(write 5 (lambda () (write 6 (lambda () (terminate)))))
```

Then

```
write-twice: -> number; write number; write number; terminate.
```

which means

```
(define write-twice
  (lambda (number)
    (write number
           (lambda () (write number (lambda () (terminate)))))))
```

Then

```
write-twice: -> number return;
        write number; write number; return.
write-twice 7; write 9; terminate
```

Which means

```
(define write-twice
  (lambda (number return)
    (write number (lambda () (write number
                                    (lambda () (return)))))))
(write-twice 7 (lambda () (write 9 (lambda () (terminate)))))
```

Then

```
+ 2 3 -> number; write number; terminate
```

which means

```
(%+ 2 3 (lambda (number) (write number (lambda () (terminate)))))
```

Then

```
count: -> start end return;
        write start;
        = start end (return);
        + start 1 -> new-start;
        count new-start end return.
count 1 10; terminate
```

which means

```
(define count
  (lambda (start end return)
    (write start
           (lambda ()
             (%= start end return
                 (lambda ()
                   (%+ start 1
                       (lambda (new-start)
                         (count new-start end return)))))))))
```

with the new definition of %=:

```
(define (%= a b consequent alternate)
  (if (= a b) (consequent) (alternate)))
```

This is the CPS expansion of this:

```
(define (count start end)
  (write start)
  (if (not (= start end)) (count (+ start 1) end)))
```

I don't know why there are parentheses in "= start end (return)" in the Io example. Perhaps it's an error introduced by Finkel.

One final example, showing the use of parentheses:

```
make-pair: -> x y return;
        user (-> client; client x y); return.
```

which means

```
(define make-pair
  (lambda (x y return)
    (user (lambda (client) (client x y)) (lambda () (return)))))
```

Here's the definition of writelist mentioned above:

```
writelist: -> list return;
        list return -> first rest;
        write first;
```

```
        writelist rest;
        return.
emptylist: -> null notnull; null.
cons: -> number list econtinuation;
        econtinuation -> null notnull;
        notnull number list.
```

Usefulness

I wouldn't want to program in Io in the raw way described above; it's pretty verbose and confusing. But it's *much* clearer than Scheme for expressing code in explicit CPS, for three simple reasons.

First, a series of nested lambdas is a flat structure rather than a nested structure as in Scheme.

Second, the syntactic overhead of the lambda is a single punctuation character, or possibly three, rather than ten characters including some letters: `(lambda())`.

Third, as a result, in the usual case, the distance between the names of arguments and the place they come from (that is, the procedure that will eventually invoke the lambda that the arguments belong to) is much less, and they appear as a unit rather than as things far apart. `+ x 1 -> x;` is quite clear. (Unfortunately, this closeness of association is misleading sometimes; consider `out x -> null out;` in the definition of `count-stream0`, where the `-> null out; ...` part of the routine is suspended for some arbitrary period of time while the rest of the program runs, and may in fact never resume.)

More Syntactic Sugar

If you actually wanted to write programs in the language, you could benefit from changing it to have a little bit more syntactic sugar.

Nested expressions

For example, you could define

```
count [+ start 1] end return
```

as an abbreviation for

```
+ start 1 -> new-start;
count new-start end return
```

and for procedures that have only a single exit point, you could imagine writing

```
{-> number; write number; write number}
```

as an abbreviation for

```
-> number return; write number; write number return
```

In cases where a "statement" contains more than a single set of square brackets, the order of evaluation could be undefined, so that e.g.

```
string-scan src [+ srcidx 1] [- len 1] c
```

could rewrite either to

```
+ srcidx 1 -> v1;
- len 1 -> v2;
string-scan src v1 v2 c
```

or to

```
- len 1 -> v1;
+ srcidx 1 -> v2;
string-scan src v2 v1 c
```

Or the order of evaluation could be defined; who cares? However, it's important for our sanity that this:

```
string-scan src [+ srcidx 1]; foobar [- len 1]
```

rewrite to this:

```
+ srcidx 1 -> v1;
string-scan src v1;
- len 1 -> v2;
foobar v2
```

and not this:

```
+ srcidx 1 -> v1;
- len 1 -> v2;
string-scan src v1;
foobar v2
```

Note that the above transformation is just the CPS transformation in Scheme for normal nested application expressions. It's just a thousand times more readable than usual because of the Io lambda notation.

One-argument lambda sugar

It might also be helpful to be able to write one-argument lambdas more concisely, with an automatic name for "the last result". In Python's REPL and in Arc, this variable is called "_". With this, for example, you could write each of the following:

```
count-stream: ; _ -> null full; count-stream0 0 full.
```

```
+ 2 3; write _; terminate
```

```
make-pair: -> x y ret; user (; _ x y) ret.
```

Mostly this is duplicative with the []-nesting idea, though. I'm not sure which is better in the cases where both are applicable. Consider this example:

```
def render(text):
    body = str(markdown.Markdown(text))
```

```
    soup = BeautifulSoup.BeautifulSoup(body)

    headers = soup('h1')
```

In Io, that looks like this:

```
render: -> text;
    markdown.Markdown text -> foo;
    str foo -> body;
    BeautifulSoup.BeautifulSoup body -> soup;

    soup "h1" -> headers; ...
```

With implicit single arguments:

```
render: ;
    markdown.Markdown _;
    str _;
    BeautifulSoup.BeautifulSoup _;

    _ "h1" -> headers; ...
```

With nesting:

```
render: -> text;
    [BeautifulSoup.BeautifulSoup [str [markdown.Markdown text]]] "h1"
        -> headers; ...
```

The nested expressions are more compact, but in this case, I think the implicit arguments are clearer.

Conditionals

It would be nice if there were a way to conveniently rejoin streams of control after a conditional. For example, it would be nice to be able to write

```
if (= x y) (write "x y equal") (write "x y not equal");
if (= x z) (write "x z equal") (write "x z not equal");
if (= y z) (write "y z equal") (write "y z not equal");
whatever
```

If the language had automatic currying, you could define this `if` quite easily:

```
if: -> cond result alt cont; cond (; result cont) (; alt cont).
```

You can use the above `if` definition without automatic currying if you write out the arguments explicitly:

```
if (-> a b; = x y a b) (-> c; write "x y equal" c)
                       (-> c; write "x y not equal" c)
```

You could, however, imagine syntactic sugar for this as well. For example, this expression could expand into the above call to "if":

```
= x y ? write "x y equal" : write "x y not equal"
```

As with the nested expressions, note that this is just the CPS transformation for `if`.

Vibratory powder delivery

Kragen Javier Sitaker, 2017-02-25 (2 minutes)

One of the problems I'm having with powder-bed processes in the ceramic studio is that fine powders, whether quartz, feldspar, or glass, are clumpy. I'm thinking I can vibrate a tool to break them up. I've ascertained that some commercial ultrasonic vibrating sieves use about 200 watts of power per kilogram of vibrating mass; I think I can get by with 10 grams of apparatus and powder (really more like 100mg of powder) and thus 2 watts, and I'm wondering if piezoelectric speakers are a plausible way to deliver that vibration.

Digi-Key's most popular "buzzer element/piezo bender" is the CUI CEB-20D64, a US$1.38 6.5kHz piezo buzzer element that takes 30 volts peak-to-peak at an impedance of 350 ohms, which I guess works out to 2.6 watts.

So the answer is yes, cheap piezoelectric speakers have enough power to do the job. How about reaching ultrasonic frequencies?

The Murata MA40S4S is a US$6.80 40kHz ultrasonic transmitter; it takes a 20-volt peak-to-peak square wave input and delivers 120 dB SPL output at 30cm with a 10Vrms sine wave. It claims a 2550 pF capacitance at 1kHz. Unfortunately, this is not enough information to estimate its power output, since the SPL (20 Pa) depends on its directionality, which is not specified.

The next most popular ultrasonic transmitter is the US$4.95 PUI UT-1240K-TT-R, 40kHz with a 70° -6dB beam angle, running on 30V peak-to-peak. It claims 2100pF and 115dB.

(I could totally calculate how much power gets stored in and paid back from that capacitance at a given frequency and voltage, but what I'm interested in is the fraction that doesn't get paid back because it's emitted as sound.)

In the "Alarms, Buzzers, and Sirens" Digi-Key category, I find the much more popular TDK PS1240P02BT, a 33¢ 3V 4kHz single-tone "piezoelectronic buzzer without oscillator circuit" that TDK markets for, among other things, "speech synthesis output"; they plot its frequency response curve out to 10kHz in the 70–80 dBA range at 10cm and 3V, but it takes up to 30V input.

These are probably in the same power range as the first buzzer, though, just less directional.

Topics

Bit difference array

Kragen Javier Sitaker, 2018-10-28 (10 minutes)

So I was thinking about the sparse difference-array representation METAFONT uses for rows of pixels: +1 at the left edge of an ink area, -1 at the right edge. Once all the ink is thus applied, potentially including overlapping strokes, the prefix sum is calculated, thus spreading the ink, and the pixels with positive, or nonzero, amounts of ink are then colored. If you instead color pixels with odd amounts of ink, you get even-odd filling rather than nonzero filling.

In METAFONT, IIRC, the difference array is sparse: it contains (X-coordinate, increment) pairs, which could be specialized to (X, ±1) if we allow duplicate Xes. This allows an arbitrarily high X-resolution, for a fixed number of edges anyway, at only logarithmic cost. For a number of edges E much larger than the number of pixel positions N, a dense array is more efficient, since it can coalesce multiple edges that happen to cross the scan line within the same pixel; it need only contain N items instead of the larger number E.

Dense arrays also have the advantage of permitting more regular processing which fits better into CPUs. In what follows, I'm only considering dense arrays.

Gray code on bit-packed scanlines

It occurred to me that, in the even-odd case, you could use single bits for the pixels, and the prefix-sum operation and its inverse are simply the operations of converting between binary and reflected-binary Gray code. Converting from binary to RBGC, the backward difference operation, is simple and efficient (`x ^ x >> 1`), but the inverse operation (RBGC to binary, prefix-sum of XOR) is somewhat less efficient on a normal CPU. Chapter 13 of *Hacker's Delight* is about Gray code, and it gives this algorithm for 32 bits:

```
B = G ^ G >> 1;
B ^= B >> 2;
B ^= B >> 4;
B ^= B >> 8;
B ^= B >> 16;
```

An additional shifted-XOR is needed for 64 bits. GCC for amd64 renders this as follows, requiring three instructions per line, 18 instructions in all, plus in this case a `retq` of overhead:

```
  400620:   48 89 f8              mov    %rdi,%rax
  400623:   48 d1 f8              sar    %rax
  400626:   48 31 f8              xor    %rdi,%rax
  400629:   48 89 c2              mov    %rax,%rdx
  40062c:   48 c1 fa 02           sar    $0x2,%rdx
  400630:   48 31 d0              xor    %rdx,%rax
  400633:   48 89 c2              mov    %rax,%rdx
  400636:   48 c1 fa 04           sar    $0x4,%rdx
  40063a:   48 31 d0              xor    %rdx,%rax
  40063d:   48 89 c2              mov    %rax,%rdx
```

```
400640:   48 c1 fa 08           sar    $0x8,%rdx
400644:   48 31 d0              xor    %rdx,%rax
400647:   48 89 c2              mov    %rax,%rdx
40064a:   48 c1 fa 10           sar    $0x10,%rdx
40064e:   48 31 d0              xor    %rdx,%rax
400651:   48 89 c2              mov    %rax,%rdx
400654:   48 c1 fa 20           sar    $0x20,%rdx
400658:   48 31 d0              xor    %rdx,%rax
40065b:   c3                    retq
```

This works out to 0.28 instructions per pixel, which is still less than 1, and furthermore a third of those are `mov`s that might disappear in the micro-op representation inside the CPU, but it's not the order-of-magnitude kind of speedup we might hope for.

(On ARM Thumb-2 (not shown) it's 28 instructions.)

If you're running this operation on an entire scanline to compute its XOR prefix sum, you need to bring in the output parity bit from the previous word as well.

Bitsliced scanlines

Another approach to this problem is to bitslice it. Suppose that we have an array of 1024 32-bit words W, each word W[i] of which has bit N set (i.e. `0 != (W[i] & (1 << N))`) iff there is a left-right boundary at (i, N). Then we can calculate the XOR prefix sum, i.e. convert each row of pixels from RBGC to binary, simply and efficiently in parallel across the scan lines:

