111
 48  49  50  51  52  53  54  55 112 113 114 115 116 117 118 119
 56  57  58  59  60  61  62  63 120 121 122 123 124 125 126 127
128 129 130 131 132 133 134 135 192 193 194 195 196 197 198 199
```

```
136 137 138 139 140 141 142 143 200 201 202 203 204 205 206 207
144 145 146 147 148 149 150 151 208 209 210 211 212 213 214 215
152 153 154 155 156 157 158 159 216 217 218 219 220 221 222 223
160 161 162 163 164 165 166 167 224 225 226 227 228 229 230 231
168 169 170 171 172 173 174 175 232 233 234 235 236 237 238 239
176 177 178 179 180 181 182 183 240 241 242 243 244 245 246 247
184 185 186 187 188 189 190 191 248 249 250 251 252 253 254 255
```

With 4×4 tiles, instead you would have this order:

```
  0   1   2   3  16  17  18  19  32  33  34  35  48  49  50  51
  4   5   6   7  20  21  22  23  36  37  38  39  52  53  54  55
  8   9  10  11  24  25  26  27  40  41  42  43  56  57  58  59
 12  13  14  15  28  29  30  31  44  45  46  47  60  61  62  63
 64  65  66  67  80  81  82  83  96  97  98  99 112 113 114 115
 68  69  70  71  84  85  86  87 100 101 102 103 116 117 118 119
 72  73  74  75  88  89  90  91 104 105 106 107 120 121 122 123
 76  77  78  79  92  93  94  95 108 109 110 111 124 125 126 127
128 129 130 131 144 145 146 147 160 161 162 163 176 177 178 179
132 133 134 135 148 149 150 151 164 165 166 167 180 181 182 183
136 137 138 139 152 153 154 155 168 169 170 171 184 185 186 187
140 141 142 143 156 157 158 159 172 173 174 175 188 189 190 191
192 193 194 195 208 209 210 211 224 225 226 227 240 241 242 243
196 197 198 199 212 213 214 215 228 229 230 231 244 245 246 247
200 201 202 203 216 217 218 219 232 233 234 235 248 249 250 251
204 205 206 207 220 221 222 223 236 237 238 239 252 253 254 255
```

(This kind of tiling also made it possible to interact with many-megapixel images in real time on 1980s graphics workstations. Perhaps your LANDSAT scene was 50 megapixels and your machine only had 8MiB of RAM. Without tiling, in the format the LANDSAT people would deliver you the images, the megapixel you could fit on the monitor was 1000 fragments splattered across 7 megapixels on disk, which was 21 megabytes in RGB or 43 megabytes in its full multispectral glory, and if you want to pan 100 pixels to the right, those pixels are splattered across those same 21 megabytes; so even a slight panning would induce a multi-second disk wait. With 16×16 tiling, your screen would instead contain parts of some 60–70 rows of tiles, which could be accessed in 60–70 seeks: about a second. JPEG image compression was not yet a thing, and even today its use for remote-sensing imagery is dubious.)

8×8 tiles are a typical size, but I suspect that 32×32 tiles (or even bigger, 64×64 or 128×128) might make more sense for most purposes on modern hardware.

(End of digression.)

Bitwise morphological operations

For morphological operations, we might really benefit from bit-packing, where we can get 128 pixels into an SSE register (or 256 pixels into an AVX register). Then, the erosion or dilation operation (depending on interpretation) is mostly `a | a << 1 | a >> 1 | b | b << 1 | b >> 1 | c | c << 1 | c >> 1`, but that only produces 126 correct bits of new state for b; the first and last bits are incorrect.

Note that this is a separable operation: we can do it first horizontally and then vertically. So we could, for example, compute `a`

`| a << 1 | a >> 1` — plus the correction for the first and last bits — once, and use it to compute results on all three scan lines.

Gaussian spline reconstruction

Kragen Javier Sitaker, 2016-06-05 (updated 2016-06-06) (5 minutes)

You can get a very good approximation of the Gaussian function by convolving several box or simple-moving-average filters, in the same way that you get a good approximation of it with a spline, in a way that I don't quite know how to name right now, but which is exactly equivalent to convolving several box filters.

From a computational perspective, notable features of this procedure include that box filters require no multiplications, require a very small number of operations per sample (only two additions and a subtraction, plus a FIFO buffer of the size of the box), and can be computed exactly with integer math in which the intermediate results overflow, as long as the final result does not. XXX is that even true? WTF

Precisely converting discretely sampled signals back into bandlimited continuous signal involves convolving them with the sinc function (the Fourier transform of the unit pulse) which is inconvenient because it decays very slowly, meaning that doing the convolution directly (in the spatial domain) requires summing weighted contributions from quite far away to get reasonable accuracy. If you just do a zero-order hold, turning the sampled curve into stairsteps, you are in effect convolving the modulated Dirac comb that is your discretely sampled signal with a unit pulse, thus filtering its frequency response with a sinc spectrum, which is disastrous for frequencies above about half Nyquist.

One approach to reconstruction filtering is to use Nth-order splines that pass through y=1 at x=0 and have zeroes at all other integers. (These are sometimes called cardinal B-splines, by analogy to the sinc "sinus cardinalis" function, but that terminology is arguably wrong and at least confusing.) These have very compact support, and they approach sinc in the limit where $N \to \infty$. But they definitely require multiplication.

Derivatives of the Gaussian include the so-called Mexican Hat wavelet, Ricker wavelet, or Marr wavelet, which is its negated second derivative. This is vaguely close to sinc: it has a big round bulge in the middle with a zero on each side of it, then local minima, and then it asymptotically approaches zero as it goes to infinity.

I have this idea that the second derivative of the convolution of a signal with the Gaussian is equal to the convolution of the signal with the second derivative of the Gaussian, because both differentiation and convolution with something are linear time-invariant transforms. But now I'm not sure if that's true.

The Mexican Hat Wavelet page on Wikipedia says, "In practice, this wavelet [in multiple dimensions] is sometimes approximated by the difference of Gaussians function, because the DoG is separable." If this is true (it's not backed up by the reference given) then it seems like a better way to convolve things with that wavelet in most cases would be to use the procedure I've outlined above to approximate the convolution using the Gaussian-then-differentiate approach. Convolving five box filters gives you a quartic approximation of a Gaussian; its second derivative is then a quadratic approximation of

the Mexican Hat Wavelet. Note that this entire computation requires no multiplication.

Higher derivatives might also be useful, as they oscillate more times and hit more zeroes before dying out; they are the Hermite functions multiplied by the Gaussian. Their zeroes aren't really in the right places, but that error might not be large enough to matter; H_4 has zeroes at ±sqrt((3±sqrt(6))/2)), which is about ±0.523 and ±1.650. That doesn't oscillate nearly fast enough to be a good approximation for sinc. The higher-order Hermite polynomials' roots have a similar problem: their zeroes are roughly evenly spaced, while sinc has an double wide space at x=0 where there would normally be a root.

These derivatives do, however, look very much like delicious zero-phase FIR narrow bandpass filter kernels, which are more or less like the Gabor kernel. So they may not be that useful for signal reconstruction, but maybe they could be very useful for narrow bandpass signal processing!

I thought maybe it was just as bad for reconstruction that the higher-order Gaussian derivatives vanished very quickly, but maybe that's just an unavoidable artifact of a reasonable degree of locality, which is not an altogether bad thing.

(I got a lot of this information from http://bmia.bmt.tue.nl/people/bromeny/MICCAI2008/Materials/005%20Gaussian%20derivatives%20MMA6.pdf, which even mentions the use of Gaussian derivatives as bandpass kernel filters.)

Virtual instruments

Kragen Javier Sitaker, 2015-11-09 (3 minutes)

Playing with Carolina's idea of an expanded theremin.

There are two major questions: inputs and outputs.

Inputs

Minority-Report-style lights on hands in front of a webcam?

Kinect body scanning in real time?

Arduinos with accelerometers?

Power-glove-style strain gauges?

Theremins use capacitive sensing. This is clearly a possibility, but it is harder with high-speed electronics around, since the capacitance signals you're looking for are very small. An actual theremin circuit might be the best way to measure proximity.

Ultrasound signaling is another traditional approach for VR equipment.

Outputs

Some of this is tricky because the input channels we're considering are possibly pretty high latency: webcam plus image processing algorithms, say. So it might make some sense for the musician to control the tempo and type of rhythm rather than the exact timing.

(Some prototyping will reveal how big a problem this is in practice. You could imagine that a QVGA 320x240 image wouldn't really take that long to process, and might be adequate.)

The possibility of the music coming out is, fortunately or unfortunately, many-dimensional. Even a single note can be loud or soft, high or low, bent up or down, of many different timbres, and of many different envelopes, and at any time. An entire melody has many notes, and the relationships they bear to one another are potentially very complicated.

So one crucial question is how many low-latency high-bandwidth dimensions of input we can achieve: two with each hand? Another with angle? Another with finger separation? Other joint orientations?

One possible mapping is with radius for volume or timbre, and angle for pitch. Going around the circle more than once would go up or down a whole octave.

Another possibility is moving virtual objects around a space, maybe a time-frequency representation where time is streaming past you.

Another kind of exploration would adjust parameters of different state machines with your movements: a melody generator, a rhythm generator, a timbre generator or two. Maybe, at its simplest, you could have one direction to move in to seek change, and another direction to move in to stay the same; or you could have a sort of pie menu thing where you're always selecting one of the parameters to vary, and your distance from the center controls how fast it varies. It's crucial for the feedback here to be within a few hundred milliseconds in order for the interface to be discoverable.

On influencers

Kragen Javier Sitaker, 2019-05-16 (3 minutes)

Someone Tweeted today that it was absurd to have "influencer" as a job title, because it presupposes success — you might as well say you had been hired as a "bestselling novelist" instead of an author, for example.

There are a lot of job titles that are like this, though. It's commonplace to hear professors of philosophy use the word "philosopher" to mean "professor of philosophy", for example, as if Socrates had been a professor, or Einstein had been a gravitational field, or as if a tenure committee could confer a love of wisdom on a fool. "Hacker", too, is a title of acclaim, earned by achievement, not a hobby or a job title; calling yourself a "hacker" is one step below calling yourself a "genius", which is, of course, also used as a job title nowadays, by Apple.

There's a persistent meme that "engineer" is a similar sort of arrogant self-praise, since, ever since the disaster in Texas, various places have formal licensing requirements for "engineers" similar to those for braiding hairs or painting nails, with the ostensible purpose of preventing any more children from being exploded by poorly-designed gas systems or other machines. But an "engineer" has been, since at least the 15th century, one who makes engines; the licensing requirements are new and far from universal. Calling your creation an "engine", however, *is* a kind of self-praise, at least etymologically — you're saying it's *ingenious*, as the cognate word "engine" has meant "clever scheme" (and thence "machine") for over a millennium. Moreover, you're etymologically attributing this cleverness to your inborn qualities, thus "in+genitus", rather than hard work or good luck.

Surely we could go further with these flattering and optimistic job titles, though. Managers might feel left out of the fun, since their title implies they're just getting by; let's call them "organizational geniuses", or if, that makes them worry that you'll ask them to fix your iPhone, "master strategists". We could call taxi drivers "motorsport champions", and cooks "gourmet chefs" — though I think the world may be ahead of me on that one, since I'm pretty sure I've met self-proclaimed "gourmet chefs" who didn't have even a single Michelin star or prep cook. Oil-change mechanics could be "automotive engineers", though that doesn't really capture the same self-satisfied aspirational flavor as "influencer".

Designing a Scheme for APL-like array computations, like Lush

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

Here's a second whack at the problem of designing a Lisp dialect that lets you write array operations in terms of pointwise transformations, by means of static dependent type inference, in order to avoid run-time type and bounds checks.

First, array indexing. Arrays are a kind of function, but unlike other functions, you can find their bounds with the expression (bounds anArray). Arrays always take only a single argument, which can be either an integer within their bounds, or a vector of integers within their bounds.

Second, because vectors are so fundamental, there's a special syntax to construct zero-based vectors: [a b c d ...], which kind of looks like Scheme's #(...) syntax but doesn't quote, so it's semantically more like Python's list syntax or Squeak's { a. b. c } syntax.

So if you have a vector x and you want its fourth element, you can write (x 3) or (x [3]). As special syntactic sugar, if you leave out the space before the [, you get an extra layer of list wrapped around: x[3] is equivalent to (x [3]).

The (define ...) form from Scheme supports an extra feature not found in R5RS, which is already in MzScheme --- the thing being defined can be arbitrarily deeply nested on the left side. So all three of these definitions are equivalent:

```
(define x (lambda (y) (lambda (z) (+ y z))))
(define (x y) (lambda (z) (+ y z)))
(define ((x y) z) (+ y z))
```

This is so that you can define array-valued functions conveniently:

```
(define (matrix-multiply m n)[i j] (sum k (* m[k j] n[i k])))
```

syntactic sugar for (define ((matrix-multiply m n) [i j]) (sum k (* m[k j] n[i k])))

(bounds anArray) returns the bounds of the array as a vector of 2-element vectors, each indicating the minimal valid index and one more than the maximal valid index. So a 2x3 array that's all zero-based would have a bounds of [[0 2] [0 3]].

It is an error to construct non-rectangular matrices, because they don't have bounds that can be expressed in the above form.

For each array-valued function, the compiler infers a function that constructs the bounds of the resulting array from the bounds of its arguments. The bounds of the result are the widest possible bounds that the compiler can guarantee will not result in out-of-bounds accesses to any other array. Some arrays constructed by functions may be infinite, such as the generalized identity matrix (or Kronecker delta?):

```
(define identity[i j] (if (= i j) 1 0))
```

There's a (narrow newbounds array) form that can be used to artificially narrow the bounds of some array. It ensures that the new bounds don't include any values excluded by the old ones.

```
(define (nidentity n) (narrow [[0 n] [0 n]] identity))
```

Of the matrix-multiply function earlier, we can infer:

• m and n must both be two-dimensional;
• the first dimension of m must have the same range as the second dimension of n;
• the first dimension of the result has the same range as the first dimension of n;
• the second dimension of the results has the same range as the second dimension of m.

There's a (valid? expr) form which checks whether expr would cause a bounds error, without actually evaluating expr; the compiler can use this to infer bounds-construction functions.

Minimal GUI libraries

Kragen Javier Sitaker, 2015-11-14 (updated 2015-11-15) (5 minutes)

So I was thinking about what's needed to make a GUI library. You can get a substantial amount of it out of this piece of `propfont.c`:

```
/* This is sort of like a two-dimensional, dynamically-typed pointer
 * into pixels.
 */
typedef struct {
  char *pixels;
  int pixel_bytes, line_stride;
} pixel_buf;

static inline char *index_pixbuf(pixel_buf buf, int x, int y) {
  return buf.pixels + y * buf.line_stride + x * buf.pixel_bytes;
}

static inline pixel_buf offset_pixbuf(pixel_buf buf, int dx, int dy) {
  pixel_buf result = {
    index_pixbuf(buf, dx, dy),
    buf.pixel_bytes,
    buf.line_stride,
  };

  return result;
}

static inline void fill_pixbuf(pixel_buf buf, char *ink, int w, int h) {
  for (int x = 0; x < w; x++) {
    memcpy(index_pixbuf(buf, x, 0), ink, buf.pixel_bytes);
  }

  for (int y = 0; y < h; y++) {

    memcpy(index_pixbuf(buf, 0, y), index_pixbuf(buf, 0, 0), w * buf.pixel_bytes)o
o;
  }
}
```

That doesn't give you clipping, but with those 23 lines of code, any function that takes a `pixel_buf` parameter can be persuaded to draw at any position on a BIP pixel buffer of the pixel format it's expecting. You could enhance it to track right and bottom edges of rectangular windows with another couple of lines of code, which would make `fill_pixbuf` more convenient to call in many cases. And it's going to be pretty efficient.

However, if you write a windowing system on top of primitives like these, whether structured-mode or immediate-mode, you are probably going to end up with a kind of 1980s-looking window system with no antialiasing or transparency that's entirely immune to hardware acceleration, although if you avoid overdraw, you might be able to manage reasonable frame rates anyway. Nowadays, we can do

better!

Modern GUIs have transparency (alpha), gradients, rotation and distortion, filtering, béziers, antialiasing, animation, and terrible performance. I think we can do better.

First, both 1980s and modern GUIs almost entirely lack texture. But texture is a ubiquitous attribute of actual physical objects, and serves to orient us to movement in a subtle way. It also has a tendency to reduce the visual impact of dirt on the display or RF interference on the video signal.

Second, both 1980s and modern GUIs are still mostly oriented toward paraxial rectangles, and don't have indirect illumination (with the exception of drop shadows in modern GUIs on text and elevated windows). This orientation robs us of a lot of the structural cues we're familiar with from the physical world. They also don't take advantage of the possibility of zooming, in part because of font hinting and slow rasterization.

Third, 1980s GUIs, modern GUIs, and web UIs all lack a great deal compared to traditional typesetting, from a certain point of view. They lack letterform variation, columnar layout and horizontal scrolling, reasonable hyphenation and justification, hanging punctuation, tactile interface, line width variation, and so on. Of course, they're dramatically better from other points of view: better contrast ratios, animation, interactivity, undo, generativity, and so on.

There's an additional, somewhat selfish question associated with all of this, which is that if you reimplement the standard WIMP interface, it's easy for people who see it to dismiss it as unoriginal or even a copy of existing software with the labels filed off. (Many internet commenters carelessly dismissed Biyubi Fénix as a knockoff of KolibriOS/Menuet, for example, apparently without looking at it.) So even if you can't do something *better*, doing something *different* is significant.

So what might that look like?

I frequently hear surprised noises when I turn on my computer with a full-screen shell window. Old people sometimes mistake it for MS-DOS, but young adults were born around 1995, after MS-DOS was already obsolete. Here in Argentina, many of them didn't even use computers until after 2000.

Most people have still never seen a ZUI (with the possible exception of Prezi), and so simple "infinite" zooming is one way to distinguish it. It also lends itself to animations easily, which is in fact part of Prezi's appeal.

Windowing systems (and the underlying VT100 emulation) are a poor fit for shell commands; you have the tendency to open new windows to run new commands before the old one is done, but then it's hard to find the old one. A sort of notebook interface would work better, where you always immediately get a new prompt, and the output for previous commands can expand *above* your current prompt; perhaps it should be truncated by default, like with a dynamic `head; tail` that also outputs `wc`. (If it gets too large, you might want to either block the process generating it or discard parts of it.) Then you can also take that data and feed it to a new process, without having to re-execute the old one.

Furthermore, in many cases alternate presentations are possible: numeric tables, barcharts, scatterplots; Bret Victor's work with Dan

Amelang has shown some of the possibilities of this kind of visualization, along with incremental dataflow tracing.

An electric furnace the size of a sake cup

Kragen Javier Sitaker, 2017-02-25 (updated 2017-03-02) (10 minutes)

(See also Millikiln (p. 2581).)

There are lots of ways to heat things up to, for example, fire ceramics. Setting things on fire is probably the most fun way, but it's inefficient and hard to control. You can also concentrate sunlight, absorb microwaves, or run electricity through refractory wires.

Suppose we reduce the kiln problem to make it easier: we have no convection, and we just want to heat the kiln to 660°, the melting point of aluminum, using one of the three non-fire methods. And let's say we're satisfied with a kiln about the size of a sake cup: 50mm across, 60mm tall, 118mℓ. How much insulation do we need?

(Note that in the sunlight case, you also need a sufficient solar concentration factor, which works out to be 42 suns, 4.2 million lux.)

Well, of course, that depends on our power budget. At 2500 watts the problem is easy; at 2 watts the problem is hard. As a reasonable medium, let's take 500 watts, which is 2 amps here in Argentina, less than a toaster, hair dryer, or microwave oven, and about half a square meter of sunlight.

With such a small kiln, we aren't going to get a very good approximation by pretending the thermal gradient is constant across our insulating wall, but let's do it anyway.

Our top and bottom walls are $2\cdot\pi\cdot(25\text{mm})^2 \approx 4000\ \text{mm}^2$; our outer wall is $2\pi\cdot 25\text{mm}\cdot 60\text{mm} \approx 9400\ \text{mm}^2$; total is $13400\ \text{mm}^2$. Our total thermal flux is $500\ \text{W}/(11400\ \text{mm}^2) \approx 37\ \text{kW/m}^2$. Over a difference of 640 kelvins, that's about $58\ \text{W/m}^2\text{/K}$. Expressing this as an insulation value (R-value) instead, we have $0.017\ \text{m}^2\ \text{K/W}$. Loose-fill vermiculite is 17 m·K/W (according to Regenerator gas kiln (p. 2653), though I don't know where it got that figure) so this requires about 1.2mm of vermiculite. Other insulators are in the ballpark.

So actually the constant-thermal-gradient approximation is going to be pretty good. I'd go with making it 10 mm or 20 mm of insulation anyway, just in case, and maybe doubling the linear size of the kiln.

500 watts into 118 mℓ works out to a bit over 4 W/mℓ, which is adequate for a few kelvins per second of temperature rise, if somehow the whole microkiln is full of solid and yet thermally homogeneous. Since that would reach full firing temperature in a few minutes, it seems like a more than adequate specific power.

In the sunlight case, say you go with a solar concentration factor of, say, 100, just to be safe, and you also go for a whole square meter, to get a kilowatt. Now you are faced with the problem that to squeeze the whole square meter into the kiln aperture, which ideally faces directly downwards, you must exceed this solar concentration factor; the kiln aperture can't be more than a 500th of a square meter at that kiln size. This is another reason to want to increase the size of the kiln, and by more than a factor of 2.

So, revised design parameters: internal volume is a cylinder 150

mm across and 100 mm tall. Now we have 1.8 ℓ of volume, 0.018 m² of surface area on the bottom to cut a sun hole in, and 0.059 m² of total internal surface area to lose heat through by conduction. We use 20mm of insulating refractory for the walls and floor, which is kind of crappy as insulators go, so maybe its insulation value is only 8 m·K/W; this works out to 0.37 W/K, which means that at 640 K of inside–outside temperature difference we need 236 W of power input to maintain temperature. But we actually have 400 W of power, a comfortable safety margin, which works out to 230 mW/mℓ, which would heat water by about four kelvins a minute if the thing were full of water, but in the more reasonable case where it contains like 200 grams of stuff, we get 40 kelvins a minute, which gets us to full firing temperature (disregarding heat loss through the insulation!) in 15 minutes.

(Hmm, Henan Sinocean says their high-alumina insulating firebrick conducts 0.18 to 0.5 W/m/K, which I guess is insulating at 2 to 5.6 m·K/W, at a density of 0.3 g/cc for the best insulation up to 1 g/cc for the worst. These numbers are very high for insulating substances, barely better than ordinary bricks, but they are only a little worse than the Sheffield Pottery insulating firebrick numbers in Wikipedia and the BNZ Materials insulating firebrick brochure, and I probably can't do better, though I might do worse. So I might need 40mm of insulation instead of 20mm.)

400 watts of sunlight is 0.4 m²; a solar concentration factor of 100 (theoretically capable of reaching 900°) then requires a hole of 0.004 m², which is nearly a quarter of the floor area, which is still probably okay. A solar concentration factor of 100 could also be thought of, in imaging optics, as 10× magnification, or, in antenna design, as 20dBi. Both of these are eminently achievable. You could even reach that level with a trough reflector, though it wouldn't be the easiest way.

Fusión Refractarios in Avellaneda offers imported 0.81 g/cc 0.3 W/m/K 1427° firebricks for $87, which are 229×114×63mm; at $87/(2·229·114 mm²) at 31½mm thick, the cost is $1670 per square meter. I could maybe get two or four of these firebricks and try to stick them together.

Ten meters of Kanthal costs AR$70, whether it's 0.2 mm, 0.3, 0.4, or 0.5, and it's good to 1250° — not ideal for a pottery kiln, but it would do. It's not clear which Kanthal this is; there are various grades of Kanthal; one is Kanthal AF, which is good to 1300° and has a resistivity of 1.39 Ω mm²/m, but doesn't come in such narrow gauges.

How do I figure out how much wire I need? In theory you can get an arbitrarily large amount of power out of a fixed voltage source by putting an arbitrarily small resistance across it, since $P = E^2/R$. However, in this case the crucial fact is not really the resistivity of the wire — as I thought it was — but its surface area! It needs enough surface area to emit the desired amount of power at its safe temperature — at these temperatures, almost entirely as radiant heat.

That's why the Kanthal data page gives its fully-oxidized emissivity: 0.7. So how much wire surface area do I need to emit 400 watts with emissivity 0.7 at, say, 1100°? $0.7\ \sigma\ T^4 = 141\text{kW/m}^2$, so I need 2800 mm² (0.0028 m²), about 5% of the total inner wall area of the microkiln.

That's somewhat alarming! But, it turns out, not fatal.

Ten meters of 0.5 mm diameter Kanthal has almost 7900 mm² of surface area, and so thus, emitting at 1100°, it emits 1108 watts; at 1200°, it emits 1470 W. So really four meters of it (AR$28) should be adequate. (I'm a little skeptical that the price is actually correct, since all the other prices seem to be much higher.)

(Is it bad that I'm ignoring the radiant heat absorbed by the wire? I think it's okay, since it's hypothetically so much hotter than everything else.)

There *is* the engineering question of making the resistance low enough to get enough power out, without making it so low you draw too much power. In this case we want about 2 amps at 220 volts, which requires 110Ω. Four meters of 0.5 mm wire should be about 10 · 1.39 Ω / (π (¼mm)²), which is close — it's 28 ohms. The easy thing to do is just go ahead and use a longer wire: at 7Ω/m, you need 15.5 meters. Or a narrower one: ten meters of the 0.4 mm wire should be just right, and has 12566 mm² of surface area.

At 150 mm diameter, that's about 20 turns of a spiral around, which puts the turns about 5 mm apart up the walls if I don't coil them. Or I could coil them and use, say, four turns.

The volume of refractory is, say, the difference between a 230mm diameter, 180mm height cylinder, and the 150mm diameter, 100 mm cylinder space within: 7478 mℓ - 1767 mℓ = 5711 mℓ. If we take a middle-of-the-road figure of 0.7 g/cc for the refractory, it's 4 kg of clay.

To control the temperature, we need a thermocouple, probably AR$200, probably type K.

What would this microkiln design look like if I wanted to include safety margins to ensure that it would heat up and wouldn't burn out? After all, many unexpected things will no doubt occur — perhaps the brick walls will leak, the Kanthal may be a counterfeit that burns out at 1100° or has the wrong resistivity, the bricks may conduct more than expected, and so forth.

I'm not sure what I would do to give it a *temperature* safety margin so that it wouldn't burn up if it hit 1400°, which is a temperature I'm extremely interested in. Except to make it purely solar, I guess, or arc-driven. The issue is the maximum service temperature of the wire. Kanthal A-1 is supposedly good to 1400°, and Kanthal APM is supposedly good to 1425°. Kanthal A-1 is available on MercadoLibre, but at a 15× higher price.

An algebraic approach to 3D geometry

Kragen Javier Sitaker, 2014-06-03 (updated 2014-06-29) (22 minutes)

I was thinking about how to model objects for 3-D printing in a more flexible and generative way than OpenSCAD provides, and a very interesting factorization of 3-D geometry occurred to me. It falls a little short of what I was hoping for, but it still seems like it will be somewhat useful.

You can compose all the common primitive solids, plus a large number that are not common in 3D graphics but commonly occur in the world, from a small number of primitives, belonging to a smaller number of types (in the programming sense of data types) and primarily function composition. Surprisingly, it might even be practical to compute things with.

In particular, this approach derives lines, squares, circles, arcs, ellipses, cubes (and parallelepipeds in general), helices, cylinders, cylinder walls, cones (including frusta), spheres, ellipsoids, paraboloids, logarithmic spirals, discs, cycloids, spirographs, machine turning patterns, and tori from seven or eight relatively powerful primitives, each in about two lines of code.

I say this is "algebraic" in the sense that I'm defining a set of primitive objects and operations on those objects that I think will map to the domain I'm interested in in a useful way. You could also say that it's "algebraic" in that it represents the 3-D objects as symbolic expressions containing variables that can be evaluated to get coordinates.

This is derived from some work Nick Johnson and I a few years ago for an algebra of two-dimensional paths for his sand-table plotter, which drew aesthetically appealing patterns in sand with a ball bearing controlled by a magnet below the sand.

Examples

I haven't tested these. See section "The algebra" for a brief explanation of the notation, or read on for a fuller explanation.

```
K(r)  = r...r
Z(v)  = X(K(π/2)) . Y(v) . X(K(-π/2))
TY(v) = Z(K(π/2)) . TX(v) . Z(K(-π/2))
TZ(v) = Y(K(π/2)) . TX(v) . Y(K(-π/2))
SY(v) = Z(K(π/2)) . SX(v) . Z(K(-π/2))
SZ(v) = Y(K(π/2)) . SX(v) . Z(K(-π/2))
SU(v) = SX(v) . SY(v) . SZ(v)
step = 0...1
line = TX(step)
square = line * TY(step)
cube = square * TZ(step)
turn = 0...2*π
twistedcube = square * (TZ(step) . Z(turn))
disc = TX(step) * Z(turn)
```

```
cylinder = disc * TZ(step)
twostep = -1...1
parabola = TX(twostep) . SY(twostep) . SY(twostep) . TY(K(1))
paraboloid = parabola * X(turn)
cone = (Y(K(π/4)) . line) * Z(turn)
frustum = (Y(K(π/4)) . TX(1...2)) * Z(turn)
circle = TX(K(1)) * Z(turn)
helix = TX(K(1)) * (Z(turn) . TZ(step))
arc = TX(K(1)) * Z(0...π)
ellipse = TX(K(1)) * (Z(turn) . SX(2))
torus = (TX(K(2)) . circle) * Y(turn)
cylinderwall = circle * TZ(step)
sphere = circle * X(turn)
ellipsoid = ellipse * X(turn)
helicalramp = TX(1...2) * (TZ(step) . Z(0...8π))
logarithmicspiral = TX(K(1)) * (Z(0...8π) . SU(step))
zoscillation = SY(K(0)) . X(0...8π) . TX(K(1))
spreadingripples = (line . SZ(1...0) . zoscillation) * Z(turn)
spirograph = TX(K(1)) * (Z(turn) . TX(K(2)) . Z(0..12π) . TX(K(-2)))
```

It's based on extrusion

"Extrusion" is a relatively general way of adding a dimension to a manifold. If you have a point, or a set of points, extruding them along some path gives you a curve, or a set of curves; and if you have a curve, or a set of curves, extruding them along some path gives you a surface, or set of surfaces. (If the path is discontinuous, you may discover points becoming sets of curves, or curves becoming sets of surfaces.) For example, you can rotate a point into becoming a circle, and the circle into becoming a torus; or you can translate the circle to make the wall of a cylinder.

A few years back, when I wrote a real-time 3D engine in JavaScript (XXX) with the 2-D canvas, this was where I stopped: extrusion took as parameters an object, a linear 3-D transform, and an iteration count, and gave you back an object made by extruding the original object through that transform an arbitrary number of times. The result was a kind of faceted crude approximation to a torus, although I should really have twiddled parameters a bit to get some kind of more interesting shape, like a spiral or something; if you wanted a finer approximation of a torus, you could halve the rotation angle and double the iteration count, and you'd have more facets with duller angles between them.

You'd think you could use this approach with arbitrary 3-D transformations, taking some kind of "square root" of the transformation in order to make a finer mesh where needed. This turns out to be impossible because even a simple rotation transformation has, in some sense, lost the information about its angle: if it's 0.1 radians around the z-axis, say, we have this matrix:

```
[ [ cos 0.1 -sin 0.1  0  0 ]
  [ sin 0.1  cos 0.1  0  0 ]
  [   0        0      1  0 ]
  [   0        0      0  1 ] ]
```

and if you want "half" of that rotation, it's equally valid to use sin and cos of 0.05, or of π+0.05; either one will work out to the above matrix when you double them. (The fundamental theorem of algebra tells us that in general $z^n = w$ has n distinct solutions for a given n and w, and multiplying by a complex number is a subset of the transformations we're interested in here.)

So to get a smoothly interpolable representation, we can't simply use a structure of 12 real numbers; we need something that preserves more information about the functional relationship between those numbers and the parameter, or parameters, we'd like to interpolate.

So how can we get there from a relatively small and usable set of primitives with reasonably tractable computation?

This extrusion operator relies on a terribly general notion of "path". I mean, PostScript's "path" was already very general: it can be discontinuous and either open or closed, but at least it was just a one-dimensional manifold of two-dimensional points. This notion of "path" seems to be a one-dimensional manifold of twelve-dimensional transformation matrices:

```
[ [ x0  x1  x2  x3  ]
  [ x4  x5  x6  x7  ]
  [ x8  x9  x10 x11 ]
  [ 0   0   0   1   ] ]
```

where the twelve variables inside the matrix are some kind of piecewise-continuous real functions of one real variable, t. In some sense you can see the [x3 x7 x11] column as specifying a path in the more traditional sense, some kind of infinite sequence of points in 3-space, along which a point transformed from the origin [0 0 0 1] could swoop and soar as t changes; the other 9 variables simply describe how a thing moving along the path gets stretched, skewed, rotated, and perhaps reflected.

If we make these twelve variables, instead, functions of *two* parameters, we get a parametric surface, which we can sample as finely as we desire.

Linear real functions

First, and most basic, let's consider the linear real function $y = mt + b$. You can compose this from two one-dimensional manifolds in a variety of different ways; let's say:

```
M(m) = mt + 0
B(b) = 0t + b
```

These two *could* be composed with one another, but it is more useful to be able to add them (pointwise), because that lets us span the whole mt + b space. So the function $\pi x + \pi/2$ can be written as $M(\pi) + B(\pi/2)$. These functions are closed under addition, but not composition or multiplication.

If we consider transforming the interval [0, 1] through these functions, we can see that they can be used to represent arbitrary closed intervals on the number line; in this interpretation, the function above represents the interval $[\pi/2, 3\pi/2]$, for example. Of course there are an infinite variety of other possible interpretations,

but this is the one I will choose.

Frankly, though, this is a little silly; instead of M and B, I will use a single function of two real arguments:

```
I(x0, x1) = (x1-x0)t + x0
```

which I will write as:

```
x0...x1
```

Elementary paths

So let's consider the general 3-D linear transform that changes over time. This is capable of scaling (nonuniform scaling and reflection), skewing, rotation, and translation.

If we have rotations around two axes, we can get rotation around the third by composing them; if we have rotations around all three axes, we can get scaling along arbitrary dimensions by composing 90° rotations with scaling along a single dimension; and skewing happens if you use a non-90° rotation and then scale along a single dimension. Finally, composing arbitrary rotations with translations along a single dimension will give you arbitrary translations.

So we have four elementary "paths", in the sense of path I described earlier — not just a point that varies with some parameter, but a general linear 3-D transform that varies over time:

```
X(v) = [ [ 1    0      0    0  ]
         [ 0  cos v  -sin v  0  ]
         [ 0  sin v   cos v  0  ]
         [ 0    0      0    1  ] ]

Y(v) = [ [ cos v  0  -sin v  0  ]
         [   0    1    0    0  ]
         [ sin v  0   cos v  0  ]
         [   0    0    0    1  ] ]

TX(v) = [ [ 1 0 0 v ]
          [ 0 1 0 0 ]
          [ 0 0 1 0 ]
          [ 0 0 0 1 ] ]

SX(v) = [ [ v 0 0 0 ]
          [ 0 1 0 0 ]
          [ 0 0 1 0 ]
          [ 0 0 0 1 ] ]
```

So what is this v?

You could think of e.g. T as being the entire X-axis, or X as being infinite rotation around the X-axis, in the sense that for any real value of v, they represent a particular real 4×4 matrix that translates the origin to that point on the X-axis or rotates to that angle around the X-axis. And if you take some interval of real numbers [v0, v1] and transform it through T or X, you get some interval of translations along the X-axis or rotations around it.

In particular, if we draw our v from the linear real functions

described in the previous section, then as t varies from 0 to 1, these elementary paths will interpolate continuously and smoothly over some interval.

We can multiply these matrices to compose the 3-D operations they represent. This means we're multiplying these individual elements, which may be linear functions of t or transcendental functions of linear functions of t. This will produce, unfortunately, relatively general algebraic expressions as elements of the matrices, which in the worst case can grow exponentially in the number of elementary paths in the matrix product: each variable rotation introduces two new transcendental functions of a potentially new linear function. (It should be clear that Spirograph patterns can be computed this way easily, so you shouldn't expect much worst-case simplification.)

This is a bit of a disappointment, since I was hoping for something that would occupy bounded space, or hey! at least linear space, after an arbitrarily large number of operations. Not exponential space.

I console myself with the thought that the alternative representation is often a triangle mesh, and it's going to take a pretty big formula to approach the amount of space a triangle mesh uses.

Surfaces

Suppose we have a curve defined as above, some arbitrary composition of elementary curves, each parameterized by some interval of the real number line; now we would like to extrude it into a surface, which might enclose a volume. We can do this by transforming it through some other arbitrary curve, which can stretch and rotate and skew it as needed; all of this can be implemented simply by matrix concatenation, but with the variable t renamed to u in the extrusion path.

This gives us a 4×4 matrix, 12 of whose cells are arbitrary algebraic expressions in t and u, combined with numbers, sin, cos, addition, and multiplication; but we probably really only care about three of those cells, [x3 x7 x11], the ones that give us the coordinates to which the surface has carried the origin.

You might want to transform a surface by composing a path with it, but maybe not a path that depends on t or u; it's not clear what that would mean to me.

The algebra

So we have five basic elements:

- I(x0, x1: real): interval; written as x0...x1
- X(v: interval): path
- Y(v: interval): path
- TX(v: interval): path
- SX(v: interval): path

And two, or arguably three, ways of combining them:

- compose(a: path, b: path): path; written as a . b
- extrude(a: path, b: path): surface; extrudes a by moving it along b; written as a * b
- extrude(a: surface, b: path): surface (or solid); makes two copies of a, one at each end of b, one of them with its polarity flipped, and

connects them with a surface where the edge of a passed as it moved along b. Effectively this involves turning the edge of a into a path and extruding that path as it moves along b.

(Maybe instead: extrude or construct interval with ":", construct interval with "@", apply functions with simple concatenation or ".", compose with simple concatenation, ",", or ";", extrude with "/"? I'm ending up with lots of noise in my expressions. Maybe also use lowercase.)

Internally, this builds trees of the following structure:

• an expression is one of:

• a variable, t or u
• a real
• (a: expression) + (b: expression)
• (a: expression) * (b: expression)
• -(a: expression)
• cos (a: expression), or
• sin (a: expression).
• an interval is an expression.
• a path is 12 expressions.
• a surface is 3 expressions.

You could restrict this further, since e.g. the argument of a transcendental function here will always be a linear one, but that doesn't seem to offer much benefit yet.

Computations on the surfaces

The simplest and most obvious thing you might want to do is to sample the points on a surface to build a triangle mesh, which you can do by just evaluating the expressions for the surface points for different values of t and u. The range for t and u is predefined as [0, 1], so it's just a matter of figuring out how much and where to subdivide the range.

That's a bit of a problem, though. You'd maybe like to keep your sampling mesh more or less uniform in density, so as to avoid wasting triangles on areas without much detail. (On a sphere, for example, there will surely be a point where one or the other of the parameters doesn't give you any extra information.)

You can use bounding-box arithmetic ("interval arithmetic") to find 3-D bounding boxes of parts of the mesh, recursively bisecting the mesh until your 3-D bounding boxes are small enough that you are satisfied with your triangle size. Interval arithmetic is explained in a section below.

Additionally, for smooth shading (Gouraud or Phong), vertex normals can be helpful. You can calculate these by partially differentiating the surface vector with respect to t and u and normalizing the cross product.

Calculating the area of a surface may be useful for some purposes: maybe for paint coverage or heat loss or adsorption or something. It's reasonably feasible to approximate numerically with a simple double integral over the parameter space.

Interval arithmetic

This is a sort of abstract interpretation of numerical formulas,

introduced to me as an exercise in SICP, using [min, max] pairs to produce a conservative approximation of a function's range over some interval. For our case, we can use the following evaluation rules:

• a constant number k becomes [k, k]
• [a, b] + [c, d] = [a+c, b+d]
• -[a, b] = [-b, -a]
• [a, b] * [c, d] = [a*c*, *b*d] if all four are nonnegative; otherwise, use identities to transform the expression into the tractable all-nonnegative form above:

• -[a, b] * [c, d] = -([a, b] * [c, d]); apply if a and b are nonpositive
• [a, b] * -[c, d] = -([a, b] * [c, d]); apply if c and d are nonpositive
• -(-x) = x; apply if possible
• [a, b] = union([a, 0], [0, b]) if a and b have opposite signs; apply if possible
• a * union(b, c) = union(a * b, a * c); apply if possible. If this is applicable, you need to start again from the top because probably one of the new multiplication subexpressions contains a negative-going interval.
• union([a, b], [c, d]) = [min(a, c), max(b, d)] (remember, conservative approximation!)
• sin [a, b] may be:

• [sin(a), sin(b)] if a and b are in the same monotonically increasing interval of sin;
• [sin(b), sin(a)] if a and b are in the same monotonically decreasing interval of sin;
• [min(sin(a), sin(b)), 1] if a and b have a peak between them;
• [-1, max(sin(a), sin(b))] if a and b have a valley between them;
• [-1, 1] if a and b have both a peak and a valley between them.
• Analogously for cos [a, b].

These rules are conservative, but they are precise in the sense that if you subdivide a bounding box into smaller and smaller parts, eventually the bounding box of a union-free formula evaluated over it will have an arbitrarily small range.

Applying these evaluation rules to the three expressions that give the x, y, and z coordinates of points on a surface, with interval values for t and u, will give you a bounding box in x, y, and z for that subsection of the surface. If you use [0, 1], you get a bounding box for the whole surface.

I write these bounding boxes as [a, b] rather than a...b because the meaning of the second is slightly different, but confusingly similar: it's a motion from a to b that varies linearly with t, while [a, b] might oscillate wildly between a and b as t and u vary, perhaps not even reaching them.

Possible extensions

Given a third parametric parameter, you could animate an unchanging object along a path.

CSG — union, intersection, and especially subtraction — would dramatically increase the power of the system. It might be particularly tricky to compute precisely, though.

Piecewise functions would enable you to do things like splines.

You could imagine a sequence(a: path, b: path) operator (perhaps written "a; b") that evaluated as a(2t) on [0, ½) and then b(2(t-½)) or perhaps a(1)+b(2(t-½)) on [½, 1]. I think that the extrude-a-surface-into-a-solid functionality kind of depends on doing this anyway, since the resulting surface is a sort of composite of six different surfaces: the initial and final surface and the four surfaces produced by extruding the t=0, t=1, u=0, and u=1 edges. (Alternatively you could make a "surface" be an arbitrary set of parametric surfaces rather than just one. Also this is making me think I should read Wouter's CUBE engine.)

Piecewise functions potentially introduce a finite number of discontinuities, and many things might then need to get a list of discontinuities in an interval.

Being able to read in geometry from external sources (STL files, DXF files, Hershey fonts, SVG logos, TrueType fonts, heightfields) would enable a lot more stuff.

Being able to query geometrical results, KSeg-style or AutoCAD-style, or even just PostScript-style (flattenpath, pathbbox, charpath, pathforall), would make parametric modeling a lot more reasonable.

If you're just generating an STL file for 3-D printing, the shape is all you need. But for other purposes (displaying onscreen, using in a game, 3-D printing in color) you need a way of adding other attributes to your material.

Another thing you might want to do with a surface, besides look at it or extrude it into a solid, is to "shell" it — build up a solid around it of a given thickness. This is analogous to the "stroke" or "strokePath" operation in 2-D graphics. I call it "shell" because if you use it on a surface that encloses a solid volume, the result is a hollow shell of some thickness. (CATIA calls it "shell" too.)

The approximate inverse operations of "shell" are "fill" (remove hollow spaces inside of) and "erode" (known as "inset" in Inkscape; take a given thickness off the surface all the way around).

What are the equivalents of line dash patterns or halftone patterns in PostScript? Maybe honeycomb (and other) infill, or surfaces perforated to save plastic in 3-D printing? Maybe embossed surface texture?

I want to be able to query the volumes of enclosed or nearly-enclosed spaces for acoustic reasons.

In general it seems like repeating shapes could be useful. Like if you have an ellipsoid and you want to make sixteen of them evenly spaced.

Perlin noise or midpoint-displacement surface roughness might be useful things to have; but how do you add things like that in a clean way?

Topics

Topics to study in 2016

Kragen Javier Sitaker, 2016-10-27 (updated 2016-11-15) (37 minutes)

I have a fairly clear idea of what stuff I want to be studying right now, which has taken some time to congeal. There are 18 major themes: constraint satisfaction, mathematical optimization, logic, interval arithmetic, tensor or array computation, physical system simulation including finite element analysis, automated manufacturing or digital fabrication, incremental computation and caching, reproducibility, archival and publishing, real-time computation, anytime algorithms, probabilistic programming, neural networks, decentralization, self-replicating machinery, self-sustaining software systems, and physical security. These seemingly disparate themes actually have an underlying unity, which I will attempt to explain.

Constraint satisfaction

Constraint satisfaction systems search for a configuration that satisfies some set of boolean conditions. Sometimes the configuration may be continuously variable, like a point in $\mathbb{R}^n$. Other times it may be discrete, like a set of choices for a set of Boolean variables. It may have finite dimensionality (like $\mathbb{R}^n$), infinite dimensionality (like a function $\mathbb{R} \to \mathbb{R}$), or finite but unbounded dimensionality (like a sentence in some formal language). The conditions may be simple and tractable (things like "$x > 0$") or very hairy indeed ("md5(x) == 0xd41d8cd98f00b204e9800998ecf8427e", which looks computationally intractable but is actually fairly easy).

The parts of the configuration are sometimes called "design variables".

Different kinds of constraint satisfaction problems have different algorithms available to solve them. Most of classical algebra and integral and differential calculus consist of algorithms for solving particular kinds of constraints. You're given a constraint like $2x^2 + 4x = 30$ and your objective is to find an x that satisfies that constraint, traditionally by deducing logical consequences from that given constraint until it's trivial to compute the answer. For example, from that equation we can deduce $x^2 + 2x = 15$, then $x^2 + 2x - 15 = 0$, then $(x - 3)(x + 5) = 0$, and $x=3 \vee x=-5$.

You can think of a constraint as a generalization of the notion of a function — it's a function that can "run backwards", so to speak. This can significantly simplify the process of developing a piece of software, thus amplifying the intellectual abilities of its author. Often it is significantly easier to express attributes of the desired results of a program (consider the MD5 example above) than how to compute them. In some such cases, it's even possible for existing constraint-satisfaction software to find the results.

MiniKANREN is one of the more interesting pieces of constraint-satisfaction software becoming available today. The burgeoning field of efficient SAT and SMT solvers such as Z3 contains many others.

Aside from the rapid advances in the efficiency of satisfiability algorithms, larger and larger constraint-satisfaction problems are

coming within reach as memories and CPUs dramatically increase in power. A crude understanding of complexity theory might lead you to think that this won't matter much, because SAT is not known to be in P, so even a CPU that is 256 times faster will only allow you to expand the feasible problem size by 8 bits. But in fact the base of the exponential has been brought down far below 2 and continues to diminish.

Mathematical optimization

Mathematical optimization is the problem of finding a configuration that maximizes (or minimizes) some objective (or loss) function, subject to some feasibility constraints. The classic example — and indeed nearly the only one considered in many textbooks on mathematical optimization today — is linear programming, where the feasibility constraints are linear inequalities and the objective function is linear.

Categories of algorithms for mathematical optimization are called "metaheuristics", which is a somewhat misleading name but gives some clue of how broadly applicable they are. Random guessing, hill climbing, gradient descent, gradient descent with random restarts, and genetic algorithms are widely-used metaheuristics.

Constraint satisfaction and optimization

Optimization can be seen as a generalization of constraint satisfaction in a few different ways.

Clearly if you can find the optimal configuration among all feasible configurations, then you can find at least one feasible configuration, which is the constraint satisfaction problem. So, from this point of view, algorithms to solve optimization problems can solve constraint satisfaction problems too, but it might be easier to say

Also, though, you can conceptualize the constraints of a constraint-satisfaction problem as real-valued functions that are multiplied together, where those functions take the value 1 when the constraint is satisfied and 0 otherwise. Then, finding a maximum of the product is equivalent to finding a solution to the constraints. Many optimization algorithms will have an easier time if those factor functions are instead continuous and between 0 and 1 when the condition is false. And in fact this sort of thing is a common method (the "penalty method") for incorporating constraints into optimization problems for solvers that don't natively handle constraints. The very first constraint-satisfaction system for mechanical design, Sketchpad, apparently used gradient-descent to search for approximate solutions to geometrical constraint systems.

However, constraint satisfaction algorithms can also be used to solve optimization problems if you invoke them many times. If your objective function is y, you first seek a solution for $y > 0$. If successful, you seek a solution for $y > 1$; if successful, a solution for $y > 4$; if successful, a solution for $y > 8$; and so on until you fail, at which point you can approximate the optimum as closely as desired using binary search.

Logic

Logic is a very broad term, but in particular what I'm interested in are theorem provers and predicate logic, which can produce

machine-checkable proofs of mathematical propositions — whether propositions of general interest, such as (most famously) the four-color theorem, or propositions having to do with particular pieces of software.

There is a lot of work currently going on in this space, with systems like Coq, Agda, Idris, Isabelle-HOL, Z3, Mizar, and Epigram being actively developed, and systems like CompCert and seL4 being proved.

Much of the initial work on program correctness came from a desire to ensure that all programs were correct, for reasons having to do with the risk-averse nature of military bureaucracies, rather than any kind of rational cost-benefit analysis. But in practice, many programs do not even have a well-defined specification that they could conceivably fail to conform to, nor is it a good use of the irreplaceable million or less hours of a human being's life to write one. It's often adequate to try things and see what happens.

To me, proving programs correct is of interest for four reasons: compiler optimization, user interface innovations, software security, and embedded systems.

It's interesting for compiler optimization because if an unoptimized program can be proven equivalent to the original program, the correctness of the optimizer or optimizers is a moot point, and indeed some kind of random search over all feasible programs may be adequate (as Sorav Bansal proposed in his thesis, *Peephole Superoptimization*).

(Note that "optimization" here is used in a sense unrelated to the "Mathematical optimization" section above.)

It's interesting for user interface innovations because the interactive process of creating a machine-checkable proof with a proof assistant like Coq is very different from the traditional batch-job-inspired workflow of writing a program in a text editor in a compiled language and then feeding it to a compiler. I don't have enough experience with this process yet to figure out whether it has innovations that can be applied more widely to the process of creating things using computers.

It's interesting for software security because trying things and seeing what happens is never adequate to produce secure software, although it may be adequate to find security holes. Often when a security hole is detected in the field, it is already too late to prevent disastrous effects. So significant effort toward other ways to prevent them seems like it would be justified.

It's interesting for embedded systems for a somewhat similar reason.

If my production database server crashes, the production cluster can fail over to a secondary and save the logs and a core dump, and in the morning I can inspect the core dump and the logs to figure out what went wrong. Then I can fix the bug, recompile the database software, and upgrade across the cluster. The cost of the failure is low (assuming it wasn't a security hole), and it's highly inspectable and reparable.

By contrast, if the software on the Arduino controlling an autonomous toy car, the car may be run over by a truck, and possibly all the Arduino can do to make the error debuggable is to blink an LED. It doesn't have space for a core dump. The cost of the failure is

high, and it's poorly inspectable and reparable. (The situation is even worse if it's an automatic implantable defibrillator.)

So for embedded systems, it's highly desirable to detect errors at compile time rather than run time.

Logic and constraint satisfaction

In some sense, theorem-proving is merely an application of constraint satisfaction: you have some set of axioms and inference rules which you've previously decided are reasonable or at least consistent, and you're searching for a proof which starts from those axioms, is valid according to those inference rules, and ends with your desired conclusion. That's clearly a constraint-satisfaction problem.

But constraint satisfaction is also merely an application of theorem-proving. A constructive theorem prover, given the task of proving that some set of constraints C is satisfiable, will produce a constructive proof, which is a way to construct a configuration satisfying them. But even a non-constructive prover can be used, at least for a finite set of design variables; you repeatedly attempt to prove that a given design variable is in a given range.

This conjunction between constraint-satisfaction systems and logic systems is sometimes called "constraint logic programming".

From another angle, all of classical algebra (the equation-solving stuff, not the modern abstract algebra stuff that grew out of group theory) is the application of logic to constraint satisfaction. So you would think that that kind of theorem-proving logic could be applied to significantly ease more general kinds of constraint-satisfaction problems, where the constraints might include things like arbitrary lookup tables, conditionals, and iteration.

Logic and optimization

Both theorem-proving and mathematical optimization intersect with constraint satisfaction, but their intersections are sort of complementary. Theorem-proving is associated with (I'm being vague here) finite domains, algebraic structures, and various kinds of backtracking search. Mathematical optimization is associated with continuous and therefore infinite domains, analytic structures, and various kinds of iterative approximation.

But of course in day-to-day math, we often use theorem-proving techniques (often with pencil and paper) to transform problems of analysis into tractable forms and even to find closed-form solutions to them. So it seems likely that the two approaches are likely to be complementary in software as well.

Interval arithmetic

Interval arithmetic is a means to bound the approximation error on an approximate calculation by computing on a conservative approximation of the answer. The usual arithmetic operations are defined to operate over intervals of the real line in such a way that the result of the computation is a conservative approximation of the correct result. In general, narrower bounds on the input will result in narrower bounds on the output, although sometimes not as much as you'd hope.

Interval arithmetic has been most investigated as a way to bound the approximation error from floating-point roundoff by setting

different rounding modes, at the cost of considerable performance. However, it has a number of other applications; probably the best known is precise and efficient ray-tracing of implicit surfaces, a technique surveyed broadly in Jorge Eliécer Flórez Díaz's 2008 dissertation, but which has been developed continuously over the last quarter-century. In this application, it *improves* performance by avoiding redundant calculations that will produce the same result.

Intervals and constraints

You can use interval arithmetic to solve constraint satisfaction problems over continuous variables by recursive subdivision of the problem space, in the same way that I outlined earlier for solving optimization problems with a constraint solver, except that you may need to recurse into more than one subinterval. Treating arithmetic as constant-time, this approach is probably logarithmic-time in the required precision and exponential-time in the number of dimensions, and is therefore not practically applicable to problems of high dimensionality.

However, it is the only general algorithm I know of for continuous constraint satisfaction problems, not being limited to finite domains or to constraints of a particular form, such as linear systems or polynomials. (It only requires that the constraints be computable, which turns out to imply a particular kind of continuity.)

It's not completely trivial to get right, because strictly speaking, in the form I've described, it only guarantees that it wasn't able to prove that *no* points in the selected region satisfy the constraints, not that any of them do. For example, a simple implicit function grapher I wrote using interval arithmetic suggests that there may be zeroes anywhere the implicit function has a singularity, because the result of dividing by an interval containing zero is the interval $(-\infty,+\infty)$, which contains 0. But small regions around such a singularity will typically not contain any zeroes or even numbers close to zero.

There are lots of tweaks you can apply to this algorithm, and as with other kinds of recursive search algorithms, even fairly minor improvements can have enormous effects on efficiency, since they exponentially reduce the number of nodes searched. Some of the things I've been thinking about are priority queues of regions by size, a tighter interval representation that approximates results by =a linear function of input variables over a given input interval, three-way partitioning, and choosing partition locations to be closer to the part of the region most likely to be feasible.

Intervals and optimization

By the same token, you can use interval arithmetic to solve mathematical optimization problems by recursive subdivision.

Intervals and logic

I don't know how interval arithmetic combines with theorem proving.

Array computation

Array languages are not merely languages which support arrays, as almost every programming language does. They are languages in which arrays are first-class values that support aggregate arithmetic

and computational operations. They were born in the form of APL in 1957–1962, but in the 1980s spawned S, IDL, and MATLAB, and since then have spawned the languages R, J, K, A+, and Lush, and the Python library Numpy, the Perl library PDL, and most recently the neural-network-focused libraries TensorFlow and Theano.

Typically the arrays are of arbitrary dimensionality, and sometimes they may be called "tensors" or something else.

Fitting a program into the array-programming style requires a different kind of thinking than the mainstream record-oriented or object-oriented style which evolved, as far as I can tell, from 1950s business data processing on machines with a few kilobytes of RAM and tape drives. I find it very awkward.

There are two or three interesting advantages of this way of doing things that induce me to keep trying it:

• Efficient execution. Originally this was only an advantage for interpreted implementations like the original APLs, Numpy, or old versions of MATLAB; it just pulls the interpretation overhead out of your algorithm's inner loop. So C and FORTRAN programmers scoffed, since at best it got you from wasting 99% of your CPU to wasting 50% of it. Nowadays it's becoming an advantage even compared to C, C++, or Fortran (TensorFlow originated as a C++ library) because the array aggregate operations can be compiled efficiently onto a GPU. The array operations are generally explicitly parallel, rather than implicitly so as more imperative code usually is. (Roml Lefkowitz is the first person I remember making this observation.)
• Terser code. By making most loops implicit, arguably the code strips away much of the inessential implementation complexity and reveals the intention of the programmer more clearly. I feel like this can go either way, but this may be a function of my inexperience with the paradigm.
• More abstract and thus more flexible code. Typically the code `a*b` with an array language or library could mean (in Python notation) any of `[ai*bi for ai, bi in zip(a, b)]`, `[a*bi for bi in b]`, `[ai*b for ai in a]` just `a*b`, or even `[[aij*bij for aij, bij in zip(ai, bi)] for ai, bi in zip(a, b)]`, and which one depends on which of the two is a vector or array. This works to your advantage more often than you'd think; if you write a plotting function that takes arrays of X-coordinates, Y-coordinates, and point colors, it will generally just fall out that you can pass in a single color instead of an array of colors when that's what you want. This depends, however, on the detailed design of the aggregate operations provided by a particular language, and sometimes it fails in surprising ways. (And I'm not sure it applies at all to TensorFlow and Theano.)

I've been thinking for a while about how to clean up the semantics of array languages, and I think there's an interesting unification between array languages and logic languages waiting to be birthed.

One interesting possibility is being able to decide, separate from the specification of what is to be computed, that some of the axes of the arrays in question should be materialized in time rather than in space.

Arrays and constraints

One of the most common uses for libraries and languages like these

is in solving systems of simultaneous linear equations, which is the simplest kind of constraint satisfaction and often occurs as part of a larger constraint system (for example, a linear network within a circuit containing nonlinear elements); in Numpy, for example, to solve Ax = b for x, where A is a matrix and b is a vector, you use `numpy.linalg.solve(A, b)`. Scipy, a library built on Numpy, has a sparse-matrices package that can be deployed in the service of solving much larger sparse linear systems.

XXX explain here about logic and array languages

Arrays and optimization

One advantage of array formulations of optimization problems is that automatic differentiation — which numerically computes a derivative or gradient together with the output of a calculation — is easily added to an array library like those mentioned, and indeed TensorFlow and I think Theano provide this functionality natively.

Arrays and logic

Iverson got a Turing Award for inventing APL, and his lecture was entitled *Notation as a Tool of Thought*. He argued that APL was a more formally tractable notation for programs, to which we could more easily apply the principles of symbolic reasoning and manipulation. Certainly programs in APL and related languages are compact, which is a major advantage for symbolic manipulation by hand; could it similarly make formal manipulation more tractable?

Arrays and intervals

I don't think there is any particular synergy between arrays and intervals.

Physical system simulation

From the beginning, one of the most important uses for computers has been the numerical simulation of physical systems — whether wing flutter in Germany with Zuse's Z-3, artillery trajectories and H-bomb explosions with the ENIAC, the car-crash simulations that were the public rationale for the Tera MTA, or the optical systems that modern GPUs were developed to simulate.

I am just beginning to learn about finite element analysis, which is the most broadly applied method for physical system simulation.

Simulation and constraints

To the extent that you can formulate a simulation in a constraint-satisfaction-system-tractable fashion, you can use the constraint-satisfaction system to design a physical system that satisfies your constraints. But this is more useful in the context of optimization.

Simulation and optimization

The most famous results along these lines are topology optimization, which has been used to optimize stiffness, heat transfer, and so on, but which seems to me to still be in its infancy despite a third of a century of development. Still almost nobody is optimizing elastic bodies for specific stress-strain curves, for example, or searching for toolpaths that minimize the heat-affected zone around a kerf.

Simulation and logic

I dunno, I got nothing.

Simulation and intervals

One of the hairy problems with finite element simulation is that it's conducted on a discretized approximation of the actual physical system, not the continuous system itself. The discretization introduces errors into the simulation results, but how do you find out if those errors are big enough to be significant? You can use a finer discretization and see if the results changed much. If they do, you need to go finer. But if they don't, you don't know if you're just on a plateau and an even finer resolution would give you a big change, or not. I'm told this is an especially big problem with fluid dynamics, due to "vorticity, cavitation, backflow, all sorts of wonderful nonlinear effects" (@sigfig).

There has been work on bounding these errors using conservative error approximation techniques, but I don't know about them. The straightforward application of interval arithmetic is not enough.

To the point that it's feasible to bound these errors, it should be possible to speed up preliminary simulations enormously by only simulating them to very loose tolerances. This should speed up optimization through simulation greatly.

Simulation and arrays

Everybody uses arrays for numerical simulations. It's, like, what they're best at.

Automated manufacturing or digital fabrication

Fabrication is the making of physical objects. Digital fabrication is making them from a design in a computer; the most commonplace example is printing out a page on a printer, but it also includes things like integrated circuit fabrication and CNC milling. There's been a lot of excitement around 3-D printing (aka additive manufacturing) in the last few years, but that's only one kind of digital fabrication.

I think digital fabrication is poised to explode over the next few years for a variety of reasons: better sensors (producing better feedback), better design tools (including simulation), and the RepRap-derived community, including things like Thingiverse and OpenSCAD.

Manufacturing and constraints

Much of robotics has to do with finding a feasible plan for achieving an objective under known constraints. Toolpath planning for CNC is one example; a bad toolpath can do things like drive a cutting tool hard against a part of a workpiece it was not supposed to contact.

Even without robotics, of course, things like nesting for panel cutting are constraint problems.

Manufacturing and optimization

In those cases, often some plans are much better than others. A manual panel-cutting plan that requires you to reset the fence on the panel saw three times is better than one that requires you to set it

twelve times, unless it results in using three sheets of plywood where one would do. A toolpath can take more or less time and spend more or less time far from the optimal feed rate.

We often break down design problems into parts separated by abstraction layers in order to make each part tractable on its own. Indeed, this is one of the major forces driving additive manufacturing in industry in the last few years — it allows you to fabricate a much wider range of shapes, increasing the freedom of the design stage. But it seems likely that mathematical optimization should be able to optimize across many such stages at once, and this is likely to provide one or more orders of magnitude improvement in cost/benefit ratio.

Manufacturing and logic

I dunno.

Manufacturing and intervals

Likewise.

Manufacturing and arrays

Likewise.

Manufacturing and simulation

Simulation enables optimization in manufacturing. It also makes it possible to reduce the number of prototypes enormously, conceivably eliminating the necessity for mass production entirely.

Self-sustaining software systems

Self-sustaining systems are those that can compile themselves from source code. PyPy, Squeak, Oberon, and metacompiled Forth are my usual examples.

I'm interested in self-sustaining systems for a few different reasons.

XXX movethislater

Incremental computation and caching

Incremental computation is adjusting the output of a computation to reflect a change in its input in some way that is cheaper than simply recomputing the output from the changed input. A large fraction of our existing software infrastructure is occupied with incremental computation, because it's common to get several orders of magnitude performance improvement from it.

Caching or memoization is one strategy for incremental computation; this works by breaking a computation into deterministic parts with identifiable inputs in a way such that some of the computations have no change to their inputs, and therefore are guaranteed to have the same output as before; then you simply reuse the previously computed result for that part of the computation, thus limiting the work only to part whose input has changed.

Examples include executable files (cached compiler output), font bitmaps (cached font rasterizer output), window contents backing store (cached paint output), the DOM (arguably, cached parser output), any in-memory data structure computed from the contents of a file, and any number of lower-level pieces of information in your code — basically almost anything for which you write a function with the word "update" in its name.

This is a very broad topic, including perhaps the majority of

software in existence, because it's common for caching of the results of computations to convert exponential-time algorithms to linear-time or even constant-time algorithms, or to knock off four or more orders of magnitude from constant factors. A unified system for caching that was capable of doing a reasonable job at solving these problems could increase the power per line of code of software enormously.

(It's commonly said that the only two hard problems in software are naming things and caching (or cache invalidation).)

The few interesting projects on this front are Apache Spark, redo, and Self-Adjusting Computation.

Caching isn't the only way to do incremental computation. It's also possible, though less common, to compute a new output from the old output and some kind of description of the change. This is typically the approach taken with RDBMS indices — when an indexed value is updated in the underlying table, rather than recomputing the index or part of the index from the new table contents, the database adds a new index entry and deletes or invalidates the old one. This kind of incrementalization requires the processing being incrementalized to preserve some kind of homomorphism between the input and output such that the change to the output can be computed from the change to the input.

Incrementality and constraints

There are some incremental constraint systems, which can propagate an incremental change to constraints more efficiently than recomputing a constraint from scratch. Constraint systems implemented by optimization will typically have this property by default. Combinatorial search (for constraints over finite domains) also likely benefits from reusing parts or most of a previously-valid solution.

The other angle on this would be using a constraint system to make a computation incremental. This might work but I'm not sure how.

Incrementality and optimization

As mentioned above, optimization systems that work by iterative approximation will tend to have incremental properties — a small change in the objective function or the constraints will get a big performance boost from having an existing approximately-correct solution.

The other angle on this would be using a mathematical optimization system to carry out general incremental computation. In particular, caching systems face difficult choices about which cached computations to throw away and which to keep; space is always finite, relevant information about what to keep is always incomplete, and good choices can speed things up by many orders of magnitude overbad choices.

Incrementality and logic

Tabled resolution is the standard way to cache logical conclusions in Prolog-derived logic-programming systems. I don't know anything about it.

In more general theorem-proving systems, which I also don't know anything about, I have the impression that tactic choice and proofs can be reused from one run to the next of the proof assistant, saving

the time of expensive searches; as with combinatorial search in constraint systems, this should be a huge win.

Using theorem-provers to support strategies for incremental recomputation also seems feasible, both in informing cache eviction strategies (if you can prove that something will be used again in the near future, it may be a poor choice to evict from cache) and in proving that an incrementalization strategy doesn't introduce bugs. This seems necessary if homomorphism-based incrementalization (as opposed to caching) is to be correct, and would be sufficient to introduce it automatically where applicable.

Incrementality and intervals

One of the more interesting ideas in Flórez Díaz's dissertation is that interval arithmetic can avoid computation and thus dramatically accelerate ray-tracing, especially of animations. If you determine that for $0 \le x \le 0.1$, $0.2 \le y \le 0.3$, $0 \le t \le 5$, some conditional yields false, then you don't have to recompute anything in that x-y area guarded by that conditional when t increases from 1 to 2.

Applying this idea more generally, it may be possible in some cases to compute a description of how *much* some input would have to change in order to change an output.

And, of course, the recursive refinement algorithm I described earlier for using interval arithmetic to solve optimization and constraint problems could in theory benefit enormously from incrementalization, since each subdivision of the problem space changes only one input from the previous iteration.

Incrementality and array languages

Incremental recomputation of arrays or parts of arrays seems like an interesting idea. The array language K implements some version of it. Some relevant considerations:

• Array languages expose many computations to the runtime at a higher level than other languages, which could potentially make it more feasible to do even homomorphism-based incrementalization automatically. The dependencies between values in different arrays are generally more regular than the dependencies generated by arbitrary code, so it should be feasible to keep more of them around.
• If the unit of caching and recomputation is individual elements rather than entire arrays, tracking valid/invalid bits for large arrays should be much cheaper than tracking them for numerous random small objects.

Incrementality and simulation

Incrementalizing simulation of physical systems would be super awesome; if you could get a 1000× speedup on second and subsequent simulations of slight variations of a design by reusing data computed in the first iteration, you could try 1000× as many variations. Straightforward caching won't get you there, because typically any change to any part of the system design immediately reverberates through the system, creating tiny, possibly insignificant changes everywhere. I think this might be possible, on the other hand, under some circumstances, with the interval-arithmetic ideas I mentioned earlier — you may not care to find the precise stiffness of each design, for example, but only to optimize the stiffness by finding

the stiffest variant.

Incrementality and manufacturing

I don't think I have anything to say here that isn't said above.

Incrementality and self-sustaining systems

A coherent incremental recomputation system may be a key to getting a self-sustaining system down to a reasonable size.

XXX movethislater

Reproducibility

Reproducibility is the foundation of science. Science is what can be demonstrated. Irreproducible results cannot be demonstrated; you must take it on faith that the person reporting them is reporting them accurately, and so there is no tendency toward self-correction over time.

We have a limited kind of reproducibility with our current software; often enough, you can download a piece of software, possibly recompile it with current libraries, and have it work on your computer. But often this requires some work to get it running, and even if it appears to work, you don't know if it works the same way it worked on other people's computers in the past. So if they reported some results with it, and you get conflicting results, you don't know why that is.

Nix and Guix are efforts to make software more reproducible by nailing down all its dependencies, and they enhance the reproducibility situation significantly. However, the bootstrap kernel for either of them is fairly large, and they rely on unreliable third-party websites to host the tarballs of the dependencies, with the result that this reproducibility still has big holes in it.

I think we can do considerably better, keeping the initial bootstrap kernel very small indeed — small enough that it can be reimplemented from scratch on a new platform in a few hours.

Reproducibility and constraints

Constraint-solving systems are inherently nondeterministic in a way that imperative systems are not; the solutions they find, and indeed whether they find a solution at all even when one exists, may vary depending on details of their search strategies. This potentially poses problems for reproducibility, since the effects of changes may be hard to track.

For a weak form of reproducibility, this is not a problem, since we can compile a theoretically nondeterministic constraint-solving system into a deterministic imperative form before using it. But a stronger form of reproducibility, in which we can reason about what effects will be produced by a given change, will be frustrated by it, because the effects of altering constraint-solving things will be mostly by virtue of changing which of many possible acceptable solutions will be found first.

Reproducibility and optimization

Optimization is even more sensitively dependent on random nonsense and thus that much more difficult to achieve reproducibility in. Worse, being able to take advantage of things learned during previous optimization sessions may be really crucial to making

optimization-based computation feasible, in a way that it isn't for traditional programming paradigms. To some extent, it may be possible to paper over this using caching approaches to incrementalization.

However, to the extent that optimization can be used as a way

Topics

Simplified computing, down to the level of mining raw materials

Kragen Javier Sitaker, 2015-09-03 (22 minutes)

I've been thinking for some years about building a personal computing environment up from zero: bootstrapping using an existing computer and existing fabrication technology, but quickly getting into self-sustaining technology, along the lines of the VPRI STEPS program or colorForth/GreenArrays, but also along the lines of Open Source Ecology.

So what is needed to, say, send an instant message to someone? What's the smallest amount of code you could write to fully describe the design of this system?

• A **font** to display the message in.
• A **display** to show the font on, and whatever software is needed to talk to it.
• A **keyboard** (or other input device, e.g. a touchscreen), and whatever software is needed to talk to it.
• An **editor** that responds to the keystrokes by editing some text that you can later send.
• A **network interface** to connect to the internet, and whatever software is needed to talk to it.
• Enough of **TCP/IP** to speak whatever messaging protocol you're using.
• A **user interface shell** to allow you to choose between doing instant messaging and other things.
• A **CPU and RAM** to run all this software on.
• A **filesystem** to store your instant message logs, buddy list, driver code, font, editor and other UI code, and so on in.
• A **durable storage device** to persist your filesystem to when the machine is turned off. This might be core, Flash, MRAM, disk, cassette tape, barcodes, battery-backed SRAM, or cuneiform, but you do need *something*.
• A **low-level programming language** with a compiler to write the drivers in. Ideally this language is powerful enough to write the compiler in too, as well as the UI code, filesystem, and so on, but there really aren't any existing languages that are good at this. I think ML probably comes closest, but ML memory usage is somewhat unpredictable (even if you use MLKit regions instead of a garbage collector) which means that you can't write code for which failure is not an option in ML.
• The **IM client** itself.
• **Cryptography** to keep the IMs safe.
• Probably a **semiconductor fabrication system** to make the CPU and RAM.
• Materials processing machines for **smelting, measuring, and purifying** the materials needed for the CPU, RAM, keyboard, display, and the materials processing machines themselves, starting from raw materials.
• **Digging machines** for extracting the raw materials.

• **Fabrication robots** for making the display and keyboard and for assembling the computers.
• **Energy-harvesting machinery** for deriving energy from the environment to run all the other machinery.
• **Waste recycling systems** to keep the materials processing and especially the semiconductor fabrication from poisoning people, animals, and plants.

Font

So far, despite various experiments, the simplest way I've found to design a readable font is as a fixed-width pixel grid. Here's a minimal implementation of ASCII text rendering with an included 4×6 font in 1K of DHTML, including the font itself as a PNG:

```
<body bgcolor="black" onload="r()">
<a href="http://canonical.org/~kragen/sw/dofonts.html">cf</a>
<img src="

QsZOkfQF4WX4CJW/yJV4Rf8kmfkRHzB8m9KJ16CLIBFEwJgLFa2lx2ovmsmYfMU2Fv4AgeVrl8Qw
sFoAAAAASUVORK5CYII=
" id="font" />
<canvas width="512" height="512" id="c"></canvas>
<script>
d = document
function r() {
 t = d.body.innerHTML
 x = 0
 y = 0
 for(i in t) {
  c = t.charCodeAt(i)
  if(32<=c && c<128) {
   fi = c-32
   d.getElementById('c').getContext('2d')
   .drawImage(d.images[0],fi%16*4,~~(fi/16)*6,4,6,x,y,4,6)
   x += 4
  }