```
for (int i = 1; i < 1024; i++) W[i] ^= W[i-1];
```

This gets compiled to the following for amd64:

```
 0:   48 8d 47 04             lea    0x4(%rdi),%rax
 4:   48 8d 8f 00 10 00 00    lea    0x1000(%rdi),%rcx
 b:   8b 50 fc                mov    -0x4(%rax),%edx
 e:   31 10                   xor    %edx,(%rax)
10:   48 83 c0 04             add    $0x4,%rax
14:   48 39 c8                cmp    %rcx,%rax
17:   75 f2                   jne    b <xor_prefix_sum_bitslice+0xb>
19:   f3 c3                   repz retq
```

This inner loop is 5 instructions (two of which contain memory references) processing 32 pixels. It takes about 2.2 µs on my 1.6 GHz Pentium N3700, or 67 ps per pixel, 9.3 pixels per clock cycle. But you can unroll it, say by a factor of 4:

```
W[1] ^= W[0];
W[2] ^= W[1];
W[3] ^= W[2];
for (int i = 4; i < 1024; i += 4) {
  W[i] ^= W[i-1];
  W[i+1] ^= W[i];
  W[i+2] ^= W[i+1];
  W[i+3] ^= W[i+2];
}
```

```
1b:   8b 47 04              mov    0x4(%rdi),%eax
1e:   33 07                 xor    (%rdi),%eax
20:   89 47 04              mov    %eax,0x4(%rdi)
23:   33 47 08              xor    0x8(%rdi),%eax
26:   89 47 08              mov    %eax,0x8(%rdi)
29:   31 47 0c              xor    %eax,0xc(%rdi)
2c:   48 8d 47 10           lea    0x10(%rdi),%rax
30:   48 8d 8f 00 10 00 00  lea    0x1000(%rdi),%rcx
37:   8b 10                 mov    (%rax),%edx          ; loop starts here
39:   33 50 fc              xor    -0x4(%rax),%edx
3c:   89 10                 mov    %edx,(%rax)
3e:   33 50 04              xor    0x4(%rax),%edx
41:   89 50 04              mov    %edx,0x4(%rax)
44:   33 50 08              xor    0x8(%rax),%edx
47:   89 50 08              mov    %edx,0x8(%rax)
4a:   31 50 0c              xor    %edx,0xc(%rax)
4d:   48 83 c0 10           add    $0x10,%rax
51:   48 39 c8              cmp    %rcx,%rax
54:   75 e1                 jne    37 <xor_prefix_sum_bitslice_unrolled+0x1c>
56:   f3 c3                 repz retq
```

This processes 128 pixels in 11 instructions, although 8 of those instructions contain memory references, so it's really more like 19 instructions. (Or more, if you count the indexing operation separately.) It takes about 1.0 µs on my 1.6 GHz Pentium N3700, or 31 ps per pixel, 20 pixels per clock cycle. Filling a megapixel thus would require 31 µs, assuming you don't incur cache misses.

These numbers give us respectively 0.156 (5/32), 0.086 (11/128), and 0.148 (19/128) instructions per pixel. That's more like it!

(That also suggests that the N3700 is managing about 1.7 instructions per clock cycle.)

You might hope that other architectures would be more efficient, but they seem to be about the same; here's an ARM Thumb-2 compilation of the same unrolled loop, which is one byte shorter and has 16 instructions instead of 11 in the inner loop; it avoids the redundant memory loads of the amd64 version, but has to use explicit loads and stores.

```
1c:   6842        ldr r2, [r0, #4]
1e:   6803        ldr r3, [r0, #0]
20:   405a        eors    r2, r3
22:   6042        str r2, [r0, #4]
24:   6883        ldr r3, [r0, #8]
26:   4053        eors    r3, r2
28:   6083        str r3, [r0, #8]
2a:   68c2        ldr r2, [r0, #12]
2c:   4053        eors    r3, r2
2e:   60c3        str r3, [r0, #12]
30:   4603        mov r3, r0
32:   f500 607f   add.w   r0, r0, #4080   ; 0xff0
36:   691a        ldr r2, [r3, #16]   ; loop starts here
38:   68d9        ldr r1, [r3, #12]
3a:   4051        eors    r1, r2
3c:   6119        str r1, [r3, #16]
3e:   695a        ldr r2, [r3, #20]
```

```
 40:   4051        eors    r1, r2
 42:   6159        str r1, [r3, #20]
 44:   699a        ldr r2, [r3, #24]
 46:   404a        eors    r2, r1
 48:   619a        str r2, [r3, #24]
 4a:   69d9        ldr r1, [r3, #28]
 4c:   404a        eors    r2, r1
 4e:   61da        str r2, [r3, #28]
 50:   3310        adds    r3, #16
 52:   4283        cmp r3, r0
 54:   d1ef        bne.n   36 <xor_prefix_sum_bitslice_unrolled+0x1a>
 56:   4770        bx  lr
```

On a 64-bit machine, we could halve all these numbers, at the expense of doubling the working set (to 8 KiB) and the data traffic to the cache, by using 64-bit words.

Unfortunately, then we need to transpose the bit matrix to get the pixels in the usual scanline order.

Oversampling

These approaches might be sufficiently efficient to permit you to do antialiasing by the brute-force approach of oversampling. For example, if you do brute-force oversampling in both X and Y, you have four subpixels per screen pixel, and thus five gray levels for each screen pixel (0, 1, 2, 3, 4).

Even-odd-filled polylines

If you have a closed polygon or polyline, in theory you can just draw the edges into your scanline buffer with XOR (`W[x] ^= 1 << y` or `W[y*w + x/N] ^= 1 << (x%N)` or whatever) and get it filled this way. But you have to be careful about vertices: in the scanline where a vertex falls, you must be careful to XOR it into that scanline only once, not once for the line that starts there and again for the line that ends there. That bug leads to an inverse-video bleed-across on that line.

Similarly, you need to be careful with local minima and maxima of the Y-coordinate along the border, particularly if there's a vertex present.

Gradient and texture fills

The above algorithms handle solid-color fills pretty well, but solid colors nearly don't exist in nature. Even objects whose color is perfectly homogeneous are usually lit by inhomogeneous lighting, either because they are curved, because of fuzzy shadows, or because of varying distances to nearby light sources, including indirect light diffused from other objects. So non-computer-screen objects almost always have gradients.

Also, non-computer-screen objects usually have texture. Wood has grain, cement or dirt has white-noise texture, hair has striation, cloth has weave, and so on. At large grain, we can handle this by drawing thousands of objects, but the grains of a brick or the hair of a crowd of people, for example, is impractical to handle this way.

Further thoughts on this in Cheap textures (p. 736).

Further notes on algebras for dark silicon

Kragen Javier Sitaker, 2016-09-17 (updated 2017-04-18) (23 minutes)

Typical computers support three algebras directly: $GF(2^n)$ (integer math), $GF(2)^n$ (bitwise operations), and floating-point math, which is its own weird thing. Combining operations from more than one of these algebras often gives surprisingly fast iteration-free code to solve problems that would seem to require iteration, like clearing the rightmost bit set in a word: `x & x - 1`. However, other operations that aren't inherently computationally expensive are still expensive with these operations — the classic example is the fixed bit permutation at the input and output of DES, which is frequently speculated to be nothing more than an attempt to artificially slow down software implementations.

With the advent of the dark-silicon age, where we can fabricate far more transistors on a chip than we can afford to remove the heat from at reasonable clock speeds, it seems that adding new instructions that are less mainstream in their applications should be worthwhile. So far, this has mostly taken the form of instructions to implement particular cryptographic algorithms (like AES-NI) and multimedia-oriented and 3-D-oriented instructions like those in 3DNow!, MMX, various versions of SSE, AltiVec, and modern GPUs. These have the advantage of adding various kinds of vector algebras.

(SSE 4.2 also added a CRC32 instruction.)

Unfortunately, the available instructions in the multimedia and 3-D sets are generally fairly incoherent, making them awkward to program with.

We could add more random instructions that compute functions like "$\lceil\sqrt{(x^3 - 50x + y)}\rceil$ over the integers", but this would be kind of a waste of time — they can already be evaluated on mainstream hardware without unreasonable overhead on top of their inherent computational cost; and they don't compose in a useful way — which is to say, they don't form an interesting algebra. Or we could add an instruction that computes the derivative of a closed-form symbolic expression, but because the set of closed-form symbolic expressions is infinite, you can't fit a symbolic expression into a fixed-size register — only *finite* algebras are of interest.

So, what other finite algebras might it be advantageous to add hardware support for because mainstream hardware currently imposes punishing overhead on them?

Things we already pretty much have

We might consider lattices of finite set containment, but in fact the bitwise operations already give us that. Many other interesting lattices are already provided by the vector-math stuff we added for 3-D rendering.

Similarly, both signed and unsigned integer math are already reasonably well supported by the $GF(2^n)$ operations thath have been in CPUs for decades.

Bitwise rotation instructions have been totally mainstream for decades (since at least the 4004); I was always mystified by these, but it turns out they're necessary for multi-precision bit-shift operations, and they're also handy for individually testing bits that you're shifting out of numbers.

We also got saturating arithmetic as part of the whole multimedia and vector instruction shit sandwich.

Linear feedback shift registers seem like they would be a pain, since in theory the next bit to shift into the register is the XOR of the tapped bits from the register. But in fact you can also implement an LFSR by shifting a bit *out* of the register and using it to conditionally XOR *all* of the tapped bits *into* the register.

Shuffling, permutation, symmetric groups, and substitution ciphers

Much of this section concerns, in one or another sense, the symmetric group on some small number of elements, typically somewhere between 16 and 256 elements. This may seem like a strangely arbitrary choice, but in fact the symmetric group on N elements is in some sense the canonical group on N elements — every other group on N elements is a subgroup of it! So, in a sense, operations that can handle arbitrary symmetric groups can handle arbitrary groups.

Computers are, at their core, code machines; they operate on arbitrary information enciphered into a representation they can deal with. Classical (pre-computer) ciphers were broadly classified into substitution and transposition ciphers. In substitution ciphers, the pieces of the plaintext tell where to put pieces of the key schedule to form the ciphertext; in transposition ciphers, the pieces of the key schedule where to put pieces of the plaintext to form the ciphertext. These are in a sense the same operation, and it is somewhat surprising that they are so poorly supported in modern hardware. Perhaps this is accounted for by the fact that they are very well supported indeed by RAM (and the 8086 has an XLAT instruction that uses RAM for this in 11 clock cycles); it's just that RAM is falling progressively further and further behind the capabilities of CPUs.

Knuth's MMIX has instructions called MOR and MXOR, which "regard the 8 bytes of a register as a 8×8-Matrix and compute the result as a matrix multiplication", or "set eacy byte of $X by looking at the corresponding byte of $Z and using its bits to select bytes of $Y" (Knuth's Fascicle 1). In effect, each bit specifies whether or not to include one of the 8 input bytes in the computation of one of the 8 output bytes. If only one bit is set in each byte of the second argument, the output is just a rearrangement or shuffle of the input bytes; but, by setting more bits, we can activate the OR or XOR mentioned in the name.

Being generalized matrix multiplications using associative operators, these operations are of course associative. I know of no manufactured CPU that implements them, but something similar is commonplace in FPGA routing — the bits in $Z amount to a crossbar switch.

As Mytkowicz, Musuvathi, and Schulte showed in their 2014 paper , the shuffle instructions such as PSHUFB in SSE3 and SSE4.2 can be

used to accelerate and parallelize finite-state-machine execution. The PSHUFB instruction (`_mm_shuffle_epi8`) and its variant VPSHUFB is something like a cut-down MOR, using indices encoded as binary integers instead of bit vectors, thus offering no possibility of combining multiple input bytes into one output byte, but it can operate on 128-bit and 256-bit registers as well as 64-bit ones. Still, because it applies a permutation to the input (which may be a permutation) it's associative too, which is how Mytkowicz et al. used it to accelerate finite-state machines.

(More recent versions of SSE include PSHUFW and PSHUFD versions, which shuffle wider chunks around.)

If what you wanted was specifically to compose permutations like that, you'd be faced with a couple of problems:

• Even a 256-bit VPSHUFB wastes 3 bits out of every index, in the sense that the maximum valid byte index is 31, so only the low 5 bits of the index are used. If you were to cut the indices to 6 bits, you could fit 42 of them into a 256-bit register; if you could somehow use arithmetic coding, you could get the number a little higher still.
• There are times when you would like to compose permutations on sets of more than 32 or 42 elements, and it isn't immediately obvious how to efficiently decompose such permutations on larger sets into permutations on smaller sets, although related questions have been explored in some depth in the context of building circuit-switched telephone systems out of crossbar switches.

Another issue is that there are a number of kinds of bit permutation that byte-shuffling (whether 8-bit or SIXBIT) doesn't help you with. Massalin famously called for a perfect-bitwise-shuffle operation in her dissertation, which is still not available in current hardware.

So here are a couple of new shuffling designs that might be worth exploring:

• A 64-bit value v is considered to consist of 16 4-bit nybbles v0 through v[15]. xbar(a, b)[i] = a[b[i]], thus providing the same permutation-composition power as a 128-bit PSHUFB in half the bits. Additional nybble-perfect-shuffle operations "hi" and "lo" provide a way to combine nybbles from different registers without requiring fundamental operations of greater than binary arity: lo(a, b)[i] is a[(i-1)/2] when i is odd but b[i/2] when i is even, while hi(a, b)[i] is a[8 + (i-1)/2] when i is odd but b[8 + i/2] when i is even.

These nybble-perfect-shuffle operations make it straightforward to use this 16-nybble-xbar instruction as a 16-byte xbar, a 16-wyde xbar, etc.; and they make it relatively straightforward to leverage them into computing permutations of larger groups of nybbles.

• The N-bit value mux(x, y, z) is computed from three N-bit values x, y, and z as follows. The bit mux(x, y, z)[i] is x[i] if z[i] is 1, otherwise y[i]. The N-bit value shuf(a, b) is computed from an N-bit value a and an N/2-bit value b as mux(a[0:N/2], a[N/2:N], b) || mux(a[0:N/2], a[N/2:N], ¬b) where || is string concatenation and ¬ is bitwise negation. The N-bit value 2shuf(a, b) is computed from two N-bit values a and b as shuf(shuf(a, b[0:N/2]), b[N/2:N]). Arguments from sorting networks suggest that it's possible to perform any permutation of N bits by providing the appropriate `b` values to (lg

N)(lg N + 1)/4 2shuf operations; when N is 128, for example, 14 2shuf operations suffice, and when N is 1024, 28 2shuf operations suffice. Arguments from `mux(x, y, z) = x & z | y & ~z` suggest that you can do this on existing hardware and don't need new hardware. XXX no this is totally wrong because the bits aren't being perfect-shuffled! I want a perfect shuffle! rewrite

• MNAND or MNOR, which are analogous to the MOR and MXOR instructions, but permit specifications of a large class of small parallel computations as a fixed sequence of $Z values.

Lerp

As Darius Bacon pointed out, you can think of linear interpolation as being a sort of generalization of C's ternary operator.

GPUs automatically provide linear interpolation between texels. Iterating linear interpolation provides Bézier curves. Alpha-blending linearly interpolates between pixel values. The usual way to do linear interpolation is with two separate multiplications and a subtraction:

```
x := 1.0 - y;
z := y · a;
z += x · b;
```

However, this uses slightly more than twice as many bit operations as necessary; you can adapt the standard binary long multiplication algorithm to lerp instead. The standard algorithm to add the product y · b to z, consuming both, is:

• Go to step 4.
• If y is odd (that is to say, if `y & 1` is nonzero), z += b.
• y ← ⌊y/2⌋; concurrently, b ← b · 2.
• If y is nonzero, go to step 2.

While implementations of multiplication on transistor-starved hardware of the distant past often used this algorithm literally, taking more time to multiply by a larger multiplicand or one with more 1 bits — the 8086 would take anywhere from 128 to 154 clock cycles for a 16×16-bit multiply, while the 80486 would take 13 to 26 — modern hardware instead unrolls the loop into a cascade of carry-save adders. To multiply two 16-bit integers, for example, it has 256 carry-save adders. This means the loop gets rewritten as follows for a 16-bit multiply:

Repeat 16 times:

• If y is odd, z += b.
• y ← ⌊y/2⌋; b ← b · 2.

The modification to make this algorithm interpolate linearly between a and b is very simple:

Repeat 16 times:

• z += (b if y is odd else a).
• y ← ⌊y/2⌋; b ← b · 2; a ← a · 2.

This is easiest to understand if we think of a, b, and y as initially representing 16-bit fractions between 0 and 1, with 1 being represented by 16 1 bits, and the 32-bit result as likewise representing a fraction between 0 and 1, but with 1 being represented by 15 1 bits

followed by 6 0 bits followed by as 1, which is admittedly a somewhat awkward representation. You can restore it to a proper 16-bit form, if lerping is what you want, by taking the leftmost 16 bits and adding their most significant bit to their least significant bit.

So, for example, the 13-instruction multiplication code example on p.54 of the 8080 Programmer's Manual would become 15 instructions, and would execute 11 or 12 instructions per iteration instead of 10 or 11.

(Most current hardware multipliers reportedly use Booth's multiplication algorithm, which is not quite as easy to adapt.)

Of course, you can replace "16" and "32" in the above with "N" and "2N".

Decimal arithmetic

In the 1950s and into the 1960s, business computers invariably used (binary-coded) decimal arithmetic, thus avoiding the need to laboriously convert numbers from binary into decimal for output using a long, slow series of divisions by 10. The IBM Type 650 was a typical example of this class; a random memory access on it took 2.5 ms, and it typically ran about 1000 instructions per second, but needed 16.9 ms for a division, so converting a single six-digit number from binary to decimal for output would have required a full tenth of a second — much longer than was required to punch it into a card.

As computers got faster, conversion to decimal ceased to be the computational bottleneck, and IBM moved its decimal-computer customers over to the binary System/360, but included instructions in the 360 instruction set for operating on binary-coded decimal numbers as well, stuffed two digits per byte, but only in memory (not in registers).

The primary instruction set we use today, AMD64, is derived ultimately from the instruction set of a 1971 Japanese pocket calculator, whose 4004 CPU was developed by Intel. The 4004 had a DAA instruction, "Decimal Adjust Accumulator", used to convert the result of a 4-bit binary arithmetic operation into a 4-bit BCD result; Intel's manual explains:

> The accumulator is incremented by 6 if either the carry/link is 1 or if the accumulator content is greater than 9. The carry/link is set to 1 if the result generates a carry, otherwise it is unaffected.

The history of this instruction is as follows:

- 1971: DAA is introduced with the opcode FB_{16} in the 4004, which, though dozens of times faster than the IBM 650, still would have suffered performance problems from having to do a series of divisions in order to update the calculator display.
- 1972: dropped in the 8008, which was a more powerful follow-on to the 4004 but with fatal flaws in its instruction set design. The 8008, with its 8 8-bit registers, has its opcodes divided into octal fields. The opcode space previously occupied by DAA and many other 4004 instructions, $37*_8$, is now dedicated to instructions that store registers into memory. All eight opcodes of $0*7_8$, one of which will be DAA on the 8080, are RET.
- 1974: DAA is reintroduced in an 8-bit version in the 8080, with the opcode 27_{16} (047_8), which had the same registers as the 8008 but was an actually usable CPU. It didn't have multiply and divide

instructions, but its stack was in RAM. Its opcodes are divided into the same bitfields as the 8008's. Like the 8008, it has 8 opcodes dedicated to subroutine returns, but now they're $3*0_8$ and are different conditional returns; maybe that was planned for the 8008 but had to be cut. Unconditional RET is a ninth return instruction, 311_8.

• 1978: renamed "decimal adjust for addition" in the 8086, and accompanied by DAS, AAA, AAD, and AAM instructions that do related things — the AAD and AAM instructions were added to enable decimal arithmetic with the new multiply and divide instructions. The 8086 had 16-bit registers instead of the 8-bit registers on the 8080, but DAA and friends still only work on 8 or even 4 bits of data. I'm not sure what to make of this — they added four new instructions to support decimal arithmetic, but then didn't bother to take advantage of the double-sized accumulator register? The 8086 isn't binary-compatible with the 8080, but DAA retains the same opcode, 27_{16}. There are four RETs: $C2_{16}$, $C3_{16}$, CA_{16}, and CB_{16}, none of which is the 311_8 from the 8080, which is unassigned on the 8086; it's later reassigned to the fairly useless LEAVE on the 80188 and 80186 in 1982.

• 1985: the entire group of instructions is preserved unchanged in the i386, which expanded the registers to 32 bits. At this point it's clearly only being preserved for backwards-compatibility — doing multi-precision arithmetic with it involves using almost an order of magnitude more instructions than doing the arithmetic in binary. This is the first of these updates that's binary-backward-compatible — the 8086 was more or less compatible with the 8080 at the assembly level, but you couldn't run unmodified 8080 binaries on it. The i386 has a variety of processor modes to enable this backward compatibility.

• 2003: AMD introduces the 64-bit Opteron, which expands the registers to 64 bits, and adds a mode bit so it can continue executing unmodified 32-bit code. In 32-bit mode, DAA and friends work as always; in 64-bit mode, they generate an invalid-opcode exception. Intel was trying to escape from backward compatibility with such nonsense with the Itanium, playfully dubbed "Itanic", because of how it sank. Intel followed AMD's lead in 2004.

So, today, if you have some decimal numbers, such as "321.23", "289.528", "9076", and "8", and you want to do some arithmetic on them on a computer, you have a few different options. You can go through a series of multiplications to convert them to binary floating-point and then do arithmetic on them in binary, accepting the inevitable rounding errors on numbers like "0.1"; you can pick a prescale, like 100, and convert them to binary integers instead (for example, "8" becomes 800, and "321.23" becomes 32123) and then do arithmetic on those; or you can use a software implementation of decimal math like the Python `decimal` module.

(The computationally expensive part, actually, is not converting from decimal to binary on binary hardware; that's only a series of multiplications, which are fast. It's converting back the other way, which is a series of divisions, which are slow.

John Cowan quoted Wikipedia:

> IBM POWER6 includes DFP in hardware, as does the IBM System z9.1 SilMinds offers SilAx; a configurable vector DFP coprocessor.2

Polynomials over GF(2)^n

Computing properties of LFSRs and CRCs require doing computations with polynomials over GF(2)^n. Addition and subtraction of these polynomials are just XOR, but multiplication and division are more complicated operations.

SSE4.2 added a CRC32 instruction which performs an XOR and a polynomial division by the polynomial $11EDC6F41_{16}$, the CRC32C polynomial; it runs a bit over twice as fast as a software implementation, which makes me think that hopefully better alternative uses for the silicon are available. As far as I can tell, though, you can't use the SSE4.2 instruction to, for example, do Rabin-Karp string search or rsync sliding-window duplicate probing.

Arithmetic Coding

???

Cellular Automata

The Cytocomputer was some custom silicon designed in the 1970s at ERIM for some machine-vision applications; essentially it was a pipelined two-dimensional cellular automaton which processed one pixel (or cell) each clock cycle, with one line plus two pixels of latency per pipeline stage, using FIFO buffers. Each generation of the cellular automaton was run on a separate hardware stage of the pipeline, which could therefore easily be programmed for a different transition rule. Typical rules did things like dilation, erosion, and edge detection.

Cellular automata, especially those with a small number of states, are just about the worst possible case for per-instruction overhead.

Complex numbers

Base -1+i, "proposed by S. Khmelnik in 1964 and Walter F. Penney in 1965," allows us to represent the Gaussian integers as finite bitstrings without needing sign bits. The addition and multiplication operations on these numbers form a commutative ring, indeed, a Euclidean domain, so even division can be sensibly defined. I am not sure if there is a way to preserve these properties with a finite bit length, the way ordinary unsigned binary arithmetic does with GF(2^n). The fourth power of the base is real ($(-1+i)^4 = -4$) and so, in the complex plane, bit shifts by multiples of four amount to scaling a 2-D plane by a power of 4 with some number of half-turns.

Complex numbers can be used to represent geometrical points, translation (by addition), and rotation with scaling (by multiplication).

So it might be worthwhile to add hardware to implement the

relevant addition and multiplication algorithms for base -1+i.

p-adic numbers

p-adic numbers (for some prime p) form a field. This gives Hehner and Horspool's "quote notation" for finitely representing rational numbers with simple arithmetic algorithms, although that notation is not now considered practical due to exponential size explosions on some common cases.

Paper editing

Kragen Javier Sitaker, 2017-06-15 (3 minutes)

Often, drawing tools on computer screens suck, especially on the tiny computer screens we're starting to use more often ("cell phones", "tablets"). But computers are coming with better and better cameras, printing on paper remains high-quality and relatively cheap, and there are a wide variety of tools available for drawing and otherwise making images on paper — pens, markers, pencils, erasers, rulers, compasses, paintbrushes, paint, ink, and so on. Furthermore, it's easier and easier for a computer to recognize barcodes and things like that on photographed or scanned paper, which allows it to precisely coregister things drawn on preprinted paper, both spatially and in colorspace.

Existing similar things

There's a web site called Fontifier where you print out a template with a box for each letter, draw letters in all the boxes, then scan in the template and upload it to their web site. The website converts the uploaded scan into a TrueType font and sells it to you.

Scantron machines optically detect the positions of pencil marks on preprinted paper slips, used to encode the answers to multiple-choice exams, marking each one correct or incorrect.

Presumably human-readable bureaucratic forms are commonly processed by OCR nowadays.

Possibilities

So, what new possibilities does this modality of interaction offer us?

Most obviously, you could print out a document that needs illustrations with blank pre-sized boxes for the illustrations, illustrate it by hand, then scan or photograph the document to automatically add the illustrations to the document. Barcodes on the paper would orient the illustration-cropping software, and if the printer is colorimetrically calibrated, color calibration patches on the paper can correct for unknown lighting color, camera white balance, and camera focal plane sensitivity.

Additionally, though, if you can print out an image in a single color channel, such as magenta, then you can use it as a reference for another image you draw on top of it in black — whether merely marking points or areas of interest on the underlying image with "X" or "O" or similar marks, marking arbitrary contours, or even drawing an arbitrary overlay image. If grayscale isn't needed, you can even do this on a monochrome printer by printing the reference image in light gray, then thresholding it away to leave only the human-made black marks.

For example, you could draw accent marks for a font on a preprinted letter glyph to provide reference, places of interest on a map (perhaps with their names or other data such as hours of operation), coloring or shading on an outline drawing, connections on a network diagram, data points on a scatterplot with a preprinted reference graticule.

Notes on the value restriction and Modula-3

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

(Warning, this note is kind of rambling with no real point.)

Finkel says, describing Modula-3's subtyping rules:

> If every value of one type is a value of the second, then the first type is a called a 'subtype' of the second. For example, a record type TypeA is a subtype of another record type TypeB only if their fields have the same names and the same order, and all of the types of the fields of TypeA are subtypes of their counterparts in TypeB.

Initially, this struck me as violating ML's "value restriction" and therefore being unsafe, but I was wrong. Suppose we say