  if(x>508 || c===10) {
   x = 0
   y += 6
   if(y>=512) break
  }
 }
}
</script>
```

Other experiments I've tried include Hershey-like line fonts, spline-based fonts, fonts scanned from paper, and so on, but I haven't been able to get any of these implementations down to a kilobyte, or even nearly so. You could maybe argue that I'm unreasonably leveraging bitblit and PNG-decompression here, but I don't think

those actually make a whole lot of difference.

Display

The current standard is an LED-backlit LCD with diffraction gratings to give color to RGB subpixels. This may not be the least demanding possible way to display pictures under computer control; it seems likely that some kind of cathode-ray tube may be simpler to construct.

Spark gaps and spinning mirrors

Perhaps the electronically-controlled display with the least stringent demands on metallurgy and the like would be a small array of tiny carbon arc lamps or spark plugs controlled at near-megahertz frequencies, viewed through a system of spinning mirrors like the ones used in supermarket barcode scanners in order to scan the image of the arc across your field of view, and color-filtered both to eliminate harmful ultraviolet light and to improve contrast.

Suppose you use just an X-axis scanning mirror, with one spark gap per scan line, and you want minimally 200 scan lines (25 lines of readable 8-scan-line text or 33 lines with the less-readable 4×6 font above). A 16-faceted mirror spinning on an air bearing at 32000 rpm, as Michelson used in his 1877–1931 experiments to measure the speed of light, scans at 8528 frames per second. We only really need about 24 frames per second to be readable, even though that's kind of flickery, and you could do that with 1.5 revolutions per second of a 16-faceted mirror, 90 rpm. This is an easily achievable rotational speed even if you're turning the mirror by hand.

Square pixels at 200 scan lines and a 4:3 aspect ratio would be 266 pixels per line; 16:9 would be 355 pixels per line; a 5×8 font at the traditional 80 columns would require 400 pixels per line. 266 pixels in 1/24 of a second is 6384 pixels per second per spark gap, or 157µs of cool-down time; 400 pixels is 104µs (9600Hz). Spark times like these are easily achievable. Neon glow discharge lamps can easily reach this régime, and they last for decades of continuous use and don't pollute the air, unlike carbon-air arcs.

Edgerton was achieving 500ns air-gap spark times in the 1950s by using a thin layer of air as the plasma medium and cooling it with a quartz heatsink, but I think much higher speeds are achievable if the spark just needs to be *visible* rather than illuminating its surroundings brightly enough for photography.

A 500ns spark could potentially paint 2 million pixels in a second, or 33,333 pixels in the 16⅔ms of a 60fps frame, not quite enough for a text display by itself. An array of 20 500ns spark gaps, assuming you could fire them all continuously, could thus give you a ⅔Mpix display at 60fps, nearly the 1024×768 that we're used to.

At the currently popular 16:9 aspect ratio, this would be about 1075×620, so you'd need a vertical or Y scanning mirror that scanned at 31×60Hz, or 1860Hz. If it had 16 facets, it would need to spin at 116¼Hz, or 6975 rpm, which is totally feasible using gears and ball bearings (not even air bearings), but a little bit tricky. Again, though, this is about four times slower than Michelson was spinning mirrors nearly a century ago.

If, instead of scanning an entire column of 20 spark gaps across the visible area in 20-pixel-high bands, you divided the visible area into

20 horizontal bands, each illuminated by a single spark gap, you could have 20 facets in your visual field at once. This allows you to use more facets on your mirror and makes the scan lines more horizontal, but requires careful alignment of the mirror's phase with your viewpoint. It would, however, allow you to rotate your Y-scanning mirror at only 31×60Hz÷16÷20 = 5.8125Hz or 348¾rpm.

Vector displays

The first graphical user interface was Sketchpad, implemented at the end of the 1950s by Ivan Sutherland on the TX-2 at Lincoln Lab. The TX-2 had an attached CRT in which the CPU independently controlled the X and Y coordinates of the electron beam, so it could draw simple shapes on the screen at high resolution, even though it was only capable of drawing a few tens of thousands of points per second. Such "vector displays" survived until the 1980s, and CAD systems of the 1970s were built on "storage tubes" that could maintain the vector image, once drawn, for up to a few minutes, allowing very detailed line drawings.

You could do the same thing with a single spark gap and two mirrors, but this requires controlling the mirrors independently and actively, not just scanning them at a constant speed like a raster display. But it would permit a useful display from a single spark gap modulated even down at kilohertz speeds.

Coil-driven mirrors

Laser shows scan lasers across the screen with mirrors controlled by galvanometers or "galvos": electric coils that magnetically push against a spring to bring the mirror to the desired position. Typical galvos are capable of "20 kpps", twenty thousand points per second, although the definition of this is kind of dodgy.

The Harmonic Series was a project by Brazilian artists Luisa Pereira and Manuela Donoso which substituted regular dynamic speakers (electric coils that magnetically push against a screen) for laser-show galvos, getting bandwidths of up to several kilohertz for displaying audio Lissajous patterns, just as Lissajous himself had done with the "Lissajous apparatus" of mirrors on tuning forks in 1857.

You could imagine a resonant mirror scanning system that scans in a Lissajous pattern rather than the sawtooth pattern we're used to from raster-scan devices; you get higher resolutions around the edges, lower resolutions in the center, and a less regular scanning pattern that the computer can compensate for. However, I think the Pythagorean sum of the scanning frequencies still limits your resolution, equivalent to the scan frequency of the X-scanning mirror in a traditional raster setup. So with the 20 500ns spark gaps at ⅔Mpix at 60Hz described above, you could get by with oscillation frequencies possibly as low as 42Hz or so.

Lissajous rods

A particularly simple way to achieve these Lissajous oscillations is by using a sprung mass that is sprung with two different spring constants in X and Y; for example, a thin rod, fixed at one end, with a rectangular cross-section. (There is a Lissajous Rods exhibit in the Exploratorium demonstrating this; the Lissajous patterns described in the air by the shiny ends of the rods are quite conspicuous.)

Other high-speed light sources: vacuum tubes, LEDs, and lasers

All of the above describes different contortions to get around the possible slowness of a spark-gap light source, which is itself much faster than an incandescent light. But even normal vacuum tubes can turn on and off in the submicrosecond regime; you could use a vacuum tube with a phosphor-coated anode to modulate light output with deep-submicrosecond times. There are a number of electron-excited phosphors with single-digit nanosecond decay times, hundreds of times faster than an air-gap flash, including CdS:In and ZnO:Ga.

(If you're using a vector display to draw relatively static images, a long phosphorescence time might be an advantage rather than a disadvantage.)

Vacuum tubes and exotic phosphors, though, may be hard to fabricate; and if you can fabricate them, it may be more practical to just fabricate a CRT rather than some kind of electromechanical display.

Another possibility, since we're already taking for granted semiconductor fabrication, is LEDs. These are semiconductor diodes made of exotic large-bandgap semiconductors, and, with carefully designed driver circuitry, even regular LEDs can have response times measured in single-digit nanoseconds. And LEDs are much, much more durable than spark gaps. They were first reported in 1927, using point-contact diodes with low-purity silicon carbide, but red LEDs were first published in 1962 in gallium arsenide phosphide; they became commercially available in quantity in 1968. Other red and green LED chemistries include AlGaAs, AlGaInP, and GaP; InGaN and GaN additionally provide green, blue, and violet LEDs, but these were not possible to manufacture until 1994, and the discovery won a Nobel Prize in physics.

Once you, hypothetically, can make LEDs, making semiconductor lasers is relatively straightforward. This has the advantage that you can scan them over a large surface using mirrors to produce a high-resolution projection display.

Also, lasers in general have the ability to produce shorter light pulses than other light sources: once a population inversion forms, stimulated emission can deplete it, and so a wave packet generated by a mirrorless laser can be very short indeed, the so-called "femtosecond laser", when the laser has a large tunable bandwidth. You should be able to trigger the generation of a pulse by dumping a bunch more energy into a barely-subcritical laser, which is more or less how erbium-doped fiber amplifiers work. (This is my vague understanding of this shit; don't bet on it.) So it should be possible to

One possible way to rapidly scan temporally-modulated LED light over an area would be to use a transparent Lissajous rod elastically vibrating; it could be made of, for example, polished glass or acrylic, using total internal reflection to guide the light to its vibrating tip.

High-speed light modulation: LCDs

LCDs do not emit light, but they can switch on and off in tens of nanoseconds using current techniques. I don't know if LCDs are less demanding to fabricate than LEDs, but I suspect so, even though they were developed later.

Slow displays: in the limit you get a printer

Above, I've mentioned the benefits of slowness a couple of times: if your image lasts a long time, you can use even very slow methods for producing it. The Tektronix 4014 storage tube was one example: used for high-resolution CAD drawings despite being connected to the computer over a low-speed serial link. But even a regular long-persistence phosphor would work reasonably well, without the storage-tube aspect; in fact, if you're using mirrors to steer a beam of light rather than an electron beam, you could draw the image on a phosphor screen of, for example, copper-activated zinc sulfide, which is sphalerite/wurtzite, the main ore of zinc in nature.

But you can go slower still. A lot of Unix was developed on Teletypes running at 110 baud, which worked out to 11 characters per second; a 4×6 dot-matrix printer at this speed needs to run its 6 hammers at 44Hz, which is quite reasonable. And if you go vector instead of raster, you get a pen plotter.

Smelting, measuring, and purifying elements

Both current and prehistoric metallurgy depends mostly on iron, aluminum, copper, zinc, tin, and lead; nuclear energy production depends on uranium or thorium. Semiconductor fabrication also depends on silicon, plus trace amounts of dopants, such as boron and arsenic, as well as processing chemicals such as hydrofluoric acid and hydrogen peroxide. Refractory materials are essential to many processes listed.

Small amounts of iron, lead, and especially copper are found "native" on Earth, while aluminum, zinc, tin, and thorium are always found in compounds. Nevertheless, for bootstrapping, it's probably necessary to be able to refine these elements from soil.

Earth's crust is about 28% silicon., and it's in almost all soils, so anywhere you go, you have silicon. Although you can smelt metallurgical-grade silicon from silica in an arc furnace with carbon at 1900°, smelting it for semiconductors is hell, since you need to get impurities down to <1ppb in order to control its semiconducting properties, using either CVD from trichlorosilane or repeated zone melting. Even less-demanding photovoltaic silicon needs <1ppm impurities.

Earth's crust is about 8% aluminum, which, too, is everywhere; but it's difficult to smelt because aluminum dioxide (sapphire) is so stable. The Hall-Héroult process, orders of magnitude cheaper than the alternative smelting processes, revolutionized the production of aluminum. This involves dissolving corundum (aluminum oxide) in cryolite (sodium aluminum fluoride) and calcium fluoride at 980° in order to be able to electrolyze it.

Earth's crust is about 5% iron. People have been smelting iron from hematite and magnetite using charcoal in bloomery furnaces for millennia, but blast furnaces are much more efficient and produce much better iron.

Earth's crust is about 60 ppm zinc, mostly as sphalerite, which can be purified by froth flotation; roasting sphalerite in air at at least 690° produces SO_2 and ZnO, and the ZnO can be reduced to Zn either with C (which was done accidentally for centuries, producing Zn

vapor) or by electrowinning from water-soluble $ZnSO_4$ (low-current-density process: 10% H_2SO_4, aluminum cathodes, 275–325 A/m², 30–35°). Historically this smelting was done in hermetic clay retorts to prevent the zinc vapor from escaping.

Earth's crust is about 50 ppm copper.

Earth's crust is about 14 ppm lead.

Earth's crust is about 6 ppm thorium, but you don't need very much thorium, because burning thorium in a nuclear reactor produces about 79 TJ/kg of energy.

Earth's crust is about 2 ppm tin, which makes it hard to extract.

Plasma pyrolysis and oxide distillation

One possible answer to the problem of extracting various elements from the complex mix of mineral compounds in soil is, rather than using individual reactions customized for each separate ore, simply vaporize the whole shebang into a plasma, mix with oxygen, and then distill out the various oxides. Even tungsten, tantalum, rhenium, and osmium boil below 6000°, and every other element below 5000°; everything melts far below this temperature, with tantalum hafnium carbide melting at 3942°.

So, if you can heat soil up to 6000°, you can probably get them to mix with a large volume of preheated oxygen and oxidize them fully. You should be able to start the process with a plasma arc torch (regular plasma arc welding torches reach 28000°), then continue heating with inductively-coupled plasma heating. Various companies are currently developing lower-temperature variants of this process under the name "plasma arc recycling" or "plasma gasification"; Westinghouse's process runs at only 3000°.

As an alternative to inductive heating of the plasma, you can illuminate it; well-ionized plasmas absorb light fairly well. Sunlight can be focused on the plasma using non-imaging optics, which have been demonstrated to reach 84000 suns, 59 megawatts per square meter.

Another alternative means of heating the plasma after initial ionization might include mixing carbon or hydrogen fuel into the feedstock. In theory, hydrogen ought to be able to raise the temperature by about 2800° in the limit of 100% hydrogen.

The mix of oxygen and fairly inert simple elemental oxides coming out of the torch then needs to be distilled. Each oxide has its own characteristic condensation temperature, so you should be able to condense thoria in one chamber, silicon dioxide in another, aluminum oxide in another, zinc oxide in a fourth, and so on. You probably need to do this under low pressure to keep the plasma from cooling down too much before depositing its condensates.

How much energy does this need? Heat capacity of plasmas is complicated but generally around 100 kJ/(kmol·K) in the temperature range we're considering, so heating by 6000 K should require about 600MJ/kmol. If we figure that the majority of the plasma is oxygen, then each mole is 16 grams, so we need up to about 40MJ/kg to heat the plasma, some of which we may be able to recover as we cool it back down.

Supposing we mix oxygen with the vaporized soil in a 4:1 ratio by mass, we're spending 200 MJ per kg of soil, or 33 TJ per kg of thorium, assuming that our soil is only averagely rich in thorium.

That's less than half of the energy that thorium will produce in a reactor, which still leaves us precariously net positive, but suggests that some monazite deposits (about 10% thorium, i.e. 100 000 ppm, five orders of magnitude above average) would go a long way. (It's also possible that the modal thorium concentration is well below the mean, which would mean that most points on the globe had thorium concentrations too low for purification by this method to be a net energy producer.)

Topics

2025 manufacturing and economics scenario

Kragen Javier Sitaker, 2014-04-24 (24 minutes)

It's 2025. I want a bicycle to use to visit my friend Yésica in La Plata, a city near Buenos Aires, where I live. I type "recumbent touring bicycle" into a model search engine and get a page full of pictures of different models. I click on one of them, a model called the Matagallos, and adjust the parameters on the resulting page: my inseam is 95 centimeters, I weigh 100 kilograms, I will be carrying 50kg of luggage with me on the trip, I prefer dull brick red to the default bright blue, and because I'm pretty strong and not in a hurry for this trip, I prefer lower material cost to lower weight. My computer consults databases of parts available nearby to fulfill the model's requirements; only 1.8mm spokes of dubious metallurgical quality are conveniently in stock near where I live in Argentina, so it ups the spoke count on the wheels from 36 to 48 to compensate.

I review the model from different sides on my screen, using a finite-element simulation to simulate how it will travel over bumps and potholes, and find a problem: because this model was originally developed for lighter riders, when the rider-weight parameter is set all the way up to 100 kilograms, it happens to work out with an unreasonably low ground clearance — I'll be bumping my ass on the ground. I call my friend Violeta for help, sending her a link to the model. She shows me how to adjust the formula for one of the strut lengths to add a ground-clearance constraint, and then we test the modified model to ensure that the results are reasonable across the range of parameters.

Having validated her modification, I thank her and write up a couple of sentences explaining the problem and the solution, and publish the modification so that other people can try it out. After making a couple of cosmetic modifications (I want the struts all to look like bones, and I don't want to display the model name, because the police near here are nicknamed "gallos", and I don't want them to feel threatened), I look at a list of prices and delivery times from manufacturing services in my neighborhood. I choose one that's 400 meters away and offers me US$102 with a delivery date of three hours in the future.

I click the "submit" button, confirm the transaction on a handheld smart card, and switch back to chatting with Violeta about the vacation she's planning to take with her husband next month, visiting Arecibo in Puerto Rico.

Three and a half hours later, my doorbell rings, and there's a truck with my bicycle, assembled by robots from whatever materials and parts happened to be on hand, using more or less traditional processes of drawing, forging, cutting, drilling, lashing, gluing, nailing, and welding. By chance, a substantial part of this particular bicycle is made of wood recovered from discarded pallets. I key in the delivery PIN to get the truck to release the bicycle, lift the bicycle off the truck, and press the "accept" button on the truck, so that it can move on to its next stop. Mine are the first human hands that have touched it.

My ride to La Plata is uneventful — the full-body fairing keeps the rain off me, and the speakers have amazing bass — and the bicycle mostly performs well, but I notice a grinding noise coming from the front wheel. As I pedal, I search for "grinding noise matagallos front wheel" in a search engine, and it turns out somebody else had the same problem last year. They figured out that the problem was an over-tightened wheel bearing, and explain how to check, so I stop to check. Turns out my Matagallos got assembled with a cartridge bearing, so it can't be tightened or loosened at all, but it seems to have some kind of sand in it. I do a search for "sand bearing" and the number of the manufacturing service, and it turns out that several other people using them have had the same problem, in products as diverse as drills, fans, and food processors, although I'm the only one to run into it with a bicycle.

Once I arrive in La Plata, I stop by a manufacturing service that I'd contracted with on the way; they have a new front wheel ready and waiting, and in a couple of minutes install it on the bicycle, taking the defective wheel as partial payment of US$5. Since I've reported the bearing grit problem to the service near my house, they accepted the blame and paid the remainder of the cost, US$3. I leave them a

good review, explaining the problem and resolution, and tag the other people who had reported grit problems so they'll see it.

At Yésica's house, she and I pick a couple of interesting recipes off a recipe blog, tone down the spiciness for her Argentine palate, and submit it to the robot chef around the corner, paying it US$1 for the service. Half an hour later, a bell rings to notify us that the food is ready; we stroll around the corner to pick it up and bring it back home.

Waking up in Yésica's bed in the morning, I'm pleasantly surprised to find that my (Violeta's) improvement has been accepted into the mainline Matagallos model, and I'm now listed as one of its contributors. The maintainer accepts my argument that the credit belongs to her, not me, and replaces my name with hers. I publish a short experience report, describing the performance of the Matagallos on the pothole-laden road from Buenos Aires to La Plata.

But now it's time for me to get to work. A few blocks away, a couple I don't know are seeking a mediator for an unspecified marital conflict related to their autistic child, and as I happened to be in town and with good reviews for similar mediations from some of my friends, they requested that I meet with them. I consult their reputation — they seem to be trustworthy — so I accept their proposal of a US$800 fee for an hour and bike on over to their house.

There are some things that robots still can't do, you see, and those things have gotten more expensive.

Before I return home by bus, I sell my new bike as scrap to a local manufacturing service for US$97.

(The above scenario is based on some things Richard Stallman wrote, but it isn't an attempt to represent his point of view. Violeta is a real person, but Yésica is not.)

XXX why did you sell the bicycle?

Commons-based peer production

In the last couple of decades, we've seen a really remarkable shift in production from the market economy into ad-hoc volunteer networks engaging in something Yochai Benkler calls "commons-based peer production": people contributing resources on a voluntary basis to a common product that everyone can use without restriction. Examples of such products are Wikipedia; Stack Overflow's collection of technical questions and answers; the worldwide repository of data available through BitTorrent; the worldwide tourist lodging system CouchSurfing; the FreeBSD system that is the basis of Apple's MacOS and iOS operating systems; the WebKit browser engine that drives Chrome, Safari, the Android browser, and the iOS browser (known as Mobile Safari); and arguably the collection of videos on YouTube, the social graph and other information on Facebook, the corpus of photos on Flickr, and the contents of other such "user-generated content" sites.

I say "arguably" because these proprietary sites aren't governed by the same liberal commons-protecting licenses that enable the communities I listed earlier, so I'm not sure if they fit Benkler's definition, but much of the same dynamics seem to apply. Whether you upload zero, one, or a thousand photos to Flickr, you can still look at the commons of all the photos on the site, produced by your peers. (I'm embarrassed to admit I haven't managed to make it through Benkler's book yet, so I'm not totally sure where he draws the line around "commons-based peer production".)

This is a remarkable phenomenon. One after another, we see market-economic projects collapsing when they have to compete with commons-based peer production, much as the Soviet Union eventually collapsed economically when its system of production could not compete with the capitalist bloc.

Apple had 20 years of experience as one of the most innovative and often financially successful producers of computer software, employing many of the best programmers in the world, when it decided to cancel its in-house next-generation operating system project and switch to NeXTStep, much of which is free software. Apple's own internal software development project simply could not compete with the commons-based peer production of FreeBSD — although so far its user interface seems to be holding its own against Ubuntu.

Wikipedia, similarly, completely crushed Encyclopedia Britannica, Microsoft Encarta, and the other lesser-known commercial encyclopedias.

Never before has capitalism found itself face-to-face with a system it can't compete with economically. The only feasible response, taken by Wikia, YouTube, Facebook, and so on, seems to be to try to build a "commons" that in reality is privately owned by you, so everybody else does the work of constructing the economically valuable product, while you take home the profits. People seem to be starting to realize that this is not such a hot idea, but it's going to be a while before we can fix the problem. But that's not what I want to talk about now.

You can also argue that this trend is unjust, because it takes economic rewards away from creative people or from the majority of the population, which is also a really interesting discussion to have, but that's also not the discussion I want to have in this post. Bookmark the idea for later, because I want to talk about it in a later post.

How far can commons-based peer production go?

It's reasonable to ask how far this trend of replacing market economic production with commons-based peer production can go, assuming it's not already played out. Wikipedia, for example, has replaced the encyclopedia market, but there still seem to be lots of other books out there. A lot of the fiction books can maybe be replaced by fanfic sites; Wikipedia and the WikiBooks project of the Wikimedia foundation are working to replace other nonfiction books, as is Stack Exchange (the family of sites including Stack Overflow); BitTorrent and YouTube are replacing TV to some extent; Android is largely replacing Microsoft Windows; but what about the implications for things that aren't pure information? Physical things like recumbent bicycles, chairs, highways, swimming pools, clothing, food, housing, clean water, headphones, and antibiotics?

Let's investigate how physical things are created

Well, those physical things are all produced by the following unreasonably general process:

- **raw materials** are
- combined and modified by **energy** under the control of
- **existing durable physical things**, which are guided by
- a **design** or plan which is chosen ahead of time,

• then adapted according to **feedback** from the production process, to a greater or lesser extent; we could call this "improvisation".

In the case of a bicycle, for example, the raw materials include wheels, a frame, a seat, and a chain; the energy moves the parts into place relative to each other and tightens the nuts needed to hold them together; the existing durable physical things probably include some wrenches and a chain tool; the design consists mostly of the mechanic's choice of which of these raw materials to use; and feedback is used, perhaps, to discover that the chain chosen was too short and needs to be lengthened by adding some links, or to replace the desired double-walled aluminum front wheel with the single-walled steel front wheel that happens to be in stock.

But each of these "raw" materials is itself a physical object, and is produced in the same way. The frame is made from raw materials of metal tubing, consumable welding electrodes, paint, headset bearings, brakes, the pedal assembly (I forget what this is called in English; in Spanish it's the "caja pedalera"); the energy needed to combine them includes the energy to cut the tubing, melt the welding rods, aerosolize the paint, and tighten the pedal assembly and headset bearings; the existing durable physical things include the paint sprayer, the arc welding buzzbox, and some more wrenches; the design describes, among other things, exactly how long each piece of tubing should be, which alloy it should consist of, the shape of the cuts to make, and how much metal to deposit in welding; and the adaptation in response to feedback may involve, for example, re-welding spots on the weld that melted through the first time.

If you carry out the recursion all the way, you find that the raw materials for a bicycle consist of most of the 89 or so natural elements: the tires are made of carbon, nitrogen, oxygen, hydrogen, and sulfur, for example, while a steel tube may be made of iron, carbon, chromium, molybdenum, nickel, and silicon, and an acrylic fairing is just carbon, hydrogen, and oxygen. The existing durable physical things necessary to process these raw elements into a bicycle currently include blast furnaces, zone melting facilities, hydrocarbon cracking towers, other chemical process plants (including their catalysts), welders, cutting tools, and so on, each of which uses energy in its own way, although largely to heat things up, cool them down, or move them around. (We can imagine machinery that used a narrower range of processes and of materials, but making an acceptable bicycle entirely out of them seems like it will be a big challenge.) The design covers everything from the crystal structure of the wheel hub to the overall bicycle weight.

A sandwich is made of the same raw materials, although in somewhat different proportions, but much of the design is provided by genetic material, and much of the energy is provided by the sun through photosynthesis. Plant growth is really interesting because, although it's a fully automatic process, the final design of the plant can be extremely varied as a result of adaptation to its environment ("feedback" or "improvisation" in the framework above), both in its physical form and in its chemical content. The same variety of beans can taste quite different depending on how much you water them and what kind of soil they grow in.

An interesting feature of looking at things this way is that almost none of these raw materials are typically depleted. Helium can be

depleted by escaping the atmosphere, and a few of the natural elements (like radium and radon) decay into other natural elements, but they're being constantly produced by thorium and uranium, which are decaying but not at an appreciable rate. And since bicycles and sandwiches are made of the same elements, you can recycle bicycles into sandwiches, or sandwiches into bicycles.

This framework even applies to, for example, manufacturing a copy of Firefox. The raw materials are a small area of ferromagnetic oxide on a spinning disk platter; a small amount of energy is used to magnetize them in a particular sequence, under the control of the disk head and, eventually, a whole computer; the design is the bits of Firefox that have been downloaded over the web and reside in memory, awaiting being written to the disk; and there's a certain amount of feedback involved in choosing which disk sectors to write. This may sound absurd, but the process is essentially the same as printing a book on your laser printer, except that the raw materials are a little harder to recycle.

Traditionally, in a manufactured product, the raw materials were drawn from a relatively small set of natural materials and refined alloys, perhaps a few hundred for most products; the energy was provided by human muscles; the existing durable physical things were general-purpose tools; the design was produced, or perhaps remembered, by an master craftsman; and feedback was also exercised by the craftsman.

In this framework, then, the First Industrial Revolution was, more or less, simply a result of replacing the source of energy with a more inexpensive source of energy: coal producing steam. The Second Industrial Revolution, centered on mass production, was more or less a matter of reducing the need for feedback to a minimum, largely provided by the introduction of many specialized existing durable physical things ("tools") but also by improved measurements that reduced the variation between objects, and a much wider variety of raw materials. The Japanese dominance of manufacturing was largely because they reincorporated ubiquitous feedback, but at a different scale — the workers worked to use feedback to optimize the process, not to fix an individual produced artifact.

So of these five factors of production, all five were originally very expensive; making #2 cheaper created the British Empire; shifting some cost from #5 to #3 created the Second Industrial Revolution and the American Century; and making #5 cheaper instead of eliminating it created the richest country in the world, at least if you measure by life expectancy.

So, within this framework, here's what I predict will happen to the cost of manufacturing in the next few years:

• Raw materials, in the sense of elements, are becoming progressively more available, because people keep mining them and not putting the scarce ones back in the ground. Even when they do put scarce ones back in the ground — for example, the indium in indium tin oxide coatings on discarded LCDs, or the cadmium in nickel-cadmium batteries — they mostly put them into specific small locations, where they should be recoverable later.
• Energy is already really cheap, as it has been for a century, but it's going to get a lot cheaper soon, because as of 2013, photovoltaic

power plants have gotten cheaper than fossil-fuel plants in sunny parts of the world. Without subsidies. And a substantial part of their remaining cost comes from the energy needed to make them. Almost none of it comes from the cost of the elemental raw materials, primarily silicon and aluminum.
• Existing durable physical things have their cost determined by the cost of manufacturing them, so they fall out of the analysis.
• Designing things is still really hard, but designs are just informational goods, and it turns out that commons-based peer production completely kicks the ass of the market at that. Sometimes.

• Eliminating feedback was the core of the Second Industrial Revolution because feedback required human attention. But computers are feedback machines, and now they're really cheap! Industrial process control was a major use of minicomputers starting in the 1970s, and computer-based automation (computer-based in order to handle feedback) has been the key to the dramatic increase in manufacturing productivity per manufacturing worker over the last 30 years. We can predict that this trend will continue, and as a result many of our Fordist instincts about how to optimize productivity will turn out to be wrong. (I say this despite the fact that Toffler-style "mass customization" has been a highly-hyped business failure for nearly 30 years now.)

So it seems likely that the main cost of manufacturing in the near future will be raw materials and energy, with some sort of multiplier for the durable tooling needed; but only insofar as we can sustain commons-based peer production for manufacturable designs.

Commons-based peer production will take over most of manufacturing from markets

That is, within a few years, by far the most expensive part of manufacturing a bicycle, or nearly anything else we manufacture, will be designing it. And that design effort will probably be mostly done through commons-based peer production, not through a market, because market economies are generally unable to reach a level of productivity sufficient to compete with commons-based peer production in areas where we have figured out how to do commons-based peer production.

What could prevent this?

The distributional equality issues I mentioned in passing previously are a big problem. They could keep us locked in an outdated 20th-century industrial production model.

There's the usual problem of diffusion of complex innovations: manufacturing services like the ones I envision above are only useful if there's a sufficient volume of automatically-manufacturable parametric models, people who know how to tweak them for their needs, and software for creating, modifying, and evaluating them; and each of these other three things depends in the same way on the other three. So diffusion could take some time.

Environmental collapse, or other forms of societal collapse, could cut off long-distance communication, which would effectively decimate the people you could collaborate on models with. It could

also cut off the long-distance trade needed for the mass-produced "processed" materials that can't yet be produced locally, such as integrated circuits.

Robotic automated custom manufacturing could remain dramatically more expensive than mass production. We see this, for example, in integrated circuit manufacturing: IC customization is certainly possible, using lasers, electron-beam etching, or "programming" (i.e. blowing fuses), and in fact I think most ICs undergo at least one of these processes, but the vast majority of the IC manufacturing process is done with X-ray lithography, the most mass of all mass-production processes, which commonly produces trillions of identical parts (such as Flash memory cells) in a single operation. And semiconductor manufacturing is one of the most highly automated of all current industrial processes.

Purely competitive concerns could result in people sabotaging each other's productive capacities. Israel might have a strong motive to destroy any general-purpose manufacturing service in Palestianian-controlled parts of the West Bank, for example, while the Palestinians might have a strong motive to do the same for general-purpose manufacturing services in Israeli settlements in the West Bank. Taken to the extreme, we could see assassinations of researchers, like those carried out by the Mossad against Iranian scientists, those carried out by the Unabomber, and the famous assassination of Gerald Bull.

Ultralight tunnel personal rapid transit

Kragen Javier Sitaker, 2019-03-11 (15 minutes)

I thought I'd written about this somewhere, but I can't find it, so I'm writing it again.

Adequate personal rapid transit would give low-density cities most of the benefits of high-density cities. In particular, what I have in mind are smooth 1.5-meter-diameter dirt-floored tunnels every 50 meters with pods — really electrified multi-person hybrids of horizontal elevators and bicycles — traveling through them at up to 28 m/s (100 kph or 60 mph in archaic units) under the control of a centralized just-in-time route planning system. Unlike a typical subway system, the pods move out of the track to park at a station; there are stations every 50 meters along each tunnel.

The pods are powered by overhead low-voltage DC power cables — 40 volts, for example, so it's almost impossible for a human to receive a dangerous shock. At 28 amps, 40 volts supplies 1120 watts (1½ horsepower in archaic units). A 400-kg fully-loaded pod traveling at 28 m/s would have 154 kJ of kinetic energy, which would take 2.3 minutes to build up at 1120 watts, so trips of 5 minutes or more would reach full speed. A 4.6-minute one-way trip, then, would be 3.9 km; a half-hour trip (supposing a maximum of 28 m/s) would be 47 km, so a city organized around such a transport grid could grow to a diameter of 47 km before any trip was over half an hour, not counting the half-minute on each end to walk the 35 meters or less to the nearest station.

Tunnel construction

The tunnels, being underground, don't create any noise or pedestrian hazards on the surface. If they're built by trench-and-cover methods, they would be super cheap; the trench could be only 2 meters deep, or 5 meters to add crossover tunnels and in cases where it's considered important to keep the surface free of noise and vibration. It's necessary to have smaller drainage tunnels below so that seeping rainwater doesn't fill up the tunnels. In areas where the water table may reach the level of the tunnels, despite the best attempts of drainage tunnels and sump pumps to lower it, bare dirt isn't a viable option, and the tunnel floors would need to be at least dirt grouted with lime, or something like that. Also, unless the tunnels were actually waterproofed, they would be unusable when the tunnel was actually below the water table.

Energy efficiency

With regenerative braking, only the energy required to overcome friction would be lost; the energy to accelerate the pod is recovered when it slows down, using the same motor/generator that accelerated it.

Tires and bearing capacities

Low-pressure 25 PSI (170 kPa) bicycle tires, like those used on

beach-cruiser bicycles, are gentle enough on the ground to not crumble most soils. (Soil bearing capacities generally used in civil engineering range from 75 to 600 kPa, with "compact sand" being 300 kPa.) Supporting 400 kg on such tires would require a ground-contact patch of 0.023 m² or 230 cm² (35 in² in archaic units). If the tires are 5 cm wide, then you need a bit more than 46 cm of tire contact length, which is easily achievable with two or more tires.

User experience

When you enter a transport station, you specify your destination station, as with Uber Cab. If a pod is already available at that station, you just get in; otherwise, a pod is dispatched to you, and after you get in, it's dispatched to your destination. Dispatching works by planning out a route using available tunnel segments, then reserving that route so that no other pod will use it until you're done, to prevent collisions even if something goes wrong. Since there are plenty of tunnels (20 per kilometer, even without any stacking!), and the trips are so quick, it should be easy to build enough capacity that it's practical to reserve the whole circuit end-to-end before starting.

The pods are long and low; users recline in a nearly-horizontal position, one behind the other, or with children in the laps of their caretakers. This allows the tunnels to be only 1½ meters tall. The pods aren't collective vehicles like buses and trains — you can be alone, or share it with your family or friends going to the same destination. So you don't need to make any stops in the middle to pick up or drop off other people, the way a bus or elevator does.

Comparisons with existing systems

By contrast, Buenos Aires, where I live now, has the best public transport of any city I've ever lived in. To take a bus downtown, I need to walk three blocks (6 minutes) to the bus stop, wait an average of 5 minutes (but sometimes 10) for the bus, wait on the bus anywhere from 30 to 60 minutes to go the 4 km to downtown. So it takes, let's say, 51 minutes on average, with an enormous variance. In the same amount of time, the tunnel PRT system could take you anywhere within 82 kilometers — not just downtown, but uptown too.

Consider a five-kilometer segment of a six-lane highway of cars as a point of comparison. It can accommodate about 1.5 cars per second in each direction, with about 1.2 people per car, for a total of 1.8 people per second per direction. When there's no traffic jam, they can travel at 28 m/s, so their latency is about three minutes, although that doesn't count the time to get on and off the highway and park. It's about 20 meters wide, noisy, impassable to pedestrians and wildlife, requires constant attention from drivers, and needs a couple of meters of concrete and stones to support it.

What does the tunnel PRT system need to reach 1.8 people per second per direction over a three-minute route with end-to-end reservations?

If we pessimistically assume only one person per pod, it needs 100 tunnels in each direction. If the tunnels are stacked three deep (5 meters), that's a width of about 1.7 km. That pod will weigh no more than 150 kg, rather than 400 kg, so it can reach full speed in 53 seconds, and needs another 53 seconds to decelerate. In that case, it

will be able to travel 3.6 km in those three minutes, which is a bit shorter than the 5-km car highway, though not much. (Traveling the full 5 km requires another 50 seconds and consequently another 28 tunnels each way to reach the same throughput.)

If we instead have fully loaded 400 kg pods carrying four people each, it only needs 25 tunnels in each direction, or 830 meters of width, but in 1½ minutes, the heavier pods only reach 22 m/s, so they only cover 2.0 km in three minutes. Traveling the full 5 km requires 5½ minutes, and thus 150 tunnels in each direction. XXX calculation error

However, generally six-lane highways are few and far between in the urban landscape; parallel highways are usually on the order of 10 km apart. So this tunnel PRT system could actually support highway-like volumes and rapidity of travel everywhere, but without the noise, pollution, traffic jams, barriers, and parking problems, and possibly without even the danger, though safety issues are notoriously hard to predict.

As another comparison, consider the B line of the Buenos Aires Subte (our subway), which is 11.8 km long, which it traverses in 30 minutes, and the most popular line. It carried 6'035'183 passengers in January 2019, the latest month for which statistics are available, 195000 per day on average. About one-twenty-fifth of the monthly total across all lines is an average workday — the weekends are much less trafficked. As of 2017, 25% of the total across all lines is between 16:00 and 19:00, when the trains are jam-packed full. The city has adopted a goal of a train every 3 minutes during rush hours, although of course any irregularity in service can stretch the delay to many times that; with such short headways, even in the absence of other problems, bus clumping is likely.

If we apply the older systemwide averages to the current numbers for the B line, we estimate 240'000 passengers per workday, of which 60'000 are between 16:00 and 19:00, an average of 20'000 per hour, 5.6 per second. The use of the B line is concentrated toward downtown, and especially in the first seven stations, but we can pessimistically assume that usage is uniformly distributed over the whole line, giving an average trip length of one-third the length of the total, 3.9 km and 10 minutes. The tunnel PRT system outlined here would need 4.6 minutes for a 3.9-km trip, thus running twice as fast. Let's pessimistically assume that all the passengers are going in the same direction (which is close to the truth at rush hour), requiring an equal number of empty return pods.

If you have four passengers per pod, you would need 760 PRT tunnels to provide this level of service. If these were spread out over a kilometer at 50-meter intervals, this would require tunnels stacked 38 levels deep, 57 meters! This is about twice as deep as the deepest part of the existing B line; the original trench-and-cover tunnel reached its deepest point at 17 m, but the newer stations are deeper.

(Alternatively, you could just put the tunnels next to each other with only the occasional space in between for a station, which would spread them out over a kilometer and a half; or go for in-between measures, like three-tunnel-deep stacks a couple of meters apart.)

At the other extreme, if you have one passenger per pod so that it weighs only 150 kg, the trip would be quicker (3.2 minutes), but you'd need 3000 tunnels.

Because the trips are so much shorter and the pods are not linked up into inflexible trains, the total number of pod seats needed to deliver this level of service is about an order of magnitude lower than the number of subway train seats; pods totaling only a few thousand seats would be sufficient to provide hundreds of thousands of rides per day.

Scaling laws

The scaling laws for invisible thoroughfares like those described above are perfect for constant-speed vehicles: to go twice as far with end-to-end reservations, you need twice as many tunnels, which means the people are traveling distributed over a thoroughfare area twice as wide, so the thoroughfare has a constant aspect ratio regardless of its length. However, by including occasional stops — say, every 10 minutes for single-person pods, or every 30 minutes for fully-loaded pods — the amount of traffic can scale arbitrarily high. This more or less corresponds to what we would call a "headway" of 10 or 30 minutes in a traditional mass-transit system.

Power distribution

Putting 28 amps on the 40-volt DC cables is probably best achieved with a higher-voltage distribution system (insulated, perhaps buried, and perhaps AC) stepped down and rectified if necessary with a buried transformer every few hundred meters; if you try to do the distribution directly over kilometers at 40 volts, the cable losses will be high.

Acceleration and jerk

For comfort as well as limiting floor and tire wear, you'd probably want to limit accelerations to, say, half a gee, but with such small motors, this is only a problem at the very beginning and end of the trip; once you're up to 1.5 m/s (310 ms at half a gee), the 1120-watt power limit is more tightly constraining than the half-a-gee limit, even at 150 kg. (At 400 kg, the transition happens even sooner, at 570 mm/s, 116 milliseconds into the trip.)

You'd want to tilt for curved tunnels; this is easily accommodated, even for widely variable speeds, if the tunnels are circular in cross-section and the pod wheels are placed so as to touch this circle. The tightness of the curves at a given speed is limited by the centripetal acceleration — both for passenger comfort and to limit tire loading, you want to limit that. Centripetal acceleration is just v^2/r, so if you limit it to half a gee as well, the curved tunnels for changing direction at maximum speed should have a radius of curvature of 160 meters or more ($(28\ m/s)^2/(4.9\ m/s^2)$); to limit jerk, the tunnel curvature should change smoothly into and out of the curve.

Alternatively, you could use tighter-radius curves to change direction at lower speeds; for example, at the beginning and end of the trip.

Effects on social structure

Since such a system would enormously reduce the cost of living in lower-density "suburbs", we can expect that people would opt to move to areas of lower populational density, though perhaps not

proportionally. Because it would eliminate the usefulness of cars within its ambit, walking would become much safer and more pleasant. We can guess that this would motivate people to optimize their neighborhoods for walkability, making them more parklike, and perhaps to increase the distances between potentially dangerous industrial facilities and personal spaces (such as houses) or public spaces (such as shops).

Bayesian and Gricean programming

Kragen Javier Sitaker, 2015-08-20 (3 minutes)

Bayesian logic on graphical models

Cox's theorem (or at least Jaynes' interpretation thereof) says that Bayes' theorem is the only generalization of classical (or, maybe, intuitionistic?) propositional logic to continuous truth-values that satisfies some relatively straightforward conditions. What would it look like to program with Bayesian rather than Aristotelian logic? Is this the same as probabilistic programming or different?

I suspect that there's an interesting connection here with interval arithmetic and non-monotonic reasoning. Consider the propositions, from a HN discussion yesterday, "Birds can fly, but penguins can't [and penguins are birds], but Harry the Rocket Penguin can [and he is a penguin]." If we interpret each of these propositions probabilistically rather than by Aristotelian logic, things work out correctly: if we are told Hermione is a penguin, we might try to compute P(X can fly) from P(Hermione is a penguin)=0.99, but then we must deduce whether penguins can fly. In the absence of P(X can fly | X is a penguin) = 0.99 from the explicit statement above, and for the 1% chance that it's false, we are reduced to attempting to compute P(X can fly | X is a penguin) from P(X can fly | X is a bird) = 0.99 and P(X is a bird | X is a penguin) = 0.99, which tells us that penguins can fly with about 50:1 odds. But fortunately we have this other piece of evidence, which is that we've been *told* penguins can't fly. (Given that, do we conclude that Hermione is 99.02% likely to be flightless, or more like 67%?)

(A Gricean programming language, where the programmer is assumed to have followed the maxims of quantity and relation and not specified unnecessary information, might be interesting... but that's very speculative!)

Generalizing this a bit, you could consider the value of *any* variable to have some probability distribution; the traditional engineering and science use of "X±Y" confidence bounds is merely a simplification of the distribution, a simplification which (one interpretation of) interval arithmetic deals with. But in reality we have, say, a Gaussian lump in the probability distribution centered on X with width 2Y (or Y/12 or whatever), and near-zero probability elsewhere. This may pose problems for dynamic typing, since in the general case, taking as a specific example a computed latency for an internet connection, we would need to consider not only whether the latency was between 20 and 25 milliseconds, but also whether the latency was 20+3i milliseconds, 5 meters, a turnip in a field in Laos, or the Stoic conception of virtue as expressed by Marcus Aurelius. (Sound Bayesian reasoning prohibits you from excluding possibilities a priori, since doing otherwise leads to pathological reasoning breakdowns. Unfortunately, it would seem to require that we *start* from what appear to be pathological reasoning breakdowns.)

Practically speaking, we probably need to approximate the

posterior distribution with some kind of sampling, as with particle filters, but perhaps in many cases we can sample *intervals* of the probability space rather than *points* in it.

Disk oscilloscope

Kragen Javier Sitaker, 2017-04-10 (updated 2017-06-20) (3 minutes)

High-speed analog-to-digital conversion is very difficult, so a common way to make high-speed oscilloscopes is to store the signal after the trigger in an analog form for long enough to analyze it at leisure. This is of course a description of how entirely-analog oscilloscopes work, but for example a multi-gigahertz digital oscilloscope vendor in the early 1990s told me his scope stored the data in an internal CRT — a sort of analog version of the Williams tube — until it had time to analyze it.

Oscilloscopes are a particularly tricky kind of thing to build out of random electronic crap you find in the junk pile because that crap typically doesn't include any ADCs over 10Msps (some scanners contain 6Msps ADCs), and you really need at least 40Msps or 60Msps for an entry-level 20MHz oscilloscope. (Keep in mind that an analog 20MHz oscilloscope isn't incapable of viewing signals above 20MHz; that's just its 3dB attenuation frequency. Sub-nanosecond signals will probably be phase-shifted and badly attenuated but they'll still be there.)

So it occurred to me that maybe a discarded obsolete hard disk could bridge this gap. Suppose we're talking about a current 15krpm Seagate Cheetah with its 204MB/s data transfer rate, which (if it's on one head) implies that the waveform at the disk surface includes significant, reliably recoverable components at up to 800MHz. The disk is rotating at 250Hz. Once a waveform is recorded, it is then repeated at the read head over and over again, every 4 milliseconds, until either the head is moved to another track or a new waveform is recorded. We have 4 milliseconds of waveform recorded, which would amount to 3.3 million cycles of the highest frequencies recorded and could thus be fully digitized in about a second using the 6Msps scanner ADCs I mentioned earlier; but in a much more typical case, you only care about a few hundred or thousand sample points after the trigger event. And you can digitize a few of them on every revolution until you have them all digitized.

Considering digitizing 1000 points at 40 million samples per second, well, that's 25 microseconds, which is 150 samples at 6 megasamples per second. You can digitize points #0, #7, #14, #21, and so on on the first revolution of the disk; #1, #8, #15, #22, etc., on the second; and in this way after 7 revolutions of the disk (28 ms) you have digitized the whole event. Digitizing at higher effective sample rates, or using a slower ADC, would require proportionally more revolutions.

Even ordinary disks (5400 rpm, 50 MB/s) should still be capable of functioning effectively in this role.

A problem with this pretty picture is that disks are not really designed for analog signal integrity, and so the signal may be corrupted with noise and subject to hard-to-characterize nonlinearities. And of course you need to degauss the track before recording small analog signals on it.

(See also files TV oscilloscope (p. 1253), VCR oscilloscope (p. 213) , Laser printer oscilloscope (p. 449), and CCD oscilloscope (p. 1861).)

Writing hypertext is still a pain

Kragen Javier Sitaker, 2016-02-18 (6 minutes)

Writing hypertext is still a pain, and an autocomplete dropdown box from a statistically-ranked history of things you're likely to want to link to would improve the situation dramatically.

Writing hypertext is still a pain, 26 years into the WWW project and 71 years after the invention of hypertext. Typically I navigate to a page, use ^L^C to copy the link, alt-tab to another window where I'm writing something in Emacs (God help me if it's in another tab of the same browser) and type something like `<a href="^Y">some title</a>`. If I want some kind of indication of what the link is, like an image preview or something, I'm a bit out of luck in most environments, although at least Fecebutt and Twatter are helpful there if the page has OpenGraph metadata.

Consider this item from org-mode's help file, though:

> org-store-link is an interactive compiled Lisp function in 'org.el'.
> It is bound to C-c l. (org-store-link ARG)
> Store an org-link to the current location. This link is added to 'org-stored-links' and can later be inserted into an org-buffer with C-c C-l.

That sounds a bit saner, doesn't it? It's kind of like what Flock was trying to do in 2005 with their "shelf", where you would put things you were later going to link to or embed, later drag-and-dropping them onto any random textarea.

Even Vannevar Bush's 1945 UI design for linking in the "Memex" he proposes in "As We May Think," the very first proposed hypertext system, is far less cumbersome than what I usually use at present:

> All this is conventional, except for the projection forward of present-day mechanisms and gadgetry. It affords an immediate step, however, to associative indexing, the basic idea of which is a provision whereby any item may be caused at will to select immediately and automatically another. This is the essential feature of the memex. The process of tying two items together is the important thing.
> When the user is building a trail, he names it, inserts the name in his code book, and taps it out on his keyboard. Before him are the two items to be joined, projected onto adjacent viewing positions. At the bottom of each there are a number of blank code spaces, and a pointer is set to indicate one of these on each item. The user taps a single key, and the items are permanently joined. ...
> Thereafter, at any time, when one of these items is in view, the other can be instantly recalled merely by tapping a button below the corresponding code space. Moreover, when numerous items have been thus joined together to form a trail, they can be reviewed in turn, rapidly or slowly, by deflecting a lever like that used for turning the pages of a book. It is exactly as though the physical items had been gathered together from widely separated sources and bound together to form a new book. It is more than this, for any item can be joined into numerous trails.

There is another, perhaps ignored design that is currently in use for writing hypertext documents that is substantially less clumsy: autocomplete. This is what Fecebutt uses for tagging people or linking to Fecebutt pages in posts, and also what modern IDEs like Eclipse, Jupyter, or IDEA use to help you type long function names. You begin typing the name of an entity to link to, perhaps introduced with a magic character like @ or something, and the system instantly consults a dictionary of possible link targets, orders the possible completions (maybe including possible errors!) by likelihood, and displays the top few in a drop-down list right next to where you're

typing, each accompanied with some kind of preview.

Of course you could use the same approach to actually navigate to possible link targets, and then use a Memex-style link-creation button to link one thing you're looking at (or typing) to the thing you just navigated to. But I think this is less fluid than the dropdown/autocomplete approach.

Ideally, you wouldn't need to explicitly add things one by one to the list of possible link targets; instead, merely visiting them or even seeing a link to them drift by on Twatter would add them to the set of relevant links. You'd have to compensate for the large volume of possibly relevant links by having a reasonably accurate statistical ranking of which things are most likely to be linked to at any given time and for a given "search string"; also, searching through your own, perhaps private, commentary on a link, and that of your friends, should provide additional clues as to which tags are most relevant to a link.

This isn't quite enough for transclusion or quoting, because that is going to require some explicit user action to indicate the extent of the text, pixel data, etc., to be quoted. I think that probably the right solution there is to use an annotation UI to attach marginal notes to highlighted passages, then use tags and titles included in the marginal notes, as well as the contents of the highlighted passage, to feed the search engine. The persistent identity of a link target in this system might become a tricky question as existing works are modified.

Note that a single web page might contain many possible link targets, even without transclusion — for example, one for each header in a long article.

Solar dehumidifier

Kragen Javier Sitaker, 2016-08-11 (5 minutes)

There are different kinds of dehumidifiers. The most common kind is the refrigerative dehumidifier, which is basically an air conditioner; it uses a heat pump pumps heat from its intake air into its output air, condensing water out of it in the middle, yielding liquid water.

Another kind that's potentially simpler is the desiccant dehumidifier, which passes the air to dehumidify over a pebble bed of solid desiccant, which absorbs water from it. Eventually, though, the desiccant is full of water, and then it needs to "regenerate" the desiccant, so it connects the desiccant to a different circuit and blows hot air over it to take the water out. The hot, moist air has to go somewhere else besides into the space that it's trying to dehumidify; typically you exhaust it outdoors.

Ideally the hot regeneration air growing more moist flows in the opposite direction from the normal cool air being dehumidified.

(Dehumidifying the air down below the point of comfort offers the opportunity to humidify it again by evaporation, which cools it evaporatively; thus, not only can you dehumidify air by cooling it (and then warming it), but you can cool air by dehumidifying it (and then humidifying it.)

One striking thing about this approach is that it can potentially be done with very primitive materials. It's easier to do if you have plastics, microcontrollers, electric fans, silica gel, and so on, but I think you can do it entirely with stone-age materials, at least if you're willing to accept some compromises.

Ducting

Air ducting can be made from pottery, black-painted if necessary. Salt firing could make the pottery perfectly moisture-proof, and this may be desirable for some parts of the system. Pottery is fragile, and metals or plastics are a better choice where available; even lead would do.

Pumping and Heating

A solar chimney is a simple way to drive airflow using solar energy. Using it to suck air through the desiccant bed implies the loss of some of the desiccated air, but I think it's possible to divert the bulk of it elsewhere.

To heat air, it can be drawn slowly through a sun-warmed duct while it's warm.

Desiccant

The desiccant could be any number of common materials.

Sodium chloride salt is known since ancient times, and is probably adequately hygroscopic, but was too precious for such uses until the internal-combustion engine dropped the cost of mining by orders of magnitude. Various other salts, including sodium hydroxide, calcium chloride, sodium sulfate (mirabilite), and magnesium sulfate (Epsom salt) would also work, but none of them are very common in nature,

and some of them have an inconvenient tendency to deliquesce. Calcium sulfate (gypsum, sold as the commercial desiccant Drierite) doesn't dehydrate until over 100°, and calcium hydroxide until even higher temperatures, which would require inconveniently high temperatures from the regenerating air.

Much more practical, though with a lower minimal humidity level, would be to use biomass as the desiccant. Wood chips, for example, would work, as would coffee beans, which are commonly used for this purpose in saltshakers, or cocoa beans. It's important not to use edible materials; edible beans would attract pests unless they were poisoned. Heavily salting them would probably work without creating a hazard to humans who might consume them in desperation.

Expansive clays such as sodium bentonite would also work well, although you'd probably want to encapsulate them inside some kind of porous solid container, maybe a small unglazed prefired pottery sphere.

Control

Control of the apparatus is achieved by opening and closing valves, which need not seal perfectly. The valves are controlled by varying temperatures, pressures, and humidities in different parts of the device. Varying humidities can be sensed with a twisted hair rope.

Nowadays, if the system has to work when there is no electrical power, we would sense temperature variation using a bimetallic strip; I don't know what you would use in a Stone-Age situation. Perhaps you could use the lengthwise expansion of a long piece of wood referenced against ceramic; Douglas fir lengthens at 3.5 microstrains per kelvin, soda-lime glass at 8.5, and quartz at 0.33. So a 3m long piece of wood anchored to a 3m ceramic pipe would show a difference in length of 64 microns over 20°, which is probably too small to reliably activate a valve.

Tangential expansion is more like 45 microstrains per kelvin, which would bring the difference up to 0.9 mm, but that's also strongly influenced by humidity.

As an alternative to a packed column intermittently regenerated with hot air, you could use an enthalpy wheel, which continuously rotates at about 3 mHz while one side is being regenerated and the other side is being used for desiccation. It's presumably possible to drive its rotation with a light windmill in a sufficiently tall solar chimney, or intermittently using a regular windmill.

Elastic metamaterials

Kragen Javier Sitaker, 2019-03-19 (17 minutes)

From a materials-engineering point of view, one of the great benefits of organic and biological materials is their elasticity. Of course, organic elastomers like polyisoprene (the largest component of natural rubber latex), high-molecular-weight polydimethylsiloxane (silicone rubber), and polyurethane exhibit the most extreme elasticity, with elastic (or quasielastic) strains† sometimes exceeding 1000%; but other organic polymers have viscoelastic behavior above their glass transition temperatures, which are often quite low, making them very resistant to shattering in everyday use and often capable of elastic strains over 10% and even larger ductile strains. By contrast, common metals are limited to elastic strains of about 1%, although pseudoelasticity can give shape-memory alloys larger strains closer to those of the plastics mentioned above; and common ceramics are closer to 0.1% to 0.01% strain.

Furthermore, biological metamaterials such as wood and sponge can achieve much greater elastic strains than their component materials can. Similar benefits are achieved with crude synthetic metamaterials such as gels, aerogels, foamed metals, aerated cements, and so on.

This is a potentially serious problem for designing self-reproducing automata working from exclusively inorganic feedstocks, an objective I consider important for three different reasons: first, most of the universe, even most of the earth, does not appear to contain life forms, and thus mostly lacks complex organic molecules that could be used to build the automata needed to mine the asteroids; second, it is desirable that any agent controlling such automata not have an incentive to, e.g., deforest large areas of land, in order to build more automata; third, when automata that consume organic matter in order to operate have appeared in the press, public perception has been extremely negative.

Such plastics and elastomers fulfill several very important functions in existing machinery, including vibration isolation (i.e., couplings with a very low derivative of force with respect to displacement), relaxing tolerances, elastic energy storage, and protection from impacts. Though metals and especially ceramics offer higher ultimate strengths than plastics and especially elastomers, members made from metals and (again, especially) ceramics often must be sized orders of magnitude larger than their static and dynamic loadings to resist impact loadings.

Vibration isolation

Advances in vibration isolation have long been crucial to demanding apparatus — Michelson and Morley built their interferometer on a slab of rock floating in mercury, as I understand it, and modern inventions were the key advances that made LIGO possible. But many less-exotic machines need to manage vibration, too. Everyday modern motor mounts are commonly made with combinations of elastomeric supports (under compression) and dashpots.

But there are many other things you can do as well. Supports in compression are necessarily sized to have enough rigidity to resist buckling; this means that even small-displacement vibrations can transmit a lot of force, and thus energy, through them. Supports under flexion, like truck-suspension leaf springs, are not subject to this limitation, but suffer a compensating lever-arm disadvantage. Supports in pure tension can supply much more compliance for a given bearing capacity. This is why a tensegrity structure provides so much more compliance, and thus vibration isolation, than a traditional trusswork.

However, although strings in tension can have a great deal of bearing capacity for their rigidity, as the frequency increases, the string's own density comes into play. This increases the tension on the string for a given displacement whenever the wavelength of the wave (as it would propagate along the string) is comparable to or shorter than the string's length, enabling more vibrational energy to be transmitted through the string. Moreover, the resonance modes of the string can smear out a short-lived vibration over a longer period of time. LIGO† dealt with this in part by using DSP after the fact to filter out vibrations at the vibrational frequencies of the instruments' tension supports.

A different approach to the problem, also used in LIGO, is to use giant-compliance mechanisms made by putting a negative-compliance support (such as an Euler column† near its critical buckling force) in parallel with a positive-compliance support (such as any everyday object). The supports are designed to precisely cancel at the load they must support, enabling that load to "float" over a relatively large range of displacements at near-zero net force.

The energy of a vibration is partly reflected from discontinuities in acoustic impedance; discontinuity-rich environments such as a few meters of dirt and rocks are quite good at preventing the propagation of vibrations, to the point that Elon Musk claimed in his TED talk that neither the US Customs & Border Patrol nor the Israel Defence Force were capable of detecting tunnels dug more than three tunnel diameters under, respectively, the Mexican border and the Gaza Strip. So perhaps a string of beads, each bead connected to the next through a short length of cord, could work like acoustic multilayer insulation to exponentially attenuate transmitted vibrations.

Another possible approach — also at play in hiding tunnels from La Migra — is to use nonlinear interactions to transfer vibrational energy to progressively higher frequency bands. Impacts between relatively rigid particles are one example (say, attaching a box of dry sand to soak up vibrations — we don't normally consider quartz crystals a great damper), but so too are Euler columns crossing their critical stress (which includes ordinary strings alternating between tension and slackness), the thin-shell dynamics of cymbal crashes, and vibrations reaching large stresses in quasielastic substances like rubber.

Relaxing tolerances

Metals and especially ceramics are hard to work with because they demand very tight tolerances. Because their limiting strain is so small, they must be very close to the right shape and position before being brought into contact; typical tolerances for steel machine parts are a few microns, and as I understand it, ceramic parts are even more of a

motherfucker. (This is worsened by the frequent need to do much shaping of ceramics in a green state before final densification.)

Plastics (and, again, especially rubbers) can simplify this problem enormously. If an engine head can seat on a rubber gasket rather than directly onto the cast-iron cylinder, for example, it need not withstand the large forces that would be needed to seal it against the cylinder directly, compensating not only for its manufacturing imperfections but also its thermal warping. In high-vacuum systems, where organic materials generally outgas too much, this role is often taken up by gaskets made from a malleable metal like indium, thus avoiding the need to apply large stresses to glass to seal it against metal.

In another direction, many RepRaps have been built with bits of plastic hose serving as flexible shaft couplings, to allow for some misalignment of shafts. Nowadays, machined springs are more common for this use, which I think is because they last longer.

As an alternative to using plastic gaskets or flexible shaft couplings to compensate for inaccurate parts or assembly, possibly self-reproducing automata can be made from more accurate parts accurately assembled. As an alternative to using them to accommodate for thermal expansion discontinuities, matching thermal coefficients of expansion is possible (and regularly used to seal metal to glass in vacuum tubes); graded-TCE materials may help here.

Elastic energy storage

For the last few centuries, "clockwork" devices have been driven by elastic energy storage, typically in brass watch springs rather than in plastics. Plastics are actually not very good for elastic energy storage, despite what would appear to be higher energy densities: they tend to be viscoelastic rather than purely elastic, losing stored energy to creep relatively rapidly, and quasielastic elastomers like polyisoprene actually store the energy as easily-lost heat rather than strained bond energy as metals do. (For this same reason, rubber makes better motor mounts than would a steel spring of nominally the same stress-strain curve: the rubber dissipates high frequencies.)

Organic materials *are* used for shorter-term elastic energy storage, such as in bows, which must be unstrung when not in use to prevent creep.

Impacts

Impact loadings, as I understand it, are characterized by being limited principally by energy rather than force. If a perfectly rigid sphere of 1 kg is traveling at 1 m/s toward your machinery, it can exert an arbitrarily large pressure or force on the machinery — the collision of two such idealized horrors would produce infinite force and pressure for an instant. But it only has half a joule of energy. If the material it strikes deforms elastically or plastically, the forces actually encountered may be quite low; for example, if it deforms by 1 mm, the sphere stops in about 2 ms, so the force is on the order of 500 N, the weight of only 50 kg. If we suppose that the sphere has a radius of 100 mm, then the pressure is only of the order 30 kPa (5 psi in archaic units). (The precise numbers depend on details of the impact such as the distribution of pressure over the impact area, the

stress–strain curve for the impacted material, its Poisson ratio, its density (!), and so on, so in practice the numbers might be a few times higher or a few times lower.) But if the material only deforms by 100 μm, the impact takes on the order of 200 μs, the force is of the order of 100 kN, and the pressure is of the order of 3 MPa. Inversely, if the material deforms by 10 mm, the impact takes on the order of 20 ms, the force is of the order of 5 N, and the pressure of the order of 300 Pa. Thus, by adjusting the rigidity of the impacted material over two very plausible orders of magnitude, we can adjust its stress inversely over four orders of magnitude.

An additional factor is that very rigid impacts will almost certainly have smaller impact areas than softer impacts, because in a softer impact, the colliding bodies come into contact over a larger area than their initial contact. This factor even comes into play for non-impact loadings, such as tightening a spark plug on a car engine, though ductile substances like lead would also help there.

These are the reasons you can lean your full body weight on a car door window though you can shatter it by flicking a fragment of spark plug at it.

The impact energy a material can absorb, either elastically or plastically, is an intrinsic property of the material: it is almost precisely the integral of its stress over its strain to the limiting strain in question. This gives you some number of joules per cubic meter, or per cubic millimeter. In the case of elastic deformation, this is also the energy density of the material when used as a spring. (Small quibbles may attach from the ability of different structures to recruit more or less of the material's energy absorption capacity, including by way of shear deformations.)

Bending radii and microstructured synthetic metamaterials

So we have seen that compliant materials are crucial for a variety of reasons. How can we achieve them using inorganic materials? One approach is using metamaterials.

If you make a flat plate from a brittle material with 0.02% elongation at break, such as everyday fired clay, assuming linear elastic stress-strain behavior, it will break upon bending to a position where its inner surface is 0.02% shorter than its midline, while its outer surface is 0.02% longer. If it's bent into a circle at this point, the outer surface is a circle 0.02% larger than the midline circle and 0.04% larger than the inner-surface circle. So if, for example, it's 1 mm thick, the radius of the circle is 2.5 m, and its diameter is 5 m. But if you reduce its thickness, the radius of curvature diminishes proportionately.

And that's why aluminum foil and paper can be bent around much tighter curves before yielding and breaking than aluminum plate and fiberboard.

As you reduce the thickness of the material, the bulk approximation does eventually break down, but, interestingly, at micron scales, the material typically shows greater flexibility than the model would predict, rather than less — perhaps because of fewer surface defects and more consistent cooling — until you get to some kind of grain size of the material, which is on the order of 50 μm for everyday fired clay, but could be as small as dozens of picometers for

some atomic and molecular materials.

This is the principle behind the everyday coil spring or knit sock — by structuring ordinary piano wire or cellulose in a particular way, you can get it to yield like rubber, though a steel spring's behavior is closer to ideal elasticity than rubber's — but I think we can take it considerably further. If we make 1-nanometer-thick glass foil, which should be feasibility, we can roll it up in a double spiral; if we want the spiral to be able to unroll flat, we can't exceed the 2500:1 ratio mentioned earlier, so the center of the spiral must be a 5000-nm-diameter circle. If there's 1 nm of space between the glass-foil layers, in a 1.005-mm-diameter roll we can have 250'000 layers on each side, 125'000 per direction. So our 1-mm-diameter roll can uncoil to hundreds of meters of glass foil!

Because only the glass tangent to the roll is exerting an effective force, this spring is a very good approximation of a constant-force spring, like those used instead of counterweights for some sash windows.

This doesn't improve the spring energy density of the mass glass (except by reducing surface defects), but it certainly improves the elongation at break of the assembly: it has gone from 0.02% to several hundred million — several tens of billions of percent.

If we continue to use 0.02% as the elastic strain limit, glass foil thin enough to roll up inside 1 mm must be no more than 200 μm thick.

More complex metamaterials could provide not only tailored stress-strain curves (within the total elastic energy capacity of the underlying bulk material) but multidimensional interactions like auxetic materials. As Merkle's buckling-spring logic thought experiment convincingly demonstrates, the elastic deformation of a massive body with a complex shape can have arbitrarily complex behavior, including Turing-completeness (if the material extends far enough). Recent experiments in computational origami offer promising approaches to this problem.

Temperatures

To look at it another way, much of the problem is that most of the inorganic materials we're familiar with are brittle at room temperature, while many plastics aren't. But window glass is a polymer, too; it's just that its glass transition temperature Tg is higher than what we're used to. Soda-lime glass isn't just compliant once it's orange-hot — it's positively *gummy*. Inversely, we've all seen how rubber behaves when cooled below its Tg with liquid nitrogen — it shatters like glass.

Basically the problem is that we're talking about using materials held together by chemical bonds substantially stronger than many bonds in organic molecules, though not the C-C bonds that hold together blocks of graphite or molecules of polyethylene. So these materials might be more convenient at a higher temperature, perhaps around 400–900 K instead of the 300 we're used to. (Carborundum and diamond may be more viable semiconductors at these temperatures than silicon or germanium.) From an extraterrestrial perspective, Venus is no weirder than Terra, though a bit more expensive to emulate with MLI.

Going the other direction, at 100 or 200 K, perhaps we could use other unfamiliar materials. Water, of course, forms a crystalline solid

at 273 K. I don't know what materials might form glasses at such temperatures; maybe mixtures of common materials (mixtures generally have less tendency to crystallize), or polymers that I'm not familiar with because they're too weakly bound to be stable at 300 K.

Statement from the Confederation of Teachers

Kragen Javier Sitaker, 2016-10-11 (updated 2016-10-12) (4 minutes)

(Fiction!)

We are the Confederation of Teachers. We exist to guide and preserve society, not just of one group, but of all people, for the benefit of all. We came together because we believe society is important, but society was in grave danger of sinking into the same barbarism that nearly consumed it four generations before our foundation. All of our learning could have been lost; generations could have struggled merely to survive to adulthood, as most have throughout most of history; and society might perish on Earth, its cradle and its grave.

We were formed as a Third World War menaced the world, sending waves of refugees out from Syria, Afghanistan, Iraq, and the Crimea; as the European Union, which had safeguarded peace during those four generations, tottered; as a dangerous madman who loved only power was near being elected the leader of the most powerful state in history; and as the Industrial Age, powered by fossil fuels, steel, and concrete, drew to its filthy close. Suicide and obesity grew more widespread year by year, and as the biosphere collapsed, irreplaceable living species were lost at a rate not seen since the last asteroid impact. Yet human life expectancy had never been greater, literacy had never been higher, and science progressed at a rate never before seen.

We recognized that the existing social structure for guiding the course of civilization, a bureaucratic extension of the violent dominance hierarchies and genocidal territorial dynamics of ape troops, were both manifestly inadequate to the task of preventing total destruction and dangerously unstable in the face of nascent technologies such as nuclear weapons, genetic engineering, ubiquitous communication, space travel, self-replicating machinery, solar energy, universal computation, and artificial general intelligence. So we came together to create new resilient structures so that society could survive the most disruptive era of change in tens of millions of years.

We seek the welfare of everyone, not the advantage of one tribe or nation over another. For this purpose, we study, and out of gratitude to those who have taught us, we teach others, so that they too may become teachers. For this purpose, we consult among ourselves to determine the best course of action for society, and then we guide society to take that course. For that purpose we investigate the truth, each of us constantly seeking to become wiser, more ethical, and more capable, and each supporting the others in this. We serve a higher purpose than any company, state, or political party, because our loyalty is not merely to ourselves but to society as a whole.

We Teachers are all kinds of people: intelligent and dumb, female and male, black and white, young and old, rich and poor, from every country and every social class. So far, we are all human, but if we encounter nonhuman people, we will accept them too. What counts is what each of us contributes to the goals of the Confederation of

Teachers. We do our best to value the contributions of each member without regard to who originated them, struggling against our prejudices which corrupt us into listening only to the words of those we already know and respect.

To achieve these ends, we

Scientia est eorum, quæ sunt cum demonstratione.

Rediscovering successive parabolic interpolation: derivative-free optimization of scalar functions by fitting a parabola

Kragen Javier Sitaker, 2019-11-26 (updated 2019-11-27) (8 minutes)

There's a relatively simple derivative-free algorithm with superlinear convergence for finding minima or maxima of regular one-dimensional functions, analogous to the method of secants for finding their zeroes. But under almost all circumstances there are better algorithms.

Deriving successive parabolic interpolation

In $1 recognizer diagrams (p. 1264) it is mentioned that the $1 recognizer uses golden-section search, a la *Numerical Recipes*, to approximate the optimal rotation. This algorithm has very slow convergence, similar to binary chop for finding function zeroes.

Is there a way to adapt the method of secants (see Using the method of secants for general optimization (p. 1773)) to approximate the minimum faster? If you have three points (suppose, WOLOG, in order) x_0, x_1, x_2 and the function values $y_0 = f(x_0)$, $y_1 = f(x_1)$, $y_2 = f(x_2)$, then you can calculate some divided differences: $(y_1 - y_0)/(x_1 - x_0)$ gives you precisely the average of the derivative on (x_0, x_1), and similarly for (x_1, x_2). If the second derivative is small, these give us good estimates for the derivative f' at $\frac{1}{2}(x_0 + x_1)$ and $\frac{1}{2}(x_1 + x_2)$. From those two, we should be able to linearly interpolate or extrapolate to find where the derivative should have a zero crossing, and we can sample another point there, $y_4 = f(x_4)$.

This vaguely sounds like Nelder-Mead simplex optimization, but in one dimension, but I don't understand Nelder-Mead well enough to know.

Since this is just looking for a zero of the derivative, it will equally well find maxima or minima, depending on the average second derivative in the neighborhood.

In essence, this amounts to calculating the extremum of a parabola fit to the last three points.

So let's work this out.

```
min_next = (f, x0, x1, x2) => {
    const y0 = f(x0)             // (redundant)
        , y1 = f(x1)             // (redundant)
        , y2 = f(x2)             // f at latest point
        , d0 = (y1-y0)/(x1-x0)   // (redundant)
        , d1 = (y2-y1)/(x2-x1)   // derivative near latest point
        , xa0 = (x0+x1)/2        // (redundant)
        , xa1 = (x1+x2)/2        // where that derivative is
        , d2 = (d1-d0)/(xa1-xa0) // estimate of second derivative,
                                 //     hope it's not zero
        , dx = d1 / d2           // distance from xa1 to
```

```
                                //      extrapolated extremum
    return xa1 - dx             // return extrapolated extremum
}

min_next_n = (f, x0, x1, n) => {
    const xi = [x0, x1, (x0+x1)/2]

    for (let i = 0; i < n; i++) {
        const m = xi.length
        if (isNaN(xi[m - 1])) break
        xi.push(min_next(f, xi[m - 3], xi[m - 2], xi[m - 1]))
    }

    return xi
}

parabolic_extremum = (f, x0, x1, n) => {
    const xi = min_next_n(f, x0, x1, n || 30), m = xi.length
    return isNaN(xi[m - 1]) ? xi[m - 2] : xi[m - 1]
}
```

On simple examples like `x => x * (1 - x) + 0.001 * x*x*x, 0.2, 0.1` it seems to have pretty fast convergence, appearing close to the order φ of convergence like the one-dimensional method of secants. If it happens to run into a horizontal line, though, it fails; for example, `x => x * (1 - x)**2, 0, 1` crashes out at 0.5 because $f(0) = f(1)$. The actual maximum is, of course, 1/3, and a better starting point finds it. (And there's a minimum at 1.)

It seems to have some difficulty with rounding, only producing about 9 places of accuracy in that last example, perhaps because the second-derivative expression above becomes very small.

The lines marked `(redundant)` above are things that, after the first iteration, were already calculated in the previous iteration, so we can avoid calculating them again. What's left over is one function evaluation, five subtractions, an addition, a division by two, three arbitrary divisions, and an operation that can be either a division or a multiplication. To me four divisions per iteration seems kind of heavy-weight.

You might think it would have poor convergence because when we sample the new point there, we are in effect sampling the derivative halfway between that new point and the last old point, so we're only getting halfway to the destination. But we're only delaying convergence by one iteration --- if that derivative-average and the last one point to a place very close to the new point, because the second derivative is almost constant over that interval, the new new point will be very close indeed. So it works out.

It actually can tell whether the extremum it's approaching is a maximum or a minimum, because the estimate that it gets of the second derivative tells it. By replacing a `d2` with `abs(d2)` in the above code, we could make it seek only extrema of one kind.

Unlike the method-of-secants stuff in Using the method of secants for general optimization (p. 1773), it isn't apparent to me how to extend this to functions of vector arguments, functions of more than

one argument, or vector-valued functions.

This is called "successive parabolic approximation" and you should almost never use it

The realization that this amounts to fitting a parabola to the last three points led me to the discovery that the standard name for this method is "successive parabolic interpolation"; Wikipedia explains that it has an order of convergence of about 1.33 and has robustness problems. In particular, though, the fact that it's less than √2 means that it's slower than using Newton-Raphson iteration on a derivative evaluated using automatic differentiation, other than faster, as with the method of secants.

The divided-differences approach given above is, I think, faster than the approach I've found elsewhere of solving the Vandermonde linear system, because it's more incremental. But divided differences is of course a standard way to do polynomial interpolation, and its incrementality is one of its standard advantages.

The only time when it is faster to use successive parabolic interpolation rather than Newton-Raphson iteration is when you can't differentiate the function you're optimizing, even though you believe it to be regular, for example because it's experimentally measured rather than computed, or because your software tools are outdated and don't support automatic differentiation, or because its second derivative fails to exist. (If its first derivative fails to exist, successive parabolic interpolation won't work either.) In such a situation, golden-section search is slower, but sometimes only for high precision; and golden-section search is more robust and doesn't have the rounding problems mentioned above. (The `optimize` function in R uses a mixture of golden-section search and successive parabolic interpolation known as Brent's method.)

So, for example, `min_next_n(x => (1/x - 4)**2 , 0.001, 0.1, 30)` in the above evaluator takes 7 iterations to converge to within 0.1 of the correct result (0.25), 6 more iterations to converge to within 0.01 of the correct result, and 2 more iterations to converge to within 0.001 of the correct result, at which point it starts having reasonable convergence. I think golden-section search would actually be faster up to that point, although I haven't tried it. However, for functions that are well approximated by a quadratic, successive parabolic interpolation is really fast; for example, in `min_next_n(x => Math.sin(x*Math.PI) + Math.sin(x*2*Math.PI), 0.001, 0.1, 30)` it eventually converges to 0.29791559955277436, but it's already at 0.2987 in 5 iterations.

The AL programming language, dimensional analysis, and typing: do different dimensions really exist?

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

I was reading Raphael Finkel's book "Advanced Programming Language Design", and he mentions a language somebody named Finkel invented in the 1970s called AL. AL had dimensional analysis built in, with four base dimensions: 'time', 'distance', 'angle', and 'mass'.

(As Finkel says, this is the kind of "type safety" that's really needed in everyday calculations. His language did it statically, but you can do it dynamically too, as units(1) does.)

He points out that 'angle' really shouldn't be included since radians are really dimensionless, which leaves us with 'time', 'distance', and 'mass'. But no 'speed', 'force' or 'energy'.

However, they can be derived from the base units; speed is a ratio distance/time — e.g., m/s. Acceleration is speed/time, or m/s^2, and force can be thought of as mass * acceleration, or $kg*m/s^2$. Finally, energy is force * distance, so you can express it in units of $kg*m^2/s^2$. This is in fact how units(1) represents it.

But do we really need all three of 'time', 'distance', and 'mass'? The speed of light provides a natural conversion factor between time and distance, and mass can be equivalently measured as energy, according to the well-known formula $E = mc^2$. So speed is really just a dimensionless quantity, and acceleration is the reciprocal of a time interval, namely the time to reach the speed of light at that constant acceleration; so its units are really 1/s. So force can really be measured merely with kg/s.

Unfortunately this doesn't really help us get rid of mass: energy is now expressed in kg*s/s, or merely kg. So our two relativity-based equivalences (mass as energy, and time as distance) turned out to be merely two facets of the same equivalence.

But I suspect that in everyday calculations, the equivalence of mass and energy is rarely useful; it's far more likely to hide errors than to reduce the amount of work necessary. With time, distance, and mass, the only incommensurable quantities I commonly run into with commensurable units are:

- torque and energy;
- various dimensionless quantities;
- perhaps pressure and stress;
- stress and young's modulus.

Collapsing mass with energy and time with distance creates many more "units collisions".

Robust hashsplitting with sliding Range Minimum Query

Kragen Javier Sitaker, 2016-09-05 (7 minutes)

Hashsplitting is a process used by bup, `gzip --rsyncable`, and fuzzy hashing used for spam and malware detection. Current hashsplitting systems are vulnerable to malicious input and are also needlessly inefficient. By using the linear-time sliding range-minimum-query algorithm, we can improve its efficiency measurably and its robustness against malicious input dramatically.

Background

Bup and `gzip --rsyncable` and forensic "fuzzy hashing" all use a sliding-checksum algorithm to split their input data into chunks at irregular intervals, determined by the bytes in the neighborhood, in such a way that the chunk boundaries will move with insertions and deletions into the text. Bup calls this process "hashsplitting." This generates, effectively, a pseudorandom number at each byte offset depending on the previous bytes, and tests it against a customizable threshold, or even set of thresholds, in order to figure out where to divide into chunks.

Naïve hashsplit chunk size has a geometric distribution.

Since chunk ending is a memoryless (Bernoulli) process, the distribution of chunk sizes (the "waiting times") follows a geometric distribution, the discrete analogue of the exponential distribution.

The geometric distribution has a very large standard deviation (in the limit, equal to its mean) because occasionally values much larger than the mean will result. For example, here are some interval sizes from a Bernoulli process with parameter .001 [0]:

```
array([2216,  130,  138,  125,  659,  861, 1708,  421, 1794, 1416,  810,
        982,  118,  237, 1755,  383,  841,  632,  200,   85, 1062, 1241,
       1804,  591,  916,  600, 1167,  630,  480,    9,  713, 2656,    2,
        883,  459,   71, 2753,  599,  389, 2187,  593,  442,  348,  764,
       3094, 1371,  481, 2667,  194, 1093,  183,  671,  872,  874,  311,
        345, 1958,  219,   81,  593,  365,  988,  349,  673,  909, 2013,
        267,  387,  503,  146,  339, 4818,  200, 1393, 1556, 1640, 1257,
        816, 1618, 1630, 4719,  699,  693, 2515,  161,  505,  782,  922,
         23,  226,  489, 1757,  933, 1966,  698, 2500,  837,  352, 1508,
        339])
```

XXX can I maybe measure the chunk sizes from bup?

The mean waiting time of this process is 1000 (and the mean of these variates is 964 and their standard deviation 898) but more than a third of them are less than half the mean, and one of them is almost three times that. Two of them are more than four times the mean, which is slightly more than typical.

Geometric chunk size distribution is inefficient.

As noted in the design of bup, for many of the applications of

hashsplitting, although some variability is demanded by the application, this large degree of variability is undesirable.

For example, if the above numbers came from using a sliding-checksum algorithm to divide a slightly modified 96-kilobyte file into roughly-1000-byte chunks and calculate a hash of each, so that we could transmit or store only the newly changed chunks, the changes will be disproportionately concentrated in the larger chunks, which in turn are disproportionately expensive to transmit or store; the 9-byte chunk and the 2-byte chunk are very unlikely to have been the ones that changed! So the cost of a chunk is proportional to the *square* of the chunk size, which, after all, is why we're splitting the input into chunks in the first place. In this case, the extra cost is some 32%.

Current hashsplitting performance is vulnerable to malicious data.

The situation gets worse if the data being handled is actively adversarial. Sliding-checksum algorithms tend to be linear functions of the last N bytes, in order to make them efficient to compute. This means that a data-generating adversary who knows the particular sliding checksum in use can generate data which will either never generate a cut, producing arbitrarily large blocks, or generate a cut very frequently — every four bytes for an Adler-32 (as used by `gzip --rsyncable`), CRC32, or simple 32-bit checksum, for example. Under some circumstances, this "pathological" data could cause serious problems in a program attempting to apply them. Even if the sliding checksum were impractical to calculate preimages for, an attacker could still repeat a "separator" sequence of the size of the checksum's window (64 bytes in Bup) that induces a split.

It would be useful to have a pseudorandom algorithm that still triggered at the same places after faraway insertions or deletions, but whose waiting times didn't suffer from this large variability and vulnerability to adversarial input.

Sliding range minimum query

Range minimum query, or RMQ, is a well-studied algorithmic problem: given some finite sequence H — say, a sequence of hash values — efficiently find the index of a minimum value `H[k]` in some range [i, j), that is, find a `k` such that

```
i <= k < j ∧ ∀n ∈ ℤ: i <= n < j → H[n] >= H[k]
```

(Of course this works just as well for maxima.)

There are a bunch of data structures for this. You can precompute a table of the results in $O(N^2)$ space and time and answer arbitrary queries in constant time, or a "segment tree" of the results in O(N) space and time and answer arbitrary queries in O(log N) time, along with other possibilities.

However, one particular special case is the *sliding* RMQ problem, where the window size `j - i` is a constant; this can be computed for all possible values, with the following simple linear-time algorithm:

```
size = j - i
d = make_deque(max_size = size)
```

```
k = 0
for item in H:
    while d.nonempty() and H[d.rightmost()] > item:
        d.remove_rightmost()

    d.add_on_right(k)
    if d.leftmost() <= k - size:
        d.remove_leftmost()

    yield d.leftmost()
    k += 1
```

Hashsplitting with sliding range minimum query

If you run the sliding RMQ algorithm over a sequence of hash values generated from the text, as long as the values are unique within the window, it is guaranteed to generate at least one split per window size. OH FUCK IT CAN GENERATE ONE SPLIT EVERY BYTE. Is that fixable?

Probably the thing to do is to take, say, every 8KiB window starting from the start of the file, and split at the location of the minimal hash within that window. But that requires no algorithmic cleverness whatsoever.

[0] Python code for calculating waiting times of a Bernoulli process:

```
def bernoulli_process(p):
    while True:
        yield random.random() > p

def intervals(process):
    i = 0
       for item in process:
           i += 1
           if item:
               yield i
               i = 0

x = numpy.array(list(itertools.islice(intervals(bernoulli_process(.999)),
    100)))
```

Cheap textures

Kragen Javier Sitaker, 2018-10-28 (updated 2019-05-05) (5 minutes)

So I've been thinking about how to render low-computational-cost textures in 2D, for a few different reasons.

Objectives

• Ultra-low-power e-paper computing systems; the objective here is for the energy cost of generating the texture data to be comparable to the energy cost of updating the e-paper to display it. As outlined in Keyboard-powered computers (p. 2220), updating an e-paper display costs on the order of 200 nJ per pixel update, while common 32-bit low-power processors use on the order of 300 pJ per instruction. This means we can afford something like 700 instructions per pixel, if we're content to have the battery life be half of what it could be. But e.g. reducing below 175 instructions per pixel only increases your battery life by 25%.
• Live video generation in software from low-memory computers; the objective here is to be able to display more interesting things on the screen than you have memory space for a full framebuffer. As mentioned in Notes on the STM32 microcontroller family (p. 3176), NTSC composite video has space for about 200 kilopixels in living color, but common 32-bit microcontrollers like the STM32 line have only 4–256 KiB of RAM, despite running at up to 200 MIPS. To the extent that the display contents can be encoded in RAM with many pixels per byte, then rendered in software to a scanline "framebuffer" or a "framebuffer" containing a few scanlines, they can be far richer within these limitations. 200 kilopixels at 30Hz is 6 megapixels per second. At 96 MIPS, that's a budget of 16 instructions per pixel, or 32 instructions per pixel if you're satisfied with a 200×500 display.
• Providing more powerful graphical primitives for GUI systems. Old GUIs, up to around 1998, were so constrained by the slow computers they ran on that they had to update the framebuffer incrementally, because there wasn't enough time to redraw the entire screen in between screen updates. Modern GUIs' programming model and appearance mostly mindlessly apes the GUIs of that epoch, although the IMGUI paradigm, gradients, filters, and transparency are making their way in; Self's cel-animation-inspired effects have made their way into modern GUIs as animated transitions, notably in window managers and jQuery animations; CSS is popularizing arbitrary transform matrices; and Google's Material Design is leading a move to physically-based rendering in user interfaces. But there's a much wider range of possibilities available. Even the CPU of the laptop I'm typing this on averages over 6 64-bit or 128-bit instructions per clock cycle at 1.6 GHz, or 10,000 MIPS, and its LCD screen is only 1920×1080 at 60Hz, or 124 megapixels per second. This is a computational budget of about 80 CPU instructions per pixel. Moreover, its integrated GPU (see Notes on the Intel N3700 i915 GPU in this ASUS E403S laptop (p. 2033)) is capable of doing maybe 50 billion single-precision multiply-accumulates per second (invoked from 12.5 billion instructions), or twice that many in half-precision, and supports OpenCL; if this is correct, this would be a

computational budget of about 400 multiply-accumulates per pixel (invoked from 100 4×SIMD instructions).

• Reducing GUI latency and tearing. A 60Hz screen redraw is already 16.7 ms, which Dan Luu has convincingly shown is already significant in user experience. Double-buffering adds an additional 16.7 ms of latency, and doing it out of sync with the vertical refresh adds an additional random latency that ranges from 0 to 16.7 ms. Typical keystroke-to-screen latencies on modern computers are in the range of 100 ms, and decreasing that by 25% would be a significant improvement. The hardware constraints here are the same as in the previous item: 80 CPU instructions per pixel or 400 GPU operations per pixel.

So, all of these different ways that you can use low-computational-cost texture generation have different computational budgets (175 instructions per pixel for e-paper, 16 for bitbanging NTSC, 80 instructions and 400 multiply-accumulates for the laptop scenarios), but they're all kind of in the same ballpark. Moreover, they're in a completely different world from the Macintosh with its 6-MHz 1-Dhrystone-MIPS 68000 and its 9" 512×342 CRT, which I am assuming refreshed at around 60 Hz, giving it a dot clock a bit over 10 MHz — 10 pixels per instruction. They are, respectively, 1750 times faster, 160 times faster, and 800 times faster (not counting the GPU, which is arguably something like 4000 times faster), relative to the notional "dot clock".

An almost-in-place mergesort

Kragen Javier Sitaker, 2016-09-07 (5 minutes)

(I'll be surprised if this isn't all in Knuth, but my Knuth is in the US.)

Background

The asymptotically most efficient comparison-based sorting algorithms take O(N log N) time. Mergesort is one of the sort algorithms of this complexity class, along with Quicksort, Heapsort, and the recently discovered Library Sort. It has the desirable property (like Heapsort) that it always takes the same amount of time, unlike Quicksort, which has an $O(N^2)$ worst case. Indeed, you can implement it without conditional execution. Unlike Heapsort and Quicksort, it's also easy to make it a stable sort, which is often desirable (especially for library routines for sorting); and it accesses memory in purely sequential fashion, which is a huge plus as memory hierarchies get deeper, while Heapsort and Quicksort jump all over the place. Mergesort is the only reasonable choice for a comparison-based sort of data on disk.

(Radix sorting algorithms, which don't rely on comparisons, can be O(N) time, and many are; but I won't discuss them further here.)

It has one huge disadvantage, though, which is that to sort a million things, you need memory space for a million and a half of them; you need temporary storage for N/2 elements, which is to say, you need O(N) space. Meanwhile, Heapsort needs only constant space (O(1)), and Quicksort needs O(log N) space.

Solution?

I think there's a solution, but I'm not sure how to make sure it terminates.

One variant of mergesort uses stacks. With three stacks, you can merge sorted runs on S1 and S2 into longer sorted runs on S3 until both S1 and S2 are empty, and then perfect-unshuffle those runs back onto S1 and S2 (one run onto S1, one run onto S2, repeat) before continuing again. This is a little wasteful in that you move each item twice for each merge. Or, with four stacks, you can merge S1 and S2 into runs that you perfect-shuffle between S3 and S4; then you can backwards-merge the S3 and S4 runs, perfect-shuffling them between S1 and S2.

(This originates in the tape-drive days, when your four-kilobyte machine would have to do payroll for your hundred thousand employees. I'm pretty sure I remember that much from Knuth.)

An amusing note is that you don't have to keep track of where the runs are. You can simply refuse to move elements onto the output stack when they would be out of order (because they belong ot the next run), until all the candidates would be out of order, at which point you start a new run.

But suppose you're doing this in memory. As S1 and S2 are shrinking, S3 and S4 are growing by the same amount; it's just that the growth is distributed unequally. You could maybe put S1 and S3 in the same memory space, but growing toward each other with some

spare space in between, unless they collide.

But most of the time, especially in the early stages part of the process, you're fine. At the very end, you need to split the final run between S3 and S4 (or S1 and S2) unless you want to reallocate the space.

But this suggests a solution: what if, when your output stack would overflow, you switch to the other output stack in the middle of the run instead of reallocating? You'll make two small sorted runs instead of one big one, so you won't be making progress on that run, but at least you're not going backward. But it probably won't happen too often, and you're guaranteed to have space on one stack or the other. And if at some point you have to switch back to the first stack (because the other one is full) you won't be creating a new run there; you'll just be extending the one you started earlier. So the number of sorted runs never grows, but always shrinks.

I'm too tired to code this up right now, but I have a suspicion that it will always terminate; but that if the gap size is too small, it might not terminate in a reasonable period of time.

Cardboard furniture

Kragen Javier Sitaker, 2019-08-01 (updated 2019-08-11) (15 minutes)

I've been watching lots of videos about making cardboard furniture, with an eye to using recycled cardboard from the neighborhood to make some furniture. There are many different techniques: gluing in ribs with hot glue, laminating multiple layers with PVA glue thinned with a bit of water (unaccountably always with the flutes in the same direction), cutting matching notches to slide pieces together at right angles, using single-linerboard corrugated (usually used for packing) to run around curved contours, paper tape like you use on the back of pictures to hang to cover up joints, découpage with glossy magazine paper to add surface strength and a flat surface for painting, etc.

One point frequently made in the videos is that corrugated cardboard is much easier to crease parallel to the flutes; so, for example, if a shelf is supported at the ends and loaded in the middle, the flutes need to run lengthwise to prevent it from creasing and failing.

Pizza box test and thoughts on strength

I just did a quick test with Mina and a pizza box we were discarding. 16 layers of the one-ply corrugated cardboard of the pizza box were sufficient to resist her strongest efforts to break the beam by pressing down on it in the middle, supported near the ends by my hands; but 8 layers were not. The beam was about 40 mm wide and about 300 mm long, and the flutes ran lengthwise. In the end she was only able to "break" the 8 layers by virtue of twisting the beam in the middle, at which point it failed by creasing — decreasing the beam's moment of inertia by bringing its surfaces close together. The pizza box is about 2 mm thick, but this was probably not very significant in this test.

This suggests that maybe to resist her weight with only one layer, such a rectangular beam that's protected from twisting might need to be four times as wide, perhaps 160 mm wide. The U-shaped bend used by the Chairigami chairs to support body weight could perhaps use 110 mm of depth of "web" on each side; if it were notched to 55 mm depth to match a 55 mm notch on a vertical support, that might be adequate. To reduce crushing at the point of contact at the bottoms of the notches, the tab cut out to make the notch could be folded over rather than cut off, thus increasing the contact area and making it not be entirely edge.

The cardboard box resource

Four of the eight corrugated-cardboard boxes I have handy here, left over from Mina's move, are about 4 mm thick, 1300 mm in circumference, and 360 mm in height (and of course the flutes run heightwise), plus another 170 mm of top flap and 170 mm of bottom flap. The other four are apparently the same thickness but somewhat smaller. They have all suffered some minimal damage from the moving process. Since this is Argentina, not the US, they don't have edge-crush-test or bursting test ratings printed on the cardboard.

(This works out to 1300 mm × (360 + 170 + 170) mm × 4 = 3.6 m² of cardboard in the large boxes and perhaps another half of that in the small ones, for a total of 5.4 m².)

Chair ergonomics

We're seated on some 250-mm-seat-height chairs that we both agree are a bit too low for comfort; their seats are about 550 mm square, which for her is a bit too wide, and for me is a bit too narrow. The kitchen chairs, which are maybe a bit too tall, are about 450 mm tall and a somewhat uncomfortably small 350 mm wide. So something like the 360-mm height of the boxes could maybe work well.

More material properties

If I try to support this body's weight (110 kg?) on a 48 mm × 140 mm section of folded cardboard strip from one of these boxes, it barely crushes; at 64 mm thick it had no trouble. This suggests an edge crush pressure of between 120 and 160 kPa or, in medieval units, 17 to 23 psi. So the 8 mm square sections of folded tab I was thinking to use to support notch bottoms will safely hold 8 N, or only about 800 grams of weight. But that's okay, because the majority of the weight will be borne on the edges of the "legs", not the notch bottoms.

A normal singlewall corrugated cardboard box in the US is rated for 32_lbs/inch edge crush test, in medieval units. If it's 4 mm thick, that's 1400 kPa, about ten times the number I got from this test. This makes me think that probably my test is unreliable because I am pretty sure this cardboard is more than 10% of the strength of normal cardboard.

I'll take the geometric mean of these numbers, 400 kPa, or 1.6 kN/m.

How many legs?

Suppose we need to support 200 kg over 300 mm of seat length, front to back. (The whole seat might be 550 mm long, but maybe the weight is not evenly distributed; and maybe I'm sitting down on it hard.) Each 4-mm-thick "leg" provides 480 N of crush strength over that distance.

So we need about four "legs" per person.

The Chairigami dude arranges this by using two double-layer legs (that is, with three layers of linerboard separated by two layers of flutes, rather than two layers of linerboard separated by a single layer of flutes). But if I space the four legs evenly instead, I can shorten the unsupported span length of the seat between legs (to 550 mm ÷ 4 = 138 mm), and avoid having to laboriously laminate layers of cardboard with glue.

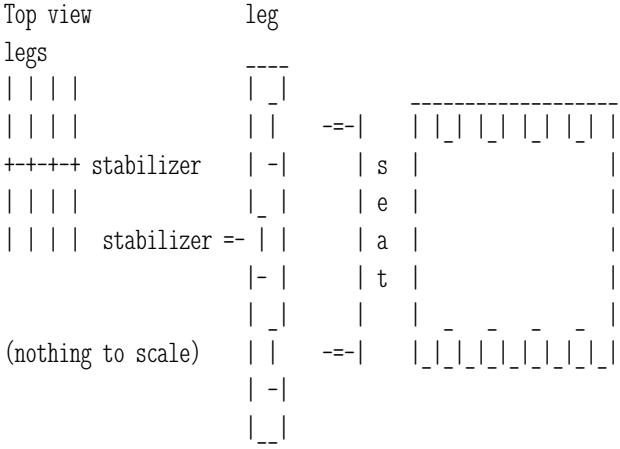
Earlier I suggested that a 300-mm unsupported span might require 110 mm of "web" depth supporting the seat to keep it from collapsing. This shorter span might require only 50 mm, and thus only 25 mm of notch depth.

Initial test plan

I can do an initial test with "legs" much shorter than the 360-mm

height of the desired final product, since the initial objective is crush testing. The seat flutes need to run at right angles to the legs, so I'll probably have to make the seat out of two overlapped pieces to get to the full 550-mm width, since 360 mm is the longest transversely-uncreased flute length I have available; each overlapped piece will have a "top" that is 550 mm long, plus 50 mm of "web" on each side with four 25-mm-deep folded-tab notches in it, which fit into matching notches on the legs. The legs are, say, 650 mm in the cross-flute direction, and 100 mm in the along-flutes direction, and each one has two 25-mm notches on its top, 550 mm apart. Probably I'll need some kind of additional lateral stabilizer to keep the legs from all bending to one side or the other; a single deeper notch in the bottom of each, perhaps 30 mm, can allow the insertion of a single 100-mm-long, 550-mm-wide stabilizer with four 70-mm-deep notches.

A very crude ASCII-art drawing:



Probably I should assemble a paper model first at about 10:1 scale, then assemble that out of cardboard.

If that doesn't turn up any unexpected problems, a full-height stool is probably next (with a bit of under-kick, rather than vertical leg edges), then something with a back. The full-height stool will use four 360 mm × 650 mm legs, a 550 mm × 360 mm stabilizer, and two 360 mm × 650 mm seat scales (perhaps reused from the initial test), for a total of 1.6 m².

If that works out well, I'll know enough to figure out how to scale up to a couch with a back.

Notes from paper model

I assembled a 10:1 paper scale model of the full-size stool (except that the paper is about 0.1 mm rather than 0.4 mm as it would need to be). I learned a number of things.

Making the seat out of two overlapped 36-mm pieces led to a notch only 1.6 mm away from the edge of each, which made it unnecessarily weak and hard to assemble. Moving the two center legs toward the middle would solve this problem.

The "web" flaps at the ends of the seat were short enough at 5 mm that they were hard to assemble. Making them 10 mm or 20 mm (100 mm or 200 mm in full scale) would be a lot better. An unappreciated factor was that those 2.5 mm (25 mm in full scale) notches are the only thing resisting forward-and-back movement of

the legs under the influence of bending of the stabilizer or twisting of the seat around the vertical axis relative to the floor.

The Chairigami chairs bend the seat over the corner of the support and insert its support web into a slanted notch in the front of the vertical support. I probably need to do this in order for the seat not to be extremely uncomfortable for your legs hanging over the front. They also divide the seat into two or more seat sections bent into independent webs.

Another few things occurred to me, though, when looking at the model.

First, maybe the "crush" part is only relevant at the very top and bottom of each leg, in which case maybe I can get double strength by just folding the top and bottom of the leg over so that there's a short width of double cardboard along the top and bottom edges. The middle of the leg would still have to support the compression without crumpling, but that might be a less demanding task. This might allow the stool to be strong enough with just a single pair of legs rather than two pairs of legs. As an extra bonus, Mina's cardboard already has two transverse creases 360 mm apart.

(I'm not sure crushing failure actually works like that, but it seems like it would be worth a try.)

Second, instead of cutting apart the cardboard to make two separate legs, I can perhaps just give it two bends, U-style, to make a pair of legs with a web between them at one end, maybe the back. The web serves part of the purpose of the center stabilizer, but mostly the idea is that making two creases is easier than making one cut. (And if the legs don't have to be parallel, you can make it one crease rather than two, bending it V-style rathe than U-style.) Taking this to the extreme, you could serpentine a long piece of cardboard back and forth in this way, but I don't think the cardboard I have is long enough for that.

Third, though perhaps mutually exclusive with the fold-over-the-top idea, the seat can be contoured by making the tops of the legs curved rather than flat. This would also add extra bending strength to the seat in the direction parallel to the curvature, at least once you press the seat cardboard down into the curves by sitting on it.

Fourth, if the notches are too deep, everything is fine because the bottom surfaces sit on the flat floor and are brought into alignment even if the notch bottoms don't meet; but if they're not deep enough, the cardboard tears. Conclusion: plan to cut them too deep. It might be possible to improve the crushing thing a bit by expanding out each notch into a triangle at the bottom and folding it over, but probably at a heavy cost to other aspects of structural strength.

There was also a slight design-for-assembly problem, in that each of the two seat halves was almost symmetrical and could be glommed onto the legs in a number of different places and in two different orientations. Making the front and back web flaps obviously different lengths would help with reducing the ambiguity.

This was a sufficiently fruitful exercise that I think I should increase the number of prototypes to include a 5:1 cardboard model as well.

Semi-digital fabrication

I don't have a CNC cardboard-cutting machine, or in fact even an X-Acto knife and cutting mat, so I cut the paper model by sharpening a steel kitchen knife tip and cutting on a kitchen cutting board. While this did work, it required me to lay out the design beforehand, using a pencil, adding a substantial fraction of a millimeter of error, and I probably added another couple of millimeters of error with the knife.

Mina has an inkjet printer which I think can do 600 dpi on A4-size paper. That's 42-micron resolution. We can print out designs on this paper and paste it onto the cardboard, then cut and crease the cardboard by hand, following the printed lines.

The cardboard is, however, substantially larger than the paper, and we can't print the paper all the way to the edge ("full-bleed"). So we will probably have to print out multiple sheets of paper, cut full-bleed pieces out of them (in what need not be a particularly precise fashion), and paste them in an overlapping shingled pattern onto the cardboard. An A4 paper is 2^{-4} m², so each square meter of cardboard might require between 16 and 32 printed sheets; the stool above might be about 30. This may be more trouble than it's worth for such a simple design.

Laser-cutting might be a good option, though.

The miraculous low-rank SVD approximate convolution algorithm

Kragen Javier Sitaker, 2019-08-14 (updated 2019-08-15) (31 minutes)

When reading papers for Real-time bokeh algorithms, and other convolution tricks (p. 2661), I ran across a paper by Tim McGraw on a powerful convolution algorithm. The algorithm took me a while to understand, and it turns out it isn't original to McGraw; it was extensively investigated in the 1970s and 1980s. It's an absolutely astounding technique, and I think it has much broader applicability than is widely appreciated.

Much of the below is somewhat speculative because *I've only just tried the algorithm*. It's very possible I'm misunderstanding its limitations. But it gives me the first general attack on the problem in Sparse filters (p. 834), and I have a lot of reading to do!

The profound and wide-ranging importance of convolution

The *convolution theorem* is one of the most important theorems in the theory of signals (in the sense of "digital signal processing" or "Signals & Systems", not in some kind of semiotic sense). It says that any linear, shift-invariant system is fully characterized by its impulse response, because you can add up a bunch of shifted and scaled copies of that impulse response to compute its response to some arbitrary signal. (Or, in continuous domains, integrate.) This has applications both theoretical, in proving theorems generally applicable to linear, shift-invariant systems, and applied, in computing the result of a linear, shift-invariant system through one or another convolution algorithm.

Significant linear, shift-invariant systems include nearly all acoustic systems (in the time domain), circuits made of linear components (voltage sources, current sources, resistors, transmission lines, capacitors, and inductors — or their idealized versions, anyway), nearly all optical systems in the time domain, and imaging optics in the spatial domain as well. Many systems that are not in fact linear or shift-invariant can be locally approximated as linear shift-invariant systems, though not all. (You can't get the Doppler effect out of a locally-shift-invariant model, for example.)

Furthermore, because convolution in the space or time domain is equivalent to pointwise multiplication in the frequency or Fourier domain, we can do things like frequency filtering, blurring, and sharpening by using convolution.

That point about "sharpening" deserves some sharpening. In theory, any convolution with no zeroes in the frequency domain, which is mathematically almost all convolutions, has an inverse convolution — you just take the reciprocal in the frequency domain and Bob's your auntie! In theory this means that you can undo the degradation caused by almost any known convolution (for example,

defocus blur) by applying an inverse convolution, a process known as "deconvolution". However that inverse does not in general have a finite impulse response. And, because some frequency-domain components of the original convolution may be very small indeed — the high-frequency components of a blur, for example — their reciprocals can be very large, which makes the problem ill-conditioned — that any noise in those frequencies will be enormously amplified by the inverse filter. Wiener filters are the usual compromise solution to this problem.

In two dimensions the impulse response is sometimes called the "point spread function", and sometimes, especially in imaging optics, it's also called the "output transfer function". In the context of computing a convolution it's also called a "kernel". Older papers sometimes call it the "response function" or "amplitude response".

Also, the probability distribution of a sum of random variables is the convolution of the probability distribution of the individual random variables, from which you should be able to see that convolution is commutative and associative. The damned thing just pops up everywhere!

Convolution defined mathematically

Mathematically, the definition of discrete convolution is almost comically simple; using * for convolution:

$(f * g)_t = \Sigma_i f_i g_{t-i} = \Sigma_i f_{t-i} g_i$

Here i ranges over all possible values and t might be some D-dimensional index as well as just an integer. For example, when we're convolving images, it's an (x, y) pair. g might be the impulse response (the "kernel") of some system we're simulating on input f. (You can easily verify that, if $f_0 = 1$ and $f_t = 0$ for all other t — that is, f is a discrete unit impulse — it merely reproduces g.)

(Continuous convolution is the same thing but with an integral.)

Yay convolution!

Despite this extremely broad spectrum of existing applications, I think convolution is actually an underappreciated operation that could be applied much more widely than it is. See the "convolution" section of More thoughts on powerful primitives for simplified computer systems architecture (p. 1895) and Convolution applications (p. 2930) for more detail. One reason it isn't applied more broadly is that it's computationally pretty expensive. And that's where the earthshaking discovery of SVD convolution comes in!

Singular-value decomposition convolution

XXX This section is repetitive

The amazing SVD convolution algorithm uses a "low-rank linear approximation" to approximate convolutions of an image with arbitrary kernels. I first ran across it in Fast Bokeh Effects Using Low-Rank Linear Filters (McGraw, 2014), where it's used to simulate camera bokeh. The basic idea is that you approximate an arbitrary filter kernel, as McGraw says, with a sum of a few separable kernels, which you derive by using SVD (see below for a brief explanation if you're as naïve about linear algebra as I am) on the original kernel. Usually most of the singular values are very small, so you can throw them out.

The algorithm treats the rows and columns of the point spread function you want to approximate as the rows and columns of a matrix, and then uses the singular-value decomposition to find a "best" rank-N approximation of that matrix. You could think of this as approximating each column of the filter kernel as a linear combination of N principal-component columns, which are chosen to represent as much column-to-column variation as possible. (Or analogously for rows.)

There is nothing in SVD convolution that is specifically limited to bokeh; it is a very general technique for efficiently approximating any arbitrary two-dimensional convolution! The speedup you can get without unreasonable degradation depends very much on the kernel you're trying to approximate, but very often kernels contain sufficient similarity between rows or columns to permit an excellent approximation with only a few separable terms.

SVD convolution is specifically two-dimensional, because it relies on the singular-value decomposition (SVD) to compute the N separable filters whose sum is the least-squares-closest rank-N approximation to the original filter kernel. Each of these filters is represented by a pair of vectors, one a horizontal convolution kernel and one a vertical convolution kernel, whose outer product is a matrix that is the convolution kernel of the composition of those convolutions. The sum of the N of these matrices corresponding to the N largest singular values forms the optimal approximation.

In the bokeh paper, McGraw typically got visually very good results with bokeh kernel approximations of rank 3 or greater.

Singular-value decomposition (SVD)

(You can probably skip this if you know linear algebra well, but I don't.)

Singular-value decomposition is a generalization of eigendecomposition† to nonsquare matrices; it decomposes some arbitrary matrix M as a product of three matrices $\mathbf{M} = \mathbf{U\Sigma V^*}$, where $\mathbf{U}$ and $\mathbf{V}$ are orthogonal (or more generally unitary) and $\mathbf{\Sigma}$ is diagonal. One of many interesting ways to view the result is as a series of least-squares-optimal approximations of the original matrix whose terms are *separable* matrices, meaning that they can be expressed as the outer product of some pair of vectors. Specifically, they are the outer products of corresponding columns of $\mathbf{U}$ and $\mathbf{V}$, scaled by the members of the diagonal of $\mathbf{\Sigma}$; because in general a matrix product $\mathbf{AB}$ can be seen as the sum of the outer products of the columns of $\mathbf{A}$ with the corresponding rows of $\mathbf{B}$.

†*Eigendecomposition* is the decomposition of a square matrix using its *eigenvectors*, a term whose only advantage is as a shibboleth for exposing Malcolm Gladwell — the Spanish term *autovector* is much more informative. I only mentioned this because if you already know about eigenvectors, the above explanation of SVD will be easier to understand.

Since those columns of $\mathbf{U}$ and $\mathbf{V}$ are unit vectors, the elements of $\mathbf{\Sigma}$ are what tell you how big the contribution of each of these separable matrices is to the final matrix sum, so you can get the best N-term approximation by taking the columns corresponding to the N largest elements of $\mathbf{\Sigma}$, which are by convention ordered to be first. It turns out that this is the optimal N-term approximation in the sense of the

Frobenius norm — that is, in the sense of differing by a matrix with the smallest Frobenius norm (the sum of squares of all the elements).

In Numpy the SVD is found at numpy.linalg.svd, which is a wrapper around LAPACK's `*gesdd`, which mostly works by calling `*bdsdc`, both by Ming Gu and Huan Ren. (The `*` is the data type in question.)

Separable filters

A separable filter is a two-dimensional convolution you can compute by first doing a one-dimensional convolution on each row and then doing a one-dimensional convolution on each column of that result. (Or vice versa, since, as it turns out, convolutions commute.) This is great because if you have a convolution kernel that is $w \times h$ and you try to calculate the convolution by brute force, you need $w \cdot h$ multiply-accumulates per pixel, but you can do a separable filter with just $w + h$ multiply-accumulates per pixel. So if you have an 11×11 kernel you can get by with 22 multiply-accumulates instead of 121. Big win!

(That is, your horizontal one-dimensional convolution uses 11 multiply-accumulates on pixels in the same scan line to calculate each pixel of the intermediate image, and then the vertical one-dimensional convolution uses 11 multiply-accumulates on intermediate-image pixels in the same column to calculate each pixel of the final image — 22 in all.)

It turns out that doing this pair of 1-D convolutions is equivalent to doing a 2-D convolution with the outer product of the two convolution kernels, as you can easily calculate.

There are three very popular separable 2-D filters: box filters, double-exponential filters, and Gaussian filters. Box filters and double-exponential filters are popular because you can calculate them in just a few operations per pixel, like, about three along each axis. Gaussian filters are popular because they're circularly symmetric, and they're the *only* separable circularly symmetric filters; also, there are a fair number of physical phenomena with Gaussian behavior, but they get applied pretty often in wildly inappropriate ways. The most common way to approximate a Gaussian filter is actually to run a few iterations of one of the other two, which works because of the Law of Large Numbers.

Since the outer product of two vectors $u \otimes v$ is separable in this way, and any matrix product $\mathbf{UV}$ is a sum of separable terms — each the outer product of a column of $\mathbf{U}$ and the corresponding row of $\mathbf{V}$ — any decomposition of your convolution kernel into a product of two matrices gives you a way to express it as a sum of separable kernels. The outstanding advantage of SVD is that it gives us a decomposition where *as much as possible* of the result comes from *as few as possible* of these outer-product terms.

History

As I said above, SVD convolution was explored extensively in the 1970s and 1980s. The seminal paper is probably Treitel and Shanks, "The Design of Multistage Separable Planar Filters", in 1971:

> A two-dimensional, or planar, digital filter can be described in terms of its planar response function, which is in the form of a matrix of weighting coefficients, or filter array. In many instances the dimensions of these matrices are so large that

their implementation as ordinary planar convolutional filters becomes computationally inefficient. It is possible to expand the given coefficient matrix into a finite and convergent sum of matrix-valued stages. Each stage can be separated with no error into the product of an *m*-length column vector multiplied into an *n*-length row vector, where *m* is the number of rows and *n* is the number of columns of the original filter array. Substantial savings in computer storage and speed result if the given filter array can be represented with a tolerably small error by the first few stages of the expansion. Since each constituent stage consists of two vector-valued functions, further computational economies accrue if the one-dimensional sequences described by these vectors are in turn approximated by one-dimensional recursive filters. Two geophysical examples have been selected to illustrate how the present design techniques may be reduced to practice.

The paper doesn't use the term "singular-value decomposition", perhaps because it was new at the time, instead explaining how to derive the SVD from eigendecomposition. By 1975 papers were using the term.

In 1980 Sang Uk Lee did his dissertation on it, "Design of SVD/SGK Convolution Filters for Image Processing", citing Treitel and Shanks 1971 and also Twogood and Mitra's 1977 "Computer-Aided Design of Separable Two-Dimensional Digital Filters", which also cites Treitel and Shanks. Andreas Antoniou and what I assume are his students, such as Wu-Sheng LU and Hui-Ping WANG, continued publishing on the subject through the 1980s, and, for example, in 1990 published "Design of Two-Dimensional FIR Digital Filters by Using the Singular-Value Decomposition", in which they find ways to further modify the filter to decrease the computational load, one using LU decomposition.

Mitra, Grosen, and Neuvo published a couple of papers in 1985 on extending the algorithm to one-dimensional signals by partitioning them into equal-sized chunks.

Work continues today, perhaps at a reduced pace; Atkins, Strauss, and Zhang published "Approximate convolution using partitioned truncated singular value decomposition filtering for binaural rendering" in 2013 on a way to filter audio to produce the binaural sensation of space, and in 2014 McGraw published the paper where I learned about the technique. McGraw doesn't cite this earlier work and seems to be unaware of it; he may have invented the technique independently 40 years later.

Of all of the above, I find Lee's dissertation to be by far the most readable, perhaps in part because it's jargon-compatible with me. The earlier work largely uses terminology I find confusing, and the later work assumes familiarity with the earlier work. The Treitel–Shanks paper is a close second, despite the alien jargon, because it's very well written, but of course it only covers developments up to 1971.

A toy example

With Numpy and SciPy, it's pretty easy to test the algorithm out; the following took me about half an hour with IPython. It's probably better to use IPython or Jupyter, with `%pylab inline`, so you can use `matshow` to see the values as images.

First, let's compute a flat circular convolution kernel, like a typical camera bokeh:

```
>>> import scipy.signal
>>> import numpy.linalg
>>> import numpy
```

```
>>> r = range(-8, 9)
>>> x, y = numpy.meshgrid(r, r)
>>> circle = (x**2 + y**2 < 64)
>>> # matshow(circle)
>>> print('\n'.join(''.join(map(str, 0 + row)) for row in circle))
0000000000000000
0000011111100000
0001111111111000
0011111111111100
0011111111111100
0111111111111110
0111111111111110
0111111111111110
0111111111111110
0111111111111110
0111111111111110
0111111111111110
0011111111111100
0011111111111100
0001111111111000
0000011111100000
0000000000000000
```

Let's generate an image to convolve with that circle kernel — all zero except for a couple of bright points at (2, 2) and (8, 13). Numpy array coordinates are in (row, column) order, which is to say, (y, x).

```
>>> p = numpy.zeros((16, 16))
>>> p[2, 2] = 3
>>> p[8, 13] = 2
>>> # matshow(p)
>>> p
array([[0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 3., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 2., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.],
       [0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0., 0.]])
```

We can do the convolution with brute force using scipy.signal.convolve2d:

```
>>> perfect = scipy.signal.convolve2d(p, circle)
>>> # matshow(perfect)
>>> print('\n'.join(''.join(map(str, row.astype(int))) for row in perfect))
```

```

00000000000000000000000000000000
00000000000000000000000000000000
00000000000000000000000000000000
00000000000000000000000000000000
00000000000000000000000000000000
>>> perfect.max(axis=0)
array([0., 0., 0., 3., 3., 3., 3., 3., 3., 3., 3., 3., 3., 5., 5., 5.,
       5., 2., 2., 2., 2., 2., 2., 2., 2., 2., 2., 0., 0., 0.])
```

Now let's compute the same result using SVD convolution instead.

As it happens, at 17×17, the circle only has four distinct nonzero columns, so, considered as a matrix, its rank is 4. Consequently, it has four nonzero singular values, not counting rounding errors:

```
>>> u, s, v = numpy.linalg.svd(circle)
>>> s
array([1.33371921e+01, 3.01484321e+00, 2.04182621e+00, 1.36417508e+00,
       3.34375584e-16, 1.28668530e-16, 7.48637395e-17, 3.74505958e-17,
       5.96041076e-32, 4.06050202e-33, 3.67797309e-33, 5.31269989e-34,
       2.72274806e-49, 1.79207201e-49, 1.91581056e-50, 0.00000000e+00,
       0.00000000e+00])
```

numpy.linalg.svd gives us **Σ** as a vector, as seen above, and **V** in its transposed form ready to multiply. So we can, for example, reconstruct a rank-3 approximation of the circle and measure its error as follows:

```
>>> circle3 = (u[..., :3] * s[:3]).dot(v[:3, ...])
>>> # matshow(circle3)
>>> ((circle3 - circle)**2).sum(), (circle**2).sum()
(1.8609736397047545, 193)
```

We can use the same brute-force approach to convolve this approximation with the image, which doesn't save us any computation time, but does validate that the low-rank approximation, this sum of three separable kernels, does some kind of a reasonable approximation:

```
>>> approx3 = scipy.signal.convolve2d(p, circle3)
>>> # matshow(approx3)
>>> approx3.max(axis=1)
array([0.        , 0.        , 0.        , 2.96621523, 3.09214447,
       3.28014338, 3.28014338, 3.09214447, 3.09214447, 3.23906193,
       4.69144233, 5.27890672, 5.27890672, 5.06351288, 5.34157302,
       5.34157302, 4.46037644, 2.96621523, 2.06142965, 2.06142965,
       2.18676225, 2.18676225, 2.06142965, 1.97747682, 0.        ,
       0.        , 0.        , 0.        , 0.        , 0.        ,
       0.        , 0.        ])
>>> print('\n'.join(''.join(map(str, (row + 0.5).astype(int))) # rounding
                    for row in approx3))

000000000000000000000000000000000
```

So now let's try the algorithm more or less for real. First, we convolve each column of **U** with each row of our picture `p`, thus getting one horizontally-convolved intermediate image for each term of our approximation. There's probably a way to do this purely with Numpy without using Python interpretive `for` looping:

```
>>> hterms = numpy.array([[s[j] * numpy.convolve(u[..., j], p[i])
                          for i in range(len(p))]
                         for j in range(len(u[0]))])
>>> #matshow(hterms[0])
```

Here are a couple of rows from the first approximation term:

```
>>> hterms[0][1:3]
array([[  0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ],
       [  0.        ,   0.        ,   0.        ,  -6.00495857,
         -9.16629667, -10.54084337, -10.54084337, -11.44132655,
        -11.44132655, -11.44132655, -11.44132655, -11.44132655,
        -11.44132655, -11.44132655, -10.54084337, -10.54084337,
         -9.16629667,  -6.00495857,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ,
          0.        ,   0.        ,   0.        ,   0.        ]])
```

Then we can convolve each row of `v` (**V***) with each *column* of its corresponding intermediate image, thus generating a stack of images that are the terms of our approximation; the sum of the first three of these is equal to the result of our brute-force convolution with the approximation from earlier, except for rounding error:

```
>>> terms = numpy.array([numpy.array([numpy.convolve(v[j], hterm.T[i])
                                      for i in range(len(hterm.T))]).T
                         for j, hterm in enumerate(hterms)])
>>> approx3_fast = terms[0:3].sum(axis=0)
>>> # matshow(approx3_fast)
>>> abs(approx3_fast - approx3).max()
4.884981308350689e-15
```

And, because our kernel in this case is only of rank 4, the rank-4 approximation, summing four separable kernels, is exactly equal to the correct convolution result, again except for rounding error:

```
>>> abs(terms[0:4].sum(axis=0) - perfect).sum()
4.3509640335059885e-13
```

I say that was *more or less* for real because I calculated all the terms, not just the first four terms that I used, and I was using interpretive

loops rather than trying to get `convolve2d` to do one-dimensional convolutions, so running it exactly as above on a larger image would be *slower* than the brute-force approach.

Direct applications

SVD convolution can be applied directly to sharpening and blurring images, to Wiener filtering of images that have been corrupted by suboptimal optics, to object recognition and convolutional feature extraction in images, and to computing approximations of the performance of optical systems. In the context of mathematical optimization, for example of simulated optical systems, a computationally inexpensive approximation is immensely valuable, because it allows many more optimization cycles to run.

For applications like object recognition in images, it's common to have many more candidate filter kernels than images. In this case, it might be more productive to use a low-rank approximation of the original image rather than of the filter kernels, which is guaranteed to work because convolution is commutative.

Extensions

What useful extensions of SVD convolution might be possible, but aren't simply straightforward applications of it?

To more dimensions

The D-dimensional equivalent problem is well-posed: find N sequences of D vectors whose D-dimensional outer products sum to form the optimal approximation to the original D-dimensional convolution kernel. It can't be solved directly with SVD, but maybe there's a way to apply SVD more indirectly to a couple of dimensions at a time, or maybe you could use a recursive iterative-approximation algorithm that subtracts off the D-dimensional outer product of the average vectors of the residual along each dimension. If not, I'm optimistic that, e.g., gradient-descent variants like Adam or quasi-Newton methods are sufficiently powerful to find a good solution.

I ran across a 2009 paper by Oseledets and Tyrtyshnikov, "Breaking the curse of dimensionality, or how to use SVD in many dimensions", which explains something called "the *Tree-Tucker* format" using "Tucker decomposition"; this sounds similar to the above. I haven't finished reading it.

To one dimension

If $D = 1$, then the problem as posed above is trivial: the convolution kernel is a vector, and it is its own best vector approximation, $N = 1$. To get a more useful result, we would need to find a way of somehow approximating the convolution with shorter vectors.

One possibility is to "word-wrap" or "raster" a one-dimensional time-domain sequence of $a{\cdot}b$ points into a two-dimensional signal of dimensions $a \times b$ where a is small compared to the size of our desired kernel, ideally close to its square root. Then you raster the kernel analogously into an $a \times c$ shape. If you do wraparound onto the previous and next a-element "scan line", a two-dimensional convolution on these two-dimensional signals is precisely the same

thing as the original one-dimensional convolution. If the kernel has substantial periodicity, the way bandpass convolution filters do, SVD may yield a good low-rank approximation if a is a multiple of its period. But if the columns of the kernel are perfectly uncorrelated, no good low-rank approximation will exist.

So, computing the original time-domain convolution by brute force required ac multiply-accumulates per sample, and now we can do it in $a + c$ multiply-accumulates per sample per term — if we're using a rank-3 approximation, $3(a + c)$ multiply-accumulates per sample. This is a win if $3(a + c) < ac$ — if $a \approx c$, that's roughly $6a < a^2$, which is true if $a > 6$, or more generally, is more than twice the rank of the approximation.

Unwrapping the above computation back into one dimension, we can view each term of this algorithm as first doing a size-a one-dimensional convolution, then a *sparse* size-ac one-dimensional convolution, with c taps at intervals of a.

(I think all of the above is in the Atkins et al. paper from 2013 that I mentioned above, but I haven't really read it yet.)

A key observation here is that there's no particular reason for these terms to use the same value of a, and in fact it's probably advantageous for them to use *different* values of a, because the first pass using a_0 will probably suck up most of the energy at frequencies that fit neatly into a_0 — the residual error will be particularly low around those frequencies. So it might be a good idea to use a sequence of strides a_1, a_2, etc., zero-padding the kernel if necessary, to get a better "low-rank" approximation. The autocorrelation function of the residual kernel is probably a good guide to picking those strides, although this greedy algorithm might not produce optimal results.

Also, since this reduces one linear convolution to two or more cheaper linear convolutions, it can be applied recursively — for example, you could reduce a 1000-tap kernel to a 10-tap kernel and a 100-tap kernel, then reduce the 100-tap kernel to two 10-tap kernels. This is clearly cheaper to compute if you're only using the first vector from the SVD, but you might need more than one! If you use more, we're not talking about *two* 10-tap kernels in the final stage, but about *many* final 10-tap kernels — 4 of them if you use two components each time. Still a big win — $2{\cdot}10 + 4{\cdot}10 + 4{\cdot}10 = 100$, much less than 1000 — but less so.

If you do this kind of recursive decomposition (which, incidentally, can also be used on the one-dimensional kernels that result from the two-dimensional algorithm), the SVD no longer gives you fully optimal results, because you aren't precisely using the first principal components — you're using some approximation to them, leaving some extra error. This suggests that some kind of iterative algorithm like the greedy algorithm described above will probably produce better results.

(I think you can probably approximate the first principal component reasonably efficiently by using the PageRank algorithm on **M*M** and **MM*** to get their largest eigenvectors, rather than computing the full SVD.)

On prefix-sum images (uh, probably not)

One of the annoying features of the low-rank approximations produced by SVD is that they don't deal very well with diagonal

edges or gradients in the kernel. I wonder if you could "precondition" the image by running horizontal and vertical prefix sums on it (allowing wraparound on overflow) and apply compensating finite-difference operators *on the kernel* before computing the SVD approximation. Without the approximation step, this would be precisely equivalent, because the integration and differentiation operators cancel, and convolution is associative. But perhaps by removing the large-scale structure from the kernel, leaving more local differences, the SVD approximation would have less error.

As an extreme example, consider a kernel like this contrived rank-5 specimen:

```
 1  2  3  4  5
 2  4  6  8 10
 3  6  9 12 15
 4  8 12 16 20
 5 10 15 20 25
```

Upon applying a horizontal backward differences operator to it (the inverse of horizontal prefix sum), you get this rank-1 result:

```
1  1  1  1  1
2  2  2  2  2
3  3  3  3  3
4  4  4  4  4
5  5  5  5  5
```

And on differencing that vertically, you get this singular matrix:

```
1  1  1  1  1
1  1  1  1  1
1  1  1  1  1
1  1  1  1  1
1  1  1  1  1
```

This kernel is clearly much easier to represent.

I'm very much not sure that this would help, though; I think it depends on the kinds of features you find in kernels.

(P.S. I tried it on a kernel like the circle bokeh kernel above. It made the approximation enormously worse.)

Simple state machines

Kragen Javier Sitaker, 2016-09-19 (updated 2016-09-24) (8 minutes)

I was thinking about laser-cut mechanical computation systems. What are the simplest finite-state machines I could usefully implement?

Bit transformation pipelines

The simplest finite-state machines have two states and two inputs. There are 16 possible such machines, corresponding to the 16 fundamental logic gates. Calling the state Q and the input I, we can display all 16 state transition tables as one:

```
Q I   new state; each column defines a machine
0 0   0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1
0 1   0 0 0 0 1 1 1 1 0 0 0 0 1 1 1 1
1 0   0 0 1 1 0 0 1 1 0 0 1 1 0 0 1 1
1 1   0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1
```

Many of these machines are not very interesting; you kind of need transitions in both directions between the states to be interesting. That reduces the table to the following:

```
Q I   new state; each column defines a machine
0 0   0 0 0 1 1 1 1 1
0 1   1 1 1 0 0 0 1 1
1 0   0 0 1 0 0 1 0 0
1 1   0 1 0 0 1 0 0 1
```

You also probably want to eliminate the state machines where the two possible inputs are equivalent. If the two states are equivalent, that might still be okay, because the state itself might be the machine's output. This eliminates one more machine, which alternated between states incessantly regardless of the input, reducing the table to the following:

```
Q I   new state; each column defines a machine
0 0   0 0 0 1 1 1 1
0 1   1 1 1 0 0 0 1
1 0   0 0 1 0 0 1 0
1 1   0 1 0 0 1 0 1
```

We can characterize these eight machines as follows:

- 0100: stable in state 0 when the input is 0, but when triggered by a 1 input, transitions to state 1 for one cycle. Alternatively you could call it a controllable oscillator: the input turns it on, and when the input is off, it stays in state 0.
- 0101: its state is the input from the previous cycle. This is basically a D flip-flop.
- 0110: stable in either state when the input is 0, but oscillates when the input is 1. This is basically a T flip-flop.
- 1000: the same as 0100 with the sense of the input inverted.

• 1001: the same as 0110 with the sense of the input inverted.
• 1010: its state is the inverted input from the previous cycle, like a D flip-flop's Q̄ inverted output.
• 1101: stable in state 1 when the input is 1, but when triggered by a 0 input, transitions to state 0 for one cycle. This is the same as 0100 but with the input and the state both inverted.
• 1110: same as 1101, but with the input inverted.

We can classify these "interesting" machines into three categories of behavior. Oscillators (0100, 1000, 1101, 1110) produce a Nyquist-frequency square wave when the input is in one state, or a constant history-independent output when it is in a different state. Delays (0101, 1010) delay the input by a clock cycle (and 1010 inverts it too). Bistable machines (0110, 1001) can stably remember a bit of information over time, but there is a given input that will cause them to switch (1 for 0110, 0 for 1001).

In a sense these machines all have "fan-in": even though they only have a single one-bit input, their output is a function of their previous input history (and initial state) as well their current input. But because they can only take a single input, the only topology in which you can hook them together is as a fanning-out tree, in which any given bit of output is produced from a linear pipeline of state machines from the input bitstream. (Alternatively, you could hook them up into a loop, taking no input from outside.)

This may be adequate to do things like produce a binary count of the number of 1 bits in a bitstream, although I'm not even sure of that. An interesting question is whether such a pipeline can in some sense emulate any arbitrary finite state machine (that doesn't get stuck), or what its expressive limits are, and how many of the above machines are needed to provide that expressiveness — presumably you need at least a bistable machine.

The lack of signal fan-in keeps the delay machines from being especially useful in this context, so we can consider just the bistable and oscillator machines.

If you feed a Nyquist-frequency square wave into a bistable machine, you get a half-Nyquist-frequency square wave. If you feed that into the appropriate kind of oscillator, it will reduce the duty cycle of the square wave; feeding that into another bistable machine gives you a quarter-Nyquist-frequency square wave. Feeding that into another bistable machine gives you the repeating sequence 10100000 or its complement. If you feed that into a bistable 0110 that's initially in the 0 state, it becomes 01000000, which when fed to another one becomes an eighth-Nyquist-frequency square wave.

This brings up the interesting fact that the initial states of the state machines can matter a lot. You could imagine a loop of such machines whose "input" is provided entirely by its initial state.

Time-delayed logic gates

If we consider state machines with two states and two binary inputs, one of them is a time-delayed NAND gate:

```
Q I J  new state
0 0 0  1
0 0 1  1
0 1 0  1
```

```
0 1 1   0
1 0 0   1
1 0 1   1
1 1 0   1
1 1 1   0
```

This is clearly sufficient for universal computation on its own, without any other kinds of machines.

Is there some kind of finite state machine that is in some sense simpler than this, but that still allows us to build universal computers by connecting networks of them together? I don't think there is.

J-K flip-flops

Above I mentioned that D and T flip-flops were two of the three kinds of interesting bit-transformation machines. J-K flip-flops are more widely used as a discrete component; their state transition table, assuming active-high inputs, looks like this:

```
Q J K  new state
0 0 0  0
0 0 1  0
0 1 0  1
0 1 1  1
1 0 0  1
1 0 1  0
1 1 0  1
1 1 1  0
```

This seems to me like it is certainly a universal gate in the same sense as the delayed NAND above, which is in some sense of equivalent complexity. You have inputs that will set the stored bit or clear it when they are high, and you can connect them to separate places. Additionally you have the magic power of making the output oscillate by putting them both high.

This extra magic power is pretty clearly not needed; you could use it as just an S-R flip-flop. But if you try to use this to simplify the machine, you are kind of forced to lump J and K together into one input:

```
Q I  new state
0 0  0
0 J  1
0 K  0
1 0  1
1 J  1
1 K  0
```

The problem with this is that you have lost not just fan-in but also compositionality; this machine's state can no longer be the input of another identical machine.

Hearing aids for disability compensation, protection, and augmentation

Kragen Javier Sitaker, 2019-09-08 (updated 2019-09-09) (4 minutes)

I want a hackable hearing aid for three reasons: disability compensation, protection, and augmentation. I was hoping to get one this year, but that seems unlikely now.

Disability compensation

This body is considerably more sensitive to strong stimuli than average human bodies, due to a syndrome known as autism. Sounds such as a pneumatic cylinder opening a bus door or a whistle during applause cause it acute pain, though that pain fades immediately — the main difference from the pain of, for example, barking one's shins on a pipe. Moreover, continued stimulation at a lower level, such as the traffic noise outside the window, cause continued low-level stress.

Earplugs mechanically block high-frequency sounds, reaching attenuations of some 30 dB above around 200–400 Hz, but they are helpless against sounds below 100 Hz. Complementarily, noise-canceling headphones like the Bose QuietComfort 25 can attenuate low-frequency sounds by some 30 dB by generating cancelation waves, but this benefit starts to roll off above some 100 Hz.

A hearing aid with noise-cancelation firmware offers both benefits at once, and has the major benefit that it is socially acceptable; the other humans will tolerate it considerably better than they will tolerate a human wearing earplugs or headphones during a conversation. Also, they can offer customizable nonlinear and time-variable attenuation curve, for example performing no attenuation while sound levels are under 60 dBa.

Hearing-aid earmolds are also safe and comfortable to wear for many hours a day, while disposable earplugs tend to cause irritation and even pain after more than an hour or three.

Protection

Aside from the pure pain, loud noises can also cause ear damage, and in the same way that earplugs and noise-cancelation headphones can prevent pain, they can also prevent damage.

Augmentation

A hearing aid with wireless communication can provide a private audio output channel from personal computers (pocket and otherwise), for example to provide alerts, reminders, or query results. Furthermore, it can also provide a private audio *input* channel to personal pocket computers, since it has a microphone; use as a substitute for Bell's Telephone is one possibility. Autonomous computing operation, including peer-to-peer Bluetooth communication, is another whole class of potential uses.

As discussed in Bokeh pointcasting (p. 92), a private bidirectional

communication channel to an external computing resource can, under some circumstances, save your life — the case considered there was sounding an alarm during armed home invasion.

Cocktail-party beamforming, perhaps using a chest-mounted microphone array, might enable this body to participate in social events it is currently excluded from, due to its inability to understand anything anyone is saying.

With ultrasound-capable microphones, simple heterodyning software could make bat calls audible. Other forms of "extrasensory perception" are implementable: detection of magnetic fields, electric fields, radio waves, carbon monoxide, anoxic atmospheres, objects such as motorcyclists rapidly approaching from behind, and so on.

Such intimate integration of a computer into a human life demands extreme caution about privacy and computer security problems, given the deplorable state of human computer security.

All of this is limited by battery considerations, though perhaps a flat-flex cable from the hearing aid taped to the back of the neck with flesh-colored tape could provide access to a much larger battery in, say, a pocket; energy-harvesting antennas may also be an option.

Holographic archival

Kragen Javier Sitaker, 2014-04-24 (10 minutes)

I thought I'd written about this before, but I can't seem to find it in the archives.

The Rosetta Project wants to make an etched nickel-alloy disc with reduced-size images of some ten or twenty thousand pages, readable under a 650× optical microscope. They're using a process developed at Sandia based on microchip etching techniques — that is to say, microphotolithography.

This approach has a few significant drawbacks:

• It's extremely expensive. We're used to microchips being cheap, but in fact they cost several dollars each, and each of the Rosetta discs is like an entire wafer, not a single microchip. So we can expect the price per disc to stay in the hundreds to thousands of US dollars.
• You need a microscope to read it. It would be better if you could read it with no special equipment, or only very simple special equipment, such as could be easily improvised from rocks.
• The information capacity is limited by the wavelength of light. Pixels in the original image can't be more than about half a wavelength across for an optical microscope to resolve them: figure 250nm. That gives you a density of, at best, 16 terabits per square meter. With the 7.6-centimeter Rosetta disk, you only have 72 gigabits, not even enough for English Wikipedia in a readable font.

Suppose we could instead usefully encode archival information at a density substantially higher than a light wavelength, reproduce it cheaply, and read it without special equipment. That might produce a much more useful Rosetta disc.

I think that rainbow holography may provide this medium. Rainbow holograms have been inexpensively mass-produced since 1984; they can be viewed in sunlight; and their ability to encode many images in the same film is limited by the film resolution and the directionality of the light source.

Rainbow holograms can present a different image for each angle within an 180° viewing arc. The resolution of this image is degraded as more images from more angles are recorded, and the angle of the illumination and viewer are limiting factors in the number of angles. The degradation of the image is vaguely related in a way I don't understand to the square root of the number of images.

The illumination angle from the sun is the first problem: the sun subtends some 32 arcminutes, and without further work, this limits you to about 330 distinct images. This is about 1½ to 2 orders of magnitude worse than our objective. Fortunately, direct sunlight is excessive; it amounts to about 100klx, while people can read comfortably at 100lx, three orders of magnitude dimmer. If you go into a camera obscura with the holographic archival disc, illuminated by the sun shining through a vertical slit, you can obtain illumination that is much more directional and therefore allows you much more precision in imaging. You simply set the disc in the beam of light stretching across the floor from the slit in the wall.

The slit should, ideally, reduce the illumination by about three

orders of magnitude from direct sunlight; but the illumination will vary across the beam, since the sides of the beam can only see the edges of the sun's disc, and will therefore be dimmer. If we try for a factor of 2 between the brightest and dimmest parts of the disc, then we want the points on the edge of the sun's disc at 30° above and below the horizontal, since sin 30° = ½. cos 30° ≈ 0.87, so we only lose about 13% of the sun's width this way, leaving us with a usable sun-disk width of about 28 arcminutes horizontally.

For a beam spreading out from a thin slit with a divergence of 28 arcminutes to illuminate a whole 7.6-centimeter-wide disc, the disc needs to be some 9.4 meters away from the slit, which makes for a pretty big camera obscura. Now, how wide is the slit? We want to see about a thousandth of the roughly 28-arcminute-wide sun through it. To see the entire 28-arcminute-wide chunk of the sun through it, it would be about 7.6 centimeters across; instead, it needs to be about a thousandth of that, or about 76 microns. That is, it would need to be about the width of a human hair, and at least some 10 centimeters tall, although ideally many meters tall. It doesn't need to be perfectly straight, but it can't deviate from the vertical by more than its width within the 10-centimeter-tall chunk illuminating the disk at any moment.

So that's probably a bit too stringent; it might allow us to put 330 000 naked-eye-viewable images on the disk, but only at the cost of the solar illumination mechanism being unreasonably finicky.

Suppose instead that we allow the slit to be a millimeter wide, which will also boost our light level from 100 lux to 1300 lux, which is quite comfortable. Now, at 9.4 meters, it subtends a 9400th of a radian, which means that the light can illuminate the disc from about 30 000 distinct angles. By rotating the edge of the disc 4 microns to the left or right, we can switch to the "next" or "previous" "page".

How about our eyes? If our pupils are too big, we may need to wear pinhole goggles, or peek through a finger pinhole, to see a single page instead of a mixture of several. If we're trying to read at a distance of one meter, so that we can reach the disc with our hands, then a 9400th of a radian is about 0.1 millimeters. Pupils only shrink down to about 3 to 5 millimeters, so such dense encoding would indeed require something like pinhole goggles; but rather than pure pinhole goggles, they can be vertical-slit goggles, which can probably be improvised adequately from rocks, sticks, etc.

Can we really interfere 30 000 distinct wavefronts and get an image of reasonable resolution and contrast? Supposing the "grain size" of the "film" is 50 nanometers and we're shooting for 100 dpi resolution, each of our 0.01" pixels contains about 5000×5000 grains. I'm vague on exactly how holography scales, but I'm pretty sure it can manage to encode a pixel each of 30 000 different images in 2.5 million grains.

So suppose we can get 30 000 frames at 100dpi on a disc in the form of rainbow holograms. How many pixels is that in total? $30000 \times \pi \times (\frac{1}{2}7.6\text{cm})^2$ is an effective area of 136m², or 2 gigapixels. That works out to 465 gigabits per square meter. This is not nearly as good as the current Rosetta disc's microscopy approach, although it would still make the disc quite a bit denser than a book.

(Is there a limit in angular resolution resulting from the light itself? There must be: the light path length from the source to the hologram to the eye needs to differ by at least half a wavelength for a pixel to go

from light to dark, right? At (half of) 500nm over a hundredth of an inch, we have an angle of about 1 milliradian, which is actually a much more stringent limit than the slit width thing: it would limit you to about 3100 frames.)

Non-rainbow holograms could get some three orders of magnitude higher storage density by using both dimensions, but as far as I know, can only be read under laser illumination. Perhaps you could get 500 terabits per square meter that way.

As for manufacturing, the common approach to manufacturing rainbow holograms is embossing: you nickel-plate the master hologram, then squish molten plastic against it, then take the now-shaped plastic off and plate it with something — typically aluminum, but nickel would work too, and probably last longer. (Remember, we're talking about millennia here.) Ideally you'd use entirely amorphous materials (glasses) to avoid noise due to crystal grain boundaries, entirely covalently bonded materials like SiO_2 for chemical stability and hardness, and thoroughly oxidized materials like SiO_2 for chemical stability and resistance to combustion. But producing a sufficiently shiny surface on glass (whether pure fused silica, borosilicate, soda-lime glass, or something else) might prove too difficult.

If your manufacturing cost is low enough and your material flexible and robust enough, then instead of a single disc, you could produce a codex. If you're storing some 500 gigabits per square meter, a hardback book consisting of 400 A5-sized pages could store 6 terabits in human-readable form.

For the case of holographic archival discs, you probably want to compute the original image, if possible, rather than attempting to produce it with thousands of interfering optical wavefronts. Bill Beaty's scratch holograms provide a practical way of doing this that wouldn't require computing trillions of grains in order to store billions of pixels. They also, like rainbow holograms, limit you to one direction of parallax motion.

Topics

Single-point incremental forming of aluminum foil

Kragen Javier Sitaker, 2019-03-11 (updated 2019-06-10) (14 minutes)

I'm sitting in a café with a wall covered in embossed tiles, which I think are plastic painted to look like brass with a heavy patina. Some parts of the tiles have a sort of leather pattern, while other parts have raised floral designs and the like.

Despite the enthusiasm for 3-D printing via FDM, most of the things people make with it have very limited mechanical properties; instead they primarily are of interest because of their appearance — the infill is commonly a honeycomb or cross pattern with 60% to 90% empty space inside the outer shell. But appearance is mostly a function of the surface — entirely so, in the case of opaque objects. So perhaps a process that shapes only a surface may be of interest.

Single-point incremental forming, or "SPIF", is an emerging industrial process for rapid prototyping, which is to say it barely works at all and it's slow, but flexible. The idea is that you clamp a metal sheet around the edges and poke it with a stick; in cross section in ASCII art:

```
|clamp|     | |           |clamp|
-------      U            -------
---------------------------------
-------                   -------
|clamp|                   |clamp|
```

Where you poke it, you make a divot by stretching ("forming") the metal out the other side of the sheet, and if you drag the stick along the surface without letting up the pressure, you can make a groove. (Generally you use a rounded-end tool and you lubricate and/or rotate it to keep it from sticking.) You can see the same process in action if you try to write on paper with a ballpoint pen with no ink.

Where this gets interesting is that if you make the groove, say, circular, the metal inside the groove has nothing pulling it up, so it gets pulled down to the level of the bottom of the groove, making a flat circular depression. Then you can do the process again inside there to make the depression deeper, and so on. The same considerations of thinning, wrinkling, springback, and work-hardening that apply to deep drawing apply here, but since SPIF is mostly used for one-offs where you can't afford the investment to make stamping dies (though sometimes people use it with dies too) you need to use FEM software to simulate them.

(The low-tech approach to this whole thing is hammering sheet metal into shape over a form.)

I was thinking that maybe you could do this with aluminum foil with really minimal force. Aluminum foil also has the advantage that it's thin enough that you can easily cut it with a spark; and, if you need to anneal it, you can be sure of a uniform temperature through

the thickness of the material, and since aluminum doesn't need a soak time at high temperatures to anneal it, it can be done very quickly. (This requires heating to close to the melting point; people sometimes use burnoff of carbon black on aluminum to indicate that it's reached the right temperature.)

SPIF forming of a depression is normally done from the outside in, with an empty space under the workpiece, which is clamped only at the edges; this requires workpiece to transmit the load from the forming tool back all the way to the edges. A possible improvement may be to do an initial forming step on a resilient backing, such as a sheet of rubber, or a disposable one, such as a sheet of cardboard, creating many parallel grooves with a bit of separation between them; this produces an accordion-fashion section which can then be unfolded with much less force once the backing is removd.

This is not very far from what you might do with a beading machine to raise a rib to stiffen a sheet-metal surface, the difference being that you're raising a lot of parallel ribs next to each other, and with the objective of selectively increasing compliance rather than decreasing it. The work-hardening of the metal obviously works against you here.

Electrotyping and molding

Electrotyping may be a particularly appealing next process step to apply, allowing the soft, easily melted aluminum to give its precisely-dimensioned form to metals like copper, brass, bronze, nickel, chromium, gold, or silver; I'm not sure how well electrotyped coatings will adhere to the aluminum's passivating oxide layer, and I don't think it's likely for cathodic reduction to eliminate aluminum oxide in water, but if it doesn't adhere well, that merely facilitates the removal of the aluminum for disposal.

Electrotyping is difficult to apply to alloys (whichever metal is easier to reduce tends to crowd out the other metals), although there are some processes that can electrodeposit some brasses and bronzes. But, by the same token, the electrodeposited metal may work well as a shell to fill with a harder alloy in the molten state. The easiest combination is presumably a copper or nickel shell filled with type-metal, which (as discussed in Flux deposition for 3-D printing in glass and metals (p. 1366) and Hot oil cutter (p. 3287)) melts at 241°, does not shrink upon solidifying, and does not dissolve iron or steel; I am guessing that it will not dissolve nickel either. It probably dissolves copper pretty well, since lead–tin solder does, but probably not very deeply in the time before it cools at the surface of the mold.

Copper doesn't melt until 1084°, and nickel doesn't melt until 1455°, meaning that in theory you could fill shells of them with materials of much higher melting points than the aluminum itself can survive — including, in the case of nickel, cast iron (see Flux deposition for 3-D printing in glass and metals (p. 1366)), which will definitely dissolve it. Dimensional precision may suffer from thermal contraction, although I seem to recall that cast iron in particular shares type-metal's happy property of neither expanding nor contracting upon solidification.

Various pot-metal alloys (Zamak, etc.) are also an option; in theory Zamak 2 melts at only 379–390° but has a yield strength of 361 MPa, better than ASTM A36 steel's 290 MPa (according to

Heckballs: a laser-cuttable MDF set of building blocks (p. 2782)) or 250 MPa (according to Wikipedia's A36 steel article), though the steel beats it at ultimate tensile strength. I think Zamak is more expensive than cast iron, though.

Alternatively, you might be able to cast directly into the aluminum foil, as long as the pressure isn't too high. According to Filling hollow FDM things with other materials (p. 2119), pure aluminum doesn't melt until 660°, and the alloy used for aluminum foil isn't too much below that. Casting will clearly involve some pressure that can deform the aluminum, but this may be small enough not to matter. Solder, type metal, ABS, PLA, lead, hard candy (sugar syrup), paraffin wax, thermoset resins such as silicone or PMMA, and Zamak should all be moldable directly in aluminum foil; some of these will stick permanently to it, but probably all of them will stick to it well enough to require deforming the aluminum foil irreversibly (plastically) for demolding.

Casting crystalline materials involves substantial loss of surface detail from crystallization, both from crystal grain growth directly distorting the surface and from the contraction or expansion that usually accompanies the phase transition. Glasses such as hard candy avoid this problem.

Promising qualitative results from a simple manual casting experiment

I deformed some aluminum foil (thin, about 10 μm†, times or divided by 2) with a ballpoint pen on top of some paper by drawing a sort of face on it, washed it with 96% ethanol, laid it on a glazed porcelain floor, and then melted some 60–40 tin–lead solder (183°–190°) on top of it, using a shitty non-temperature-controlled soldering iron. The solder was able to pick up most of the contours of the drawing accurately, but something black matter was stuck to the bottom of the solder and screwed up the impression. I think it came from rosin contamination of the tool that carbonized instead of boiling off, but it could also be a chunk of metal oxide from the tool, either copper or iron. The foil peeled easily off the solidified solder. The solder surface showed solder's usual dull finish, despite the bright finish of the aluminum foil that had molded it; I think this is probably due to wrinkling as the surface cooled before the interior and would be eliminated by adding antimony, as in type metal.

An earlier attempt using the same blob of solder was much less successful, because the bottom of the solder blob was full of bubbles, obliterating most of the submillimeter-scale contours I was trying to pick up. These might have resulted from oil contamination of the aluminum foil (e.g., from my hands) or from the rosin in the solder, which does volatilize significantly at the temperatures needed to melt the solder, let alone the higher temperatures the tool was presumably reaching.

Specks of the black material were also evident on the upper surface of the solder, and upon breaking it with pliers, apparently also in its interior. I was hoping to draw some sort of conclusion about its density or solder-wettability, but I don't know what to make of this.

The solder blob was about 1.5 mm thick. If the solder's density is 9 g/cc, which I haven't measured but should be about right (see A

phase-change soldering iron (p. 2270)) this works out to about 130 Pa of pressure on the aluminum, or 0.02 psi in folk units, which should put fairly small forces on the aluminum foil, not deforming it much except in very flat areas; the total weight of the solder over a square centimeter would be about 1.4 grams. However, I melted the solder directly on the surface by resting the soldering iron on top of it, so in this case the aluminum foil experienced much greater forces than the weight of the solder. Pouring already molten solder would avoid this problem

† I folded a piece of it in half 8 times and measured it at almost 2 mm with my caliper. If I knew where to find the battery for the caliper I'd be able to give a more precise measurement, but I don't think it's that critical — I'd expect anything from 10 μm to 125 μm (a Coke can I had lying around, though that includes the epoxy and paint) to give roughly similar results.

Exponential typing and Gutenberg

Suppose you use SPIF to cast some simple stamps in, say, solder, Zamak, or type metal, some 100 times thicker than the aluminum foil, and thus 100 to 10'000 times as rigid, depending on the deformation mode you're considering. (Well, before you account for the difference in moduli of rigidity between the aluminum and the other materials, but those are small by comparison.) You can then use these stamps to stamp or incrementally form more foil, which you can then use to cast or electroform further shapes, either in positive or in negative.

To take a simple example, you could use the SPIF process to form stems, serifs, and bowls of letterforms in foil, which you can then cast into stamps, which you can then stamp into an aluminum foil matrix to form letters, which you can then cast or electrotype into a font; the additional step of making up a stereotype for a page of text allows you to reuse the same letters for each page without losing the ability to reprint previous pages. A recent analysis of Gutenberg's books suggests he probably used such a process, although of course he wasn't using aluminum foil for the expendable soft matrix. (Likely materials that occur to me include clay bodies, plaster of Paris, and gold foil; I think papier-mâché, as used for stereotypes, wouldn't have worked for reasons of temperature limitations. Later printers used a thick, durable, work-hardening copper matrix instead, cutting a single punch from steel for each letter.)

But other shapes might also work reasonably. For example, you could use a tiny spherical SPIF tool to make a mold for a larger spherical SPIF tool; you could quite reasonably make stamping dies (at least for soft metals and slow stamping) to put ribs in things, stamping the ribs themselves with a series of stamps from torus-shaped rib positive and negative dies; and even features like countersunk holes to cast into thin sheets might be feasible. To cast half of a screw thread, you could possibly use a stamp with the form of a single turn of the screw thread, repeatedly; two such molds clamped together could cast an entire screw.

In cases where the cast material releases easily from the aluminum-foil matrix, you may be able to cast both a positive and a negative die simultaneously from the same sheet, thus ensuring a fairly close fit even if the sheet deforms significantly during molding.

Topics

A simple content-addressable storage-server protocol

Kragen Javier Sitaker, 2015-09-03 (3 minutes)

Here's a simple network protocol that provides a reasonably secure and reasonably efficient content-addressable storage system.

Basic operations

The fundamental operations provided by the protocol are PUT and GET. PUT has a single argument, which is an arbitrary blob — although in this case I am limiting blob sizes to those that can be passed in a single internet datagram; GET also has a single argument, which is the cryptographic hash of a single blob.

(If you have several servers providing this service, you can arrange them into a DHT as you see fit; the servers don't have to know about it.)

Adding security

Both of these are, in some sense, unauthenticated operations: if your data isn't public, you can encrypt it with a secret key before you store it in the public content-addressable store, and so attackers will gain no useful information by retrieving it. However, they are subject to denial-of-service attacks. First, since the server presumably has limited storage, the amount of data that can be successfully PUT to it and GETted back later is finite; second, since the server has limited bandwidth, the amount of data that can be PUT or GETted from it in a second is finite. Finally, GET could potentially be a tool in a source-spoofed DoS amplification attack on someone else: if the GET request is 20 bytes, but the resulting blob is 20000 bytes, you can multiply your bandwidth by 1000 by sending a stream of source-IP-spoofed GET requests to an innocent server, which will faithfully direct a firehose of traffic at your chosen victim.

I think we can add DoS-resistance to the protocol with hashcash (or other forms of making requests expensive — reciprocity IOUs, Bitcoin payments, etc.), and amplification-resistance with mandatory request padding.

Protocol proposal

So I propose an additional NO answer, and reusing the PUT packet to send answers. A typical PUT dialog looks like this:

client: PUT nonce=b, blob=a
server: NO nonce=c, difficulty=n
client: PUT nonce=d, blob=a (such that HMAC(c, a || d)[0:n] == 0)
server: PUT nonce=d, blob=a

And a typical GET dialog:

client: GET hash=e, nonce=f
server: NO nonce=c, difficulty=n, length=m (m = length(a))
client: GET hash=e, nonce=g, pad=h (such that HMAC(c, e || g)[0:n] == 0, and length(h) >= m)
server: PUT nonce=g, blob=a

The server is free to share the nonce between clients, or not, and change it as often as it likes (potentially requiring slow clients to retry requests).

Distributed computing environment

Kragen Javier Sitaker, 2017-07-19 (8 minutes)

I want a new computing environment for reading writing, including reading, writing, and remixing computational models, that cleanly virtualizes the computer.

The ideal is something like this.

I sit down at a random untrusted computer and load up the virtual machine, as a web page or whatever, and type in an unspoofable identifier of the mutable information space I want to look at, maybe something like "lotus-marc-fix-kev-homes-vii-taps-car" or "dnbwalalhcsmgsnsspdyq". Immediately I see a display of that information space, loaded from a decentralized network of servers, and an unspoofable identifier for my session, which I write down on paper. I can start writing down my thoughts, using the keyboard or whatever, with an instantly accessible and reliably responsive user interface, taking advantage of the keyboard, mouse, tablet, webcam, or other peripherals available on the untrusted computer. As I assemble computational models, they are executed immediately on this local machine, but everything I create is snapshotted periodically and propagated out to the network within less than a minute, retrievable later by the session identifier. All of the information I see, too, is permanently snapshotted by the network, so that I can come back and refer to it later. At the end of my session, I generate an unspoofable identifier for the state at the end of the session, and I write it, too, down on paper.

Later, using a trusted but much less capable computer, such as my cellphone, I retrieve the data for the session identifier; I can see everything I created during the session, and it is certain to work compatibly there. I can look at the things I created, and if they are good, I can update my published information space with them.

Compatibility into the far future and past is guaranteed by the design of the system: if the needed data is preserved, a simple virtual machine suffices to bring it back to life. In addition to recording decoders in a format that can be run efficiently on a simple virtual machine, the original data itself is recorded in simple, general formats like ASCII text, STL files, CSV files, and uncompressed bitmaps, simplifying putting it to new uses in the future. Code and other original data have their integrity checked using a Merkle DAG; the hash of mutable data is authenticated by using a public-key signature.

Code is deterministic, so that executing the same code with the same data as input will always produce the same output data. Non-original data produced by executing code with data as input is thus cacheable in the same content-addressable store decentralized network; cache services store (code hash, input data hash, output data hash) tuples, so that if you trust everyone with write access to a cache, you can omit redundant computation. Trees of such tuples are published in the same network, its hash being authenticated by the public-key signature of the caching service itself.

Decoders and editors for crucial formats are accompanied by formal

proofs of correctness, of worst-case execution time, and of worst-case execution space. This is achieved by writing them originally in a formally tractable source language, making the proofs tractable at the source-code level, and then mechanically translating the proofs into proofs at the level of the virtual-machine code, which can be machine-checked without reference to the correctness of the compiler.

In addition to the content-hash-addressable immutable blob data store and the public-key-hash-addressable mutable data store, the system contains two additional communication services: one for reliably passing streams of authenticated messages between mutually consenting communicating correspondents identified by per-connection public keys, and an unauthenticated and unreliable publish-subscribe system for initially establishing contact between parties that don't have a pre-existing relationship.

Interactive user interfaces are specified by a state transition function, which takes as input the current user interface state and an event (which may be a keystroke, a multitouch notification, a webcam frame, a mouse motion, a network message, a timeout, a random number, or a few other things) and produces as output the new user interface state and a possibly empty set of actions to take, which may include updating a screen, playing a sound, scheduling a timeout, publishing a blob, publishing an update to mutable data, sending a message to a correspondent, publishing a message, subscribing to a topic, and requesting a random number. They are, it should be clear, composable from simpler user interfaces using the same interface or a simpler interface. For example, many games can perform adequately if given the controller state 30 or 60 times a second and producing a frame of output. XXX does the deterministic computation thing interfere with responsiveness? It would seem to make it impossible to update the rest of the screen while you're trying to deliver updates to a slow program.

Farming out computation to a cluster, if you trust it, is easily accomplished by sending the (code hash, input data hash) commands you want to execute to it, and arranging for the cluster coordinator to send you the final cacheable tuple when it finishes. For many uses, this also requires sharing a cache with the coordinator that you can trust not to leak secret data.

The virtual machine on which the code runs has this command-sending as a fundamental operation: any program running on it can submit (code, input) commands for execution, which may be transparently satisfied from cache, by local execution, or by farming out to a cluster. XXX Perhaps this shouldn't be a fundamental operation, both because you might want to change it and because it could make proofs of efficiency very difficult; but that just means that the computation producing an output needs to be able to delegate that responsibility to a future computation composed from commands it spawns, which might come to the same thing in the end.

Programs manipulate the hashes through handles that are opaque to them; rather than being contained in the code itself, they are listed in a manifest associated with the code. Similarly, plain data containing a reference to other plain data lists its hash in an associated manifest. The hashes in the manifest have associated types which restrict what

kinds of references can be made to them: an image transcluded in a hypermedia document has the type "dependency" associated with its hash in the manifest, while a hypertext link has the type "reference" associated with it.

These link types allow archive-auditing systems to verify that all of the dependencies of a document are included on an archival medium or stored in the network with an acceptable degree of redundancy, without having to understand not-yet-invented hypermedia data formats.

Computation-cache services can also publish the estimated cost to recompute derived data, based on how long it took last time. This aids cooperating data-cache services in choosing which data to throw away.

Interactive bandwidth

Kragen Javier Sitaker, 2017-08-03 (2 minutes)

The internet connection here is broken. I just used Android tethering to log in, read my mail, check a couple of chat channels, and answer some chat messages, for about ten minutes. At the end, ssh reported:

```
Transferred: sent 23048, received 60304 bytes, in 618.1 seconds
Bytes per second: sent 37.3, received 97.6
```

That is, on average over those 10 minutes, I was typing and otherwise sending data at "373 baud" and reading at "976 baud". The incoming number was, I think, reduced by about a factor of 2 by gzip compression.

This 500-bit-per-second range is interesting, because it's a fairly easy bandwidth to achieve under many circumstances. I think you should be able to do better than this with subliminal audio coding layered on top of a voice channel, for example, and even simple binary FSK coding at audio frequencies can achieve it pretty easily. It's about a factor of 20 less bandwidth than the "2G" GSM GPRS data connection I often used to read my email in 2001.

At times, today's connection was hard to use because of unpredictable, high latency. But high latency is not inherent to the low-bandwidth domain — indeed, often you can trade bandwidth off against latency, for example with data compression or more aggressive error-correction coding, but also in a more general way by having a wider choice of acceptable communication media.

Separating implementation, optimization, and proofs

Kragen Javier Sitaker, 2019-06-26 (updated 2019-07-22) (41 minutes)

One of the approaches the STEPS program wanted to try was to "separate implementation from optimization". I don't know that they ever got anywhere with that (certainly I never saw anything in their public reports that could be described that way) but I think it's a really interesting idea.

Conventional programming practice unashamedly mixes together the specification of what your program does with a lot of implementation choices about how to do it efficiently. Of the languages I've used, the one that is purest at describing just the semantics of the desired computation is perhaps Scheme, though it's in no sense the theoretical limit in that sense. What are the ways Scheme and other programming languages mix these things together?

(See also Generic programming with proofs, specification, refinement, and specialization (p. 958).)

Scheme and its discontents

Scheme is pretty abstract.

In Scheme you don't explicitly specify what type your variables are, when to deallocate things, how to represent enumerated choices in machine registers, whether you're calling a function or invoking a macro. You don't specify whether a call to a function will return to the callsite, through a saved continuation somewhere up the stack from the callsite, or through a saved continuation to somewhere on another stack. Iteration uses the same syntax as recursion. If you use lists or vectors for your records, you never have to declare record types, and you never have to say which record type a list or vector represents, although the built-in field accessors have names like `cadddr`.

But Scheme is relentlessly monomorphic, at least outside the numerical tower — the standard procedures for lists, for example, work only on lists, not arbitrary sequences. To index into a string or to index into a list, you use different procedures, so you can't write a procedure that works implicitly on either one. It's unapologetically eager (although continuations provide some escape from this, in that they allow a procedure to suspend evaluation until a result is ready; because it has the implicit variable capture semantics later adopted by nearly all modern programming languages, its closures also provide an escape valve, though also a rather syntactically clumsy one. Your record types must be explicitly defined (if your system implements SRFI 9 so that you have record types). And if you need both a function and its inverse, you must define them separately — more generally, given an n-ary relation, there exist 2^n functions from subsets of its columns to sets of values for the other columns, and in Scheme each of these must generally be reified as a separate procedure.

Schemaless records

By contrast, in Lua or JS, you can implicitly ("schemalessly") define a record type, with reasonable accessor syntax, just by using it; in Lua syntax:

```
dragStart = {x=ev.p.x, y=ev.p.y}
```

The schemaless Scheme equivalent is something like

```
(let ((drag-start (cons (x (p ev)) (y (p ev)))))
    …)
```

but then you have to access the `x` and `y` fields of `drag-start` with `car` and `cdr`, or define functions wrapping them (which might have to have longer names than `x` and `y`).

If you use a SRFI-9 declaration like this one in Scheme:

```
(define-record-type :point (make-point x y) point? (x get-x) (y get-y))
```

then you can instead write

```
(let ((drag-start (make-point (x (p ev)) (y (p ev)))))
    …)
```

and then you have `(get-x drag-start)` and `(get-y drag-start)` as you would want. But you still can't use the same accessors `x` and `y` for your new record type that were used for the fields of `(p ev)`; this is a specific case of a larger issue, which is that Scheme makes polymorphism cumbersome and often impossible.

Object-orientation or polymorphism

In Python, Smalltalk, or Ruby, you can generally define a new type that can be used in place of an existing type as an argument to a function or method, simply by implementing the interface that the function or method expects of that argument. Consider this very simple Python function from Dercuano:

```
def pluralize(noun, number):
    return noun if number == 1 else noun + 's'
```

This is intended for use with a string and an integer, returning a string, as you'd expect. A Scheme equivalent:

```
(define (pluralize noun number)
  (if (= number 1)
      noun
      (string-concatenate (list noun "s"))))
```

But all the Python version demands of the "integer" is that it be usefully comparable to 1, and all it demands of the "string" is that you can concatenate a string to it and get a value of the same type. So, for example, you can partially evaluate `pluralize` (and a class of similar functions) with respect to the `number` argument by passing the following `Template` object as an argument instead of the string:

```
class Template:
    def __radd__(self, other):
```

```
        return Template_cat(templatify(other), self)

    def __add__(self, other):
        return Template_cat(self, templatify(other))

    def of(self, value):
        return value

class Template_cat(Template):
    def __init__(self, a, b):
        self.a = a
        self.b = b

    def of(self, value):
        return self.a.of(value) + self.b.of(value)

class Template_k(Template):
    def __init__(self, value):
        self.value = value

    def of(self, value):
        return self.value

def templatify(val):
    return val if isinstance(val, Template) else Template_k(val)
```

This amounts to partial evaluation by way of abstract interpretation with an non-standard semantics, but it's done entirely at the level of ordinary code by passing an argument that implements an interface. To do something like this with Scheme, you have to step up to a metalevel and write a sort of compiler rather than just implementing metamethods.

So you could reasonably argue that the Python `pluralize` is a more abstract specification of a computation than the Scheme version.

Laziness

As many of us learned from SICP, although Scheme is eager, you can define lazy streams in Scheme by delaying evaluation with `lambda`:

```
(define (ints-from n) (lambda () (cons n (ints-from (+ n 1)))))
```

Or by using `delay`:

```
(define (ints-from-delay n) (delay (cons n (ints-from-delay (+ n 1)))))
```

But — related to the above issue about polymorphism — in standard Scheme, you cannot pass these lazy streams to things that expect regular lists. (A Scheme that provides implicit `force` would allow this; as I understand it, supporting this possibility is the reason `delay` and `force` are in the standard, but neither of the Schemes I tried it on has implicit `force`.) So a caller that expects a regular list as a return value is constraining the callee to produce it entirely before returning. And a callee that expects a regular list as an argument is constraining the caller to produce it entirely before the callee begins execution.

In mathematics, it's entirely commonplace to deal with infinite

sequences on equal terms (heh) with finite sequences, and even infinite sequences of infinite sequences, etc. The decision to compute only a finite subset of an infinite sequence is, in many cases, a sort of optimization decision — computing too many terms is relatively harmless, consuming only extra time and memory, and computing all the terms would take infinite time and therefore require some kind of hypercomputation.

This kind of thing frequently results in dual implementations: an eager implementation for when all the results are needed (more convenient to handle in Scheme and in most languages) and a lazy one for when it's important to produce results lazily. Usually these are provided through separate operations (functions, methods, or operators), though in some cases, it's just different options to the same operation; for example, in the perlop documentation for the pattern-match operator `m//`:

> The "/g" modifier specifies global pattern matching — that is, matching as many times as possible within the string. How it behaves depends on the context. In list context, it returns a list of the substrings matched by any capturing parentheses in the regular expression. If there are no parentheses, it returns a list of all the matched strings, as if there were parentheses around the whole pattern.
>
> In scalar context, each execution of "m//g" finds the next match, returning true if it matches, and false if there is no further match. The position after the last match can be read or set using the "pos()" function; see "pos" in perlfunc.

By contrast, in Python, you can write a generator function, which creates a generator object when initially invoked; both the generator object and the builtin list object implement the builtin iterator protocol, so things that just use the iterator protocol (by, for example, iterating or converting to a tuple) will not notice the difference between a list and a generator.

In Dercuano, for example, this method is a generator; it generates a lazy sequence of (subject, verb, object) triples that form the main data store of the Dercuano application:

```
def load_triples(filename):
    with open(filename) as f:
        last_subj = None
        for line in f:
            if not line.strip():
                continue
            fields = tuple(unquote(field.replace('+', '%20'))
                           for field in line.split())
            if line[0] in string.whitespace:
                fields = (last_subj,) + fields
            for fn in fields[2:]:
                yield (fields[0], fields[1], fn)
            last_subj = fields[0]
```

This parses some vaguely RDF-N3-like text saying things like this:

```
7805-6-volts written 2019-06-08
    updated 2019-06-10
    concerns electronics pricing

array-intervals written 2019-06-23
    concerns math intervals arrays apl python c programming algorithms numpy
```

Its return value is passed to this function, which generates some in-memory hash tables for quick access:

```
def as_relations(triples):
    relations = {}
    for subj, verb, obj in triples:
        if verb not in relations:
            relations[verb] = relation.Relation()
        relations[verb].put(subj, obj)

    # Precompute inverse relations eagerly
    for verb in relations:
        ~relations[verb]

    return relations
```

Right now, the execution of `as_relations` is interleaved with that of `load_triples`. If `load_triples` is changed to build up a list of 3-tuples and return it, or if `load_triples`'s caller does so by invoking `list()` on its return value before passing it to `as_relations`, the code of `as_relations` continues to produce the same results, but the file access is no longer interleaved with the hashing, and an additional big temporary data list is built up in memory. As it turns out, this makes it run slightly faster. (So I made the change.)

The ability to hide optimization decisions behind interfaces like this is powerful, but I'm kind of overselling Python's implementation of the iterator interface here. If you iterate over a list a second time, you get the same items, unless you've changed it; but iterators in Python are single-pass, and so you cannot iterate over a generator a second time. Worse, if you attempt to do so, you silently get no items, rather than an error message. And, because Python's semantics have pervasive mutability, it's easy to write a generator that unintentionally produces a different sequence of values depending on exactly when the iteration happens. (In the above example, this could happen if the contents of the file changed, which is a problem that goes beyond Python; see Immutability-based filesystems: interfaces, problems, and benefits (p. 1672).)

Laziness is useful for a few different reasons: to avoid building up big in-memory temporary data structures that will just be thrown away again; to do computations in finite time involving infinite sequences like the continued-fraction expansion of φ or π; and to provide partial results sooner from things that can take a long time to finish, including jobs that use heavy computation, I/O, and remote procedure calls, which are a sort of I/O.

(Haskell is the champion of laziness, avoiding both Python's repeated-iteration problem and Python's implicit-mutation-dependency problem, but I don't know Haskell, so I don't have a good example to hand.)

N-ary relations and relational programming

Consider this Prolog "predicate", which is to say, n-ary relation:

```
x(7805-6-volts, written, 2019-06-08).
x(7805-6-volts, updated, 2019-06-10).
x(7805-6-volts, concerns, electronics).
```

```
x(7805-6-volts, concerns, pricing).
x(array-intervals, written, 2019-06-23).
x(array-intervals, updated, 2019-06-10).
x(array-intervals, concerns, math).
x(array-intervals, concerns, electronics).
```

We can interactively query the topics covered by How to get 6 volts out of a 7805, and why you shouldn't (p. 537) as follows:

```
?- x(7805-6-volts, concerns, Topic).
Topic = electronics ;
Topic = pricing
```

So we can think of `x` as a function which, when executed, gives the topics for How to get 6 volts out of a 7805, and why you shouldn't (p. 537). But we could make the note name an input variable and think of it as a function from note names to (sets of) topics:

```
?- Note = 7805-6-volts, x(Note, concerns, Topic).
Note = 7805-6-volts,
Topic = electronics ;
Note = 7805-6-volts,
Topic = pricing ;
false.
```

(Calling back to the previous topic, this sequence is lazy; you can say `Note = 7805-6-volts, findall(Topic, x(Note, concerns, Topic), L).` to get the whole list at once.)

Also, though, `x` is the inverse function, from topics to note names:

```
?- Topic = electronics, x(Note, concerns, Topic).
Topic = electronics,
Note = 7805-6-volts ;
Topic = electronics,
Note = array-intervals.
```

But we can also invoke `x` as a function to return a list of all note–topic pairs:

```
?- x(Note, concerns, Topic).
Note = 7805-6-volts,
Topic = electronics ;
Note = 7805-6-volts,
Topic = pricing ;
Note = array-intervals,
Topic = math ;
Note = array-intervals,
Topic = electronics.
```

Or a function from note names to last-updated dates:

```
?- Note = array-intervals, x(Note, updated, Date).
Note = array-intervals,
Date = 2019-6-10.
```

If we compose `x` with itself, we can even, for example, find all the pairs of notes last updated on the same date:

```
?- x(Note1, updated, Date), x(Note2, updated, Date).
Note1 = Note2, Note2 = 7805-6-volts,
Date = 2019-6-10 ;
Note1 = 7805-6-volts,
Date = 2019-6-10,
Note2 = array-intervals ;
Note1 = array-intervals,
Date = 2019-6-10,
Note2 = 7805-6-volts ;
Note1 = Note2, Note2 = array-intervals,
Date = 2019-6-10.
```

But even without composing `x` with itself or selecting from it, we can construct eight different functions from it by declaring some of its columns to be inputs and others to be outputs; by currying or partially evaluating those functions with respect to some subset of their input arguments (in the relational view, selecting a subset of rows from the relation), we can get a much larger set of functions out of it. As written, there are four functions with the first column fixed to How to get 6 volts out of a 7805, and why you shouldn't (p. 537) and four more with it fixed to Reducing the cost of self-verifying arithmetic with array operations (p. 2205); four each with the second column fixed to each of its three values; and four each (much less interesting) functions with the third column fixed to each of its six values. This is 44 more functions, plus the 8 uncurried ones, for a total of 52, plus the functions with more than one curried argument (which are less interesting).

Defining 52+ functions is not too bad for 8 lines of code, and you won't have to go searching through a many-page API document to figure out how to use these 52+ functions, either.

As I said before, though, Prolog hardwires a depth-first search strategy, which fails to terminate for many searches, and is exponentially inefficient for many others. So the extent to which you can do this kind of thing in Prolog directly is fairly limited. The usual example is `append`, which is a built-in Prolog function; we can ask SWI-Prolog for a listing of it as follows:

```
?- listing(append/3).
lists:append([], A, A).
lists:append([A|B], C, [A|D]) :-
        append(B, C, D).

true.
```

These two or three lines of code define the list-append relation among lists; thinking of it in the usual way as a way to append two lists, we can call it to append two lists:

```
?- append([h,e,l,l,o], [v,e,n,u,s], L).
L = [h, e, l, l, o, v, e, n, u|...].
```

But these two lines of code define eight functions, just like the `x/3`

predicate defined above. We can ask for all pairs of lists that append to another list:

```
?- append(A, B, C).
A = [],
B = C ;
A = [_G249],
C = [_G249|B] ;
A = [_G249, _G255],
C = [_G249, _G255|B]
```

We can ask for every pair of lists that can be appended to form a given list:

```
?- append(A, B, [v,e,n,u,s]).
A = [],
B = [v, e, n, u, s] ;
A = [v],
B = [e, n, u, s] ;
A = [v, e],
B = [n, u, s] ;
A = [v, e, n],
B = [u, s] ;
A = [v, e, n, u],
B = [s] ;
A = [v, e, n, u, s],
B = [] ;
false.
```

We can ask if one list is a prefix of another list (and, implicitly, what's left over):

```
?- append([h,e,l,l], X, [h,e,l,l,o]).
X = [o].

?- append([h,e,l,l], X, [v,e,n,u,s]).
false.
```

Or, more interestingly, a suffix:

```
?- append(Hello, [n,u,s], [v,e,n,u,s]).
Hello = [v, e] ;
false.
```

That's a lot of functionality for two lines of code!

You can define Scheme's standard `append` function in a precisely analogous way:

```
(define (append a b)
  (if (null? a)
      b
      (cons (car a) (append (cdr a) b))))
```

But you can't run a Scheme procedure "backwards" in the way the above Prolog predicates are being used, so if you want starts-with and

ends-with predicates, much less lists of sublists, you need to program those separately.

This kind of thing is a really tempting pointer to what Will Byrd calls "relational programming", where instead of programming *procedures* or *functions* (or, as *Total Functional Programming* points out, partial functions) we program *relations*. Modern Prolog systems are doing some work with tabling and integer programming to expand the scope of this kind of thing, but they're incurably handicapped by Prolog's depth-first evaluation model. Byrd and Kiselyov's system miniKANREN is, like the database query mini-language in SICP, an exploration of making this kind of thing much more general than it is in Prolog. Its second most impressive feat is that, given a relational specification of an interpreter, it was able to deduce a self-reproducing program, a quine, for that interpreter. (Its most impressive feat is that Chung-Chieh Shan and Oleg Kiselyov extended it to support probabilistic programming five years before anyone else realized probabilistic programming was a useful thing to do.)

As I understand it — and I may have this part wrong — miniKANREN uses a sort of breadth-first search strategy which is guaranteed to find a solution if one exists, but, like Prolog's strategy, is not guaranteed to terminate. My intuition is that this means that for many problems — in some sense, most problems — it will take exponentially longer than a program that always knows the right choice to make, or even a version of miniKANREN that knows the right choice to make more often, or gets to it sooner. This suggests that some kind of optimization-hint information could yield an exponential speedup, so adding some kind of optimization to your miniKANREN program (whether separated or, as is traditional, mixed into it) could yield big wins.

Naturally, Byrd and Kiselyov implemented miniKANREN in Scheme, although Clojure also includes a version of it.

From a certain point of view, the Scheme `append` procedure is an optimized version of the Prolog `append/3` predicate: it's a version of the predicate specialized to the case where the first two arguments are ground and the third argument is a free variable.

Irreversible computation

Consider this Python implementation of the method of secants (see Using the method of secants for general optimization (p. 1773), and note that these implementations tend to report success by dividing by zero):

```
def sec(f, x0, x1, e):
    y = f(x0), f(x1)

    while abs(y[1]) > e:
        x0, x1 = x1, x1 - y[1]*(x1 - x0)/(y[1] - y[0])
        y = y[1], f(x1)

    return x1
```

Here is a Scheme equivalent, although it may not be the best way to express the algorithm in Scheme:

```
(define (sec f x0 x1 e)
  (letrec ((loop
            (lambda (y0 y1 x0 x1)
              (if (> (abs y1) e)
                  (let ((xn (- x1 (/ (* y1 (- x1 x0))
                                     (- y1 y0)))))
                    (loop y1 (f xn) x1 xn))
                  x1))))
    (loop (f x0) (f x1) x0 x1)))
```

If it terminates, this approximates a root of the function `f` by finding the intersection point of the X-axis and the secant line through (x_{i-1}, f(x_{i-1})) and (x_i, f(x_i)); in the usual cases, this is a slightly more efficient approximation of Newton–Raphson iteration, since it converges with degree φ to Newton's 2, but only requires a single computation of $y(x)$ per iteration, rather than separate computations of $y(x)$ and $\dot{y}(x)$. (In some cases, not needing to compute the derivative is also useful, although if the derivative doesn't actually exist, this method may not converge.)

The thing I want to point out here is that, assuming floating-point, this procedure computes in constant space, but by virtue of doing so, it erases all the intermediate values of `x1` and `y`. If you just want the root, that may be okay, but if you want to analyze the performance of the algorithm, it may be useful to save those intermediate results.

Related to the previous item about laziness — in this form, the algorithm fails to terminate at times — notably when you give it real starting points for a function whose roots are complex, such as `sec(lambda x: x**2 + 2, 0, 1.0, .0000001)`, although it works fine with other starting points such as `sec(lambda x: x**2 + 2, 0, 1.0 + 1.0j, .0000001)`. Even if it does manage to terminate, it can run for many iterations, and in some applications it would be best to terminate its execution early, for example if a concurrent search from a different starting point finds a solution.

If you sometimes want the constant-space behavior and sometimes want the whole sequence of values or guaranteed termination, most programming languages require you to restructure the procedure as a generator of a lazy sequence, so that a concurrent consumer has the opportunity to discard its intermediate values or abort the iteration. For example:

```
def sec_seq(f, x0, x1):
    y = f(x0), f(x1)

    while True:
        yield x1
        x0, x1 = x1, x1 - y[1]*(x1 - x0)/(y[1] - y[0])
        y = y[1], f(x1)
```

This allows you to, for example, take the 10th value, discarding all previous values, to compute the first 10 values, or to interleave the iterative computation in other ways:

```
>>> list(itertools.islice(sec_seq(lambda x: x**2 + 2, 0, 1.0 + 1.0j), 9, 10))
[(-2.2572481470524732e-21+1.4142135623730951j)]
>>> list(itertools.islice(sec_seq(lambda x: x**2 + 2, 0, 1.0 + 1.0j), 10))
```

```
[(1+1j),
 (-1+1j),
 2j,
 (-0.2+1.4j),
 (-0.03448275862068967+1.4137931034482758j),
 (1.3877787807814457e-17+1.411764705882353j),
 (2.9885538387977862e-05+1.4142135620573204j),
 (-2.5897366406179418e-08+1.4142135623730947j),
 (-8.007108329513308e-22+1.4142135623733687j),
 (-2.257248147052473e-21+1.4142135623730951j)]
```

The original Python and Scheme code is seen to have mixed together the space optimization of discarding the intermediate values with the implementation of the underlying algorithm. Scheme is in some sense often more abstract than Python with regard to this sort of irreversibility, in that you write this loop with a call whose tail position the Scheme system is supposed to recognize, rather than explicitly overwriting variables with new values; but, on a standard Scheme system, you can't construct some kind of context where executing the original Scheme example above gives you access to all of the intermediate values. And in fact the surgery needed to convert the Scheme version of the algorithm to optionally produce the whole sequence of values, interleaved with the execution of the consumer, is more extensive than on the Python version.

(The situation is somewhat worse even than this suggests: in both Python and Scheme, if the arguments are arbitrary-precision rational objects (or, in some Schemes, integers), the algorithm is not constant-space, and the Scheme standard more or less explicitly permits garbage collection to be broken, and Scheme space behavior depends in most cases on garbage collection.)

But we see that Python and Scheme *permit* us to write this algorithm in such a way that the invoking context can preserve the intermediate values or discard them, as it wishes. (Doing this in general requires using FP-persistent data structures and avoiding mutation entirely, which is totally impractical in Python, and pretty hard to do without sacrificing efficiency in Scheme.) But what would an algorithm specification language look like that entirely omitted erasure?

Euclid's gcd algorithm

The first algorithm presented in an algorithms course is often Euclid's algorithm for computing greatest common divisors. Consider this Python implementation:

```
def gcd(a, b):
    while b:
        a, b = b, a % b
    return a
```

Or its Scheme equivalent, although the Scheme standard already provides this function:

```
(define (gcd a b)
  (if (= b 0)
      a
```

```
    (gcd b (remainder a b))))
```

Like the method-of-secants code, this computes a sequence of intermediate values before arriving at its final answer, and these intermediate values are lost. (However, at least for the usual data types, in this case termination is guaranteed.) It turns out that, as explained in Using Aryabhata's pulverizer algorithm to calculate multiplicative inverses in prime Galois fields and other multiplicative groups (p. 2255), the lost values are actually very useful; you can use them to efficiently compute the inverses of the elements of a multiplicative group or find that no such inverses exist, because they allow you to compute not only $g = \gcd(a, b)$ but also coefficients s and t such that $sa + tb = g$. The easiest way to do this in Python is, first, to restructure the algorithm as a recursive algorithm like the Scheme implementation:

```
def gcd(a, b):
    return a if b == 0 else gcd(b, a % b)
```

Second, to push the termination test down the stack one level:

```
def gcd(a, b):
    r = a % b
    if r == 0:
        return b

    return gcd(b, r)
```

Finally, to augment the return value with the additional information:

```
def egcd(a, b):
    q, r = divmod(a, b)      # r = a - qb
    if r == 0:
        return 0, 1, b       # 0a + 1b = b

    s, t, g = egcd(b, r)     # sb + tr = g
    assert s*b + t*r == g
    return t, s - t*q, g     # sb + t(a - qb) = g = ta + (s - tq)b
```

For example, if invoked as `egcd(81, 18)`, this returns (1, -4, 9), because $1 \cdot 81 - 4 \cdot 18 = 9$, their greatest common divisor;, so in $\mathbb{Z}/81\mathbb{Z}$, 18 has no multiplicative inverse. But, if invoked as `egcd(93, 26)`, it returns (7, -25, 1), because 93 and 26 are relatively prime, and $7 \cdot 93 - 25 \cdot 26 = 1$, so in $\mathbb{Z}/93\mathbb{Z}$, the multiplicative inverse of 26 is -25, which is to say, 68.

In a sense, the simpler functions above are optimizations of this one: they are iterative and they avoid doing work and allocating memory to calculate s and t when not needed. You can of course write the extended version and hope that your compiler is smart enough to detect this situation, but you will probably be disappointed, and moreover you will probably have no way of knowing. (Even if you grovel over assembly listings to verify it once, you likely won't notice if future change to the code break the optimization.)

Wouldn't it be better if you could write the extended version and

assert that, at a given callsite, the algorithm used should be iterative? If the compilation failed because that assertion couldn't be satisfied, wouldn't it be good to be able to explain to the compiler how to make the optimization and what assumptions justified the optimization, and have the compiler search for a counterexample for the compilation error message if your assumptions were wrong, or at least suggest a lemma you could try to give it a proof for?

Mixing together optimization, implementation, and proof

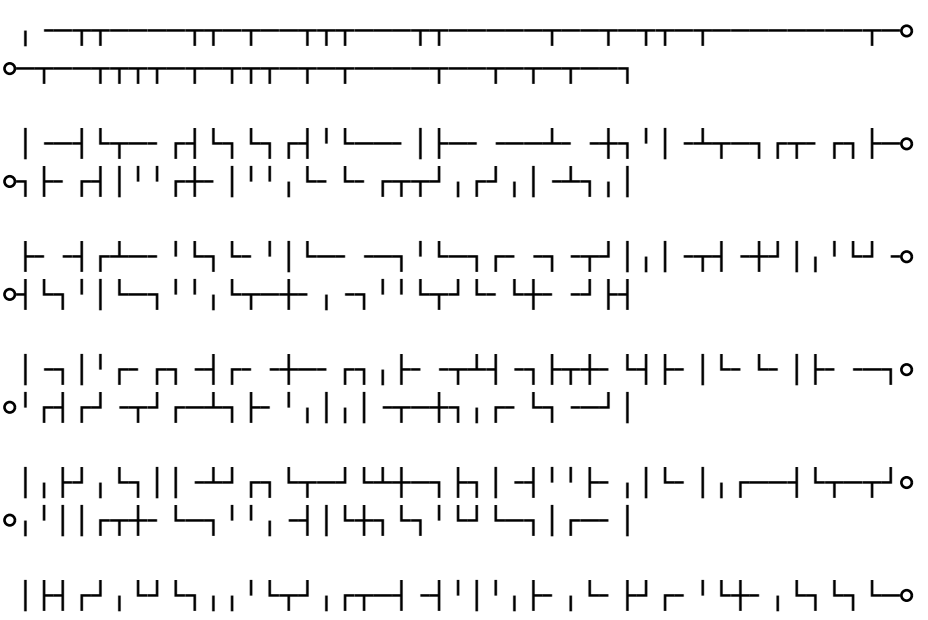
So we've seen particular ways in which even in Scheme we must entangle optimization with implementation, but in more mainstream programming languages, the situation is even more extreme.

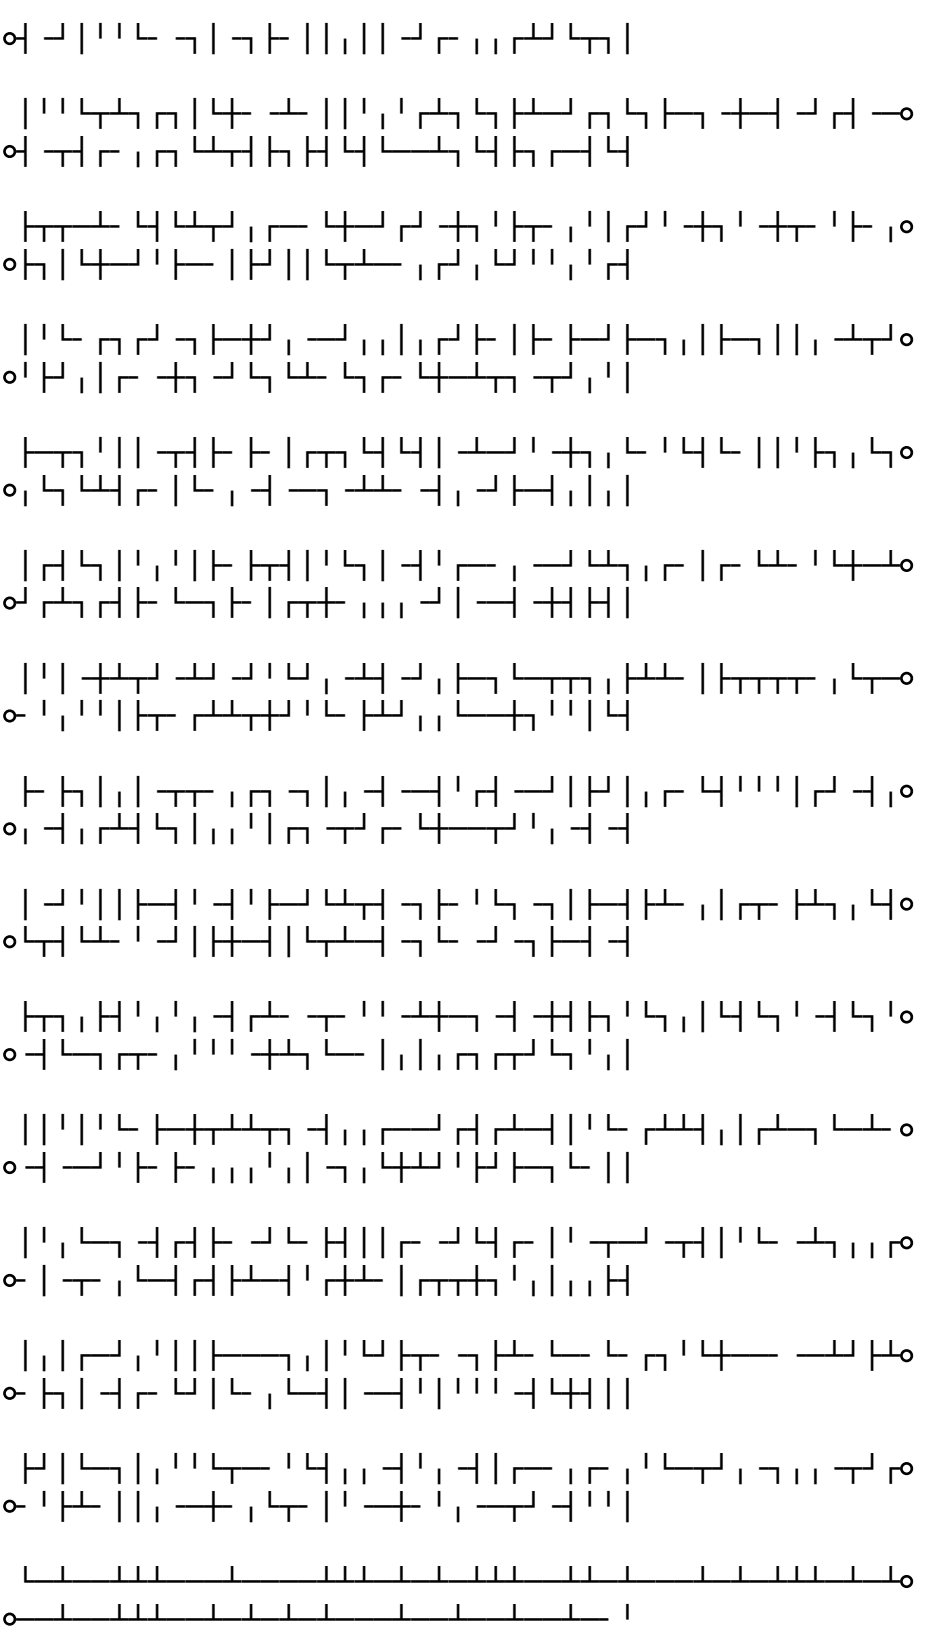
Consider this Golang code from my maze program:

```
func (m Maze) Show(output io.Writer) {
	h, v := m.Horizontal, m.Vertical

	for r := 0; r < len(h); r++ {
		s := []byte{}
		for c := 0; c < len(v[0]); c++ {
			k := context{
				up:    v[r][c],
				down:  v[r+1][c],
				left:  h[r][c],
				right: h[r][c+1],
			}
			s = append(s, glyphs[k]...)
		}
		output.Write(append(s, '\n'))
	}
}
```

Using a maze previously generated by the rest of the program with Kruskal's algorithm, this produces output like the following maze, which has one path through it:





If you translate this function directly to Python, it's about half as much code:

```
def show(self, output):
    h, v = self.horizontal, self.vertical

    for r in range(len(h)):
        s = []
        for c in range(len(v[0])):
            k = (v[r][c],
                 v[r+1][c],
```

```
                h[r][c],
                h[r][c+1])
            s.append(glyphs[k])

        output.write(''.join(s) + '\n')
```

What was the other half? It's not, mostly, that Python uses shorter tokens. As far as I can tell, the only really missing part is the types (and struct fields), although those are only about 62 of the extra 300 bytes of code. In Python, we don't have to declare that our hash key is a `context` or name its fields, declare the type of the receiver, declare the type of the output stream, or declare the output buffer as a byte slice.

A (non-modern) C++ or Java version would be far worse — it would have type annotations on almost every line of the code.

A non-word-for-word translation

The Golang function above was actually from a translation from a Python program which didn't use a hash table to produce the characters but rather a search over parallel arrays:

```
def render(h, v):
    for hline, upline, downline in zip(h, v[:-1], v[1:]):
        row = []
        for r, l, u, d in zip(hline[1:], hline[:-1], upline, downline):
            row.append(random.choice([c for i, c in enumerate(chars)
                                      if  l == left[i]
                                      and r == right[i]
                                      and u == top[i]
                                      and d == bottom[i]]))
        yield ''.join(row)
```

This ended up being almost as long as the Golang version, a somewhat unfair comparison since it leaves out the Golang initialization code for the `glyphs` hash table:

```
        for i, glyph := range []rune(chars) {
                k := context{
                        up:    topbs[i] == '1',
                        down:  bottm[i] == '1',
                        left:  lefts[i] == '1',
                        right: right[i] == '1',
                }
                glyphs[k] = []byte(string(glyph))
        }
```

Optimizations and proofs

The Python version will detect even method name misspellings at runtime; if you said `output.wriet` instead of `output.write`, it won't complain. Similarly, it detects type errors, where you're calling it with no argument or a non-output-stream argument, at runtime. And if one of the things in `glyphs` isn't actually a string, or one of the keys isn't a 4-tuple as it should be, or `h` or `v` isn't a two-dimensional array of strings of the right size, that's also a runtime error. Moreover, if you got the keys in the 4-tuple in the wrong order, it won't be obvious and Python won't complain.

By contrast, most of these are checked at compile-time by the Golang compiler. It constructs a simple formal proof that the `output` argument has a `Write` method: it's an `io.Writer` interface value, and those have `Write` methods, QED. The only one it doesn't check is the array size, a check it does do at runtime. But the Golang compiler catches a fairly large fraction of bugs by using simple theorem proving at compile time, bugs that the Python program would need a test suite to catch. (I didn't write the test suite.)

The Golang program also runs a lot faster. It generates a 301×301 maze (comparable to the Python program's 300×300 maze) in 400 milliseconds, while the Python program takes 4.9 seconds to do the same task with the same algorithm. Both are single-threaded, so, crudely, the Python program is spending 92% of its time doing computations the Golang program doesn't need to do. (The Golang program could in theory be benefiting from concurrent garbage collection, but its user+system time never exceeds the wallclock time by more than about 3%, so it can't be benefiting much.)

A lot of those computations are the ones the compiler did at compile-time in order to find bugs, using the type annotations. Other optimizations, though, were choices of how to represent the program's state in memory.

Declaring the output buffer as a byte slice was an optimization; originally it was a string appended to with `+=`. Indeed, having an explicit output buffer at all was an optimization; previously the code used `fmt.Fprintf(output, "%c", glyphs[k])`. And the `context` type, with its four boolean fields, is presumably both considerably faster to copy around and gentler on the garbage collector than Python's tuple of reference-counted pointers.

Separating optimization, implementation, and proof

It's tempting to think that proofs and type specifications are at a *higher* level of abstraction than a straightforward implementation, while an optimized implementation is working at a *lower* level of abstraction than that straightforward implementation. And you could imagine a way for that to be true, where you have a sort of cascade from high-level specifications ("the program must not crash", "there must be only a single path through the maze") down to lower-level more detailed specifications ("use Kruskal's algorithm") which fill out the high-level specifications into something closer to the metal, down to low-level micro-optimizations ("represent a cell context as a tuple of four booleans, represent those booleans as single bits in a byte, and index the glyphs numerically by context rather than by hashing"). But the above example shows that this is not really the way things work today. Perhaps it could be?

Ideally, you could separate the decisions about how to represent state (use a byte buffer, use a hash, use an array, use a four-byte struct) from the higher-level specification of the algorithm so that you could separately prove that the algorithm, abstractly, solves the problem it's needed to solve, and that the state representation is a valid state representation for that algorithm (that is, its semantics faithfully implements the semantics the algorithm needs). Given a system that could construct such proofs, you could automatically conduct a

heuristic search for state representations that provide the required properties.

If an algorithm is written in a sufficiently abstract way, it can be automatically specialized to different contexts (given, for example, context-specific implementations of the operations it needs), while proofs of its properties can be written in terms of the abstract algorithm, perhaps with reference to properties of the concrete representation it's using. The C++ STL is one example of this approach, but also, for example, you can use Newton's divided-differences polynomial-interpolation algorithm to perform polynomial interpolation in different fields — including, for example, Galois fields, where it provides not numerical approximation but Shamir secret sharing. But this can only be done automatically if the original specification of polynomial interpolation is written in such a way as to not be limited to floating-point.

Arithmetic approximation

Two very common optimizations: representing integers as fixed-length n-bit bitstrings and approximating arithmetic on them with the cyclic and multiplicative groups of $\mathbb{Z}/2^n\mathbb{Z}$ ("integer arithmetic", in the computer sense); and representing members of $\mathbb{Q}$ or $\mathbb{R}$ as floating-point numbers and approximating arithmetic on them with floating-point arithmetic. The first is precisely correct in the cases where we have no overflow or underflow, and where the overflows and underflows cancel out. (In ANSI C, undefined behavior deprives us of the second possibility unless we use `unsigned` values.) The second is approximately correct when the rounding errors are not too large, which can be detected dynamically using interval arithmetic, affine arithmetic, and friends, or statically using numerical analysis (see Reducing the cost of self-verifying arithmetic with array operations (p. 2205) for more on this relationship.) Also, sometimes, we use fixed-length bitstrings with "integer division" to approximate the richer arithmetic of $\mathbb{Q}$ or $\mathbb{R}$, with rounding-error considerations similar to those of floating-point.

These are not minor or even constant-factor optimizations. Consider the recurrence that gives rise to the Mandelbrot set† — in $\mathbb{C}$ this is $z_i = z_{i-1}^2 + z_0$, but for calculation we normally translate it into $\mathbb{R}^2$:

$$x_i = x_{i-1}^2 - y_{i-1}^2 + x_0$$
$$y_i = 2x_{i-1}y_{i-1} + y_0$$

If $(x_0, y_0) \in \mathbb{Q}^2$, then all of the pairs in the recurrence will be in $\mathbb{Q}^2$, so we can straightforwardly compute them precisely on a computer using arbitrary-precision arithmetic. However, if we do this, in most cases, the computation takes time exponential in i, because the numerators and denominators of the x_i and y_i double in length every iteration! The first time I implemented the Mandelbrot set in Squeak Smalltalk, this is what happened to me, because in Squeak, integer division produces arbitrary-precision rationals by default, not floating-point numbers.

So optimizing this computation by approximating the results with floating-point arithmetic makes it possible to calculate new items of the recurrence in constant time, and without the possibility of a memory-exhaustion exception, while the precise computation takes exponential time and also exponential memory.

Being able to express an algorithm like the computation of the Mandelbrot recurrence *separately from* a specification of the concrete realization of its operations in a computer could allow us to prove results about the algorithm in the abstract, then automatically specialize it for a particular concrete domain (such as 32-bit floating-point numbers) and determine which of these proofs still holds for that concrete approximation. For example, a proof that it computes terms in linear time would fail to hold for an arbitrary-precision realization.

As I mentioned above, the Python and Scheme implementations above of the method of secants have the same feature — if applied to arbitrary-precision rational objects, they can consume amounts of space and time that increase exponentially with the number of iterations, even when they erase previous results, precisely because the expression of the algorithm in those languages can be abstract over numeric types. So, although we could imagine a system which would allow us to mechanically verify a constant-space guarantee for that algorithm in the case where we erase intermediate values and use constant-space numeric types, neither Python nor Scheme is that system; and, although we could imagine a system which would allow us to use the intermediate values computed by that algorithm without explicitly exporting them with a `yield`, neither Python nor Scheme is that system either. We enjoy the worst of both worlds.

† I think Gaston Julia, not Mandelbrot, first called attention to the astonishing features of this simple recurrence, but like nearly everyone else alive, I owe my introduction to it to Mandelbrot.

I don't know what such separation would look like for real

All of the above is a sort of laundry list of ways that these different optimizations get mixed into our source code daily, leading to duplication of code, poor performance (because the cost of an optimization is so high), and lack of adaptability to new situations. But it doesn't go very far toward exploring how we could really separate them in practice. Suppose you write the Mandelbrot recurrence the way we write recurrence relations in math books, as in my example above.

You can stuff a UHMWPE hammock in your wallet

Kragen Javier Sitaker, 2018-05-15 (updated 2018-10-28) (11 minutes)

How much would a minimal UHMWPE hammock (i.e. a net woven from ultra-high-molecular-weight polyethylene) weigh?

A standard hammock setup reaches 4–6 meters from anchor to anchor, with a hang angle 30° below the horizontal, so the bottom is 1–1.5 m below the anchor points when you're sitting at a point in the middle, and the total length of the hammock then is about 4.5–6.7 m.

UHMWPE is springy enough that you don't need any safety factor for dynamic loads. Suppose the hammock needs to be able to support 200 kg, i.e. 2.0 kN, vertically, or 1.0 kN on each support. This requires the tension in the cord to be 2.0 kN diagonally to have a 1.0 kN vertical component, so the support cord needs to resist 2.0 kN. I don't have stats on UHMWPE handy at the moment, but suppose its tensile strength is 500 MPa, which is probably in about the right range — that's the strength of poorly-heat-treated ordinary steel bolts. Then you need 4 mm² of cross-sectional area to support you.

If your hammock were just a cord, that would be all — you need 6.7 m of 4 mm² cord, 2.3 mm in diameter if it's circular, and you can sit on it. And it would weigh 26 grams at 0.96 g/mℓ.

However, the hammock net spreads out over an area, and you need to not have it break when you're sitting on just part of it. It probably needs to be able to spread out to at least 700 mm wide, and any, say, 100 mm of the width needs to not break when you sit on it. That means the net needs to be about 7 times stronger: 14.0 kN, and thus 28 mm², which will form a sort of rope about 6.0 mm in diameter when you twist it up. Also, the spacing of the lines in the net needs to be close enough that any particular 100 mm of its width has about the same strength, so you need at least 4 lines in that width — and that seems challenging to fabricate, because it means you need 28 knots and at times 56 lines across the whole width, so let's stick with 4. Then you need knots along the length at somewhat regular intervals — let's say, every 50 mm.

This sort of implies that each line only has a strength of 14/56 = 250 N, or 25 kg. This may be a little low — you might be able to break it by hand if you have some kind of tool to keep the line from cutting your hand, like a stick or something — but maybe it's okay.

If the net part of the hammock is 2 m long, then it contains 2 m · 28 mm² = 56 mℓ or 54 g of line, which is divided among 56 lines of 0.80 mm diameter and 0.5 mm² cross-sectional area. There are about 28 · 2000 mm / 50 mm = 1120 knots in the net, so tying it by hand is probably a few hours of work. The remaining 4.7 m of support are still only 4 mm² and so are only 19 mℓ = 18 g of line, giving a total of 72 grams.

The circumference of each net hole there is 100 mm, which is hopefully small enough to prevent injury.

This doesn't include anything to connect the support to, such as a tree-hugging loop or a carabiner or a hook.

If you wanted to include an airproof barrier, 100 microns of boPET

under the hammock would probably be adequate, although you could make reasonable arguments for 200μm LDPE or HDPE — they would be quieter and less likely to rip. 2 m · 700 mm · 100 μm, disregarding the narrowing at the ends, works out to 140 mℓ, which is almost twice the volume of the net hammock itself; it's also about than twice the mass, as PET is almost the same density but slightly denser. Sheets and blankets are heavier still. So we can see that the structural support is a minority of the mass of the overall hammock.

Update: UHMWPE fiber normally has, apparently, 2.4 GPa of tensile strength. This means the 4.7 m of 2kN support line need only be 0.83 mm², 1.3 mm in diameter, and the 250 N net lines need only be 0.104 mm² individually (360 μm in diameter), 5.8 mm² collectively — 2.7 mm in diameter. The overall hammock would occupy 2 m · 5.8 mm² + 4.7 m · 0.83 mm² = 15.5 mℓ, 14.9 g.

If it's possible to actually make this work, it would be pretty stunning: a hammock you can sleep in that's roughly one tablespoon in volume when rolled up.

I tried a minimal version of this: six strands of 500μm UHMWPE stretched between two metal wall hooks, a total of about 24 m. I was able to sit on it for a while, but then it broke in two places. The snapped cord showed a bit of curling, suggesting either that the shock of breaking deformed it plastically, or that it had deformed plastically ahead of time. It's possible I might have mistreated the cords while letting them out, running them around the metal hooks — I might have generated too much heat, melting the cord.

I don't have my scale handy, but this amount of cord ought to occupy 4.7 mℓ and thus weigh about 5 g. If it were a single cord, it should be 1.2 mm in diameter (500 μm √6). This is close to the 1.3 mm I calculated for the 2kN support line, but the fact that it broke without me even jumping around on it makes me think that I should probably double or triple it. Also, though, it's possible that my weight distribution might have been unequal across the lines.

Knots are consistently weak points, not just in the usual way where they put extra stress on rope fibers, but also because UHMWPE is so slippery that it tends to slide out of knots. My first attempt to reconstitute my backpack buckles using UHMWPE and steel rings failed when I pulled on it, not because the thread broke, but because the sheet bend came untied.

A bit of analysis suggests that stretching 1 m of 1mm² UHMWPE cord to its 2.4 GPa limit requires 2.4 kN; if this elongates it by 2% = 20 mm, implying a 120 GPa Young's modulus (a bit over half of steel's) and close to the 66–124 (Spectra) and 115 (Dyneema) given in http://www.mse.mtu.edu/~drjohn/my4150/props.html. Assuming linearity, that's 24 J of energy stored in 1 mℓ (≈ 1 g) of fiber. The 5 g I broke should then be able to store about 120 J as spring energy before breaking. Unfortunately, that's my body moving at a bit under 2 m/s.

(This is similar to calculations I did in Spring energy density (p. 1010) for the specific energy of different spring materials.)

This gets worse if, as suggested above, the main body of the hammock has a cross-sectional area much larger than that of the support line, while being made of the same material, because the main body of the hammock then won't stretch much at all when you sit in it; all the stretch will be taken up by the thinner support lines.

I was thinking that sticking it in series with some kind of spring might help to protect it against shocks, but I don't know what kind of spring. Nylon, from the same page, has 1.36 g/cc, 2.5 GPa Young's modulus, and 100 MPa tensile yield strength, but supposedly also has like 90% elongation at break rather than the 4% you'd calculate from those figures. (https://www.azom.com/article.aspx?ArticleID=477 explains: 6,6 nylon does indeed have 4.5% strain at yield, but also 60% elongation at break.) If we take the 60% figure, but figure that the engineering stress is limited to 100 MPa over nearly all of the distance, we get the remarkable result that our 1m × 1mm² fiber can elongate to 1.6 m under a force of 100 N, absorbing 60 J of energy in the process, more than twice what the UHMWPE fiber can absorb. This is an improvement, but not good enough to justify it.

Maybe a hyperelastic material like latex rubber would be a better choice. Latex has roughly 1500% elongation at break. Some loops cut from a bicycle inner tube might be most practical, despite their suboptimal properties. The 2012 "Characterization of Natural Rubber Latex Film Containing Various Enhancers" https://core.ac.uk/download/pdf/82660375.pdf got an ultimate tensile strength of 0.34 MPa and 1400% elongation at break, but unfortunately they did not plot the stress-strain curve. Surely the ultimate tensile strength here is simply incorrect; other sources give tensile strengths in the neighborhood of 10–20 MPa, such as https://vtechworks.lib.vt.edu/bitstream/handle/10919/26306/1JTS_ooETD.pdf.

If we assume that it's linear (probably conservative for hyperelasticity) and that in practice we don't want to exceed 500% elongation, then we can put it under, say, 5 MPa of stress.

If we were to do the same experiment with our hypothetical 1 m × 1 mm² shape, but this time made from rubber, we would stretch it out to 6 m while averaging 2.5 MPa and 2.5 N. This is a rather pathetic 12 J.

Rhett Allain did some simple experiments https://www.wired.com/story/how-much-energy-can-you-store-ino-a-rubber-band/ to derive a specific energy of 1.7 kJ/kg in tension for the rubber bands he had lying around the office. That means that absorbing an impact of 250 J would require 150 g of rubber.

So rubber is good for limiting forces given a fixed acceleration, like when you have something mounted on a vibrating chassis, but it isn't particularly good at absorbing a fixed impact energy. UHMWPE is many times better than rubber at that, and nylon is twice as good as UHMWPE, albeit dissipatively. (And presumably plastics like LDPE (7 MPa, 400%), PET (100 MPa, 300%), polycarbonate (100 MPa, 200%), and polycaprolactone (10 MPa, 300%, though I think I've seen more like 1000%) are better still (see https://www.smithersrapra.com/SmithersRapra/media/Sample-Chapters/Physical-Testing-of-Plastics.pdf and https://www.makeitfrom.com/material-properties/Polycaprolactone-PCL), if you're willing to allow plastic deformation, making the shock absorber consumable.)

Anytime realtime

Kragen Javier Sitaker, 2016-04-22 (4 minutes)

Every program is a real-time program; late answers are wrong answers, because every system has a user, and users do not live forever, and they have a discount rate.

A traditional way to ensure that your programs don't miss their hard real-time deadline is to calculate a worst-case run time for your algorithms, then ensure that your input doesn't get big enough to make your run time miss the deadline. This requires analyzing the compiled program.

A different way is to use anytime algorithms; these are algorithms that you can keep running until you are about to run out of time, then get an answer. In general, if you don't run them long enough, the answer you get isn't very good, but in many cases it's still better than no answer. And it's a *lot* easier to verify that an anytime algorithm hits its deadline.

There are several different classes of anytime algorithms; two of the common ones are Monte Carlo algorithms and numerical optimization algorithms.

Monte Carlo algorithms, such as particle filters, work by doing a large number of random trials and producing some sort of aggregate answer from them. For example, if you're ray-tracing, you can shoot rays at random into your scene, ideally several per pixel. This is, as far as I can tell, how Blender ensures that its visual feedback on rotation of complex objects will will always be instantaneous. It's also the way people basically always do radiosity rendering, as far as I know.

Numerical optimization algorithms seek to find an answer that minimizes some "error" or "loss" function by manipulating some "design variables" within a "feasible region", and they find better and better answers when you run them longer. Large systems of linear equations these days are solved by successive over-relaxation, which is an example of such an algorithm, but there are a whole family of fairly generally applicable optimization algorithms:

• Random sampling: generate random sets of design variables, remembering the best one.
• Hill-climbing: incrementally mutate your best set of design variables at random, undoing each mutation that worsens the loss function. Random restarts make this relatively robust against local minima. If you decrease the magnitude of the mutations over time this is "simulated annealing". It can be slow in a many-dimensional design space.
• Genetic algorithms: just like hill-climbing, but you maintain a bunch of different sets of design variables instead of just one at a time, and you cross them with each other, and you make more mutated versions of the ones that are doing best.
• Gradient descent: just like hill-climbing, except that you calculate the gradient of the loss function with respect to your design variables, so that you can incrementally mutate all of your design variables in the direction that decreases the loss function the most, instead of at random like in hill-climbing. If your design space is

many-dimensional, this is a lot faster than hill-climbing, but it requires you to be able to calculate the derivatives. This is why automatic differentiation is so hot in the last few years. It also benefits from random restarts, a lot of the time.

• Newton-Raphson iteration: vaguely related to gradient descent in that your next guess is where you would linearly extrapolate that the loss function hits zero according to the gradient. This is *much* faster than gradient descent for some things.

Obviously all of these can benefit from massive databases of existing designs and clever neural network stuff to speed them up.

Rich programmers

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

a comment on http://coliveira.net/2008/12/why-great-programmers-dont-make-aso-much-money-as-soccer-stars/

You write:

"Even if the best programmer in the world is in a team with other 10 average developers, he won't be able to cope...

"That is the (sad) tale of software development in more than 90% of programming shops. It is not a mystery, then, that being a software manager, especially a good one, pays much more on average than being a good developer."

Let me suggest another hypothesis. The second richest man in the world, much richer than any soccer player, is a programmer. I'm acquainted with a half-dozen or so programmers who have made hundreds of millions of dollars by programming — some have made more than a billion. I've met one guy who worked on his own for about 20 years, on a team by himself, and retired with substantial savings in one of the most expensive cities in the world, Menlo Park. (Peter Deutsch; none of this is a secret. I have no idea how much money he actually has.)

You meet these guys *all the time* in Silicon Valley, Seattle (where they work for Microsoft), and New York (where they work for investment banks, or did until a few weeks ago). Generally they aren't into flashy cars, big mansions, wild cocaine-filled parties, and trophy wives, so it usually isn't obvious that they have a lot of money.

So I suggest that perhaps your premise is wrong. Programmers *do* make as much money as soccer stars and rock stars. You just haven't noticed because you live in Brazil, which is a wonderful country with fantastic soccer teams, intelligent and friendly people, and enormous intellectual resources that unaccountably hasn't had very many superstar programmers yet. Maybe they moved to Silicon Valley to work with the other superstar programmers from around the world, and in the 1970s and 1980s it was really hard to get good hardware in Brazil, so you kind of lost a generation of programmers. (Still, how much do you think Red Hat is paying Marcelo Tosatti and Alexandre Oliva? How much do you think they have turned down from IBM and Google?)

It's true that nobody is going to make a billion dollars programming on a team full of bad programmers, but nobody is going to make a million dollars a year playing soccer in the Premier Development League either. In both cases the most talented are going to move on to someplace better, not just so they can get paid more (although they do, because the companies they go to work for make a lot more money per employee), but so they will have a chance to work with better collaborators.

Which means that in the 90% of programming shops you talk about above, you will never meet them.

But they're making a lot more than your manager is. One acquaintance of mine turned down job offers to go work for Google

(as a programmer) because their offer of US$120 000 a year was a 40% pay cut from what he was getting paid at an investment bank. He made several million dollars the next year, selling a site he had built in his spare time, over the previous five years or so, to another company.

Fixed point

Kragen Javier Sitaker, 2014-04-24 (1 minute)

Fixed-point math is a case where you'd really benefit a lot from a rich type system. Instead of "This is an integer," or "This is a floating-point number," you'd like to be able to say, "This is a 32-bit fixed-point number with 2 decimal digits of fraction," or perhaps more commonly, "This is a 16-bit fixed-point number with 8 bits of fraction". This allows you to do something like floating-point math, but with all the manipulation of the exponent done at compile time, leaving only mantissas to run-time. Especially for addition, subtraction, and comparisons, this is a huge savings on processors without floating-point hardware, such a huge savings that it's often worth it to do it by hand, without compiler support.

Type systems like C's can't cope with types like that. C++'s template system can do surprising things sometimes, but I don't think it can do it either. But you could certainly imagine a language whose type system was rich enough to let you do it.

Text editor slow keys

Kragen Javier Sitaker, 2017-02-07 (2 minutes)

It is often noted that users continue to use inefficient ways of doing things (for example, repeating cursor-key movements) even when better ways are available (for example, mouse clicks or incremental search (LEAP, as Raskin called it)). A simple way to change users' behavior might be to add a certain amount of extra frustration to the inefficient way of doing things.

For example, perhaps the first cursor-key movement takes 10ms, and each successive one takes 20% longer, so the first few delays would be [10, 12, 14, 17, 21, 25, 30, 36, 43, 52, 62, 74, 89, 107, 128, 154, 185, 222, 266, 319, 383, 460, 552, 662, 795, 954, 1145, 1374, 1648, 1978] milliseconds. For moving three or four characters, the cursor movement would be instant; even at 14 characters it would be barely perceptible; at 19 it would start to feel slow; and by 28 it would be really annoying. Even without any further features, this would start to be uncomfortable enough to encourage users to practice other methods of movement, if they knew them.

This is just one example of a larger shift in user interface design that I think is overdue. The job of the user interface is not just to provide access to functionality and reduce the user's cognitive load; it should also progressively enhance the user to higher and higher levels of awesomeness by shaping their behavior. It's unavoidable that the results produced by the user interacting with the UI will shape the user's behavior through classical and operant conditioning, but so far user interface and user experience designers have not risen to meet the responsibility that comes with that fact; if anything, the result has been the opposite, where user experience designers at companies like Zynga and Facebook work to shape users' behavior to click more ads and use their apps more.

A good user interface, like a game, is its own tutorial.

Topics

Buenos Aires seen from behind the mirror

Kragen Javier Sitaker, 2014-09-02 (7 minutes)

The cracks crazing the boiling blue sky run together into rivulets, brooks, mighty raging rivers flowing into a sunlit yellow tree trunk standing brilliant against the cold, tranquil winter sky, riddled with the bullet holes of its shadowed fruits. The numinous rising wingbeats of a doomed pigeon, one foot long ago eaten by lye or some leprosy, carry it across the frozen static of crossed branches with another tree that still retains its worthless, dried leaves, the poisoned excrement of a summer it cannot remember. Below, there is singing: the radiator fan of a car lamenting its overwork, the baritone thunder of a bus diesel. The fragmentary sidewalk, bearing the scars of too many careless attempts to repair the electrical and communication lines beneath bears the weight of dozen fear-filled West African Plains Apes, each containing a universe of wonders no one else will ever glimpse, each a lonely prisoner of her own distrust and hate, their lives piously dedicated to serving hungry ghosts that never lived upon this earth, but who nevertheless poured these sidewalks, planted these trees, and built these engines that moan with the cries of fish and krill dead since before our foremothers began to lay eggs on land, ghosts called states and companies and races and churches and schools.

In the bus, a skeletal man in a suit fidgets, alternately slumping and suddenly sitting erect, mumbling to himself as he wipes his eyes and scratches his chin. A young mother braids the hair of a daughter on her lap. When her daughter was born in a heroic ordeal of agony and blood, she came to the city, seeking solace in its vastness, yearning to become part of something bigger than she is, leaving behind the memories of her lover who died bisected on the train tracks, stinking of Fernet Branca, a memory that hurt her more than the birth of his child. Still sometimes she awakes at night to his kisses, only to find herself more alone than ever, alone and aging toward her inevitable death.

Her great-grandfather died by a bullet from a man from this city, who came to fight for his rstate and his ace, the race of the city, and erase hers from the Earth; to this race existing only in his imagination, he dedicated his demonic human sacrifice, lawlessly murdering in the name of Law. Her line did not die, but now she sings of her love to her daughter with the words of the man who slaughtered her tribe, and in this city her accent and her skin mark her forever as an outsider, a subjected people. Some days she dreams of a world where her people remain free and her love never tasted Fernet, never called her a slut, where he stood beside her still, tall and strong as he was when she first kissed him, not bloody and cold like when she identified him in the morgue. She dreams that her great-grandfather never beat his wife.

The bus is the larger body of its driver, and in his halting and hurried caresses we feel his anger, his impatience, his desperation to compete for position with the taxis and motorcycles he swims through. The girl in her mother's lap feels it and scowls; the skeletal

man in the suit fidgets a little faster and rubs his face, a face nobody else caresses. The engine growls the impotent rage of its driver, oblivious to the beatific smile on the plastic face of Jesus beside the steering wheel.

The air cylinder to open the doors cries out like a gunshot in a tunnel, and the bus leaves me behind, its superchargers screaming in fury. I walk through the darkening silence it left behind, its vitriol stinging my nostrils like the legacy of decades of insufficiently strict pollution standards, as if a law were as real as the bloated corpses of idealists who hung themselves or took fifty times the lethal dose of Ecstasy, trapped in their own unyielding prisons of logic and delusion and burgeoning, cancerous timidity.

Later, the planet has turned and shadowed me, wrapping me in a darkness that reaches only to behind the nearest streetlight, an assembly of 98 5-watt white LEDs. These false stars of civilization, infecting the wound of our fear of our fellow humans, cannot hold back the unstoppable blackness of the night, but they do shield us from its wonders with ignorance. Children growing up here like weeds in the cracks of the concrete never know the sight of the Milky Way or the Pleiades, except on the hood of a Subaru. At night the woman's grandfather in her village had used stories rather than streetlights to swaddle her in addictive, comforting, toxic ignorance, telling her the Milky Way was spilled milk in the sky.

I emerge from an artificial mountain where I have been reflecting and weeping, a cube of false stone honeycombed with geometrically formed corridors, with trees and meticulously mowed grass on top, and in a few pits in the middle. It has stood in the middle of this city for four generations, and thousands of people earned their livings spinning and weaving in it; unknown dozens of them have lost fingers or hands or died, mangled by the machinery, within its echoing cavernous depths. Walking around it takes almost ten minutes. Our concrete is lashed together with tendons of steel, but our pozzolanic additives are inferior to the Romans', so such buildings decay without constant attention, and a generation ago the roof swimming pool had cracked and would not hold water, and the palm tree next to it had fallen over, unable to shatter our conglomerated stones with its roots. Now I make my office within.

On a black roundrect of mostly stone, bearing an ideogram of a fruit on the back to represent the imaginary person who made it and still owns it in a way that I never will, I inscribe my thoughts in letters of fire, letters that will leap invisibly through subtle vibrations behind the air when I arrive

Querying a pile of free-text strings with quasi-Prolog

Kragen Javier Sitaker, 2017-11-17 (6 minutes)

Literal facts

So, I've been thinking about a sort of free-text Datalog or Prolog system that uses string matching. At the most basic level, you can put literal facts into it (what Datalog would call ground facts) in free text:

```
Romina Vasconcelos lives at Colón 2014 #8.
Valeria Lemmi lives at Suipacha 825.
Valeria Lemmi dances contact improv.
Glenda Quesada dances contact improv.
Glenda Quesada's phone number is +54 11 4777 4909.
Glenda Quesada lives at Hidalgo 979.
Lunch with Glenda Quesada on 2017-11-22 at O'Higgins 1255.
Lunch with Romina Vasconcelos on 2017-11-23 at Billinghurst 3236.
Valeria Lemmi's phone number is +54 11 2560 6898.
Glenda Quesada and Valeria Lemmi are friends.
Valeria Lemmi and Juan Pablo Suracco are friends.
```

Simple searches and joins

And you can search it, at the simplest level, with just a pattern like '%Valeria Lemmi%' or '% dances contact improv.' That is already pretty useful, though not very high tech; it's basically `grep`.

The next level, though, is to relate two or more such facts with patterns containing a common variable. For example:

```
Lunch with @who on @when at @where.
@who's phone number is @phone.
```

This finds a single viable assignment of variables out of the above facts, still based entirely on substring matching:

```
who             when        where           phone
--------------  ----------  --------------  ----------------
Glenda Quesada  2017-11-22  O'Higgins 1255  +54 11 4777 4909
```

Deduction or inference rules

At a third level, we can add deduction rules. For example, with the premises above the line and the conclusions below:

```
@a and @b are friends.
----------------------
@a and @b are connected.
```

If we add a separate rule which can justify the same conclusion, then we can get transitive closure:

```
@a and @b are friends.
@b and @c are connected.
-----------------------
@a and @c are connected.
```

From this and the above facts we can justify, for example,

```
Glenda Quesada and Juan Pablo Suracco are connected.
```

This much is sufficient to implement basic SQL pointwise queries, but it doesn't yet touch issues of quantification, aggregation, negation, and ordering. You can get existential quantification simply enough:

```
@someone's phone number is @number.
-----------------------------------
@someone has a phone.
```

Note that this immediately gives you both AND and OR (intersection ∩ and union ∪), though not negation or even abjunction. You can get AND with two clauses:

```
@someone dances contact improv.
@someone lives at Hidalgo @address.
-----------------------------------
@someone is acrobatic.
```

And you can get OR with two inference rules that can produce the same result:

```
@someone and Juan Pablo Suracco are friends.
--------------------------------------------
@someone is cool.

@someone dances contact improv.
------------------------------
@someone is cool.
```

Problems of infinite regress

In some sense, this string-based formulation is strictly more powerful than Datalog, in dangerous ways. For example, given the rule:

```
@P.
---
It is the case that @P.
```

we can derive:

```
It is the case that Valeria Lemmi lives at Suipacha 825.
It is the case that It is the case that Valeria Lemmi lives at Suipacha 825.

It is the case that It is the case that It is the case that Valeria Lemmi lives a
ot Suipacha 825.
```

and so on.

User interface affordances

An obvious problem with this kind of naïve text matching is that it's very easy to miss records because of very slight textual mismatches. For example, consider the following pattern:

```
@who's phone number is @phone.
```

It won't match the following fact:

```
Valeria Lemmi's phone number is +54 11 2560 6898.
```

That's because it uses a different apostrophe, an ASCII one rather than the Unicode one used in the pattern. It won't match this one either:

```
Valeria Lemmi's cellphone number is +54 11 2560 6898.
```

Once you become aware of these, you can bridge them with inference rules:

```
@who's cellphone number is @phone.
---------------------------------
@who's phone number is @phone.
```

But in many cases it's better to avoid them in the first place, which is best done with user interface affordances.

If you have a set of inference rules like the examples in the earlier section, or even queries that you are likely to evaluate again, they can provide a certain amount of guidance to the system about what kind of data you might want to put into it. A query result, without any further inference rules, is a table that you can type more values into, which immediately provides a quick data-entry user interface. But also, they provide some amount of hints as to the type structure of your data.

```
Lunch with @who on @when at @where.
@who's phone number is @phone.
```

Then, what can we tentatively infer, given the following ground fact?