```
type Ushort = 0..65535;
     Long = -2147483648..2147483647;
     TypeB = record
       Data: Long;
     end;
     TypeA = record
       Data: Ushort;
     end;
```

Now it seems that `Ushort` is a subtype of `Long`, because every value of type `Ushort` is a value of type `Long`. So it is safe to assign a value of type `Ushort` to a variable of type `Long`. `TypeA` and `TypeB` have fields of the same names in the same order, and the single field in `TypeA` has a type that is a subtype of the single field in `TypeB`.

However, I guess if you're passing by value, you can safely copy a record of type `TypeA` into a variable declared as a record of type `TypeB`, and you're still safe with no run-time type checks.

Mutable Aliases Introduce Problems

It's only once you get into aliasing that you start running into problems; if you have a record that is mutably accessible through both `TypeA` and `TypeB` pointers, you can set its `Data` to `-1` through the `TypeB` pointer and then access it through the `TypeA` pointer.

It seems that if you could ensure that the `TypeB` pointer were `const` --- that is, didn't allow modification of the pointed-to value --- you could avoid this. That would allow the following subtyping rule:

```
if                  TypeA is a subtype of TypeB
       ------------------------------------------------------
then   pointer to TypeA is a subtype of pointer to const TypeB
```

That allows you to copy a pointer to `TypeA` into a variable declared as pointer to const `TypeB`. Which is pretty much equivalent to copying a `TypeA` into a variable declared as `TypeB`, but more efficient.

Arrays

When it comes to arrays of the same element type but varying sizes, the definition of "A is a subtype of B" that works in the above

subtyping rule is "A's indices are a superset of B's indices". That is, if you have an `int[100]` array, it's perfectly OK to copy a pointer to it someplace that is expecting a pointer to a `const int[10]` array; no run-time type checks will be needed. Actually, though, that's true even if that pointer isn't `const` --- which I guess is Finkel's point when he distinguishes "extensions" from "subtypes".

Lack of Conclusions

Anyway, just some interesting things I hadn't realized before about safe static typing. There's a subtyping relation that still applies after you take mutable references, and another one that doesn't, and the one that doesn't can be pretty broad.

Two-thumb quasimodal multitouch interaction techniques

Kragen Javier Sitaker, 2018-04-26 (11 minutes)

Most of the time people use their multitouch Android phones with one or two thumbs, the better to type on the keyboard at the bottom of the screen. But the direct-maniplation possibilities of this interaction paradigm are not very well explored, beyond tapping items to select them and scrolling vertically.

One-finger scrolling is such a ubiquitous interaction that not supporting it — or turning it into something incompatible — is going to be painful.

However, you could quite easily use one-thumb quasimode shifts to identify an action to be taken using objects selected using the other thumb. It's easy enough to support three or so separate buttons per thumb, and sliding after touch could select from a pie menu or adjust two parameters. Ideally actions like "undo" should require a slide, so that you can touch the button to see what you can slide to without fear of invoking an action. If you have three buttons per thumb and six slide directions, you have 36 actions or quasimodes available plus 6 further quasimodes.

Also, when you tap an object to select it, you can pop up another radial menu around the object, which can display detailed properties of the object; tapping on the menu items can pop up submenus accessible by dragging, invoke quasimodes, or permit a two-dimensional continuous adjustment of two parameters. A common pattern might be to display the numerical value of an attribute, drag to adjust it continuously, or tap to enter a new value with the keyboard. Under the same six-direction constraint, this allows another 42 object-specific actions.

Initially I thought that perhaps the object context menu should disappear as soon as your touch ends, so that the menu itself was a sort of quasimode; but that introduces three problems. First, you can't select from that menu by dragging, because that would interfere with one-finger scroll, so you have to use your other thumb — but half the time the menu item you want will be on the wrong side of the menu, so you have to cross your thumbs, or start over. Second, part of the menu is hidden under your thumb, so you can't see what the options are. Third, you give up the possibility of quasimodal menu items on the object menu.

Here are some example applications.

Interactive geometry

(See also Interactive geometry (p. 508).)

This is a program like KSEG, with points, lines, line segments, rays, circles, labels, and measurements, computed in a DAG, each possessed of color and layer properties; layer visibility can be toggled.

Panning, zooming, and rotation of the canvas are conducted using one-finger drags and two-finger pinches and rotations. Tapping an object highlights it and brings up a context menu depending on the object type; additionally it may bring up other menu options

elsewhere on the canvas.

All operations that you might want to apply to a number of objects at once or in quick succession, or on no objects, are necessarily on global quasimode options rather than individual object context menus.

The lower left corner has translucent quasimode buttons for "move", "trash", and "create point". Tapping in an empty space flashes the "create point" quasimode button, since maybe that's what the user meant to do. While that button is held, any taps on the canvas create points, which are initially selected and thus display their context menus. While "trash" is held, skulls and crossbones hover over all the objects visible on the canvas; tapping them will delete them. "Move" causes chaos symbols to hover over all the objects visible on the canvas, and the objects can then be moved with another finger — indeed, you can move more than one object at a time this way.

While you are holding down one of these buttons, the lower-right quasimode button cluster is replaced with a popup view of the radial menu of the button you're currently on, with a shaded cone connecting it to that button to clarify that it's a sort of magnified view. Dragging up and left on the "trash" button executes "undo"; dragging down and right executes "redo".

The lower right corner has a similar set of quasimode buttons. One is the "layer" button, which displays the name of the current layer and whether it is visible. Holding it invokes a quasimode that moves any object then tapped to that layer. Dragging it down and left and up and right cycle among the layers, with the possibility of cycling through more than one layer if the motion is extended. Other drag directions let you change the name of the layer, toggle its visibility, or add a new layer (initially labeled with the ten Heavenly Stems). Another is the "style" button, which shows the current style applied to new objects on this layer (or objects moved to this layer), and which either primarily shows color, line style, or point style (selectable by dragging up and right or down and left), and invokes a quasimode to change its focused aspect of objects while held. Other drag directions on "style" allow you to change attributes of the focused aspect of the style (for example, by invoking a modal popup color selector, or changing the thickness and dash pattern of lines) or to hide or show labels (itself a quasimode that causes all objects' labels to appear in gray, allowing you to tap objects to hide or show their labels). The submenus associated with these pop up in the lower left-hand corner, replacing the left-hand buttons.

The "layer" button in particular allows you to easily create a new layer with one drag, hold it to point to the objects you want to move onto it (tapping them a second time to undo the action, perhaps), and then tap it again to hide them all. Layers are automatically unhidden when switching to them. This provides a conveniently reversible way to hide objects.

Constructions with two objects as inputs are handled entirely through object context menus, because you can't really tell where you're going to start a drag — fine selection requires that you be able to correct your course by dragging after making initial contact. So, for example, to create a triangle, you create three points with the point quasimode, then tap one of them to bring up its context menu.

Holding the "segment" option on the context menu to activate a segment quasimode, the other points light up (as would, for example, tangent points on a circle and perpendicular points on lines and segments) and you tap two of them, then release "segment". Then you tap one of them, hold its "segment" item, then tap the other and release. While the quasimode is active, possible objects to construct appear dimly, lighting up when your finger is touching in the right place to construct them.

Other context-menu two-input constructions include perpendicular through a point, parallel through a point, circle from center and radius, circle from center and point on circumference, perpendicular bisector, angle bisector, or line or ray through two points. Also, you can constrain or unconstrain a point to lie on some other object, go to the object's layer, make the object's style the current style, or change the object's style.

So, for example, circle-from-center-and-radius is just a tap, a hold, and a tap, and creating two circles with the same radius and different centers just requires one additional tap, as long as you had the foresight to start the construction from the radius rather than the center. In Geometer's Sketchpad, each circle is two clicks to select the inputs and two clicks in a pull-down menu, so you pay eight clicks for two circles instead of three taps and a hold.

However, intersection points, midpoints, and points constrained to an object are constructed using the point quasimode — you just drag your finger around until you get the option you want, displayed in a callout.

Constructions of more than two inputs use a different interface. The third lower-right button opens a cartoon of the construction on top of the canvas; you then specify correspondences between the formal-parameter objects in the cartoon and the corresponding actual parameters in your sketch by touching them at the same time — effectively the formal parameter objects are quasimodal. Once only one formal parameter remains unspecified, you can see previews for possible formal-parameter values as you drag around the canvas.

Dragging on that constructions button scrolls around a universe of possible constructions to try.

A drawer that can be slid out from the right side with a tab contains a step-by-step textual description of the sketch, and objects can be selected in either the canvas or the text.

Other miscellanea include creating text objects, creating formulas, creating loci, creating new constructions (including by refactoring), entropy-minimizing point coordinates via implicit slow snaps, and file management.

Whenever an object is selected, its parents and children are also highlighted in different colors.

Prototype plan

To see if that's a good idea, I need to write a prototype, and DHTML is the easiest way to do that. But right now I don't have hardware that I can usefully get multitouch events from in DHTML: I can't find my new iPhone, my modernish Android phone has a power fault, I don't have a charger for my old iPhone (and I don't know if it will charge), and although my ancient Android phone delivers touch events in its browser, it seems to unavoidably collapse

into pinch-zoom mode as soon as there's more than one touch on the display at once.

So I'm going to start by prototyping on my laptop, using the keyboard for the quasimodes.

The very most minimal functionality that can possibly be interesting to look at at all is:

- Making points.
- Making lines between those points.
- Moving the points.

Can you eliminate backpatching?

Kragen Javier Sitaker, 2019-12-17 (8 minutes)

Conventional compilers, assemblers, and linkers require some non-sequential access to their output stream in order to insert forward references: places where a piece of code must contain the address of some later piece of code or data. Normally this is done by maintaining the output program in RAM along with a database of unresolved references and "backpatching" it when one of those references is resolved.

But can we avoid this, so that all code can be output as soon as it is generated, and still have a practical programming system? I mentioned this in a conversation with Jeremiah Orians, and I think I see a couple of ways.

How assemblers backpatch

In assemblers this is conventionally fairly unrestricted: you can mention an undeclared label `foobar` wherever, and this generates an undefined relocation for that label. If you define `foobar` later on, either as a label or with EQU, the assembler may go back and backpatch all the previous `foobar` references, but if you don't (and maybe even if you do), it leaves the job to the linker.

In conventional assemblers, this single mechanism provides for procedure call, looping, conditionals, exception handling, other local control flow, function pointer generation, and references to statically-allocated variables, and in some cases even to things like thread-local variables.

How Forth backpatches

Forth systems normally don't do a lot of this. Forth words are defined purely in terms of words (subroutines and variables) defined previously, textually prior to them, so they don't need to do any forward referencing for procedure calls, access to statically-allocated variables, or function pointer generation, and so no backpatching is needed in these cases. Mutual recursion can be arranged by defining a "DEFERred" word which is later updated to invoke a word defined textually later in the source; in a sense this is backpatching, but DEFER permits this definition to be changed multiple times, including at runtime --- it's a statically-allocated function pointer variable.

For control flow within a subroutine, though, Forth systems conventionally do backpatch in three cases: loops that may run zero times (such as ?DO loops), loops that may exit in the middle (such as BEGIN WHILE REPEAT loops), and conditionals (IF ELSE THEN). For these purposes, they maintain a compile-time stack both to compile backward jumps (which require no backpatching) and to backpatch forward jumps.

Is there no way to avoid this?

A sorting linker

As I said before, if your compiler or assembler relies on the linker to put in the forward references, it doesn't need to backpatch them itself,

so it can emit code immediately, at least if it doesn't care too much about optimizing it. But that just palms the distasteful random access off on the linker; it doesn't eliminate it. Can you do a linker without random access?

Well, sure, if you accept a lot of sequential access instead. You can shred the code into snippets that start at each symbol reference, each tagged with its start address (which may mean that you have some zero-length snippets), and mergesort them by the symbol name, while you mergesort the symbol definitions in a separate file. Then you can do a sort-merge join between the two files, formatting each symbol in the appropriate way for each relocation, to produce a file of properly linked snippets, still in symbol-name order. Then you can sort this file by start addresses and merge the overlaps where there were multiple symbol references at the same address, probably of different relocation types. Easy. Lots of "compilers" in the 1950s worked this way, I imagine.

But it's not highly efficient, if your objective really is to compile programs substantially larger than your RAM; you may need quite a few passes over your sequential files to finish the link.

Conditional returns

Suppose instead we structure all of our conditionals as conditional returns. Consider abs(x) = x if x > 0 else -x. You can compute this with the following sequence of operations:

```
result = x
x > 0?
if so, return
negate result
return
```

The "if so, return" conditional requires no backpatching to implement, perhaps a forward jump over a return instruction, and indeed instruction sets like ARM (see My very first toddling steps in ARM assembly language (p. 1684)) implement it directly.

However, this comes at a heavy cost. The more general case f(x) = g(x) if h(x) else j(x) can be implemented straightforwardly like this:

```
result = g(x)
h(x)?
if so, return
result = j(x)
return
```

But this involves computing g(x) in cases where we don't want it; this is at least computationally wasteful, and if g(x) has some observable effect, actually incorrect. You can do it correctly at moderate cost with an auxiliary function:

```
f'(x, c) =
    c?
    if not, return
    result = g(x)
    return
```

```
f(x) =
    c = h(x)
    result = f'(x, c)
    c?
    if so, return
    result = j(x)
    return
```

Note that this can be compiled purely in sequence from the definition "f(x) = g(x) if h(x) else j(x)", as long as we allow ourselves to revise our notion of f's entry point once we get to the "if"; and this is true for arbitrarily long inline computations in place of g, h, and j, *as long as j contains no conditionals*. That is, it doesn't generalize to the usual conditional cascade form "g(x) if h(x) else (j(x) if k(x) else m(x))", since the test for h(x) would need to come after the test for k(x) in the object code to prevent forward references. Although this is much less useful, it does generalize to the form "(g(x) if h(x) else j(x)) if k(x) else m(x)", which arises from PHP's incorrect associativity of `?:`:

```
f''(x, c') =
    return unless c'
    result = g(x)
    return

f'(x, c) =
    c' = h(x)
    result = f''(x, c)
    return if c'
    result = j(x)
    return

f(x) =
    c = k(x)
    result = f'(x, c)
    return if c
    result = m(x)
    return
```

All of these pieces can contain arbitrary exit-at-the-bottom loops and other computations, though.

If we replace the `return` at the end with a jump back to the top of the function, what we have is a normal exit-at-the-top while loop where the code before the conditional can do arbitrary computation, like Forth BEGIN WHILE REPEAT.

So this approach requires you to write your code in a pretty strange style with, usually, at most one conditional per function, and the conditional written *after* the consequent but before the alternate, as in Python conditional expressions. But it does seem feasible.

Conditional call and return

If we suppose that we have a conditional call instruction (or instruction sequence), we can do this a little more reasonably:

```
f'(x) =
```

```
    result = g(x)
    return

f(x) =
    c = h(x)
    result = f'(x) if c
    return if c
    result = j(x)
    return
```

If we have conditional call, we don't really need conditional return:

```
f'(x) =
    result = g(x)
    return

f(x) =
    c = h(x)
    result = f'(x) if c
    result = j(x) unless c
    return
```

However, this restricts the form of the j(x) expression; it needs to be nothing more than a function call. No such restriction applies to g or h, and if you have both conditional call and conditional return, it doesn't apply to j either.

Using the method of secants for general optimization

Kragen Javier Sitaker, 2019-07-22 (updated 2019-11-26) (13 minutes)

The method of secants is an algorithm the humans have been using for some 3000 years to solve a fairly wide variety of inverse problems, or, to their modern way of thinking, find zeroes of a fairly large class of functions. Given a function f from some vector x to the underlying field of that vector, such as $\mathbb{C}$ or $\mathbb{R}$, we compute a sequence of iterative approximations:

$$x_n = x_{n-1} - f(x_{n-1}) \cdot (x_{n-1} - x_{n-2}) / (f(x_{n-1}) - f(x_{n-2}))$$

You can think of this as a variant of Newton–Raphson iteration, using the secant approximation to the tangent line.

Unlike Newton–Raphson iteration, it doesn't require computing the derivative of the function, and it has slightly faster convergence under the usual assumptions used to prove the convergence of Newton–Raphson iteration — under those circumstances, the error after each iteration is the previous error to the power $\varphi \approx 1.618$, but each iteration only requires computing a single new value of the function being solved for, while Newton–Raphson iteration requires computing a new value of the function and also of its derivative, which is usually about twice as much work. So in some sense it converges about 31% faster.

However, it needs two guesses to get started instead of one, which makes its convergence conditions somewhat more complicated to describe.

Some ideas occurred to me about how to use the method of secants, so I thought I'd write them down.

I used the method of secants as an extended example in Separating implementation, optimization, and proofs (p. 780).

(This is probably crushingly naïve compared to all the work out there on optimization methods I don't understand yet, like Nelder–Mead, Broyden's method, and the Levenberg–Marquardt algorithm, not to mention the stunning successes in recent years with variants of gradient descent; but I thought it would be worth writing down.)

(Unrelated: the Method of Wecants, a technique for declining to do something you don't want to do while blaming someone else.)

Vector-domain functions

The method of secants is normally described as a one-dimensional root-finding method, but above, I said that you can generalize the domain of the function to be a vector, as suggested by the form of its recurrence relation. What happens in practice if you try that?

Consider $f : \mathbb{R}^2 \to \mathbb{R} = \lambda(a, b).a^2 + b^2 - 1$, a paraboloid which is zero everywhere along the unit circle. If our initial starting guesses are $x_0 = (1, 1)$ and $x_1 = (2, 0)$, the values just sort of randomly oscillate:

- 1, 1
- 2, 0
- 0.5, 1.5

- −1, 3
- 0.8, 1.2
- 1.04545455, 0.95454545
- 4.29411765, −2.29411765
- 0.89511609, 1.10488391

That's because each x value in the method of secants is an affine combination of the previous two values, so there's no way for them to get off the line $b = 2 - a$; and, as it happens, that line doesn't intersect the unit circle. If you're looking for an intersection of that line with the circle, or more likely some hairy implicit function, that might be great — although, if there are multiple intersections, there's no guarantee about which one you'll get, unlike with signed-distance-function raytracing. But if you're trying to find *any* solution, it's not so great that you need to start by picking two points that are collinear with it.

Other pairs of starting points converge just fine for the same function:

- 1, 0.5
- 2, 0
- 0.90909091, 0.54545455
- 0.86206897, 0.56896552
- 0.80697224, 0.59651388
- 0.80049797, 0.59975101
- 0.80000430, 0.59999785
- 0.8, 0.6

There are different approaches to solving this problem. Perhaps the simplest possible one is to use a secant, not through the last two points, but through the first and last of the last m points:

$$x_n = x_{n-1} - f(x_{n-1}) \cdot (x_{n-1} - x_{n-m}) / (f(x_{n-1}) - f(x_{n-m}))$$

In theory this should allow the last m points to be a simplex of an $m-1$-dimensional space, so their affine combinations would be that $m-1$-dimensional space, at the expense of somewhat slower convergence. This seems too dumb to work, but it does seem to. Here's a Python implementation:

```
def secnd_seq(f, x):
    x = list(x)
    y = [f(xi) for xi in x]

    while True:
        yield x[-1], y[-1]

        div = y[-1] - y[0]
        if not div:
            return

        x.append(x[-1] - y[-1] * (x[-1] - x[0]) / div)
        y.append(f(x[-1]))
        x.pop(0)
        y.pop(0)
```

Given random points from $[-5, 5]^2$, this converges to a point on the unit circle about ¼ of the time with 2 starting points (the orthodox

method of secants), but almost always with 3 or more starting points, because three points is enough to span the whole 2-D parameter space almost surely. However, the algorithm frequently takes several thousand iterations to converge! Increasing the number of starting points to 4, 5, or 6 makes it less frequently need more than 100 iterations or more than 1000 iterations, but since it usually converges in less than 50 iterations with 3 points, it might make just as much sense to do a random restart if the algorithm is failing to converge. Still, increasing the number of points more makes the completion time more consistent.