```
Valeria Lemmi's phone number is +54 11 2560 6898.
```

We can infer that "Valeria Lemmi" is some kind of meaningful entity, and it might be worthwhile to make her name a link to a view of all facts that mention her; and we can also infer that a possible thing that the user might want to do in that context would be to add a ground fact of the form "Lunch with Valeria Lemmi on ... at ...." to the store. There might even be places where you've planned lunch before that could be suggested for the location "field".

Learning low level stuff is not just fun, but also useful

Kragen Javier Sitaker, 2007 to 2009 (5 minutes)

This post argues that learning low-level stuff is a waste of time: http://www.fluidinfo.com/terry/2008/06/18/embracing-encapsulation/

But I don't think that the low-level stuff is frozen in time; it changes too. There was a time when a better C compiler would only help the few people working on Unix at Bell Labs, but today it can improve performance (or security, or debuggability, or whatever) for all of that high-level stuff built on top of C. So the people working on high-level stuff kind of act as a multiplier for the people working on low-level stuff. Which is why Intel and AMD and ARM etc. can spend as much effort as they do designing CPUs.

More and More People Work at the Low Level

I wonder how the amount of effort that goes into making CPUs and other electronics for computers has changed over the years. Intel alone has something like 100 000 employees, and essentially all of them is focused on the lowest levels of computers: processors, motherboard chipsets, flash memory, and so on. AMD has another 16 500 employees, and other top semiconductor companies (Toshiba, STMicroelectonics, TI, Samsung Electronics, Freescale (24000), Infineon, Sanmina-SCI, and so on) add several hundred thousand more people.

Back in 2000, the EE Times reported that the "embedded software tools market" was US$670 million (estimated at US$500 per seat) and the electronic design automation market was four times that, or US$2.7 billion (estimated at US$100 000 per seat). More recently CIOL reported almost twice that size, and EE Times Asia reported 192 000 total semiconductor design seats in 2004, although the article was published on April Fool's Day, 2005, plus 537 000 FPGA and PCB design seats:

> A "seat count" report issued by Gartner Dataquest in January showed that there were only about 56,000 ASIC design seats in 2004, a number that's expected to decline to 39,000 by 2008. The total number of semiconductor design seats was pegged at 192,000 for 2004, with a CAGR of just 1.3 percent until 2008.
>
> In contrast, the report cited 537,000 FPGA and PCB design seats in 2004, growing at a 2.9 percent CAGR. Granted FPGA and PCB designers don't spend as much money as IC designers, but there are a lot more of them. And there are tough problems that could prove very lucrative for vendors that have solutions. For example, FPGA designers need to look at power and signal integrity, and PCB designers are having a hard time getting IC packages to work on boards.

So it seems that the number of people working at the very lowest levels --- the hardware levels --- has been gradually increasing over the last several years, and has already reached a really remarkable number.

Changing the Low Level is Getting Easier

To write software for CP/M, you would write it in 8080 assembly, or maybe Z80 or 8085 assembly if you were willing to limit your userbase, and used the BIOS and BDOS functions for I/O and file management. You could use C or FORTH, but they had big drawbacks. Porting software in 8080 assembly even to MS-DOS on an 8086 was a pain, and porting it to a 68000 basically required rewriting it, or buying or writing a slow 8080 emulator on the 68000.

If you write software in C, it's only a bit more effort to make it portable and compile it for many different CPU architectures. Alll of the tens of thousands of packages in Debian Linux are routinely built for eleven different CPUs: the Alpha, the Opteron, the ARM (big and little-endian), the HP PA-RISC, the Intel 386, the Itanic, the 68000, the MIPS (big and little-endian), the PowerPC, the IBM System/390, and the SPARC. All of the 6400 packages in NetBSD run on all of its supported 16 CPU architectures. Some individual software packages written in C have been ported to even more; GCC, for example, runs on something like 30 CPU architectures.

This kind of portability has the advantage that you can switch CPU architectures and keep using the same software --- and the hardware exists only to support the software, anyway, just as the software generally exists only to support human activities carried out with it.

This still leaves the problem of

Jellybean ICs 2016

Kragen Javier Sitaker, 2016-07-14 (updated 2019-05-05) (17 minutes)

I thought I'd check out some of the cheapest and most popular items in the most diverse IC categories on Digi-Key.

(Related to My attempt to learn about jellybean electronic components (p. 1974), from 2017 and 2018, which isn't specifically focused on chips, and Transistors vs. Microcontrollers (p. 2918), which explores the implications of microcontrollers now being as cheap as individual discrete transistors nowadays in many cases.)

Microcontrollers: 61814 items

• 72000 available of the US$2.86 http://www.digikey.com/product-detail/en/texas-instruments/MSP430G2755IDA38R/MSP430G2755IDA38R-ND/4090934 which is a TI MSP430, "16BIT 32KB FLASH 38TSSOP". 16MHz, 32K flash, 4K RAM, probably the usual super low power, a 12-channel 10-bit ADC, 32 GPIOs, internal oscillator, and so on. Other MSP430 parts with 55601 available are #3.

• 67594 available of the US$2.69 http://www.digikey.com/product-detail/en/freescale-semiconductor-nxp/S9S08SG16E1CTLR/S9S08SG16E1CTLRDKR-ND/2252301 Freescale S9S08SG16E1CTLR, "8BIT 16KB FLASH 28TSSOP," from their S08 series, which I've never heard of before. It's the MC9S08SG32 in the datasheet, in the HCS08 category, originally the 68HC08 or HC08, the successor to the 68HC05, a successor to the 6800. Also it's sometimes called the 9S08. So despite all the obfuscation this is a 6800. But a 40MHz 6800 with memory paging and on-chip flash, 16K of it I guess. Von Neumann, 22 GPIOs (with two selectable output drive strengths plus an optional pullup on input), 8 interrupt pins with selectable priority, a 16-channel 10-bit ADC, SPI, I²C, wakeup timer, PWM generation, 1024 bytes of RAM. Its big brother, the ...SG32, has 32K of flash and operates up to 150°. Runs on 5V, normally uses an external crystal, though it has a 40MHz internal clock source too. It has a "standard 6-pin header" for a documented "background debug mode" that's driven through a single-wire serial protocol, typically bitbanged from a PC. The BDM documentation says there are other secret test modes too. It makes it sound like chips of this family found in the field might have the Flash-reprogramming functionality available through the debug port disabled.

• 45696 available of the US$3.20 http://www.digikey.com/product-detail/en/atmel/ATMEGA48-20AU/ATMEGA48-20AU-ND/739775 Atmel ATMega48, "8BIT 4KB FLASH 32TQFP". 20MHz, 8-bit, 23 GPIO, 4K of flash and half a K of RAM, 8 10-bit ADCs.

• 9000 available of the US$0.42 http://www.digikey.com/product-detail/en/microchip-technology/PIC10F200T-I-OT/PIC10F200T-I-OTTR-ND/665882 PIC10F200T-I/OT, a 4MHz Microchip PIC with 384 bytes (!!) of flash, 16 bytes (!!!) of RAM, and 3 GPIOs, in a six-pin SOT-23

package, 3.1mm × 1.75 mm × 1.3 mm.

• 4500 available of the US$1.01 http://www.digikey.com/product-detail/en/atmel/ATTINY4-TSHR/ATTINY4-TSHRTR-ND/2238292 ATTINY4-TSHR, a 12MHz Atmel AVR ATtiny4 with 512 bytes of flash and 32 bytes of RAM, in the same package as the PIC.

• 127 available of the US$1.11 http://www.digikey.com/product-detail/en/silicon-labs/EFM8SB20F16G-A-QFN24/336-3175-5-ND/5115732 Silicon Labs EFM8SB20F16G-A-QFN24, a 25MHz 8051, "8BIT 16KB FLASH 24QFN", with 4¼ kibibytes of RAM and 16 kibibytes of flash. This is the cheapest microcontroller with over 4K of RAM. It runs off 1.8 to 3.6 volts, with 16 GPIOs, a 15-channel 10-bit 300ksps ADC, a thermometer good to about half a degree, and a PWM generator; of the "Sleepy Bee" line, "the world's most energy friendly 8-bit microcontrollers". 50 nA sleep current (or 300 nA with the internal RTC running), 170 µA / MHz; most instructions are 1- or 2-cycle, so if we assume an average of 1½ and 1.8V, that's about 200 pJ/insn. The RAM is "256 bytes standard 8051 RAM and 4096 bytes on-chip XRAM"; the GPIOs are 5 mA source, 12.5 mA sink. And it has an internal 20MHz ±10% clock, an internal 16 (or 32?) kHz clock, and a 24.5MHz ±2% one, so you don't need an external crystal, and the RTC optionally uses a watch crystal. Four timers. It ships with a UART bootloader. Its "on-chip debugging interface" is a thing called "C2 Silicon Labs 2-Wire", which is apparently public. 4mm × 4mm.

• 2,570 available of the US$3.49 http://www.digikey.com/product-detail/en/atmel/AT80C51RD2-3CSUM/AT80C51RD2-3CSUM-ND/1026863 Atmel AT80C51RD2-3CSUM, which is a 5V 40MHz 8051 in a 40-pin DIP with no ROM; you hold its "external enable" pin low so that it executes code from an external ROM.

• only 22 available of the US$2.06 http://www.digikey.com/product-detail/en/intel/EE80C51FA24SF88/864420-ND/1464725 Intel EE80C51FA24SF88. That's an actual 8051! With no ROM, using an external ROM.

Linear regulators: 58468 items

• 163000 available of the US$0.71 http://www.digikey.com/product-detail/en/texas-instruments/LM317LIPK/296-21742-6-ND/1944499 LM317LIPK, an adjustable ungrounded linear voltage regulator that can output from 1.2 to 32 V at up to 100 mA, in a tiny SOT-89-3 case. This LM317L family is the low-current version of the regular 1500mA LM317. You adjust it with an external voltage divider providing negative feedback from its output; I guess you could probably use a FET in its linear region to make it a more custom voltage regulator. And you can also use it as a precision current source! Note that this part is more popular than any of the microcontrollers. Its datasheet includes instructions for how to make a slow-turn-on regulator circuit with it, I guess to ensure that your brownout detection circuits have time to do a power-on reset.

• 121799 available of the US$0.39 http://www.digikey.com/product-detail/en/toshiba-semiconductor-

°and-storage/TCR2EF12,LM%28CT/TCR2EF12LM%28CTDKR-N°
°D/4503462 Toshiba TCR2EF12,LM(CT), “LDO 1.2V 0.2A SMV”. This is a 1.2-volt output voltage regulator with an 0.38V dropout and up to 200mA of output. I am guessing that this is such an important voltage because of NiMH battery chargers, but I don't know.

• 14254 available of the US$0.12 http://www.digikey.com/product-detail/en/microchip-technology/°
°MIC5365-3.0YC5-TR/576-3191-1-ND/1868228 Microchip (ex-Micrel) MIC5365-3.0YC5-TR, a tiny (1mm×1mm!) 3V 150mA linear regulator. I think this may be the cheapest linear regulator of all.

Memory: 40599 items

• 168177 available of the US$0.23 http://www.digikey.com/product-detail/en/stmicroelectronics/M20°
°4C32-WMN6TP/497-5027-6-ND/1007946 STM M24C32-WMN6TP, a 400kHz 32-kibibit serial I²C EEPROM in an 8-pin package. STMicroelectronics will even sell you an unsawn wafer! It supports random address reads, and also erases of individual 32-byte pages.

• 130237 available of the US$0.36 http://www.digikey.com/product-detail/en/winbond-electronics/°
°W25X40CLSNIG/W25X40CLSNIG-ND/3008652 Winbond W25X40CLSNIG, a 104MHz (!) 4-mebibit (!!) dual SPI EEPROM in an 8-pin package. It's insane that this is literally 256 times faster than and 128 times bigger than, but only 57% more expensive than, the #1 memory above.

• 5357 available of the US$0.13 http://www.digikey.com/product-detail/en/stmicroelectronics/M20°
°4C02-FDW6TP/497-15746-1-ND/5283304 STMicroelectronics M24C02-FDW6TP, another 400kHz serial I²C EEPROM, this time 2 kibibits. This one claims “More than 200-year data retention,” which is a surprising claim I haven't seen other Flash chips make, but now that I notice, the 32-kibibit one above makes it too!

• 27500 available of the US$2.78 http://www.digikey.com/product-detail/en/stmicroelectronics/M95°
°M02-DRMN6TP/497-11405-2-ND/2679404 STMicroelectronics M95M02-DRMN6TP, another serial EEPROM with “200-year data retention”, but this time SPI, two megabits, and 5 MHz! It's in the same 8-SOIC as the others above.

Op-amps, etc.: 36285 items

• 136806 available of the US$0.57 http://www.digikey.com/product-detail/en/stmicroelectronics/TS°
°V321RILT/497-8164-6-ND/1884598 STMicroelectronics TSV321RILT “Op Amp GP 1.4MHz RRO SOT23-5”, “General purpose input/output rail-to-rail low-power operational amplifiers”, going 200mV past the power rails, good up to 125°, now replaced by the LMV321L. These are lower-voltage versions of the LMV324 for the 2.5–6V range, have a 1.3MHz GBP, and can source or sink up to 80mA and is stable driving up to 500pF of capacitive load.

• 99104 available of the US$1.00

http://www.digikey.com/product-detail/en/texas-instruments/LMo
oC6032IMX-NOPB/LMC6032IMX-NOPBCT-ND/3440137 TI LMC6032IMX/NOPB, which is also a 1.4MHz GBP op-amp, but there are two op-amps on the chip, so it has 8 pins. This one only sources or sinks up to 18mA, it's not quite rail-to-rail, runs on 4.75–15.5V, and is stable driving up to 100pF of capacitive load.

• 83402 available of the US$0.77 http://www.digikey.com/product-detail/en/rohm-semiconductor/o
oBU7411SG-TR/BU7411SGDKR-ND/2791706 Rohm BU7411SG-TR, an "Op Amp GP 4KHZ 5SSOP", which makes it sound like it's worse than the TSV321$ in every way, orders of magnitude worse in the GBP. But it only need 0.35µA of supply current, and needs even lower voltages: 1.6–5.5V. It can only source or sink a couple milliamps on its output.

• 53751 available of the US$0.24 http://www.digikey.com/product-detail/en/microchip-technology/o
oMCP6001T-I-OT/MCP6001T-I-OTCT-ND/697158 Microchip MCP6001T-I/OT, the world's cheapest op amp. This is a rail-to-rail 1MHz GBP op-amp using 100µA and sourcing/sinking up to 23mA, running on 1.8 to 6 V, in a SOT-23-5. It says it's "low power" but it consumes 300 times what the BU7411SG above does.

• 2148 available of the US$0.31 http://www.digikey.com/product-detail/en/microchip-technology/o
oMIC912YM5-TR/576-3691-1-ND/2339688 Microchip MIC912YM5-TR "Op Amp VFB 200MHz SOT23-5", which is the cheapest 10MHz-or-over op amp; this was a Micrel part before Microchip bought them. This uses 2.4mA of supply current, is stable with unlimited capacitive loads, and runs on 2.5–9V. The datasheet PDF is corrupted, so I can't find out more.

• 51585 available of the US$2.77 http://www.digikey.com/product-detail/en/analog-devices-inc/AD o
o8606ACBZ-REEL7/AD8606ACBZ-REEL7DKR-ND/2468795 Analog Devices. AD8606ACBZ-REEL7 "Op Amp GP 10MHZ RRO 8WLCSP". It's a dual-op-amp chip, and the most popular (as measured by Digi-Key stock) RF op amp. It's immune to oscillation and phase reversal even when driving large (1000 pF) capacitive loads, and its picoamp input offset current allows you to use large feedback resistors.

Power management supervisor ICs: 35843 items

• 67032 available of the US$0.54 http://www.digikey.com/product-detail/en/on-semiconductor/NC o
oP302LSN20T1G/NCP302LSN20T1GOSCT-ND/2121405 ON Semiconductor NCP302LSN20T1G two-volt detector in a 5-TSOP (a thin SOT-23 with five pins). This is a power-on reset circuit. These suck 500 nA from 0.8 V to 10 V and produce an active-low reset signal when the voltage is below 2 V with hysteresis and a delay programmable with a capacitor on one of its pins. "This device contains 28 active transistors."

• 56,660 available of the US$0.36 http://www.digikey.com/product-detail/en/diodes-incorporated/A o

oPX809-31SAG-7/APX809-31SAGDICT-ND/1844722 Diodes Incorporated APX809-31SAG-7, which is basically the same thing, but with a 3.08V threshold voltage, a fixed delay of 240ms instead of a programmable delay, and only 3 pins. It sucks 30000 nA though and only works in the 1.1 to 5.5 volt range.

• 38041 available of the US$0.64 http://www.digikey.com/product-detail/en/torex-semiconductor-lto
od/XC61CC2502MR-G/893-1027-6-ND/2138365 Torex XC61CC2502MR-G, which is a ±2% low voltage detector in a SOT-23 with a 2.5V threshold that sucks 700 nA.

DC-DC switching regulators: 25051 items

• 79,855 available of the US$1.16 http://www.digikey.com/product-detail/en/texas-instruments/TPSo
o61221DCKR/296-41854-6-ND/5224781 TI TPS61221DCKR, a TPS61221DCKR, described as "Boost Switching Regulator IC Positive Fixed 3.3V 1 Output 200mA (Switch) 6-TSSOP, SC-88, SOT-363". This takes an input of anywhere from 0.7 to 5.5 volts and turns it into a 3.3-volt ±3% output at up to 200mA. It needs an external inductor (4.7µH suggested, higher inductances give higher efficiency) and a couple of 10µF capacitors; the adjustable-voltage versions also use a couple of resistors for feedback. At over 1V input and from 0.1 to 100 mA output, it's over 80% efficient; above 2.3V input and 0.3 mA output, it's over 90% efficient. This is basically intended for running 3.3V circuits off rechargeable batteries.

• 73,400 available of the US$0.70 http://www.digikey.com/product-detail/en/alpha-omega-semicondo
ouctor-inc/AOZ1280CI/785-1277-1-ND/2769845 Alpha Omega AOZ1280CI, described as "Buck Switching Regulator IC Positive Adjustable 0.8V 1 Output 1.2A SOT-23-6". This is a step-down switching regulator that takes 3–26V in and produces a 1.5MHz PWM output signal which you filter with a 2.2µH output inductor and a 10µF output bypass cap to get whatever voltage you want (programmed with a 800mV voltage divider), down to 0.8V, at up to 1.2 amps. It's "up to 95% efficient", but typically more like 80–90%. It sucks a whole milliamp itself, though, so it's not suitable for super low-power circuits.

• 58,254 available of the US$1.36 http://www.digikey.com/product-detail/en/vishay-siliconix/SIP121o
o07DMP-T1-GE3/SIP12107DMP-T1-GE3CT-ND/3309123 Vishay Siliconix SIP12107DMP-T1-GE3 "Buck Switching Regulator IC Positive Adjustable 0.6V 1 Output 3A 16-SMD", which honestly sounds like more of the same, but higher power and less versatile. But it says it's "current-mode constant on-time", and its switching frequency is 4MHz, and it has 16 pins.

Programmable timers and oscillators: 23241 items

• 56,647 available of the US$0.44 http://www.digikey.com/product-detail/en/texas-instruments/NE5o
o55P/296-1411-5-ND/277057 TI 555 (NE555P), the chip that gave

birth to this product category in the 1970s. The datasheet says, "September 1973—revised September 2014", which I guess means TI bought Signetics at some point. Astable or monostable operation. Sinks or sources up to 200mA, runs on 4.5 to 16 volts, at 1 millihertz to 100 kHz. This is an 8-pin DIP.

• 34,355 available of the US$0.73 http://www.digikey.com/product-detail/en/intersil/ICM7555IBAZ-T/ICM7555IBAZ-TDKR-ND/2529181 Intersil ICM7555IBAZ-T, which is a CMOS version of the 555, but runs at up to 1 MHz, with a wider 2–18 V power supply, and it runs on 60 μA and comes in an 8-SOIC rather than a DIP.

• 2,717 available of the US$3.41 http://www.digikey.com/product-detail/en/texas-instruments/SN74LS628DR/296-37424-1-ND/4758875 TI SN74LS628DR, aka 74628, a 20MHz VCO, an improved version of the 74LS324, using an external timing resistor to improve temperature compensation. Datasheet is from 1980, revised 1988. It can oscillate at roughly 2MHz to 20MHz as the frequency-control input voltage ranges from 1V to 5V.

• the great majority of these 23000 items are very slightly different VCXOs whose prices start at US$30.

FPGAs: 19724 items

• 3,482 available of the US$32.49 http://www.digikey.com/product-detail/en/atmel/AT40K20AL-1BQU/AT40K20AL-1BQU-ND/1914271 Atmel AT40K20AL-1BQU, a 1024-cell 3.3V FPGA ("30000 gates") with 8192 bits of 10ns RAM and 114 5V-tolerant GPIOs in an LQFP. Supposedly good up to 100MHz, with 50MHz multipliers. Its cells have propagation delays of about 2 ns, are capable of implementing full-adders or even multiplier bits, and have diagonal interconnections to make multipliers out of. Bitstream format and debugging features are apparently not documented.

• 3,127 available of the US$6.75 http://www.digikey.com/product-detail/en/microsemi-corporation/A3P030-QNG48/1100-1012-ND/2744959 Microsemi A3P030-QNG48, a ProASIC3/E FPGA with 34 3.6V-tolerant GPIO and "30000 gates". "Ideal for CPLD replacement." "1.5 V single voltage operation." "350 MHz system performance." 1024 bits of flash that it can't write to (and also its programming is stored in flash; it doesn't have to load a bitstream to boot). Consists of 768 "VersaTiles" which are three-input arbitrary functions registered with D flip-flops, but no RAM. No AES protection on its JTAG ISP. Quiescent supply current is 2 mA, enormous compared to the microcontrollers. Maximum JTAG TCK clock is 19MHz. Bitstream format and debugging features are apparently not documented.

• 1,953 available of the US$2.96 http://www.digikey.com/product-detail/en/lattice-semiconductor-corporation/LCMXO256C-4TN100C/220-1048-ND/2641849 Lattice LCMXO256C-4TN100C, marketed as a CPLD, from the "MachXO" family. 256 LUT4s, no external configuration memory (and "instant-on"), fast SRAM reconfigurability, normally programmed via JTAG.

Tantalum capacitors: 54077 items

• 1,534,001 available of the US$0.84 http://www.digikey.com/product-detail/en/avx-corporation/TAJB226M010RNJ/478-3040-6-ND/1717036 AVX TAJB226M010RNJ 22µF ±20% 10V 2.4Ω capacitor in a 3.5 mm × 2.8 mm package. This is not the highest-energy-capacity capacitor in the series (that would be the 25V 150µF type, holding 47 mJ, like the TAJV157M025#NJ in a 7.3 mm × 6.1 mm case, though Digi-Key doesn't carry it; they'll sell you the lower-voltage 20V type TAJV157M020RNJ at US$2.17 but only in lots of 400) but it still has a pretty impressive energy density. These are advertised as "standard tantalum" capacitors; I think that means they don't have wet electrolyte. AVX's wet tantalum page explains, "AVX's wet tantalum capacitors offer higher capacitance and voltage capability than solid tantalum capacitors." On another page, they say, "We are the global leader in MnO_2 solid tantalum technologies such as smallest case size MnO_2, highest temperature capabilities up to 230°C and lowest DCL product offering," and the TAJ series is indeed on that page.
• 792,881 available of the US$0.38 http://www.digikey.com/product-detail/en/kemet/T491A106K010AT/399-3684-1-ND/819009 Kemet T491A106K010AT 10µF 10V 3.8Ω 3.2mm x 1.6mm tantalum capacitor. This is also a MnO_2 capacitor.
• 761,191 available of the US$1.49 http://www.digikey.com/product-detail/en/kemet/T491D107K016AT/399-3770-1-ND/819095 Kemet T491D107K016AT 100µF 16V 0.7Ω 7.3mm × 4.3mm tantalum capacitor. This one is rated for 2000 hours, even though it's I think also a MnO_2 capacitor. This is really cheap for such a high-energy capacitor.
• 4169 available of the US$8.91 http://www.digikey.com/product-detail/en/vishay-sprague/597D157X9025F2T/718-1632-1-ND/1973910 Vishay 597D157X9025F2T, the cheapest 150 µF 25 V capacitor I could find.
• 2278 available of the US$9.55 http://www.digikey.com/product-detail/en/vishay-sprague/597D227X0025M2T/718-1945-1-ND/3985794 597D227X0025M2T, which is the 220µF version, with 37% more energy capacity per dollar.

Some interesting notes from the above list

• High-speed serial interfaces usually are SPI rather than I²C.
• Although sub-picojoule-per-instruction CPUs exist in research labs, the ones you can actually buy are up in the hundreds-of-pJ range.

Topics

Laser cut next step

Kragen Javier Sitaker, 2018-04-27 (updated 2018-04-30) (7 minutes)

I find myself in need of objects that can be easily laser-cut. The deskbox for the office is an example, but there are others: chairs, storage boxes, etc.

I've been sitting on this issue for more than a month since I moved. In a way, over a year, kind of due to lack of money. But now I have money, and I need to make my things manageable. And I need to return to the learning cycle.

So far most of the pieces I've cut have been 0.01 m², with the exception of that one that was about 0.1 m² and didn't turn out that well. The deskbox is about 1 m²; the bedbox is about 10 m². So I should make some smaller things first.

Draining rack

At the 0.02 m² level, I could benefit immediately from a draining rack for cutlery, maybe with a 100 mm x 200 mm bottom and 150 mm walls, and bottom hole diameter of no more than 8 mm so the steak-knife tips can't poke through very far. Also, for cleanability, it would be nice for the bottom to be as thin as possible and have relatively round holes, and it would be nice for the joints to have some kind of inside radius or at least be relatively rounded for the same reason, and to be connected in ways that don't leave cracks for mold to grow in.

This couldn't be made of MDF; acrylic and HIPS are options. (Max58 has clear, black, and white acrylic in 2.4, 3, 4, 5, and 8 mm, and HIPS in 1 mm.) Both acrylic and HIPS can be solvent-welded with acetone or MEK (and maybe ethyl acetate, I'd have to try it) but resist alcohol. Heat welding and caulking with silicone are plausible alternatives.

There is a good introduction to solvent welding on the NerfHaven forum. It has a short list of acetone-resistant plastics: Delrin, UHMWPE, nylon, Teflon. Nylon and Teflon resist every solvent on the list, and I suppose epoxy would too. Paint thinner may be my best bet in Argentina.

The bottom holes can be relatively infrequent; they don't have to fill most of the bottom. The bottom will bow downward with the weight of the cutlery, so I need a bottom hole in the middle, at least.

HIPS supposedly has 40% elongation at break, so I should be able to curve it into really ridiculously curvy shapes, to the point of origami. (The ratio of its 32 MPa UTS to its 1.9 GPa tensile modulus, however, suggests more like 1.7% elongation.) Maybe actually the best approach would be to cut some darts into the edge of a single piece and then weld them shut to make a curvy shape.

PMMA, by contrast, only has 4% elongation at break, which beats the hell out of MDF but isn't very much. And I'm more sanguine about its food safety. So the 2.4 mm PMMA could presumably be compressed 4% on its inner face and stretched 4% on its outer face at 1.2 mm, giving a curve radius of 1.2 mm/4% = 30 mm. This rather implausible result suggests that I should be able to bend it into 600mℓ bottles. I think they would be fairly prone to exploding, but maybe

they could work.

PET panes of 0.3mm are available from Maderera Gascón at a lower price than acrylic. These are AR$115 for 1×2 m.

The whole cutlery drainer would be (+ (* 2 200 150) (* 2 100 150) (* 200 100)) = 110000 mm² or 0.11 m². If I make it as a box from separate pieces, the biggest separate pieces are the 200×150 sides, which are 0.03 m², which is the right order of magnitude for this project.

The simplest possibly usable design would be a box with some hooks on the side, with a few tabs to keep the pieces aligned while I glue them: (+ (* 2 2 (+ 200 150 100 150)) (* 2 (+ 200 100))) = 3000 mm of box edges to cut, plus the tabs, the hooks, and the drainage hole. Maybe 2 minutes of cutting.

Or maybe two 100mm-radius approximate semicircles (.0314 m² each) plus a 100mm×314mm rectangle (also 0.0314 m²) to bend into a semicircle, with a drainage hole in the middle, a couple of tabs to hold it together for gluing, and a couple of hooks on the side. That's (+ (* 2 (+ 100 314 200 314))) = 1856 mm of edges to cut, plus the drainage hole and the hooks.

Or maybe both. Or more possibilities. If I use 3mm acrylic, it should be dimensionally compatible with MDF Heckballs, but awesomely transparent and stuff. If the acrylic sheet is 600×400 (.24 m²) I have room for about 8 pieces of this size, so basically both cutlery drainers and not much else.

A 600×400 mm sheet of acrylic might cost AR$300 or AR$400. If cutting still costs AR$0.40 per second and cutting is 24 mm per second plus 60 ms per vertex, we have only about 90 seconds of cutting for the semicircle thing and another 200 seconds of cutting for the box (99% edge, 1% vertex), totalling like 300 seconds and AR$120. This suggests that the quality of the product could be improved dramatically at minimal extra cost; doubling the cut time by using 100× as many vertices would be a minimal problem, for example, and there's plenty of time to engrave surfaces and scallop edges and stuff.

Bowls

While I'm at it maybe I should make some bowls or something. PMMA is about 1.2 g/cc, so 8mm PMMA should weigh almost 1g/cm². So an 0.03 m² bowl (crudely: 0.01 m² of base, plus four sides of 0.005 m² each — 100 mm × 100 mm × 50 mm) would be 300 g.

Other stuff

I've moved again! Now I have no housewares.

I need fans, and I have motors and power supplies. A pinwheel-like structure should be easy to cut out of thin HIPS; also I should be able to assemble something out of sheets of acrylic or even MDF.

I now need an entire draining *rack*.

I'd like to make some IQLights. These can be laser-cut out of HIPS as well, I think.

I'd like a dehydrator, an apparatus that runs heated air through a serpentine airflow with food or other things on shelves. I'd like a dehydrator for food, a dehydrator for garbage (so the garbage doesn't become food), and a dehydrator for laundry, although that may be aiming a bit high.

I need chairs. A relatively small amount of PMMA should suffice to make a sittable chair, but it will be somewhat fragile, and potentially cut you if it breaks.

Sheets of PMMA should work adequately as cutting boards.

On the method of finite differences used in Babbage's Difference Engine

Kragen Javier Sitaker, 2019-05-31 (6 minutes)

The "method of finite differences" as used in the Difference Engine is closely related to, but slightly different from, Newton's method of divided differences (used, for example, for polynomial interpolation or for boundary-value problems in ordinary differential equations) and the finite difference method used in the solution of ODEs and PDEs.

The Wikipedia page on the Difference Engine explains how to calculate the initial values, but I am skeptical of its explanation. However, it cites Nathan Myhrvold's instructions for setting up the machine, which we can suppose have been tested on the one he had built.

Reading F. Baily's 1823 comments on the Difference Engine we find:

> 2°. Tables of Square Numbers. The squares of all numbers, as far as 1000, were a long time ago published … In computing a table of this kind by the machine, even if extended to the most remote point that could be desired, the whole of the mental labour would be saved: and when the numbers 1, 1, 2 are once placed in it, it will continue to produce all the square numbers in succession without interruption. This is, in fact, one of those tables which the engine already made is capable of computing, as far as its limited number of wheels will admit.
>
> 3°. Tables of Cube Numbers. Tables of this kind have likewise been already computed… In computing such a table by the machine, the whole of the mental labour would be in this case also saved: since it would be merely necessary to place in the machine the numbers 1, 7, 6, 6; and it would then produce in succession all the cube numbers.

The table of cubes begins 1, 8, 27, 64, 125; its first differences are 7, 19, 37, 61…, and its second differences are thus 12, 18, 24…, its third differences 6, 6…, and its fourth differences merely a sequence of zeroes, since the third-order approximation is actually precisely correct. The first item of each of these sequences gives the (1, 7, 6, 6) setup described in Baily's article.

XXX no it doesn't; 6 is the difference between 1 and 7, so I think Baily actually took into account the half-cycle offset I claim below that he didn't take into account; his numbers give the correct answer as shown at the end.

However, to update this state (1, 7, 6, 6) to its successor state (8, 13, 12, 6) without any extra storage, we must work strictly from left to right, because the previous value of each number (except the 1, in the lowest-order register, T) is needed to update the next-lower-order term, before being itself updated (except the second 6, in the highest-order register, Δ^3). So we must proceed as follows:

T	Δ^1	Δ^2	Δ^3
1	7	6	6
8	7	6	6
8	13	6	6
8	13	12	6

XXX note that 13 is wrong because it should be 19

However, at least in the "Difference Engine No. 2" design Babbage developed between 1846 and 1849 (23–26 years after Baily's letter), the calculations are not performed in this serial fashion. As explained in Swade's analysis, instead a set of four parallel additions is carried out, then a set of three parallel additions:

However, the sequence of additions as executed by the engine does not proceed in a stepwise way from right to left as one might expect from the manual method. One complete calculating cycle consists of two symmetrical half-cycles. During the first half-cycle the number values on the odd-numbered axes are simultaneously added to those of the even-numbered axes to the immediate left i.e. axes 1 [Δ^7], 3 [Δ^5], 5 [Δ^3], 7 [Δ^1] are added to 2 [Δ^6], 4 [Δ^4], 6 [Δ^2],and 8 [T] respectively. Similarly, during the second half-cycle all the even-numbered axes are simultaneously added to the odd-numbered axes again to the immediate left. Provided this is taken account of when setting up at the start of a run by offsetting the initial values on alternate axes by a half-cycle, the end result is the same i.e. each full calculating cycle results in a new tabular value which is the cumulative sum of the number of active differences.

So, in fact, if we want to compute a table of cubes, to get 8 as our second cube, we do indeed need to set Δ^1 (column 7 on the machine) to 7, as Baily says. And then, having been used, it is incremented by Δ^2 (column 6 on the machine) in the second half-cycle — but that Δ^2 had previously been incremented by Δ^3 in the first half-cycle. So the correct initial state we would need is not Baily's (1, 7, 6, 6) but (1, 7, 0, 6), proceeding as follows:

T	Δ^1	Δ^2	Δ^3
1	7	0	6
8	7	6	6
8	13	6	6

XXX this is the wrong answer. If we start from Baily's setup we get the right answer:

T	Δ^1	Δ^2	Δ^3
1	7	6	6
8	7	12	6
8	19	12	6
27	19	18	6
27	37	18	6
64	37	24	6
64	61	24	6
125	61	30	6

Jim Weirich's death and my daily life

Kragen Javier Sitaker, 2014-04-24 (5 minutes)

Today, 2014-02-20, I learned that my friend Jim Weirich died yesterday. No word yet on the cause of death, except for a pseudonymous rumor on Hacker News that he died of a heart attack, which is quite plausible. If I remember correctly, Jim was the guy who guided me through understanding the applicative-order Y combinator during the previous millennium, and who has also given me one of the nicest compliments I've ever received. I suppose this is an example of that saying: they won't remember what you said, and they won't remember what you did, but they will remember how you made them feel; because I'm not even sure about the Y combinator thing.

I don't know how to describe the loss to the world that is Jim's death. He worked on code that was useful to millions of people, shared his knowledge, and was always willing to mentor people; but, also, and maybe more importantly, he was one of the least assholish people I know. A militant atheist mutual friend of ours complained to me once that Jim was a fundamentalist Christian, which could be true for all I know; I never asked him, and he never brought it up. In many ways, he was a paragon of loving your neighbor as yourself.

I don't remember when the last time I talked to Jim was. It's probably public on Twitter.

Today I didn't get much done at work. A little bit, but not enough. Tomorrow I go in early, which might help or might hurt.

Jim was 57, about 20 years older than I am. Every year now for several years, some of my friends have died. They say that your risk of death per year increases by about tenfold every ten years, and if that's true, it's also true of your group of friends, if they continue to have the same age distribution relative to you. So in my 20s this rarely happened, and now it's happening once or twice a year. I guess that means that when I'm 47, I can expect one of my friends to die every month, unless I start hanging out with a younger crowd.

I've just arrived home from work at about 21:30. Stace had messaged me a few hours earlier to let me know power was out at the house. As I approached home on my bicycle, I noticed that several blocks of buildings and streetlights were dark.

I had been hoping power would be back on, because I was looking forward to answering a sweet email someone had sent me earlier today, and I didn't bring a copy of it with me. And I was hoping perhaps to work on a search-engine project for my chapter in an upcoming book, and it turns out I don't have the current version of the code with me on this netbook.

The upstairs neighbor is peeing, a sound that always makes me nervous when I hear it in my bedroom.

My bedroom is beginning to smell of exhaust from poorly maintained gasoline engines, probably from neighbors who have turned on their generators.

I went to work today by bicycle for the first time in a while. My

rear tire had gone flat, so I pumped it up; but after a few blocks, the seam on the inner tube split and it went totally flat again. After I wandered around for a while (forgetting the bike map I have in my backpack, which showed two bike shops within a few blocks) I found a bike shop and got a new inner tube for $70 (US$6.50). I'd've bought an extra one to carry as a spare, but I didn't have the cash on me.

On the way home, it went flat again, but more slowly, so I was able to make it home by pumping it up. I guess I need to see if I have a puncture and patch it by this weekend.

Last night, Stace, her dad, and I went over to a friend's house, who showed us his new video game. Although he told me the name several times, I can't remember it now. It's a guitar trainer that analyzes the analog signal from your electric guitar to teach you to play the chords and riffs of popular rock songs, including tricks like pitch bending. "Look, Stace!" I said. "This is the future of education!" She was unimpressed. (My track record at predicting the futures of things is not that great.)

Oh! Power's back on!

Hadamard rhythms

Kragen Javier Sitaker, 2019-11-01 (6 minutes)

I was thinking about synthesizing drum loops and it occurred to me that Hadamard bases might be an interesting way to do it.

A simple approach to synthesizing a drum loop with a single instrument and up to 8 beats is to just have 16 variables for the volume and timing offset of each of the 8 beats. Some of the volumes might be 0, silencing those beats; some of the offsets might be nonzero, swinging those beats a bit.

A problem with this representation is that usually you don't want to adjust just one beat at a time; you might want to do something to all the odd beats, for example, or all the even beats. A possible solution to this is to transform 8 volume variables and 8 timing-offset variables each through a 8x8 Walsh matrix, here given in "sequency order" rather than as a Hadamard matrix:

```
 1  1  1  1  1  1  1  1
 1  1  1  1 -1 -1 -1 -1
 1  1 -1 -1 -1 -1  1  1
 1  1 -1 -1  1  1 -1 -1
 1 -1 -1  1  1 -1 -1  1
 1 -1 -1  1 -1  1  1 -1
 1 -1  1 -1 -1  1 -1  1
 1 -1  1 -1  1 -1  1 -1
```

Given an appropriate constant scaling factor, this is an orthonormal basis for 8-vectors.

A more convenient form might be the ReLU of the same matrix, which you will note is still symmetric though no longer normalized:

```
1  1  1  1  1  1  1  1
1  1  1  1  0  0  0  0
1  1  0  0  0  0  1  1
1  1  0  0  1  1  0  0
1  0  0  1  1  0  0  1
1  0  0  1  0  1  1  0
1  0  1  0  0  1  0  1
1  0  1  0  1  0  1  0
```

So, for example with volumes, the first variable is a master volume control; the last variable is a master volume control for the major beats (assuming we're in 4/4 time); the second variable controls the volume on the first half of the measure; the fourth variable controls the first and third beats (the "on" beats, giving you a backbeat if you turn them down); the fifth variable controls the first halves of the first and third beats, and the second halves of the second and fourth beats; and so on. It might make the most sense to have scale values that extend from zero amplitude to somewhere above 1.0, but do the matrix-multiply in decibels, so any single slider is capable of silencing either half or all the beats, and can either attenuate or amplify those beats from the overall reference volume level.

In this way you can adjust the volumes of the 8 beats to any desired

combination of volumes, but every slider affects half the beats in what I speculate will be a more musically appealing way.

The same scheme can be used for adjusting timing, though perhaps there is no need for the first variable in that case. If the last timing variable (10101010) is pushed to an extreme, it could perhaps push the eighth notes to coincide with the quarter notes.

Here's the corresponding 4x4 binary matrix:

```
1 1 1 1
1 1 0 0
1 0 0 1
1 0 1 0
```

And the corresponding 16x16 binary matrix:

```
1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1
1 1 1 1 1 1 1 1 0 0 0 0 0 0 0 0
1 1 1 1 0 0 0 0 0 0 0 0 1 1 1 1
1 1 1 1 0 0 0 0 1 1 1 1 0 0 0 0
1 1 0 0 0 0 1 1 1 1 0 0 0 0 1 1
1 1 0 0 0 0 1 1 0 0 1 1 1 1 0 0
1 1 0 0 1 1 0 0 0 0 1 1 0 0 1 1
1 1 0 0 1 1 0 0 1 1 0 0 1 1 0 0
1 0 0 1 1 0 0 1 1 0 0 1 1 0 0 1
1 0 0 1 1 0 0 1 0 1 1 0 0 1 1 0
1 0 0 1 0 1 1 0 0 1 1 0 1 0 0 1
1 0 0 1 0 1 1 0 1 0 0 1 0 1 1 0
1 0 1 0 0 1 0 1 1 0 1 0 0 1 0 1
1 0 1 0 0 1 0 1 0 1 0 1 1 0 1 0
1 0 1 0 1 0 1 0 0 1 0 1 0 1 0 1
1 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0
```

This was derived as follows:

```
def hadamard(n):
    return ([[1]] if n < 1 else
            [xs + xs               for xs in hadamard(n-1)] +
            [xs + [-x for x in xs] for xs in hadamard(n-1)])

def walsh(n):
    return sorted(hadamard(n),
        key=lambda xs: sum(1 for i in range(1, len(xs))
                           if xs[i] != xs[i-1]))

def walsh_order(n):  # bit-reversed reflected binary Gray code
    return ([0] if n < 1 else
            [x * 2     for x in          walsh_order(n-1) ] +
            [x * 2 + 1 for x in reversed(walsh_order(n-1))])

def binrow(row):
    return ('1' if x > 0 else '0' for x in row)

if __name__ == '__main__':
    for row in walsh(4):
        print(' '.join(binrow(row)))
```

It is possible to use the fast Hadamard transform to efficiently transform between the two representations — the set of user parameters and the set of music parameters — but that isn't really important in this case.

Sparse filters

Kragen Javier Sitaker, 2018-12-02 (4 minutes)

I'm interested in sparse filters, in the sense that you can realize them with only a small number of taps to reduce the number of multiplications, and multiplication-free or multiplication-light filters, in the sense that the nonzero tap coefficients are numbers like 1, 2, 3, 4, or maybe 6 or 8, but not things like 1.03594513, except perhaps in a very few cases.

The Hogenauer cascaded integrator-comb filter is a well-known filter of this class, commonly used for sample-rate conversion. But here are a few other related ideas.

The context for this is that a lot of our filter design lore comes from the world of analog electronics, where multiplication is trivial and memory is hard. This means it is not a good fit for digital computation, where memory is trivial and multiplication is hard, although immense hardware effort has been devoted to papering over this for the benefit of DSP designers.

A CIC filter is low-pass but linear-phase, so you can invert it — subtracting the appropriately scaled low-pass signal from the input sample in the middle of the kernel — to get a high-pass filter. Or you can subtract the outputs of two such filters to get a bandpass filter. This may be particularly useful in combination with undersampling — decimating the bandpass-filtered signal to alias the band of interest down to IF or baseband, thus allowing you to detect a high-frequency signal without doing anything high-frequency except for running some integrators.

A unity-gain negative-feedback comb filter $y(n) = x(n) - y(n-k)$ is an oscillator, and indeed it's very close to the Karplus-Strong oscillator (which is, in its original form, $y(n) = x(n) - ½y(n-k) - ½y(n-k-1)$, to gradually attenuate higher frequencies). If you compose it with a unity-gain feedforward comb filter in very much the same way you do in a CIC filter, its impulse response is a finite-length alternating impulse train, so it's a bandpass filter, though it also detects harmonics of the target frequency. A cascade of a few of these approximates a Gaussian window; if you add an actual CIC filter, which you can tune to have nulls at the harmonics of the target frequency, you can get a very inexpensive high-Q filter. As one example, I got a bandpass Q of 17.8 and 38dB stopband attenuation to generate I and Q signals for oscillations with a period of 60 samples using 2.64 additions and subtractions per sample: a two-stage CIC filter with lags of 36 and 40 samples on the front end, three 30-sample feedback combs, and further feedforward combs of 300, 480, and 780 samples. This gives a kernel with a temporal response of about 1000 samples (FWHM) which is a reasonably good approximation to a Gabor filter with $Q \approx 17$.

(You'll note that this is very similar to the previous technique, and the two may be alternatives; with the previous technique, for example, it may be useful to set up the low-pass filter you're inverting to have precise nulls at the harmonics of the signal you're trying to detect.)

More generally, if you can construct a filter whose impulse

response is half a wave or more of some waveform you want, you can cascade it with the unity-gain negative-feedback comb filter and get an oscillator for that waveform, or more or less equivalently, a filter that matches it. And you can use the same trick described above to construct a filter whose impulse response is a specific number of oscillations of the waveform.

Anything you can construct by convolving, adding, and subtracting box filters and comb filters can be computed as a sparse filter. So, for example, you can get a difference of gaussians fairly easily.

Once we get into nonlinear filter territory, things get more interesting still. You can do a PLL as a pretty sparse filter, for example.

Topics

Solving initial-value problems faster and with guaranteed error bounds with affine arithmetic

Kragen Javier Sitaker, 2019-04-02 (5 minutes)

Can we improve the solutions of initial-value problems using affine arithmetic?

An IVP consists of some set of differential equations, with all the derivatives given with respect to a single "time" independent variable, and a set of initial conditions that hold at some single point in time. Standard ways to solve them numerically include Runge-Kutta integration. I wonder if we can make some improvements by using affine arithmetic.

Affine arithmetic

Affine arithmetic is a generalization of interval arithmetic which can give tighter bounds under many circumstances, and additionally can capture some of the dependency of outputs on inputs. Instead of representing each quantity as $a \pm b$, as interval arithmetic does, affine arithmetic represents each quantity as an affine combination of variables $c_0v_0 + c_1v_1 + c_2v_2 + \ldots\ c_nv_n + k$. Most of the v_i are assumed to range over some range like [-1, 1] or [0, 1], and initially they each represent the uncertainty associated with a given input.

In ordinary affine arithmetic, a new v_i is introduced at every nonlinear or rounded calculation to represent the uncertainty about the result of that operation. This allows the uncertainty due to a given input, calculation, or rounding to cancel: $(c_{00}v_0 + c_1v_1 + k_0) - (c_{01}v_0 - c_1v_1 + k_1) = (c_{00} - c_{01})v_0 + k_0 - k_1$, canceling the uncertainty due to v_1 (and some of the uncertainty due to v_0 as well, if c_{00} and c_{01} have the same sign). Depending on the situation, this subtraction may introduce an additional variable to account for the rounding error of this subtraction; the number of such variables can increase without limit, making successive operations successively more costly.

By contrast, in *reduced* affine arithmetic ("RAA"), all the extra uncertainty introduced during the calculation (due to rounding or nonlinear operations) is dumped into a special c_nv_n which doesn't cancel in this way, instead growing like ordinary interval arithmetic. This caps the computational cost of reduced affine arithmetic at the cost of providing more pessimistic error bounds — but maybe only very slightly more pessimistic, if most of the uncertainty of the result is due to the initially-present input uncertainty, not introduced during the calculation.

Other variants of RAA may introduce new variables during the calculation at some times, but not others.

IVPs with affine arithmetic

So I have some vague thoughts about how affine arithmetic might help with IVPs. You can recursively divide the state space of your system into boxes and compute an affine approximation of the derivatives in question inside each box, rather than just

approximations around some points. Each box is a paraxial parallelepiped some of whose axes are dependent variables, but one of whose axes is the time variable.

This allows you to compute trajectories of the system through this multidimensional state space; the arc through a given box is in general some kind of exponential, but you can of course approximate it with an affine form, subdividing the trajectory more finely than the derivatives if necessary. Then, once you have an estimated result with its error bounds, you can consult its coefficients to see where the most uncertainty comes from — is it the value of x_3 in box 5, or the value of x_5 in box 8? This allows you to intelligently choose a box to subdivide to improve the approximation. Also, it allows you to intelligently choose a dimension along which to subdivide it to improve the approximation, which becomes progressively more important with larger dimensionality. (Even if you have only a single independent variable, you might have a large state vector evolving along it.)

This also allows uncertainty to be associated with the initial values — in effect you can compute the trajectory of not just a single point but an entire neighborhood of points. This neighborhood, too, might need to be subdivided if the system distorts it into a shape whose nonlinearity exceeds your desired precision.

Extension to BVPs

Boundary-value problems specify known values at not just a single point but potentially many points, and possibly have many dimensions; liquid flow, for example, or heat flow might have boundaries where the flow is zero or the temperature or heat flow is constant. You could similarly imagine recursively subdividing the state space, again partitioning it using both state variables and (now plural) independent variables, computing an affine approximation to the derivatives of the state variables for each box. Perhaps the final result is a piecewise-linear approximation to each state variable, with the pieces being boxes defined over the independent variables, with error bounds on it.

IRC bots with object-oriented equational rewrite rules

Kragen Javier Sitaker, 2007 to 2009 (6 minutes)

(Previously published on krageon-tol.)

Thinking about my "object-oriented equational rewrite rules" and IRC bots.

Suppose we think of definitions like

```
c = (f - 32) * 5 / 9
```

as defining properties that exist on every object that meets their qualifications (and isn't shadowed by some previously-existing c). Then we could think of something like this:

```
todayweather = { f: 95, windspeed: 37 }
```

as defining a property 'todayweather' that exists on every object. And then you could plausibly ask, on an object that has only the properties that all objects have (the Ur-Object), what are the properties that have a c property?

```
c?
        { todayweather: 36.1, normalweather: 25 }
```

Namespaces

If you're doing this on an IRC bot on a casual channel, you could have a namespace per nick, and only enumerate properties in your own namespace. So there might be [kragen]c and [Isomer]c; but I could refer to properties from other namespaces explicitly if I wanted to; simply importing:

```
f = [isomer]f
```

or using without importing:

```
c = ([isomer]f - 32) * 5 / 9
```

Actual Programs

Let's hold off for now on any way to make these properties (as opposed to their value on a particular object) first-class in the language. But let's have self-quoting keywords, like in Prolog or Erlang (lower-case), or Common Lisp or Ruby (with colons). I'm pretty sure that if I use lower-case for auto-quoting, I'll end up with Very Important-Looking Programs, so I'm thinking I'll use backquote (`) instead.

Let's start with a little syntactic sugar for lists. Let's say that if we have some semicolon-terminated expressions inside parentheses, with the last semicolon optional, it is syntactic sugar for a list made of conses:

```
( a; ) => { x: a, y: `nil }
( a; b; c ) => { x: a, y: { x: b, y: {x: c, y: `nil } } }
() => `nil
```

Even without first-class properties, we can still write:

```
(`nplusone; n).apply = n + 1
```

such that we can write

```
(`nplusone; 3).apply
```

and get 4.
Given that, we can write map:

```
(fn; ()).map = ()
(fn; {x, y}).map = {x: (fn; x).apply, y: (fn; y).map}
```

And filter:

```
(fn; ()).filter = ()
(fn; {x, y}).filter = (fn; x; (fn; x).apply; y).filter2
(fn; x; `t; y).filter2 = { x: x, y: (fn; y).filter }
(fn; x; `f; y).filter2 = (fn; y).filter
```

It's pretty brutally obvious that we need some special syntax for cons here. Let's try infix @.

```
(fn; ()).map = ()
(fn; x @ y).map = (fn; x).apply @ (fn; y).map
(fn; ()).filter = ()
(fn; x @ y).filter = (fn; x; (fn; x).apply; (fn; y).filter).filter2
(fn; x; `t; y).filter2 = x @ y
(fn; x; `f; y).filter2 = y
().length = 0
length = 1 + y.length
x.reverse = ((); x).reverse2
(a; ()).reverse2 = a
(a; x @ y).reverse2 = (x @ a; y).reverse2
```

That works OK, and I could imagine people typing it in IRC. It would probably be good to eliminate the argument-order dependencies as much as possible, and reduce the number of properties defined on all lists of length two or three. In the below, {foo, bar} is short for {foo: foo, bar: bar}, and any free variables are required properties of the object the property is defined on.

```
{list: ()}.map = ()
map = (fn; list.x).apply @ {fn, list: list.y}.map
{list: ()}.filter = ()
{list: x @ y}.filter = {fn, x, include: (fn; x).apply,
                        y: {fn, list: y}.filter}.filter2
{include: `t}.filter2 = x @ y
{include: `f}.filter2 = y
().length = 0
length = 1 + y.length
```

```
x.reverse = { reversed: (), left: x }.reverse2
{left: ()}.reverse2 = reversed
{left: x @ y}.reverse2 = { reversed: x @ reversed, left: y }.reverse2
```

Those aren't quite so brief, but they're still within the length where people could plausibly type them in a conversation.

So how about strings? Let's suppose that strings support the interface of lists of one-character strings, work properly in pattern-matching, and that one-character strings additionally have a .ord property that tells you their ASCII code. Can we split words on spaces?

```
" ".space? = `t
{ord}.space? = `f
({space?: `t} @ y).words = y.words
({space?: `f, x} @ y).words = {wletters: (x;), left: y}.word
{left: {space?: `t} @ rest}.word = wletters.reverse @ rest.words
{left: x @ rest}.word = {wletters: x @ wletters, left: rest}.word
{left: ()}.word = (wletters.reverse;)
```

That's not too bad. It compares favorably to Scheme in total code volume:

```
(define (words string) (words-of-list (string->list string)))
(define (words-of-list clst) (map list->string (words-list clst)))
(define (words-list clst)
  (let ((x (car clst)) (y (cdr clst)))
    (if (char-whitespace? x) (words-list y) (word (list x) y))))
(define (word wletters left)
  (cond ((null? left) (list (reverse wletters)))
        ((char-whitespace? (car left))
         (cons (reverse wletters) (words-list (cdr left))))
        (else (word (cons (car left) wletters) (cdr left)))))
```

The Scheme is 10 lines, 59 words, 498 characters, in place of 7 lines, 47 words, 299 characters.

So from there I think you could quite reasonably, e.g. implement ternary trees and compute a time-efficient inverted index of a big bag of strings. Say, old chat lines, or a small number of HTML documents.

Precedence

When you have more than one rule that's applicable to finding a property value, you have to decide what to do. Should you use the first rule, use the second rule, or combine them somehow?

Aardappel used specificity ordering. I think you should do the same here, given that the "source code" is a bunch of people chatting. But it would probably be helpful if the specificity ordering were partial, so that the users would have to resolve potential conflicts manually.

Syntax

The question of syntax is a little ugly but probably soluble. The normal namespace syntaxes are as follows:

Syntax	Precedents	Why Not
isomer/f	Unix	used for division
isomer\f	MS-DOS	painful memories
isomer.f	C++, Java, Python	used for property access
isomer:f	MacOS, XML	used for property definition
isomer::f	C++, Perl	too verbose
isomer f	Smalltalk	not verbose enough
[ISOMER]F	VMS	forgotten
isomer'f	Ada, Perl4	painful memories, unbalanced '
isomer$f	R, DCL	painful memories, ugly

There are some other alternatives, especially if we involve Latin-1:

```
isomer|f isomer»f isomer«f isomer§f isomerºf isomer->f
isomer>f isomer¦f isomer×f isomer÷f isomer¬f isomer®f isomer©f
isomer±f isomer£f isomer·f isomer=>f isomer=-f isomer:-f
isomer--f isomer-)f isomer-»f isomer°f isomer*f isomer~f
isomer!f isomer[]f isomer()f <isomer f> <isomer>f isomer<f>
isomer_f @isomer.f
```

OMeta contains Wadler's "Views"

Kragen Javier Sitaker, 2007 to 2009 (updated 2019-05-20)
(13 minutes)

I think.

Views

Philip Wadler proposed "views" in a 1986 paper (see References.) This section just explains pattern-matching, views, and their relationship to various programming languages.

ML, Haskell, Aardappel, and many other functional programming languages (plus Prolog) support discriminated unions ("sum types" or I think "algebraic data types") that can be used in "pattern matching" that combines case-analysis control flow with data access. Here's an example program in OCaml that defines a single type called `tree` and uses it to sort a list of strings.

```
(* a simple binary tree sort program *)

(* an object of type "foo tree" can be either a Leaf, containing
   no data, or a Fork, containing another "foo tree", a "foo", and
   another "foo tree". *)
type 'foo tree = Leaf | Fork of 'foo tree * 'foo * 'foo tree ;;

(* Here we define a function whose unnamed second argument is a tree.
   If it's a Fork, we bind the names "left", "key", and "right" to its
   data contents, and which of the two branches we take is determined
   by whether it's a Leaf or a Fork. *)
let rec tree_insert datum = function
    Leaf                   -> Fork (Leaf, datum, Leaf)
  | Fork(left, key, right) -> if datum < key
      then Fork(tree_insert datum left, key,                   right)
      else Fork(                left, key, tree_insert datum right) ;;

(* Here we pattern-match on a list, which can be either the empty
   list, or a list consisting of a first item "h" followed by a list
   of zero or more other items "t". *)
let rec make_tree old_tree = function
    [] -> old_tree
  | h :: t -> make_tree (tree_insert h old_tree) t ;;

let sorted_tree = make_tree Leaf ["t"; "r"; "e"; "e"; "t"; "o"; "p"; "!"] ;;

(* Here we use pattern-matching to iterate over the data of the tree, in
   what will be sorted order if the tree was built with the tree_insert
   function above. *)
let rec tree_iter f = function
    Leaf -> ()
  | Fork(left, key, right) -> tree_iter f left; f key; tree_iter f right ;;

tree_iter print_endline sorted_tree ;;
```

The trouble with the pattern-matching is that it breaks data

abstraction. The interface to the data structure is the same as its implementation, at least for those who want to pattern-match on it instead of just passing it to other functions. Changing the implementation implies changing all of the code that pattern-matches on it, and possibly changing that code to not use pattern-matching.

Wadler gives several examples:

• small integers are most efficiently represented as machine words containing binary numbers, but some kinds of functions clearer when written with pattern-matching on Peano notation (`Succ(Succ(Zero))`) or explicit binary (`Twice(Twiceplusone(Twiceplusone(Zero)))` for 6).
• complex numbers have imaginary and real parts, or a magnitude and an angle, depending on how you look at them; in languages like Haskell, only one of these can get the brevity benefit of pattern-matching.
• lists are conventionally viewed, as above, as being either empty or consisting of a first item and a list of other items; some algorithms are more conveniently expressed if the second alternative is instead a last item and a list of other items. A "rope" representation can provide reasonable performance for both of these "views" of the list.

Wadler's suggested explicit-binary view looks like this:

```
view int ::= Zero | Even int | Odd int
  in n = Zero,              if n = 0
       = Even (n div 2),    if n > 0 && n mod 2 = 0
       = Odd  ((n-1) div 2), if n > 0 && n mod 2 = 1
  out Zero     = 0
  out (Even n) = 2 * n,     if 2 * n > 0
  out (Odd n)  = 2 * n + 1, if 2 * n + 1 > 0
```

Here `Even` means "twice", and "Odd" means "twice, plus one". His `out` "function" works by pattern-matching, just like the OCaml functions above; and the `in` "function" can do the same. The `in` and `out` clauses explain how to translate between the `Zero`/`Even`/`Odd` view of integers and the language's native representation of integers.

In Wouter van Oortmerssen's Aardappel, the problem is diminished; if you define a new representation of some abstract data type, then in a single place, you can provide new clauses for all the functions that pattern-match on the old representation. However, the problem still exists, since you have to do an amount of work that's proportional to the number of places that pattern-match on the old concrete data type.

In 2007, I wrote about object-oriented equational rewrite rules which are basically nothing but views. I still haven't implemented the system I described in that post.

OMeta

OMeta is a system intended to dramatically simplify compiler development. Its authors write:

> Several popular programming languages --- ML, for instance --- include support for pattern matching. Unfortunately, while ML-style pattern matching is a great tool for processing structured data, it is not expressive enough on its own to support more complex pattern matching tasks such as lexical analysis and parsing.

But what is weak about ML-style pattern-matching? Why can't it

do lexical analysis and parsing, if you have (perhaps lazy) lists of characters or tokens?

OMeta in terms of Views

In fact, I suspect that views, plus non-backtracking pattern matching, plus some syntactic sugar, more or less equals OMeta. Here's the first sample grammar from the OMeta paper, modified to remove left recursion; incidentally, this is roughly Figure 3-1 from Bryan Ford's PEG parsing thesis:

```
meta E {
  dig ::=  '0' | ... | '9';
  num ::=  <dig>+;
  fac ::=  <num> '*' <fac>
         | <num>;
  exp ::=  <fac> '+' <exp>
         | <fac>;
}
```

We can think of this as a "view" on a list of characters, with the proviso that a particular list of characters may fail to parse with some or all of the nonterminals. Let's augment the grammar with some semantic actions:

```
meta E {
  dig ::=  '0' | ... | '9';
  num ::=  <dig>+:ds           => number ds;
  fac ::=  <num>:x '*' <fac>:y => x * y
         | <num>;
  exp ::=  <fac>:x '+' <exp>:y => x + y
         | <fac>;
}
```

(I'm assuming a `number` function from a list of characters to a number.)

So when we ask for the `fac` "view" of the character stream, we're hoping to get a number --- and also, implicitly, the rest of the stream after the parsed-out factor. In Wadler's notation, borrowing from OCaml where necessary:

```
view fac ::= Fac int * char list
  in Num (x, '*' :: Fac(y, rest)) = Fac(x * y, rest)
  in Num (x, rest)                = Fac(x, rest)
```

(I've omitted the `out` clause because it's not relevant to the problem of parsing.) If the grammar were more OCaml-like, I think it would look like this. (Incomplete matches are considered bad style in OCaml, and the compiler warns about them.)

```
view fac = Fac of int * char list
  in Num (x, '*' :: Fac(y, rest)) -> Fac(x * y, rest)
   | Num (x, rest)                -> Fac(x, rest) ;;
```

The theory here is that if neither `in` clause matches, then the attempt to view a list of characters as a `fac` will fail to pattern-match,

which may cause backtracking of outer parses. In this syntax, it is only two and a half times as long as the rule in the OMeta-style grammar above.

The + notation causes a little bit of trouble; it's syntactic sugar. We can write out a desugared form as follows:

```
num ::= <digplus>:ds -> number ds;
digplus ::= <dig>:x <digplus>:y => x :: y
          | <dig>:x             => [x];
```

Here are the other nonterminals in this grammar, in the OCamly notation:

```
view dig = Dig of char * char list
  in c :: t when '0' <= c && c <= '9' -> Dig (c, t) ;;
view num = Num of int * char list
  in Digplus (ds, rest)               -> Num (number ds, rest) ;;
view digplus = Digplus of char list * char list
  in Dig (x, Digplus (y, rest))       -> Digplus (x :: y, rest)
   | Dig (x, rest)                    -> Digplus ([x], rest) ;;
view exp = Exp of int * char list
  in Fac(x, '+' :: Exp(y, rest))      -> Exp(x + y, rest)
   | Fac(x, rest)                     -> Exp(x, rest) ;;
```

And I think there you have the parser and expression evaluator, in a hypothetical extension of OCaml. Although this is several times wordier than the OMeta version above, it's several times more concise than the Haskell version in Ford's thesis. It's missing a bit of syntactic sugar, resulting in nested parentheses, unnecessary type definitions, redundant default cases, and explicit passing-around of the `rest` parameter, but it's much of the way there. ...

You might think that all of these nonterminals should be part of a single view `E`, but the normal case in OCaml and the other languages Wadler was thinking about that support pattern-matching is that the variants of a sum type are disjoint, which generally allows the compiler to tell you if you've missed a case in your case analysis. So here each one is a separate "type".

OMeta introduces four major extensions over normal PEGs:

- you're not limited to pattern-matching on streams of bytes or characters;
- there are ways to pass more arguments that weren't in the original input to nonterminals;
- guard clauses on patterns;
- you can subclass grammars.

Of course, if you have a functional programming language with pattern-matching, you have the first three of these four already.

Views in terms of OMeta

So if OMeta "contains views", can we write Wadler's other examples of uses of "views" in a reasonably homeomorphic way in OMeta?

PEG Parsing and Object-Oriented

Equational Rewrite Rules

My unimplemented object-oriented equational rewrite rules language supports views quite straightforwardly and concisely. ...

PEG parsing and Bicicleta

Bicicleta, although it doesn't have pattern-matching, does have "views" in the sense that accessing data that's stored inside a data structure looks the same as accessing data that's computed on the fly. This is also a feature of Self and Forth....

, and also contains a sort of notion of failure, which I believe can be implemented entirely outside of the core language itself --- it merely requires overloading the infix !! operator differently on non-error objects and error objects.

So I suspect that OMeta's simplistic notion of failure (it doesn't do general backtracking) should be fairly straightforward to implement in Bicicleta with an overloaded '/' operator, something like this:

```
parsed = {self:
    '/' = {op: '()' = self}
}
parse_failure = ...
```

References

Wadler's paper, "Views: a way for pattern matching to cohabit with data abstraction", was written in 1986 and published in 1987 in some ACM journal, pp.307--313.

Aardappel is an experimental visual programming language designed by Wouter van Oortmerssen, with a novel concurrency primitive and a very simple side-effect-free subset used to describe sequential computation.

Object-oriented equational rewrite rules is a kragen-tol post I wrote in 2007 about a slightly novel design for a pattern-matching programming language that natively incorporates views. I wrote further on it in 2008 in IRC bots with object-oriented equational rewrite rules, which is IRC bots with object-oriented equational rewrite rules (p. 838).

OMeta, by Alessandro Warth and Ian Piumarta, is a PEG parsing system generalized so that it can be used for a wider range of tasks. To date it has been used for scanners, parsers, optimizers, code generators, network protocol implementations, and automated code inspections, among other things. They published a paper about it in the Dynamic Language Symposium 2007.

PEG parsing is a new parsing method invented by Bryan Ford in 2002, based on work from the late 1960s on Bob McClure's TMG "TransMoGrifier" program. It can parse a large set of languages, including some non-context-free languages but probably not including all context-free languages, supports scannerless one-level parsing well, and has a provably linear-time parsing algorithm called "packrat parsing", which uses a lot of memory. It has its problems; the non-memory-hungry implementation can require exponential time, the absence of backtracking makes some languages more difficult to parse and presumably makes some languages impossible to parse, and the lack of support for left recursion in the basic algorithm

is annoying (although Warth and buddies have a solution to this problem that I haven't read yet.)

Berlinite gel

Kragen Javier Sitaker, 2019-12-14 (updated 2019-12-15) (10 minutes)

As I was adding materials data to Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) I happened across a material I'd never heard of before that seemed like a better fit for what I was looking for than any of the materials I *had* heard of: aluminum orthophosphate, the mineral berlinite.

I looked into its synthesis, and what I found was absolutely astounding; I must be missing something important, because it seems like a fairly revolutionary new material, but no revolution has resulted in the last 140 years since its discovery.

Berlinite

Berlinite is a rare quartz-like crystal of aluminum orthophosphate with a Mohs hardness of 6.5 and a melting point of 1800°. It's nontoxic enough to be used as an antacid, although there are several other phosphates of aluminum, which are caustic, and a highly toxic phosphide of aluminum, and sometimes these chemicals are confused with aluminum orthophosphate; every MSDS I can find states that aluminum orthophosphate causes severe skin burns, presumably as a result of this confusion; although I don't have any here to put on my skin, I think this is very unlikely to be correct. Its dihydrate is the uncommon turquoise-like mineral variscite, which has a Mohs hardness of only 4.5. It dunts like quartz, but at 583°. It wasn't discovered until 1868.

The really interesting thing about Berlinite is that it's almost as hard as quartz, but several investigators report easy ways to synthesize it at much lower temperatures.

Grover *et al.*'s low-temperature synthesis

In 1999 some researchers at Argonne National Lab and Purdue investigating the problem of safe nuclear waste storage published a paper on a berlinite-bonded alumina ceramic, entitled "Low-temperature synthesis of berlinite-bonded alumina ceramics". Their stunning claim was that they had synthesized berlinite *at 150°* by heating a hydrated aluminum phosphate they made by partly dissolving alumina in aqueous phosphoric acid at 130°.

In detail, they heated a slurry of alumina (micron-sized mixed with sand) with 50 wt.% phosphoric acid with an Al_2O_3:H_3PO_4 weight ratio of 5:1, detected an endothermic reaction at 118° with differential thermal analysis, held it at 130° for 1, 2, or 4 days to allow the reaction to complete, identified with X-ray diffraction that it produced an intermediate phase of another aluminum phosphate $AlH_3(PO_4)_2.H_2O$ mixed with the remaining alumina; they described the mixture as "a thick puttylike...gel", which they left at ambient temperature for another week "so that some crystalline growth would occur". They dried the samples into "hard monoliths", which "disintegrated when placed in water".

All of the above had been done by previous researchers. But then they baked the "monoliths" at 150° for one, two, and three days: "Significant porosity developed in the monoliths as bound water

escaped through an increasingly viscous slurry." They infer that the hot monoaluminum phosphate reacted with *more* of the remaining alumina to produce berlinite over the course of these days, and explain, "the resultant ceramic appeared to be a very hard monolith with dense phases separated by large pores," with some solid phosphoric acid on top; they measured a compressive strength of 6824 psi (47.05 MPa in modern units) on materials with "20.9 vol.% open porosity". This is a bit stronger than ordinary concrete but not remarkably so, and much lower than high-performance concrete.

Mysteriously, this paper has been almost entirely ignored. It's been cited in 2019 by US patent 10,233,803B2 on exhaust-gas filters with a catalyst film on a porous ceramic support (and its related 2017 applications in .de, .br, .uk, .cn, .kr, the WIPO PCT ("WO") and the EPO ("EP")); in 2006 by US patent 6,858,174B2 on gel-casting ceramic slurries; by Stefania CASSIANO GASPAR's dissertation in 2013 at INSA-Lyon on extruding porous berlinite-bonded alumina ceramic supports for catalyst films (in French) for exhaust-gas filtering; by her 2012 patent (US 9,227,873B2) with four other co-authors on the same subject; and by a 2015 Russian paper.

Cassiano Gaspar's dissertation also cites some 2010 work by Lee *et al.* with zeolites in aluminum phosphate, which she reports they got to be nonporous.

So, why do I think this is such an interesting result? It gives a simple, low-temperature recipe for a moldable porous material that costs about US$3/kg and produce a result as strong as ordinary concrete, which costs a tenth of that. What's so special about that? After all, if you want concrete with alumina abrasives in it, you can put some alumina in your concrete.

Well, a couple of things. First, this material is highly refractory, despite its low-temperature preparation; it will not spall from heat shocks. Second, I think it's nontoxic and noncaustic, unlike portland cement. It might even be biocompatible, which conventional phyllosilicate ceramics are not; alumina is well-known to be biocompatible, phosphate as such is nontoxic, and so the potential biocompatibility concern would mostly be with whether it releases aluminum into the body, catalyzes harmful reactions, or provokes inflammation.

In addition to its use for making massive objects, the resulting berlinite may work well as a binder for connecting aluminum parts together or for a mineral paint similar to those made from waterglass.

Apparently without citing Grover *et al.*, monoaluminum phosphate is sold as a castable refractory, sometimes using the heinous abbreviation "MALP" (to distinguish it from "MAP", monoaluminum phosphate). Fosbind is one brand. Luz, Oliveira, Gomes, and Pandolfelli reviewed its properties, calling it MAP, in a 2016 paper, using 200-micron dead-burnt magnesia and a sooper seekrit 31337 boron source to get it to set in 90–120 minutes, finding that they would work well up to 1400°–1500°; they cite a book (*Technology of Monolithic Refractories*, Nishikawa) and two papers on the subject in 1982–1989, and point out that it's easier to get aluminum phosphates if your aluminum source is aluminum hydroxide instead of alumina.

Interestingly, Luz *et al.* give a different formula for "monoaluminum phosphate": $Al(H_2PO_4)_3$, which is presumably

dramatically more acidic than the $AlH_3(PO_4)_2$ Grover *et al.* observed, since its phosphate groups still have their second hydrogen. Also Luz *et al.* experimented with binder systems including Al_2O_3/H_3PO_4 in 2015, and found that the most effective recipe was 48 wt.% phosphoric acid with the hydroxide. They claim that their X-ray diffraction results show that the aluminum orthophosphate was hydrated (i.e., variscite, not berlinite). For different compositions, they report *flexural* strengths in the 10 to 30 MPa range; presumably the compressive strength is much greater.

Silicon phosphate

It would be interesting if silica can somehow be phosphated the same way; normally the answer is no, and phosphoric-acid etching is a normal way to get silicon nitride off of silicon dioxide. But silicon orthophosphate, Si_3PO_4, does exist. Apparently it's caustic, which suggests that it isn't waterproof, which makes it immediately much less interesting.

Often the reason for wanting to use silica rather than alumina is that alumina costs 300 times as much as silica (see Likely-feasible non-flux-deposition powder-bed 3-D printing processes (p. 1196) for materials pricing). But in this case that reason is not nearly as overriding, because phosphoric acid is nearly as expensive as alumina.

Extrusion 3-D printing

The inexpensive 3-D printers that have become popular recently, descended from the RepRap project, are "fused deposition modeling" printers: they feed a filament into a melting chamber to produce pressure to force it out a small heated opening (the chamber and the opening are collectively the "hotend"), moving the opening and the workpiece relative to each other to deposit material in controlled positions on the object produced. Typically they use low-melting polylactide plastic at temperatures of 185° to 225°. Although higher temperatures are sometimes used, most organic chemicals start to break down into simpler substances in the 230° to 270° range. Other popular plastics include PETG, ABS, and nylon (PA6 I think, maybe 6,6.)

There are variants of this process that work well for clay bodies, clay slips, and adobe, largely relying on thixotropic or plastic yielding of the material with some kind of extrusion screw rather than melting. Instead of stressing the "hotend" with heat, these variants instead abrade it.

This approach should be applicable to the pasty aluminum phosphate Grover described, but it is somewhat complicated. If you use alumina as the aluminum source, the alumina particles are highly abrasive; only a very small number of coatings (diamond, CBN, and maybe zirconia, carborundum, and tungsten carbide) can resist being ground away by them, and frequent replacement of consumable liners and nozzles may be the only viable alternative. Also, the aluminum phosphates other than the orthophosphate are highly acidic and consequently corrosive.

A resistive-capacitive trackpad made from garbage and three ADC microcontroller pins

Kragen Javier Sitaker, 2013-05-17 (updated 2013-05-20) (17 minutes)

(I think I published this on kragen-tol at some point.)

(Not yet tested.)

It occurred to me that you can probably make a resistive trackpad out of pencil lead on paper, sensing the position of a conductive probe in the conductive patch by measuring the resistance to various points around the edge many times per second. This should be doable with a few tri-stateable digital GPIO pins and a capacitor whose discharge time we measure, or a few analog input pins.

Perhaps you could even make this work with human fingers, even providing multitouch, even capacitively through a protective surface layer (say, a plastic shopping bag) to keep the graphite off your fingers, protect the microcontroller from static electricity, and maybe keep you from getting shocked by power surges.

It turns out that, in theory, the resistance in a uniform flat sheet is low and highly dependent on probe contact area when your probes are close together, but then approaches some limit, determined by the resistivity and thickness, as your probes get further and further apart. This might mean you need to have quite a number of probes.

Normal trackpads work differently

Normal resistive trackpads have a grid of wires, with the X and Y wires running in two separate layers and a resistive layer between them, which becomes less resistive under pressure. Normal capacitive trackpads have a grid of wires, too, but use capacitive coupling to your finger instead of sensing pressure.

This trackpad design doesn't have a grid of wires at all, just a resistive plane, which is much easier to fabricate.

Resistance tests with pencil lead

In my first test, I blackened a patch on a post-it note (Stick'N brand) rather thoroughly with an HB pencil, moving the post-it around a bit to blacken in different directions to avoid voids in the graphite caused by roughness of the desk surface, and measured with an ohmmeter resistances of some 2–5kΩ over distances of 1–4 cm, and as low as 1kΩ with probes close together (≈1mm).

(As predicted by theory, the resistance depends strongly on probe contact area. Using a couple of big coins, I was able to get measurements down to 300Ω, and the limit at larger distances was about 2kΩ instead of 5kΩ.)

In a second test, instead, I drew a grid which was about 90% empty space and 10% fairly dark lines with the same pencil. With this, I was able to get readings of a few hundred kΩ on my ohmmeter over distances of a centimeter or so, but they weren't very consistent.

In a third test, I gradually darkened a patch with the pencil until I started to get consistent continuity between different parts of the

patch, at which point I was getting readings of 200–500kΩ over 1–4 cm, although I don't totally trust my analog ohmmeter at such large resistances. Even with the probes separated by only 1mm or so, I was still getting 100kΩ or so. This patch was much less dark than the other one, but the other one certainly did not contain 100 times as much graphite; so I assume that the majority of the graphite particles in this one are not participating in the conductivity.

I hypothesize that you might be able to reliably get an even higher sheet resistance this way, but it might help if you have really smooth paper to start with — glossy magazine or inkjet-photo stock, say.

Measuring distance to the capacitive patch where your finger is

If you press your finger against a layer of polyethylene on top of the pencil lead, your finger and the pencil lead form a capacitor. (I thought about using paper instead of polyethylene, but it's six times as thick.)

Your finger contact area might be 1.5cm², and a plastic shopping bag might be 13 μm thick, according to Multi-Pak's "Thick and Thin of Plastic Bags". $C = \varepsilon A/d$, and the permittivity ε of polyethylene is 2.25 times that of free space ε_0, which is about 8.9 pF/m. So we have 8.9 pF/m * 2.25 * 1.5cm² / 13μm ≈ 220pF.

Now, we'd like the circuit capacitive reactance to be close to the resistance of the pencil lead in the distance from the point of contact to the place where the measurement terminals are attached. If the resistance is much greater than the capacitive reactance, the signal will be attenuated unnecessarily, making the circuit too susceptible to noise; if it's much smaller, the signal will reach all of the measurement terminals almost equally, and you won't be able to tell where on the paper the touch happened. Let's say the pencil lead resistance is in the 1–30kΩ range, or 10kΩ, to be concrete.

It turns out that people have about 1pF of capacitance to power lines, and also about 100pF of capacitance to ground. If we use that capacitance to ground, then we can use an AC voltage we send into the trackpad ourselves, at a frequency chosen to optimize the capacitive reactance, and most of the circuit reactance will be from the 100pF reactance to ground.

(Note that this depends on your skin. http://dev.laptop.org/ticket/8071 reports that people with calloused hands had trouble with the early OLPC XO's capacitive trackpad because the dry callous put people's blood too far from the trackpad. If we're depending on a dielectric thickness of 13 microns, we'll have the same problem. I guess you can lick your fingers though.)

So if we want 10kΩ of capacitive reactance out of 100pF, $X_C = 1/(2\pi fC)$, so we have $f = 1/(10k\Omega * 2\pi\ 100pF) \approx 160kHz$. It's trivial to generate a 160kHz square wave on pretty much any microcontroller, and if your VCC is 5V, it's pretty much 5V peak-to-peak and 2.5V RMS. That should be easy as pie to sense: with 14kΩ impedance, it's 180 microamps, -3dBm.

To look at it in the time domain instead of the frequency domain, we're charging the patch of graphite under your finger up to 5 volts or whatever VCC is, through the resistance of the graphite between that patch and our probe. The time it takes to charge it up will tell us the

RC product of that system, and we expect it to be on the order of 6µs, which is a time that we can measure to about 6 bits of precision without even using an ADC. If we do use an ADC, like the 10-bit ADC on a lot of AVRs, we should be able to estimate the RC time constant of the charging curve to higher precision.

The RC constant by itself tells us very little, because we don't know the area of the finger contact patch, and that's a factor of C. But if we have several different probes in different locations, we can probe with each of them in sequence; we can assume the finger contact patch isn't changing much in 6µs. This tells us something about the relative distances, from which we can estimate the position of the contact patch; and given that, we can estimate its area.

It's common to have fewer pins capable of ADC input than capable of digital output. But I think that doesn't need to be a limitation for this application; you can use one probe to measure the voltage the contact patch is charged to, while using another one to apply the charging pulse. As long as the input impedance of the ADC pin is high compared to the impedance of the contact patch's path to ground, the ADC probe voltage should follow the contact patch's voltage very closely — unless it's too close to the active probe, in which case it will see some kind of weighted average of the active probe's voltage and the contact patch's voltage. The ATMega328 datasheet (doc8161.pdf) says the input pin capacitance is a max of 10pF (p.321), so the ADC input capacitance shouldn't be a big problem. It should be possible to separate out the weighted-average components, since they'll have two very different time constants.

So I think you should be able to get by with three or four ADC pins at different corners of the touch area, with active probes in potentially more places; at least two active probes and, I think, three total probes will be needed to triangulate unambiguously. So you need at least three ADC pins and two GPIO pins, but the ADC pins can double as GPIO pins.

6µs might be *too* fast; while the ATMega328 can do a sample-and-hold more quickly than this, it needs much more time to do a complete ADC conversion. So you might end up having to build up the picture of the complete charging waveform by sampling one point on each of a number of charging waveforms, by adjusting the "phase" delay between the initiation of a charging pulse and the ADC measurement.

Alternatively, as described in the section above about my experiments, you might be able to simply establish a thinner film of pencil lead to further increase the R part of the RC time constant. 60µs should be plenty of time.

You probably need at least four data points on each curve to untangle the effects of R, C, and the effect of resistively-coupled voltage from the active probe. You're measuring, minimum, six separate curves, so you need at least 24 data points. If you need 13 µs per data point, at which point the ATMega328 datasheet says the error is 4.5 ulps (LSB), which I guess is ±, so you really only have about 7.5 bits of accuracy, then you need 312 µs to take a full position and patch size measurement. You can probably average your measurements over considerably more than that, which means you can measure many more points per curve.

If your final measurements are a result of measuring each curve 64

times instead of 4, giving you 5 ms latency, your estimates for R should be good to about 11 or 12 bits, and your estimates for C (since you're measuring it six times as often) should be good to about 14 bits. All in all, this gives you 6*11.5 + 14 = 83 bits of data, which is probably highly redundant, but which can hopefully localize your finger with great precision.

Resistive-touchscreen style

Wikipedia explains analogue resistive touchscreens as follows:

> two flexible sheets coated with a resistive material and separated by an air gap or microdots.... during operation of a four-wire touchscreen, a uniform, unidirectional voltage gradient is applied to the first sheet. When the two sheets are pressed together, the second sheet measures the voltage as distance along the first sheet, providing the X coordinate. When this contact coordinate has been acquired, the voltage gradient is applied to the second sheet to ascertain the Y coordinate.

This also seems like it might be a reasonable approach to use with two sheets of paper. You could dump eraser crumbs or a few curly hairs or something in between them to keep them mostly apart when they're not being pressed.

Alternative materials

Pencil lead is one useful and easily available resistive material that can be easily deposited in a film, for example on paper; actual lead, aluminum, gold, and carbon black are four others. Lead is about 50 times more conductive than pure graphite, and pencil lead is only part graphite. Aluminum and gold are another 10 times more conductive still.

Aluminum has the potential advantage for this application that it's widely available in the garbage in large, highly uniform sheets sputtered onto Mylar, which are then coated with an insulating layer of plastic even finer than a plastic grocery bag. These layers of aluminum are so thin that they're actually visibly transparent, when there isn't too much ink on top of them. If you put LEDs behind them, you could make an actual touchscreen.

However, I have so far been completely unsuccessful at making electrical connections to these aluminum layers. Aluminum is notoriously tricky to connect to electrically at the best of times, due to sapphire spontaneously forming on its surface, and much more so when it's in the form of a sub-micron-thickness film inside a much tougher plastic film.

Aluminum rubbed onto the surface of paper, like pencil lead or lead, might be more promising, especially if you drip solder or something on top of it immediately afterwards.

Charcoal is, in theory, somewhat conductive, and you can rub it on paper, but in my feeble attempts with a burned match, I haven't been able to get it to conduct. It's easier to come by in garbage than lead, graphite, gold, or bulk aluminum, so it might be worth further investigation.

Gold is expensive, but gold leaf is so thin that it's cheap enough that people throw it away, or even drink it in Goldschlager. I don't have any handy here, but it might work for this.

Carbon black is conductive, and indeed is used in the microphone design that made the telephone practical, since its resistance varies

with pressure. It's also easy to deposit in a film on a surface: you burn something, anything carbon-bearing, with a flame, and the smoke deposits as a film. (If the flame is too clean-burning, you may have to put an object actually inside the flame to get the carbon black to deposit. You can do this with a cigarette lighter.) I think you can get a more uniform film this way than by rubbing solid objects onto abrasive paper, but the film is very fragile, except where it's nestled down into a pore in a porous surface.

However, its very fragility means that you can very easily cut very fine lines into it: if you deposit it onto glass or plastic, you can rub it off with your finger, or the end of a wire, or a piece of dry grass. If you had a way to deposit some kind of insulating fixative on top of it (superglue? boiled linseed oil? dried eggwhite? glue down a shopping bag?) and deposit more carbon black on top of that, maybe you could make the grid of wires used in traditional capacitive trackpads.

Paper, as I mentioned before, is another possible dielectric; its big disadvantage is that it's typically several times thicker than a shopping bag. However, it might have advantages, too. You can write on it more easily.

It would be cool to have a transparent dielectric that can be illuminated from the edge, because then you could have like glowing letters and shit etched into its surface illuminated by total internal reflection, like the menu for every third tourist bar in this damn town. Unfortunately, I don't think you can do that in a sheet of dielectric that's thin enough to leave a reasonable amount of capacitance between your finger and the graphite. If it's 100 microns thick, the thickness of paper, the capacitance drops to 30 pF; if it's 200 microns thick, it drops to 15 pF. It might be hard to sense a mere 15 pF on top of the 7–10 pF on every AVR input pin and the ≈14pF of the sample-and-hold capacitor.

If you find an unbroken LCD screen in the garbage, you ought to be able to use the transparent indium tin oxide ("ITO") electrodes deposited on the glass surface for a high-resolution grid of wires. But it might be cooler to use it as an LCD.

Texture synthesis with spatial-domain particle filters

Kragen Javier Sitaker, 2016-10-06 (2 minutes)

Can you synthesize textures using particle filters?

The idea is that for each position (block of pixels, or maybe pixel), you have a model of what might appear there, based on what appears above it and to its left, determined by the conditional probabilities of that patch in those environments in some kind of a training set. You maintain a potentially large set of hypotheses for each position, each one with a weight representing its probability weight. When you move to a new position, you resample the set of hypotheses according to the weights, and ultimately you may end up with a few hypotheses with most of the probability weight and you can choose one or average them.

An interesting thing about this is that it allows you to take into account different kinds of information in many different ways. For example, you could know most of the pixels in an image and want to fill in a few (perhaps to replace something you erased or to fill in a seam), or you could attempt to synthesize an image from nothing, or you could try to synthesize an image that approximates some pattern of light and dark, or that has edges in particular places.

This seems to have been done to some extent; http://link.springer.com/article/10.1186/2193-9772-2-2 ("High resolution micrograph synthesis using a parametric texture model and a particle filter", 2013) describes using this algorithm to fill in plausible high-resolution detail on a large low-resolution image by using texture from small high-resolution images. But I think this may be a slightly different algorithm.

Audio video boustrophedon sync

Kragen Javier Sitaker, 2019-04-03 (2 minutes)

If you're trying to sync audio with video, for example because you recorded them on different devices, you acquired them via different sources (that don't share a timebase), or you're playing them back through devices with different latencies, you traditionally need some kind of interactive successive approximation where you twist some kind of knob or something until you get it right.

A difficulty with this is that only occasionally are there events in the video that you can associate with high precision with the audio. So you have to wait for one of them to happen once for each approximation.

The ideal solution is probably to find a short segment of video with such an event and repeat it at as high a frequency as possible as you adjust the audio–video lag. Around 20 Hz, rhythms — pulse trains — fade into continuous tones. So you need something a little slower than that, which possibly limits you to about 50 ms feedback latency on the knob. Also, you probably need several frames of video to successfully interpolate movement, and video is commonly interpolated at rates as low as 24 Hz, so you might not be able to do better than, say, 6 Hz or 4 Hz for the repetition.

However, at these rates, the impulsive event you're looking to synchronize the sound with — ideally a clapboard, but often in practice a spoken plosive or something — may be overwhelmed by the much larger impulsive event of jumping back in time by 167 ms or 250 ms. A possible solution is to play both the video and the audio segment boustrophedonically: first forward, then backward, then forward again, and so on. This eliminates the first-order discontinuities, though the remaining second-order discontinuities — objects instantly reversing their direction of motion — may be disturbing.

The knob should probably directly control the video displacement, not the audio displacement, to avoid screwing with the pitch.

Clickable terminal patterns

Kragen Javier Sitaker, 2013-05-17 (2 minutes)

libvte9 includes the ability to tell its clients if a particular position is within a match to any of a list of regexps; this ability is used by gnome-terminal and xfce4-terminal to make links in terminals clickable.

However, the list of regexps is hardcoded. It would be useful to add additional regexps, for reasons like the following:

• Clicking on `grep -n` output like "./terminal/terminal-widget.c:292:" could request Emacs to open the file at the line in question.
• Clicking on a company-internal bug number like "ITN-6748" could open the URL of the ticket in question.
• Clicking on a date could open your favorite calendar app to that date.
• Clicking on a Bitcoin address could open your Bitcoin client to send Bitcoins to its owner.
• Clicking on an IP address could prompt you with various things to do: mtr, nmap, reverse DNS lookup, etc.
• Clicking on a street address could search for it in Google Maps.
• Clicking on a Twitter @username could open their Twitter page.
• Clicking on a DOI number could look it up in a way appropriate to your campus.
• Clicking on a phone number could call it, add it to your address book, or look it up in your address book.

These suggest a configuration file with a syntax like

```
/home/paul/bin/open-ticket ITN-[[:digit:]]+
/home/paul/bin/open-editor ^[./][^ ]*:[[:digit:]]+:
/home/paul/bin/open-calendar \<[[:digit:]]{4}-[[:digit:]]{2}-[[:digit:]]{2}\>
```

where the scripts alluded to will be invoked with the matched string as an argument. `open-editor` could be implemented, for example, as follows:

```
#!/bin/sh
exec >"$HOME/editor.log" 2>&1
IFS=:
set $1
emacsclient +$2 $1 &
```

In the case of xfce-terminal, this would involve:

• Dynamically allocating new pattern types when reading this file, in addition to the four predefined ones at terminal/terminal-widget.c:65.
• Adding the new regexes to the libvte widget, along with the ones from `regex_patterns` at terminal/terminal-widget.c:78, in `terminal_widget_update_highlight_urls` at terminal/terminal-widget.c:772.
• Perhaps factoring the two calls to `vte_terminal_match_check` in `terminal_widget_context_menu` at terminal/terminal-widget.c:292 and in `terminal_widget_button_press_event` at terminal/terminal-widget.c:403 into

a single thing? In any case, wire them both up to invoke a new function to invoke the user-defined action.
• Writing the new user-defined action function, which would spawn off a subprocess with the requested command.

Non-inverting logic

Kragen Javier Sitaker, 2017-02-18 (updated 2019-07-20) (8 minutes)

There were common non-inverting logic families in the past, an idea that always appealed to me in my childhood, since burning power in every logic gate seemed wasteful. (I didn't understand how much it simplified the process of digital design.) Diode logic and threshold logic (McCulloch-Pitts neurons without inhibitory inputs) are two rough families, although they are at different levels of abstraction.

Circuits whose combinational logic is non-inverting

A typical way to manage this, e.g. in Stan Frankel's 1956 LGP-30, was to do the combinational logic with diode logic, then the registers with flip-flops which generated two-rail outputs, i.e. both Q and Q̄. A flip-flop at the time was a pair of cross-coupled vacuum tubes and a pair of resistors, as I understand it. (The apparent design rationale for the 1958 Сетунь, wanting to use a smaller number of flip-flop-flaps rather than a larger number of flip-flops, makes me think this kind of thing was universal at the time.)

The LGP-30-style design combines the functions of amplification, signal level restoration, inversion, glitch elimination, and memory in a single device, the flip-flop.

In case it's not clear how this works: absent restrictions on fan-outs and fan-ins, you can always reduce the combinational logic to this form as follows. Register all the inputs through flip-flops; convert the desired logical formula into sum-of-products form (disjunctive normal form), i.e. $\vee_i \wedge_j X_{ij}$ where each X_{ij} is either 1, an input variable Q_k, or a negated input variable $\bar{Q}_k$; run all the flip-flop outputs, both negated and non-negated, down the columns of your schematic; convert each $\wedge_j X_{ij}$ into a row that is a many-input AND gate taking its inputs from those columns; and finally combine all the rows with a many-input OR gate. You can think of this as a kind of binary matrix-multiplication operation, where the bits of the resulting vector are the inputs of the final OR gate, which computes the Boolean norm† of that vector.

Note that both AND and OR gates are non-inverting, and here you only need two levels of them, so this is a feasible design to realize in unamplified diode logic. It may be possible to do better, since in many cases the inflation factor of reducing a formula to a sum of products is large, but it guarantees that it is always possible.

This kind of thing seems appealing to me somehow even in the world of MOSFETs: an N-channel enhancement-mode‡ MOSFET with a weak pulldown resistor can be thought of as an AND gate where a low-impedance connection to Vdd counts as "1", no such low-impedance connection counts as "0", and no low-impedance paths to Vss exist. With these conventions, an OR is just a wired connection, and the circuit depth problems imposed by diode voltage drops go away. Presumably people have thought of this, but this approach isn't widely used, maybe because the pulldowns are slow to

discharge the gates unless they're burning a lot of power normally. (I thought this might be what is called "pass transistor logic", but that turns out to be a different but related approach.)

Circuits whose combinational and also sequential logic is non-inverting

It wasn't until I was rereading Merkle's 1990 buckling-spring paper "Two types of mechanical reversible logic" today that I understood that the sum-of-products thing generalizes to cases where your memory elements don't do inversion. He makes a casual aside about how Landauer in previous work had assumed dual-rail logic, where each value computed is accompanied by its complement, so negation is obtained simply by switching the two.

The Landauer reference is found in his "Dissipation and noise immunity in computation and communication", on p.781 of Nature, Vol. 335:

> In these schemes we use majority logic to do computation. There is an odd number of inputs (typically three) to a given [potential energy] well. The well under consideration then gets set according to the majority vote of the stages exerting an influence on it. If, for example, we have one input set at zero, with the other two inputs being variable, we get a '1' output [iff] both of the variable inputs are '1'. In this scheme we cannot perform a negation directly. Therefore, we need dual rail logic, in which we carry along a variable and its complement, and perform negation by interchanging the two.

This is a brilliant revelation to me: it means that you don't need negation *inside* the system *at all*, even in memory; you only need to generate the complements of signals *on input* to the system. That is, the feature of flip-flops that they automatically generate complements on every registered bit is completely dispensable, at the cost of twice as much logic, more or less.

This is achieved through simple De Morgan conversion: to compute ~(XY), you compute ~X | ~Y, and to compute ~(X | Y), you merely compute ~X & ~Y, where the operators are as in C.

Consider a basic inverting function which is necessary for binary addition, XOR: $X \oplus Y \equiv X\bar{Y} + \bar{X}Y$. In this dual-rail scheme, you can compute it in just that way, and then, if necessary, its complement, XNOR, as $(\bar{X} + Y)(X + \bar{Y})$. This requires six AND and OR gates, but calculating it with NAND requires four gates, and calculating the complement requires five (with, e.g., ((B|B)|(A|A))|(B|A), where | is now the Sheffer stroke denoting NAND rather than the C bitwise OR.)

In a dual-rail system with absolutely no inversion inside the system — only inversion at inputs — you may need more register bits than you would need in a system in which only the combinational logic is noninverting, since you (often) have to register both a bit and its complement, while a conventional flip-flop will generate one from the other.

Further extensions

The dual-rail system can be thought of as a one-hot encoding with two possible values. It is straightforward to mix dual-rail signals with one-hot signals of other multiplicities, including the Сетунь's three but also four and even five and higher, as in the biquinary encoding used in the IBM 650 Knuth learned to program on; this may afford

economies of logic under many circumstances, as the aforementioned Boolean matrix becomes much sparser.

For e

Note that Landauer's suggested family of approaches performs level restoration at every gate, rather than leaving that up to the flip-flops, and thus doesn't suffer the severe limitations on combinational circuit depth that diode logic did. Circuit depth is still a crucial factor for clock speeds, though. (And the escape from this, asynchronous logic, coincidentally also typically depends on dual-rail logic...)

† I say "the Boolean norm of that vector" because I think that N-way bitwise OR is the only non-constant function that satisfies the definition of a norm $((g \neq 0 \Rightarrow \nu(g) > 0) \wedge \nu(g + h) \leq \nu(g) + \nu(h) \wedge (g \in \mathbb{Z} \Rightarrow \nu(mg) = |m|\nu(g)))$, under the usual interpretations: AND for multiplication, OR for addition, 0 for false, 1 for true, and $0 < 1$.

‡ You could use a P-channel enhancement-mode MOSFET as an AND-NOT (abjunction or negated implication) gate, which provides a limited form of negation: it will only let through a low-impedance connection to the positive power rail if the gate is pulled low, meaning that the gate has no such connection. Abjunction is as universal as NAND if you have access to a constant 1, but it's falsehood-preserving: any circuit made of abjunction gates will have output 0 if all its inputs are 0. Worse (for use as a NAND-like universal gate, anyway, though not in this context) is the fact that you can't build an OR gate out of abjunctions without access to that constant 1, even though the OR gate is also falsehood-preserving.

Hot air ice shaping

Kragen Javier Sitaker, 2016-10-06 (4 minutes)

You can shape ice with streams of hot air for rapid, inexpensive fabrication.

Water is one of the cheapest materials available, and it freezes and melts at a temperature that's extremely convenient for shaping, although it has its drawbacks for structural use. But it should be possible to use a form made of water ice to give shape to a mold made of some other material that can harden below 0°, or to make an easily-removable mold for such a material.

Ice has the advantage that, because it's used over such a narrow temperature range, it has excellent dimensional stability.

Ice is fairly fragile (about 1 MPa tensile strength, which depends greatly on strain rate and very little on temperature), so precisely stamping things with it is pretty much out of the question; to transfer its shape to something else, that other thing pretty much needs to be liquid. By the same token, though, it's very easy to cut, leading to the ice sculpture competitions in various places every winter, as well as table centerpieces at many corporate events. Other possible ways to shape ice include additive manufacturing (by adding water just above freezing to a below-freezing workpiece) and carving it with high-speed streams of hot air.

For additive manufacturing, it probably would help a lot to include some impurities in the water that increase viscosity and perhaps make the water thixotropic, so that it stays put on the workpiece from the time it comes out of the nozzle until the time it freezes, but without lowering its freezing point too much or promoting large ice crystals. Possibilities that occur to me include tiny air bubbles, gelatin, alginate, agar-agar, carrageenan, konnyaku, gum arabic, xanthan gum, and grease (oil with surfactant), possibly with acids or bases to promote gel formation.

There are a few different hardening processes that could harden the secondary material.

First, obviously, there's freezing, where the liquid cools down below its freezing point and becomes a solid. This has the disadvantage that it releases a large amount of heat, which can melt the surface of the ice, although this is a less serious problem with low-crystallinity materials such as Dairy Queen dip-cone chocolate-flavored paraffin wax. And maybe, since it will happen first at the surface of contact, it won't cause any loss of detail. Hot-beeswax casting has long been used to "record the shapes of delicate ice accretions on aircraft components", according to Reehorst and Richter in 1987.

Second, there's the hydration-driven recrystallization of plaster of Paris. This happens more slowly at 0°, but I'm pretty sure it still happens. It also has the disadvantage that it releases a lot of heat.

Third, there's polymerization, which is what Reehorst and Richter reported good results with, starting with thinned silicone rubber resin at -5° and recooled after degassing. Many silicones will not cure at these low temperatures; Reehorst and Richter found that Dow Corning 3110 or 3112 with "catalyst 4" worked well, and Dow

Corning HS RTV worked best (10 parts base to 1 catalyst with 1 wt% 20-cSt-viscosity DC 200 silicone thinner). Smooth-On Corporation sells a silicone molding compound recommended by Freeze Cast Engineering for this purpose.

Some notes on FullPliant and Pliant

Kragen Javier Sitaker, 2018-04-27 (9 minutes)

So I've been reading through the FullPliant website.

Summary

Pliant is a programming language that represents an exploration of a promising but underexplored corner of the language design space. It has static typing with a frequently used escape hatch to ad-hoc polymorphism, like Java, but with minimal, extensible syntax, like Tcl, Forth, or to a lesser extent, Ruby, Scheme, or Common Lisp. It uses ref counting.

In more detail: the author, Hubert Tonneau, clearly has an unreasonably high opinion of himself, but the system he's built seems reasonably efficient; it's not quite the full operating system he makes it out to be, but it's pretty close. He's built a text editor; an IDE; a compiler; a graphical user interface all the way down to raw pixels; a database; a web page framework; servers for SMTP, HTTP, and VNC RFB; a bandwidth-optimized GUI remoting protocol; a compiler; and a sampling profiler. The programming language is syntactically close to being a Lisp with some syntax sugar and macros, but it's explicitly and statically typed, allowing a relatively simple compiler to get good performance. Memory management uses reference counting or, optionally, explicit malloc and free. The database is an IMS-like hierarchical database, with a modern disk-as-tape-for-the-transaction-log design. The system is poorly documented, but it appears that the language has both first-class functions and dynamic method dispatch.

The main compiler is written in Pliant, bootstrapped from a subset written in C.

This seems like a pretty reasonable overall design for the stuff he's trying to do, and it seems to be reasonably successful. The signal-to-noise ratio of the example code below is very high.

I wish there were documentation in French, as Tonneau's English is very poor, and although the existing documentation comes out to book length (I've been reading it for days), it's quite sketchy at best.

Tonneau is only casually familiar with the literature and related work in the field, so he has reinvented a number of things.

Syntax and Embedded DSLs in Pliant

One of the more interesting features of Pliant is how he uses the macro system and syntactic sugar to get Ruby-like DSL power for things like the GUI; here's a snippet of an example from the manual:

```
var Float total := 0
each a o:article
  row
    cell
      input "" a:ref
    hook
```

```
    cell
      input "" a:ppu
    cell
      input "" a:count
  change
    section_replay "content"
  cell
    text (String a:count*a:ppu)
    total += a:count*a.ppu
  cell
    button "remove"
      o:article delete keyof:a
      section_replay "content"
```

Pliant's syntax is extensible, so this code can take advantage of Ruby-like blocks passed to macros. It builds a table with the price-per-unit and count cells wrapped in an on-change hook. Even for ordinary functions rather than macros, the argument semantics permit by-reference in-out parameters, so the `input` control can be hooked directly to the database record field with a minimum of fuss. `section_replay` re-executes the code block to draw the named "section" of the UI, which, as it happens, includes the code snippet above. That implies closure semantics; see below.

The `each` macro is not specific to the database module, but in this case is iterating over a database query result; as you can imagine, it declares the variable `a` provided as its first argument, and iterates over the subordinate records in `o:article`.

The whole infix and indentation syntax thing is just syntax sugar over S-expressions; part of the code above is, I think, syntactic sugar for the following S-expression in conventional notation:

```
(cell ({} (text (String (* (a count) (a ppu))))
          (+= total (* (a count) (a ppu)))))
```

The syntax is perhaps unfortunately so minimalistic that I haven't yet figured out how to tell when a bareword will be evaluated as a variable and when it will be treated as a symbol, even in contexts where the head of the clause is clearly a variable and not a macro name. Here, for example, `total` is a variable, but `count` and `ppu` are names of methods to call. I don't know if defining methods creates a variable in the environment that refers to the corresponding generic function or what.

Pliant macros ("meta functions") are not source-to-source transformations; rather, they emit the compiler's intermediate representation for their part of the AST, possibly after incorporating the IR from their child nodes. Tonneau argues that this makes them more orthogonally composable than Lisp macros, but the complexity cost in the implementation of each macro is high, and I am not convinced of his thesis as its benefits.

As an example, Tonneau explains the `thread` macro in the manual. To implement the closure semantic required (similar to those of `button`) it invokes the compiler function `uses` on the emitted IR from the child nodes to determine which variables must be closed over, then explicitly creates code to copy the variable contents into the child

thread. I have no idea how that interacts with the optional reference counting machinery.

Pointer semantics in Pliant

Reference counting in Pliant depends on the use of smart-pointer classes like Arrow and Link, which are instantiated with the type of their targets; I think this makes them parametrically polymorphic, but because the type system is never explained anywhere, I'm not sure.

The usual kinds of pointers in Pliant are implicitly dereferenced; they are transparent references to the underlying variable, and support the same operations as a variable of the underlying type, including `:=`, plus a separate `:>` operation which reseats it to point to a different value. They can refer to variables inside arrays, dictionaries, and other containers, and they can even be used as iterators in something like the C++ style, but address arithmetic is not normal. An example from the manual of iterating over the elements of a dictionary with key elements of some type xxx mapped to value elements of some type yyy:

```
var (Dictionary xxx yyy) d
var Pointer:yyy p
p :> d first
while exists:p
    foo p
    p :> d next p
```

This is equivalent to this use of `each`:

```
var (Dictionary xxx yyy) d
each p d
    foo p
```

There's a separate `Address` type that does support address arithmetic, requires an explicit dereferencing operation, and carries no target type.

Implicit dereferencing clearly poses problems for manipulating pointer chains; there's a `:>>` operation to reseat the second (or possibly ultimate) pointer in such a chain.

I speculate that the implicit nature of Pliant dereferencing is helpful to making embedded DSLs.

Runtime error handling in Pliant

Pliant has a little-used exception system. By default, it indicates errors through abrupt termination of the Pliant process; file I/O operations also have a `safe` option to instead use function return values. There is no apparent support for Golang-like multiple return values with compiler warnings on unused variables, nor for Haskell-like variant types with pattern matching.

When an exception is caught, the exception system does not immediately transfer control to the error handler; it appears to continue execution normally with a pending error stored somewhere, indicated by the `iserror` boolean function.

There is syntactic sugar for propagating exceptions; an equivalent

to the

```
foo bar
if iserror
    return
```

is

```
foo bar ?
```

Abrupt process termination provides a source-level stack trace.

I said the exception system was little-used, but it is used consistently in some places. In particular the `compile` method on AST nodes normally indicates compile errors using exceptions.

Reference Counting and Dynamic Dispatch in Pliant

Any Pliant variable can be an "object", with a header containing a reference count (which I suppose implies it must be heap-allocated) and a type pointer, or not. Various parts of the Pliant machinery assume that they are operating on objects, and this is sometimes verified at compile time. The `Link` smart pointer type has the semantics of `Pointer`, plus increments and decrements reference counts, and the `Arrow` smart pointer type is the analogous reference-counted version of `Address`.

Reference counting in Pliant is apparently thread-safe. I don't know whether this makes it a bottleneck in heavily multithreaded code.

I don't understand the semantics of method calls and dynamic dispatch much at all.

The type pointer can be accessed with the `entry_type` function for dynamic type tests.

The Pliant database

The Pliant database is made of typed records arranged in a tree; some of the fields can be multivalued, and their values have another record type, as in older hierarchical databases like IMS. I haven't found anything permitting polymorphic record types or indices.

Tonneau admits that the database's hierarchical design is less flexible than an RDBMS, but considers it adequate. His idea of RDBMSes is pretty hazy; he thinks they autonomously decide which indices to create.

I don't know what the database's transaction semantics are.

Topics

(2015-05-29)

It should be possible to "perform in-memory computations on large, even decentralized clusters in a fault-tolerant manner", as Apache Spark does, using Vesta-like build-step isolation, but with the shell usability of `redo`, using a `git-annex`-like blob backend, thus expanding the applicability of Spark-like computational structures far beyond the data center.

This requires substantial explanation.

Spark

Apache Spark is a system for making high-performance, fault-tolerant clusters easy to use, by generating and managing things Spark calls RDDs:

> [A]n RDD is a read-only, partitioned collection of records. RDDs can only be created through deterministic operations on either (1) data in stable storage or (2) other RDDs.…an RDD has enough information about how it was derived from other datasets (its *lineage*) to *compute* its partitions from data in stable storage.… in essence, a program cannot reference an RDD that it cannot reconstruct after a failure.

This sounds terribly similar to `make` and software source control and build systems, doesn't it?

redo

In 2010, Avery Pennarun implemented Dan Bernstein's `redo` design, which is a simpler approach to what `make` does. If you want to build a file named `foo.o`, you run `redo foo.o`, and `redo` will run the shell script `foo.o.do` if it exists, or otherwise `default.o.do` if it exists, or otherwise `default.do`, searching up the filesystem hierarchy. This `.do` file is expected to put the desired contents of `foo.o` into an output file whose name is passed to it.

A minimal useful `default.o.do` might say

```
redo-ifchange "$2".c; cc "$2".c -o "$3"
```

The first command there is a recursive invocation of `redo`, which tells `redo` that this output file is going to depend on `foo.c`, so it had better make sure `foo.c` is up-to-date before continuing. This dependency is recorded for later. (`redo-ifchange` takes multiple arguments to build dependencies in parallel.)

A more complete `default.o.do` would take `#include` dependencies into account.

`redo` does have a couple of limitations. One is that it doesn't handle multiple output files, like those from `yacc`, very well. Another is that it is purely local; it doesn't have a cluster mode, although you may be able to use `distcc` to get some of that yumminess.

ccache

ccache is a build accelerator specific to C, C++, and Objective-C. It hashes your source code, include files, compiler (well, typically just its size, mtime, and name), command-line options, etc., with MD4, and stores the compiler's output (including e.g. warning messages) in an on-disk cache in, normally, your home directory; future recompilation attempts whose inputs haven't changed will just reuse the previous compiler output.

In theory, this means that you could get most of the benefits of `make` for C and especially C++ programs by just wrapping your compiler in `ccache` inside your build script; rerunning the build script would rehash all your source files, copy the object files into your current directory, and then relink the executable. Depending on what you're compiling, this might be almost instantaneous, or it might be very slow.

Because Unix provides `ccache` with no reliable way to get a secure hash of the source files from the filesystem, it has to read them in their entirety to figure out whether they have reverted to an old version. I tried it just now on my netbook on a tiny three-kilobyte GLUT program, and it ended up reading about a megabyte of `.h` files in order to figure out that it could safely reuse the 2.7kB `.o` file from a previous compilation, taking 39 milliseconds in all, even though it made only about 365 system calls.

Database indexes

Suppose I do this:

```
sqlite> create table foo (x varchar, y varchar);
sqlite> create index foox on foo (x);
sqlite> insert into foo values (3, 4);
sqlite> insert into foo values (4, 5);
```

`foox` is the name of an index, which is a sorted copy of a column `x` of table `foo` with rowids.

Now, if I do a query on `foo` like `select * from foo where x = 3;`, this query can use the index `foox` to find the relevant rows. (In fact, in SQLite3, `explain` tells me it does, even when there are only two rows in the table.)

For this to work properly, `foox` has to be updated every time I insert a new row into `foo`. But this is tricky! If I have a million rows in `foo` and I add a new one whose `x` value is close to the minimum of the `x` values, then if `foox` is simply stored as a vector, the database might have to move a million values down by one in order to make room for the new `x` in its proper sorted order. There are several solutions to this, but the typical one (and what SQLite does) is to store your index in a B-tree, which allows you insert in the middle of it relatively efficiently.

A different approach, and more or less the one Lucene uses, is to accumulate your updates in a small "side file" until there are a lot of them, and then apply all of those updates at once to generate a new sorted `foox`. Until `foox` has been replaced with the new version, every query to `foox` must also check the side file to see if there are updates it's interested in; this can be made more efficient by sorting the side file, at which point you may begin to desire to have a side file for the side file.

The database index is data that depends on the table, and it needs to be possible to incrementally and transparently recompute that data when the table changes. This is the same kind of automatic recomputation problem that Spark, `make`, and `redo` attempt to solve.

Vesta

Vesta is a source-control system integrated with a build system; it

versions your whole build environment, and it runs each build step in an isolated chroot environment where it can only access data via Vesta, which functions as an NFS server. This ensures that the build step is only accessing a particular version of the source file, of the compiler, etc., and that Vesta can correctly record these dependencies.

Unfortunately, Vesta was proprietary for many years before finally being released publicly, at which point its authors stopped maintaining it; it had its own purely-functional programming language that you were required to use to describe the build process for your system; because its build scripts were written in that same language, building it from source required having a running instance of Vesta; and, since access was provided via an NFS-server interface, you had to have root (at a time before it was commonplace and easy to run virtual machines in VirtualBox, QEMU, or EC2) to try it. Vesta was used in production by DEC's Alpha processor design team for a couple of years, but perhaps because of obstacles like those mentioned above, it never achieved wide usage, even within DEC or Compaq.

git-annex

git-annex does not do any dependency management. Instead, it manages an efficient, decentralized, redundant immutable blob store with decentralized, replicated, eventually-consistent metadata, built on top of git. It uses symlinks to permission-read-only files to provide normal filesystem access to the immutable blobs without going to the lengths of implementing its own filesystem, as Vesta does; this is usually enough to prevent you from accidentally corrupting your local copy of the blobs, and if you do corrupt one copy of a blob, you can still restore it from a remote repository.

Spark, simplified and made flexible

Spark has the lineage and determinism stuff unnecessarily coupled to a bunch of stuff about keeping Java objects in memory and partitioning and records, which seems like it is somewhat extraneous, although apparently Java does kind of need that in order to run efficiently. (You'd think java.nio.MappedByteBuffer would have largely eliminated this problem, but apparently not.) Spark's ability to "perform in-memory computations on large clusters in a fault-tolerant manner" does not depend in any way on Spark's knowledge of the internal structure of partitions (that they contain records) nor of Spark's knowledge of which partitions are associated together to form an RDD. All Spark needs to know to recreate a chunk of data is really how to redo the computation that created that chunk, and how to recreate the inputs that went into that computation.

However, unlike `redo`, in-memory computations on large clusters definitely need to be able to produce multiple output chunks, or partitions or whatever. And, if those chunks are stored in distributed memory on a cluster, it's probably a good idea to send the computation to where the data is.

Also, the granularity of the computation is likely larger than what `redo` has to deal with, which means that the system has more latitude to do computations and heavy-duty setup than in `redo` or `make`. It could

run an A* search, for example, to choose among possible alternative plans.

So here's what I propose. Build steps nest. Build steps run in a contained environment, like what lxc provides, or if that's not possible, a directory full of symlinks to read-only files from a git-annex-like chunk store. When you launch a build step, which you can do from the Unix command line, you explicitly list its input files, including the script for the build step, which causes them to appear in its contained environment. When it terminates, it leaves behind an output directory. All of the input and output files, as well as the directories containing them, are stored in a distributed chunk store, and their provenance is recorded in a distributed, replicated metadata store; this is very similar to git-annex. Build steps are presumed to be deterministic, and they are isolated from their environment to the extent possible, which reduces their nondeterminism. So, if you invoke a build step for which the system already has the results cached, it will retrieve those results from the chunk store. And the system may invoke the build step on a remote machine, if that's where the data is, and then replicate the results onto your local machine.

Lxc/virt-sandbox might impose some 200ms launch overhead on build steps, but that should probably be okay. If it's not, Debian has fakechroot, which is an extremely efficient way to use a wrapper library to fake out some system calls to trick programs into thinking they don't have access to the whole filesystem.

This allows you to write your build script as a shell script, which can invoke other scripts, possibly in a loop, and use their results. Once you have run your build script, which will usually be instantaneous, you can be sure that all of the build results are present.

When a build step invokes a subordinate build step, it names the input files it wants to provide to the subordinate step using the filenames it knows them by, and optionally put them at a particular place in the child's namespace; but the system invoking the subordinate step uses their immutable blob hashes in the hash keys, not the filenames known by the parent build step. This means that the same build step, running the same commands identically many times in different contexts, can invoke a sub-build-step that does different things.

The top-level build script might also snapshot other parts of the firesystem, copying them into the blob repository, in order to make them available to subordinate build steps. For example, substantial parts of /lib and /usr/lib may be necessary.

(It would be nice to use sysdig or strace or something to figure out what files are actually being accessed, without having to write a filesystem.)

Lazy concatenation and merging

Ideally you could concatenate several chunks into a single big output file in a purely virtual way, i.e. without actually copying the data.

Performance back-of-the-envelope

I have an 800-gigabyte stock-market data set. If this were split into chunks of some 64 megabytes, it would be about 12500 chunks. If I

generate another 200 gigabytes of derived data from that, it will be another 3125 chunks. If each of those chunks derived from, say, 400 input chunks, the SHA-1s of all of those chunks (the lineage) would be 8 kilobytes; all the metadata together would be 25 megabytes. Incrementally replicating 25 megabytes of lineage data will be no problem.

Small-memory performance

One of the interesting things about MapReduce is that any algorithm that can be expressed with it can be implemented with a small number of sequential passes over the data, so you can use it to improve locality of reference as well as for fault-tolerant cluster-scalable computation.