```
unit_circle = lambda (x, y): x**2 + y**2 - 1

def test_nd(d=3, n=1000, maxiter=100, eps=1e-15, f=unit_circle):
    ok = not_ok = 0

    for i in range(n):
        x = [numpy.random.random(2) * 10 - 5 for j in range(d)]
        items = list(itertools.islice(secnd_seq(f, x), maxiter))
        if abs(items[-1][-1]) < eps:
            print "ok:", x, items[-1][0], len(items)
            ok += 1
        else:
            print "not ok", x, items[-d:]
            not_ok += 1

    return ok, not_ok
```

(After several thousand trials, it did find a three-starting-point state from which convergence failed after 10000 iterations: three points reported as [array([-2.57650664, -4.90971528]), array([-0.17240513, -3.30215595]), array([-4.9655625 , 3.50688737])]. Unfortunately, that point converges in 82 iterations; like Lorentz's, my attempt at reproducibility has apparently been defeated by rounding.)

This experimental result suggests that this approach may be usable in high-dimensionality spaces to find zeroes, perhaps, like gradient descent is for finding minima. But I wonder how it compares to running gradient descent, or one of its modern variants like AdaGrad or Adam, on the square of a function?

Finding a zero of a vector-valued function

Suppose you want to find an intersection (x, y) of two circles: $(x - x_0)^2 + (y - y_0)^2 - r_0^2 = 0 \wedge (x - x_1)^2 + (y - y_1)^2 - r_1^2 = 0$. You could think of this as finding a zero of a vector-valued function $f(x, y) : \mathbb{R}^2 \to \mathbb{R}^2 = ((x - x_0)^2 + (y - y_0)^2 - r_0^2, (x - x_1)^2 + (y - y_1)^2 - r_1^2)$. But we can't directly apply the method of secants, because we need to divide by the difference of two function outputs, and you can't divide vectors.

However, we can take a norm of the result vector to get a scalar which will only be 0 when the vector is 0; for example, the $\mathbf{L_1}$ norm: $|(x - x_0)^2 + (y - y_0)^2 - r_0^2| + |(x - x_1)^2 + (y - y_1)^2 - r_1^2|$. Or, in Python:

```
def circle_intersection(x0, y0, r0, x1, y1, r1):
```

```
    def f(xv):
        x, y = xv
        return (abs((x - x0)**2 + (y - y0)**2 - r0**2) +
                abs((x - x1)**2 + (y - y1)**2 - r1**2))

    return f
```

This of course has a discontinuous derivative whenever we cross one of the circles, and so although the procedure above is able to find intersections successfully, it takes several hundred iterations to do so. But, surprisingly, things get even worse if we try to use the L_2 norm:

```
def circle_intersection_L2(x0, y0, r0, x1, y1, r1):
    def f(xv):
        x, y = xv
        return (((x - x0)**2 + (y - y0)**2 - r0**2)**2 +
                ((x - x1)**2 + (y - y1)**2 - r1**2)**2)

    return f
```

I think this is because the quadratic convergence condition of both Newton–Raphson iteration and the method of secants requires the function to have a nonzero derivative in the neighborhood of its root, and the L_2 norm instead has a zero derivative. Still, by using enough initial points, we can usually get to the solutions this way; this converges on 997 out of 1000 attempts, but usually takes between 1000 and 2000 iterations:

```
test_nd(d=20, maxiter=10000,
        f=circle_intersection_L2(0, 0, 1, 1, 0, 1),
        eps=1e-13)
```

The L^∞ norm is just as bad.

Optimization

Thomas Simpson pointed out that, if you can compute the first and second derivatives of a function, you can use Newton–Raphson iteration to numerically approximate its critical points — saddle points, local minima, and local maxima. Its global minimum must be one of these or, if its domain is compact, a point on the boundary of the domain. (If its domain is finite and open it may not have a minimum, just an infimum.) In low dimensionalities with sufficiently polite functions, this can enable you to quickly find the global minimum, even by manual computation. This approach has expanded into a whole field of "quasi-Newton methods", but these involve maintaining an approximation of the Hessian matrix of the function being optimized — and in n dimensions, the Hessian has n^2 elements.

Similarly, you can use the method of secants to numerically approximate a critical point of a function if you can compute the function's derivative — for example, using automatic differentiation. Earlier, I suggested that maybe you could square a function, at least a real one, and use generic optimization algorithms to find its zeroes. Now I'm suggesting almost the opposite: differentiate a function and

use generic root-finding algorithms to find the zeroes of its derivative, then test them to see which one is lowest.

If we are attempting to find a minimum of a function $f: \mathbb{R}^n \to \mathbb{R}$, we can start by using automatic differentiation to compute points of ∇f, which are in $\mathbb{R}^n$. Then we can, perhaps, use the extended method of secants in the way described above — taking some norm of that gradient and attempting to extrapolate to where it becomes zero, using something like $2n$ or $3n$ points — with only on the order of $3n + O(1)$ operations per iteration, rather than the $O(n^2)$ required by quasi-Newton methods. (However, I suspect that convergence, if it happens at all, may be slower per iteration with this approach, so overall it may be faster or slower than quasi-Newton methods.)

Genetic algorithms

"Genetic algorithms" is a catchy name for a popular metaheuristic based on Darwinian and Mendelian metaphors. You have a "population" of "chromosomes" over which you compute "fitnesses"; then, to create a new "generation", you "crossbreed" members of the population chosen randomly (with higher probability increasing with fitness) by combining their "genes" with "crossover" and apply "mutations" to the results. As long as the crossover and mutation operations aren't too destructive to fitness, each generation of the population will tend to have higher and higher "fitness".

It occurred to me that the method of secants sort of fits into this mold, but with an especially powerful "crossover" mechanism — it attempts to extrapolate from the differences between the two "genomes" it's crossbreeding to find the optimum. The offspring is necessarily within the space of affine combinations of the two parents, but its fitness may be much higher than theirs. (But sometimes it's not.)

The above approach of just drawing secants from further back in the history of approximations, in order to handle higher dimensionality, can be seen as a sort of degenerate genetic algorithm in which we only crossbreed two individuals at a time, and they're always the oldest and youngest. Presumably more judicious choice of parents would yield faster convergence.

As an example, I was thinking of approximating an image (see Image approximation (p. 2394)) with a set of Lambertian spheres of the same color and some lighting, and using the method of secants as above to generate new combinations of spheres. The function being optimized would be a combination of the difference between an image rendered from a given configuration of spheres and a penalty for the complexity of the configuration; the configuration would consist of an (x, y, z) direction for the directional light, an (r, g, b) color for the ambient light, and parameters $(x_i, y_i, z_i, R_i, r_i, g_i, b_i)$ for each sphere in the configuration. Mutation operations would add noise to everything and occasionally clone a sphere. Initial renderings would be low in resolution to speed up the initial search.

Dunno, maybe something like that could work for the structure-from-shading or even structure-from-motion problem, though in the second case you additionally have to estimate the camera path relative to the object. And maybe gradient descent and its variants are better fits.

Topics

A stack of stacks for simple modular electronics

Kragen Javier Sitaker, 2017-06-27 (5 minutes)

(See also files Graph construction (p. 3226) and Circuit notation (p. 1161).)

I was reading about Ekawahyu Susilo's "SnapBloks" modular circuit design kit, each of which has an STM32 microcontroller inside, and I had an idea.

Stack machine instruction sequences are nice and flat, even as they express nested expression trees. Even three or four levels of stack are adequate for fairly complicated trees.

What about physical circuit building blocks you can plug together into a linear sequence? Things much more primitive than an entire microcontroller. Like resistors. Maybe you could have, say, nine wires, representing a stack of seven signals plus two power rails; simple passive wiring components would be adequate for DUP, SWAP, DROP, ROT, pushing Vcc and GND onto the stack, and shorting the two top stack-input lines together; two-terminal components like diodes and capacitors would be packaged to connect between the "input" and "output" on the top-of-stack line, running everything else straight through; logic gates and transistors and the like would fit into the scheme reasonably easily. Physical distances between components could be fairly short if each layer in the stack were only, say, 1 mm thick.

A Forth-style two-stack version with enough wires would be adequate for any series-parallel circuit, I think, as well as many that aren't.

If you could change the orientation of processing modules in the stack, you might be able to get some extra expressiveness. Diodes, of course, could be turned around, but perhaps you could flip things around to select which of two stacks you were operating on.

A "vectorized" version in which each signal line was replaced by, say, a four-wire bus, would be no less expressive (you could always ignore the extra wires, though driving them would consume power) and more expressive for some uses. You'd want some extra "permuting" and "reducing" kinds of operations to interconnect the bitplanes.

If you had eight "stack items" of four wires each, plus power and ground, you'd have 34 lines. If the spacing was the standard 1.27 mm SOIC pin spacing with a 6×6 square matrix, the whole module size would be 6.35 mm square plus the width of a pin — say, 7 mm × 7 mm. This is a practical size to recognize by eye and manipulate by hand. An assembled circuit containing 50 elements and 50 passive "stack operations" might then be 7 mm × 7 mm × 100 mm (and cost about US$50 in parts, plus maybe another US$1000 in modules that were sitting around that you didn't use). A huge variety of circuits can fit within these constraints, especially when the available components include things like programmable microcontrollers.

About orientations: a square pin array like that could be oriented in eight orientations (four in-plane rotations and two flips), while the

slightly denser hexagonal packing would have twelve possible rotations. Getting these rotations to do something useful would be an interesting challenge, the alternative being to add a forcing function to reduce the possible number of rotations.

By way of size comparison, a AA battery is 14 mm × 14 mm × 50 mm. In that size, you could fit four separate such stacks of 50 items, totaling 200 modules and about 100 electrical component modules (i.e. not just passive wiring). So this seems like it might be a very reasonable alternative to breadboarding.

If the hypothetical 34 lines were distributed around the edges of the board at the same 1.27 mm spacing, you'd need 43.18 mm circumference, 13.74 mm diameter, the same as a AA battery. This could conceivably enable a larger number of possible rotations, but you'd have to figure out how to hook up the power rails, maybe with coaxial pins in the center of the board.

Is 1 mm a reasonable thickness? Common 0805 surface-mount resistors are 2 mm × 1.2 mm × 0.45 mm. A TQFP is nominally 1.0 mm, not counting the leads bending down below the body; an MLF is also nominally 1.0 mm. Standard PCB thicknesses (including 4-layer and 6-layer PCBs) are 0.031" and 0.062", apparently without regard to the number of copper layers, which work out to 0.79 mm and 1.57 mm. So 1 mm is maybe a bit low, but 3 mm should be doable. (Of course, not all the modules have to have the same thickness.)

I don't know what kind of connectors the boards would have to use between them. I assume zebra strip would have unacceptably high resistivity for many uses.

Why Minetest is so addictive

Kragen Javier Sitaker, 2019-04-20 (8 minutes)

I haven't played Minecraft, but I'm terribly addicted to Minetest, an open-source clone of it. What is it that makes the game so captivating?

When I start a fresh game, there's a carefully graduated slow exponential increase in the character's power. At first they can only dig dirt, break trees with their hands, and transplant plants; once they've acquired some wood to make a wooden pickaxe, they can mine stone and make a stone pickaxe, which allows them to mine stone more quickly, and then a stone axe, which allows them to chop trees more quickly; and some coal, which allows them to make torches, which makes it practical to mine underground and in caves, which makes it far easier to find coal and then metals; and so on. The sequence varies a bit depending on what environment your character finds themself in. I had a world where I had to travel a long way to find any wood, for example, and where I never did find any roses, which are necessary to make a bed. In the world I'm currently playing, it took me a long time to find a jungle, which is where you find the jungle grass you can convert into cotton seeds in order to start farming cotton, also necessary for beds.

There's a certain balance needed between surface farming and deep mining. There's a progression of tool types — wood to stone to steel to bronze to crystals (diamonds and the softly glowing mese crystals) — which roughly corresponds to how deep you need to go to find the necessary materials. But to dig deep quickly you need ladders, and ladders require lots of wood, which can only be obtained on the surface. (Mina likes playing with mods that add monsters, make ladders cheaper, and add hunger, which also generally requires that you go to the surface to satisfy it.) At different points in the game, different resources are the limiting resource for whatever you want to do, and you can play for many hours before you run out of things in the world that surprise you.

And, in the mining process itself, you're always looking for something that's fairly rare, and you will run across its random occurrences at a frequency proportional to how hard you look. At the surface, even coal may require searching for quite a while, and iron is not found at all. Later, once you have iron tools, you can easily dig down far enough that you can find more coal and iron than you need, but if you know bronze tools are better, it takes a while to find enough copper. And once you're deep enough to find enough diamond and mese that you don't need to use metal tools any more, it can still take a lot of searching to find each new crystal deposit, and you're frequently in danger of stumbling into lava. This proportional variable reward mechanic means that, in addition to the overall macroscopic reward schedule for continuing to play, you have a microscopic reward schedule where you know that the very next stone you punch with your pick could have diamonds or mese crystals behind it, making the whole journey down from the surface worthwhile. This makes it easy to keep playing for just one minute more. In fact, it makes it easy to forget to eat in real life. Or sleep.

Or go to class. Or go to work.

All this is to say that the reward schedule is well calibrated, somewhat randomized, and robust to player strategy. But I think there's another reason as well.

My apartment is three meters wide, 2.6 meters tall, and thirteen meters long. At one end, it has a glass window, which is about two meters square. The walls, ceilings, and floors are white, and there is a bit of a recess around the edges of the ceiling. I pay US$300 a month to live here, despite the inconstant and often uncomfortable temperature and troublesome noises, especially on weekend nights.

I just constructed a sort of replica in Minetest, in a world where I had already been playing and thus already had crystal tools, about 40 meters underground rather than in the sunlight. Replicating my real-world living space as described above took me 33 minutes; although that doesn't include the time to cultivate, harvest, and mine the wood, diamond, sand and coal consumed in the process, I think the direct labor on the building was the bulk of it. Merely digging out a 13×3×3 space out of gray rock would have been much quicker, less than five minutes, but I made the extra effort to reduce the ceiling height from the usual 3 meters to 2.5, adding the glass window at the end with a light source behind it, and making the walls, ceiling, and floor white with a sandstone pattern like the one printed on my real-world ceramic floor tiles.

Of course, the Minetest replica doesn't have a bidet, air conditioning, internet access, hot water, natural light, or conveniently walkable 24-hour hamburger shops like my real-world apartment does. But it's a lot tidier, and I can remodel it completely in another half-hour if I want. Moreover, I'm not likely to run out of space to put things, which in real life can be a problem; this world currently has about 1 km × 2 km generated horizontally, and I've dug almost 500 meters down, and it's only 49 megabytes, very little of which is the underground palace I added the apartment replica onto.

Aboveground, the palace does have its own stand of lumber trees, a giant outdoor fountain I built and am using to irrigate a cotton crop, and a watch tower with a beautiful view of the sunrise; indoors, it has a mushroom cultivation area, a 49-square-meter dojo with a mosaic floor, chests full of copper and gold ingots, ovens baking bread from wheat cultivated upstairs, a fireplace, and a room illuminated through its glass floor by lava running below. (In another Minetest world, I built a continuously erupting volcano visible from my balcony that, unfortunately, burned down a forest.)

So, like nearly all video games, Minetest offers a sense of competence and progressively increasing power. Minetest is also a medium of expression like that provided by painting and CAD programs. But, probably most addictively, Minetest is a sort of animated dollhouse: a vehicle for a convincing fantasy of living a good life, though it is a life involving a great deal of smashing rocks and hauling them up mine shafts. Like literal dollhouses, you can play in it alone or with friends or even strangers; it supports sharing your virtual reality over a LAN or the internet.

Also, in some ways, it goes beyond literal dollhouses: it provides an illusion of travel. Like any first-person three-dimensional game, the screen contents are in almost constant apparent motion toward you, triggering your orienting response and making it easy to pay

attention, and you can travel around, explore the world, learn where things are, and find more things.

Alastair thesis review

Kragen Javier Sitaker, 2013-05-17 (1 minute)

Reading Alastair Porter's master's thesis.

It provides a comprehensive overview of how current audio fingerprinting algorithms work, what they are used for (both for good and for evil), and a more detailed comparison of the open-source Echoprint and Chromaprint algorithms and an open-source Matlab implementation of the Landmark or Shazam algorithm.

It's a gold mine of references to things I didn't know about, or that I hadn't heard of before Alastair told me about them: mel-frequency cepstral coefficients, the freesound archive, the Shazam and Soundhound smartphone apps for song identification, the three open-source audio fingerprinting algorithms he evaluated, a list of other companies that do audio fingerprinting, the Fourier-Mellin transform, an adaptive FFT, Query By Humming, the Codaich dataset, the Acoustid and Echoprint servers, etc. Its overview of the history of audio fingerprinting for automated censorship in Napster, YouTube, and other applications may be shocking for those who aren't familiar with the situation.

The research involved making a fingerprint database of the thirty thousand two hundred eighty-three songs in the Codaich dataset and running twenty thousand queries (trying to match some audio fragment) against it. But they didn't just do that once; they did it many times with different fingerprinting algorithms and different kinds of degradation on the queries.

Multitouch and accelerometer puppeteering

Kragen Javier Sitaker, 2019-08-29 (updated 2019-09-01) (12 minutes)

In Dercuano drawings (p. 64) I've talked a bit about possible tools for illustrating Dercuano without bloating it, and in Two-thumb quasimodal multitouch interaction techniques (p. 1765) and $1 recognizer diagrams (p. 1264), among others, I talked about possible multitouch interaction idioms that could make this more practical. But now I want to talk a bit about possible ways of doing *animations*.

Bret Victor's turning-leaf animation demo

Bret Victor's lecture *Inventing on Principle* contains a demo of a prototype multitouch animation application designed to circumvent the limitations of things like Flash by, among other things, recording the motion paths of fingers and using them to define motion paths for cels, not just in position but also other dimensions such as rotation. I had never seen an animation program work like this before, but it turns out that the pioneering animation program GENESYS already worked this way in 1970, I think on the TX-1, though using a light pen rather than a capacitive multitouch screen.

There's a 1970 video of GENESYS on YouTube; watching that and *Inventing on Principle* are essential inspirations.

Two-dimensional puppeteering

GENESYS's motion paths were essentially recorded puppeteering, but were only capable of supplying two dimensions at any given time. This requires an additional pass over the animation to supply other information, such as when to switch the image of a character between different images — in GENESYS's case, as in traditional cel animation, discrete images, but as I pointed out in $1 recognizer diagrams (p. 1264), morphing between pen strokes is a straightforward thing to do.

Dimensions you might want to supply to a character path in an animation are nearly unlimited — even with a single sprite image and enough computrons to remap space in real time, they could include X, Y, rotation, scale, stretch angle and direction, transparency, brightness, contrast, tint, and two dimensions of perspective distortion. If an animation character has multiple images available, they can be arranged in a multidimensional space using dimensions like position-in-stride, mouth openness, age, fury, angel wings, deadness, left hand X and Y, right hand X and Y, head position, and explodedness, or a smaller number of dimensions could be used with a sort of K-nearest-neighbor interpolation instead.

More dimensions

In Victor's demo, he concurrently supplies a third dimension — rotation — by using a second concurrent finger. As I noted in Two-thumb quasimodal multitouch interaction techniques (p. 1765), this is typically the limit of what people do with modern

hand computers — although typical screens and OSes track up to five touches, it's unusual for people to use more than two at a time. Moreover, it's common for one or both of the touches to be thumb touches confined to an area near a corner of the screen, while the rest of the user's hand is supporting the computer from behind.

(Some of them also track touch size and orientation, but these variables are not very controllable, and are not available on all touchscreens.)

I think it might be feasible to get people to puppeteer an animated characters using two fingers on handles near the character, as with pinch-zoom but with less finger occlusion, while their thumb near the corner navigates a couple more dimensions of animation space. Moreover, more than two handles may be available, so the position at which they bring down a second finger onto the screen can indicate which dimensions they would like to be puppeteering at that moment.

(Choosing among different candidate characters to puppeteer is another reason for using handles positioned near the characters onscreen.)

Some animated characters, like Victor's leaf, will rotate freely, but many characters have a preferred orientation: a car or a text string might be horizontal, while a human figure might be vertical. Even rotatable characters might not rotate all the time. This means that with two fingers on handles near the character, the user can both move the character freely and continuously vary two more behavioral dimensions (rather than zooming and rotating with the second finger), such as mouth position and eyebrow position. The thumb in the corner can simultaneously be varying another pair of dimensions or invoking other operations.

Marionettes are commonly operated primarily with a 6DoF controller consisting of two crossed sticks, with the option to pull additional strings with a finger. The accelerometers in modern hand computers similarly offer two more degrees of freedom, which can perhaps be used advantageously.

This suggests that it should be possible to use a modern hand computer for real-time puppeteering with 8 degrees of freedom varying simultaneously in real time, with some of them chosen from among some 10 to 16.

Interaction with previous recording

The above is perhaps fine for when you're recording a new animation, or puppeteering live for an audience or to play a game, but when you're editing an existing animation, there's the question of how new puppeteering movements interact with the previously recorded ones. Perhaps they overwrite them — this should at least be an option — or perhaps they normally just add to them. This is especially troublesome if the primary handle you use to select a character to puppeteer is also the handle you use to move it around: does that mean you have to overwrite the existing movement path in order to add new eyebrow movements? Perhaps there's a fuzzy transition from merely selecting to overriding movements.

We could think of these degrees of freedom as "tracks" that we're recording, like in a multitrack digital audio workstation; as in GENESYS and Victor's demo, we'll need to be able to see the tracks

on the screen, select parts of them to be copied, moved, or erased, and so on.

Track inference

Probably by default some characters should infer tracks like moving through walking paces, making jumping motions, breathing, and turning to face different directions from lower-dimensionality data, like position and movement direction and speed. Butterflies flutter, falling leaves twirl, cars rock back and forth, humanoids turn to face the direction they're walking, toons wind up and screech to a halt, balls bounce, frogs hop, and so on. Users can always control these tracks explicitly if they like.

To some extent you could think of this as being like the "artistic style transfer" problem that so many artificial neural network papers have made so much spectacular progress on recently: for a character to walk realistically, they need to move not only their legs but also their hips, their arms, their shoulders, and their spine, and ideally those movements can be generated from a model of the movements the puppeteer is controlling explicitly. I suspect some kind of K-nearest-neighbors kind of thing based on an existing motion corpus, mixed with some linear prediction, might be sufficient, but maybe you'd end up needing a more sophisticated model like a neural network. Regardless, the space is of very small dimensionality relative to the spaces recent papers are training neural networks on, so the problem should be significantly more tractable once you have some data.

Face tracking

An alternative to puppeteering facial expressions with multitouch is to use the hand computer's front camera to detect a human user's facial expressions in real time so they can be used to provide some of the tracks. (Latency may be a problem at present.) This is most intuitive for humanoid character facial expressions, of course, but it could be used for a variety of other tracks as well.

Multiscreen puppeteering

Many popular puppets are operated by more than one person simultaneously in order to handle more degrees of freedom than a traditional marionette, without losing the immediacy of real-time performance. Different people, each using a personal hand computer, could also do this.

Extending this further, you could strap several old cellphones with accelerometers (and perhaps with broken screens) to different parts of a person's body in order to get a real-time feed of rotoscoping-like information, with two degrees of freedom per cellphone; then you might be able to entirely avoid the use of touchscreens.

Yaw-axis and position detection

Above I suggested that the accelerometers in a modern hand computer offered two degrees of freedom, because most of the signal they provide just tells you which direction gravity is. In fact they usually provide six readings: three axes of accelerometer and three of "gyroscope", but these do not provide absolute position and yaw

information, just pitch and roll, as it were. Typically they also have a flux-gate compass as well, but its readings are slow and noisy, so you have to filter it over a considerable period of time to get a useful reading.

However, you might be able to use the slow filtered compass reading to provide a sort of low-frequency yaw signal, then the faster (but relative, so high-frequency-filtered) gyroscope signals to update it in real time. Similarly, it might be reasonable to assume that on average (over, say, a minute) the computer is stationary, and use the shorter-term variations in accelerometer readings as adjusted by the gyros to compute where in the local space it is.

Of course, none of the above is new — inertial navigation systems have worked like this since, I think, the 1940s, though using actual gyroscopes and larger accelerometers. But using it for puppeteering or rotoscoping purposes seems to be new.

Photogrammetry could provide an additional source of high-precision ground truth for absolute yaw measurements.

Non-sprite virtual puppets

In addition to simple 2-D sprites, you could use this approach to puppeteer 3-D models of varying degrees of sophistication, as well as 2-D models more complex than simple sprites: 2-D models with skeletons, say, or assemblages of separate sprites for different body parts. Particle systems can be attached to the puppets, perhaps just in certain circumstances. Drawings can be progressively traced.

Dancing in more abstract spaces

Of course, interactively defining a time-indexed parametric curve in spaces of 16 dimensions or so, with real-time feedback, has many applications other than imitating Walt Disney. Modern video-game character models commonly have more dimensions than this, but the games have only very clumsy ways of navigating them, navigating from slider to slider.

Ad-hoc mathematical models of phenomena — physical system simulation, like Victor's active-filter example in the same talk, or otherwise — can easily have that many dimensions to explore.

Fractal graphics commonly have many continuous parameters which are interesting to explore.

A music synthesizer, too, has many such parameters, and recording how they change over time is a crucial part of recording music. This, especially with the accelerometers, is of course the core of Onyx Ashanti's inspiring work on Beatjazz.

Plots of multivariate data can only display a few dimensions at a time; varying plot parameters dynamically, as with one of Victor's other demos in the same talk, is useful not only for exploration but also for explanation to an audience.

Theater lighting is another case where you need to record a path through a continuous multivariate space and then play it back, typically with some degree of interactive control over timing.

Manually planning a motion path for an industrial robot or CNC machine is another possible use. Of course, you can also use this approach for control of such a machine in real time.

A sketch of a minimalist bytecode for object-oriented languages

Kragen Javier Sitaker, 2017-03-20 (updated 2017-06-20) (13 minutes)

Suppose you have a programming system with a garbage-collected object-graph memory where objects are type-tagged immutable vectors of fields. You really only need two stack-bytecode operations for the object memory:

```
NEW ( class [ val0 val1 ... -- ref )
AT ( ref idx -- val )
```

Here `[` is a PostScript-style stack mark for variadic function invocation.

`AT` fetches a field value, and `NEW` creates an object containing the given fields. Alternatively, you could bake `idx` into AT's bytecode and have it always operate on `self`, the receiver containing the executing method, and NEW could be an ordinary method call on `class` which is implemented with magical native code. Either way, you need bounds-checking either at compile-time or run-time.

With a reasonable generational garbage collector, this can be the most efficient way to do many things. Other algorithms, however, also need mutation, so you need a third operation to mutate fields: ATPUT.

For a Pythonish language (see Thredsnek: a tiny Python-flavored programming language (p. 1172)) you need built-in dict, list, int, float, and probably string classes, plus reflection, dynamic dispatch of variadic method calls, an iterator protocol, and exceptions; and, of course, control flow.

So a minimal OO Pythonish bytecode might need INVOKE, AT, ATPUT, VAR, VARPUT, LIT, IF, GOTO, LOOP, [, and RET: 11 operations. I'm not quite sure how to implement exceptions; catch and finally blocks are rare enough in garbage-collected languages (unlike in C++ or Rust, where every new variable sort of introduces one) that doing it the straightforward way with PUSHJMPBUF and POPJMPBUF opcodes might be adequate.

An alternative block-structured design might unify method scope, object scope, and global scope as simply being three arbitrary levels of an arbitrary set of nested scopes, and this does have benefits to recommend it. However, this requires recovering at compile-time or even run-time further information that was available in the programmer's mind: in particular, which blocks might become closures (i.e. when objects are created) and which variables are captured by those blocks (i.e. the instance variables of the implicitly created objects).

Looking at existing bytecode may be instructive. Here's disassembly of the CPython bytecode for a somewhat arbitrarily chosen Python library function, the `difference_update` method of the deprecated `sets` module.

```
Disassembly of difference_update:
```

```
479           0 LOAD_FAST                0 (self)
              3 LOAD_ATTR                0 (_data)
              6 STORE_FAST               2 (data)

480           9 LOAD_GLOBAL              1 (isinstance)
             12 LOAD_FAST                1 (other)
             15 LOAD_GLOBAL              2 (BaseSet)
             18 CALL_FUNCTION            2
             21 POP_JUMP_IF_TRUE        39

481          24 LOAD_GLOBAL              3 (Set)
             27 LOAD_FAST                1 (other)
             30 CALL_FUNCTION            1
             33 STORE_FAST               1 (other)
             36 JUMP_FORWARD             0 (to 39)

482     >>   39 LOAD_FAST                0 (self)
             42 LOAD_FAST                1 (other)
             45 COMPARE_OP               8 (is)
             48 POP_JUMP_IF_FALSE       64

483          51 LOAD_FAST                0 (self)
             54 LOAD_ATTR                4 (clear)
             57 CALL_FUNCTION            0
             60 POP_TOP
             61 JUMP_FORWARD             0 (to 64)

484     >>   64 SETUP_LOOP              33 (to 100)
             67 LOAD_GLOBAL              5 (ifilter)
             70 LOAD_FAST                2 (data)
             73 LOAD_ATTR                6 (__contains__)
             76 LOAD_FAST                1 (other)
             79 CALL_FUNCTION            2
             82 GET_ITER
        >>   83 FOR_ITER                13 (to 99)
             86 STORE_FAST               3 (elt)

485          89 LOAD_FAST                2 (data)
             92 LOAD_FAST                3 (elt)
             95 DELETE_SUBSCR
             96 JUMP_ABSOLUTE           83
        >>   99 POP_BLOCK
        >>  100 LOAD_CONST               1 (None)
            103 RETURN_VALUE
```

The original source code:

```
def difference_update(self, other):
    """Remove all elements of another set from this set."""
    data = self._data
    if not isinstance(other, BaseSet):
        other = Set(other)
    if self is other:
        self.clear()
    for elt in ifilter(data.__contains__, other):
```

```
        del data[elt]
```

Here's a longer method, from another obscure standard library module, `netrc.netrc.__repr__`:

```
Disassembly of __repr__:
130           0 LOAD_CONST               1 ('')
              3 STORE_FAST               1 (rep)

131           6 SETUP_LOOP             137 (to 146)
              9 LOAD_FAST                0 (self)
             12 LOAD_ATTR                0 (hosts)
             15 LOAD_ATTR                1 (keys)
             18 CALL_FUNCTION            0
             21 GET_ITER
        >>   22 FOR_ITER                120 (to 145)
             25 STORE_FAST               2 (host)

132          28 LOAD_FAST                0 (self)
             31 LOAD_ATTR                0 (hosts)
             34 LOAD_FAST                2 (host)
             37 BINARY_SUBSCR
             38 STORE_FAST               3 (attrs)

133          41 LOAD_FAST                1 (rep)
             44 LOAD_CONST               2 ('machine ')
             47 BINARY_ADD
             48 LOAD_FAST                2 (host)
             51 BINARY_ADD
             52 LOAD_CONST               3 ('\n\tlogin ')
             55 BINARY_ADD
             56 LOAD_GLOBAL              2 (repr)
             59 LOAD_FAST                3 (attrs)
             62 LOAD_CONST               4 (0)
             65 BINARY_SUBSCR
             66 CALL_FUNCTION            1
             69 BINARY_ADD
             70 LOAD_CONST               5 ('\n')
             73 BINARY_ADD
             74 STORE_FAST               1 (rep)

134          77 LOAD_FAST                3 (attrs)

          >>  145 POP_BLOCK

137       >>  146 SETUP_LOOP              85 (to 234)
              149 LOAD_FAST                0 (self)
              152 LOAD_ATTR                3 (macros)
              155 LOAD_ATTR                1 (keys)
              158 CALL_FUNCTION            0
              161 GET_ITER
          >>  162 FOR_ITER                68 (to 233)
              165 STORE_FAST               4 (macro)

138           168 LOAD_FAST                1 (rep)
              171 LOAD_CONST              10 ('macdef ')
              174 BINARY_ADD
              175 LOAD_FAST                4 (macro)
              178 BINARY_ADD
              179 LOAD_CONST               5 ('\n')
              182 BINARY_ADD
              183 STORE_FAST               1 (rep)

139           186 SETUP_LOOP              31 (to 220)
              189 LOAD_FAST                0 (self)
              192 LOAD_ATTR                3 (macros)
              195 LOAD_FAST                4 (macro)
              198 BINARY_SUBSCR
              199 GET_ITER
          >>  200 FOR_ITER                16 (to 219)
              203 STORE_FAST               5 (line)

140           206 LOAD_FAST                1 (rep)
              209 LOAD_FAST                5 (line)
              212 BINARY_ADD
              213 STORE_FAST               1 (rep)
              216 JUMP_ABSOLUTE          200
          >>  219 POP_BLOCK

141       >>  220 LOAD_FAST                1 (rep)
              223 LOAD_CONST               5 ('\n')
              226 BINARY_ADD
```

```
           227 STORE_FAST               1 (rep)
           230 JUMP_ABSOLUTE          162
       >>  233 POP_BLOCK

142    >>  234 LOAD_FAST                1 (rep)
           237 RETURN_VALUE
```

Here's the original source code:

```
def __repr__(self):
    """Dump the class data in the format of a .netrc file."""
    rep = ""
    for host in self.hosts.keys():
        attrs = self.hosts[host]
        rep = rep + "machine "+ host + "\n\tlogin " + repr(attrs[0]) + "\n"
        if attrs[1]:
            rep = rep + "account " + repr(attrs[1])
        rep = rep + "\tpassword " + repr(attrs[2]) + "\n"
    for macro in self.macros.keys():
        rep = rep + "macdef " + macro + "\n"
        for line in self.macros[macro]:
            rep = rep + line
        rep = rep + "\n"
    return rep
```

I feel like these two functions are relatively typical Python code.

From a few arbitrary files including the above, I disassembled about 2650 bytecodes. The top ops are:

```
LOAD_FAST (630 bytecodes),
CALL_FUNCTION (242 bytecodes),
LOAD_GLOBAL (238 bytecodes, usually in order to call a global),
LOAD_ATTR (228 bytecodes, largely split between
    self attributes (preceded by a LOAD_FAST of self) and
    method calls (followed by a CALL_FUNCTION)),
LOAD_CONST (179 bytecodes),
STORE_FAST (150 bytecodes),
RETURN_VALUE (132 bytecodes),
POP_JUMP_IF_FALSE (95 bytecodes),
POP_TOP (89 bytecodes), and
COMPARE_OP (80 bytecodes).
```

These add up to 2063 bytecodes, about 78% of the total. COMPARE_OP makes it there because it's a catchall for a variety of comparison operators, including exception-matching, `==`, and `is`, but also `in`, `>`, and the like. Most other binary operators have their own bytecode, like `[]` (BINARY_SUBSCR, 30 occurrences), and `+` (BINARY_ADD, 26 occurrences).

Stack operation density

I've tried a number of things, but so far I haven't been able to find a way to get tighter code than with a stack machine. On average, a binary operation (two inputs and one output) on a stack machine has about one associated stack manipulation operation, which is typically between 5 and 8 bits.

Typical two-register code has a 3- or 4-bit field for each operand, so 6–8 bits, and sometimes has an additional MOV instruction associated to prevent one of the inputs from being clobbered; three-register code avoids that at the cost of a third operand field, which in extreme cases (like Lua bytecode) means 24 bits of operands per operation, but is more typically 12–18 bits.

The Mill architecture's "belt" is a third alternative; like stack machines, the output of each instruction is implicit, but unlike them, inputs are not consumed. Consequently operands must be implicit. I did some speculative analysis (Golomb-coding operands as belt offsets likely won't increase code density much (p. 1605)) of variable-length encoding of a two-address belt code and found that in the code I looked at, the spans were very nearly geometrically distributed, so nearly the optimum was Golomb coding with a bin size of 1, which reduces to unary coding, and this works out to a bit over 5 bits of operand information per two-operand computational instruction (would be 4 if the geometric distribution was exactly correct), which is essentially exactly the same code density as the stack code, just much more expensive to decode.

(An encoding variation I haven't explored in more detail: since about half of the operands are the output of the immediately previous instruction, make that implicit for two-operand instructions, and insert an extra copy instruction in the other cases. It probably won't work to improve density further, but it might.)

The TRIPS or EDGE ("explicit data graph execution") architecture is sort of a mirror image of the "belt", where instruction inputs are implicit, but outputs are explicit, and point to other instructions in the same block. Presumably this works out about the same.

So I think that probably stack code is the best approach; it typically uses about 10–12 bits per binary computational operation, of which about 5–6 bits is operand information (in the form of stack manipulation operations), which is comparable to the other alternatives; I'm not yet convinced that anything is better. It's faster to decode and interpret than variable-length instructions, though slower than fixed-width register-based instruction sets. And it easily accommodates operations that consume or produce unusual numbers of values.

Truncation and Packing

The F18A core in the GreenArrays GA4 and GA144 chips has four 5-bit instructions per 18-bit memory word (when there are no jump targets; immediate literal constants are pushed on the stack by a `@p` instruction anywhere in the previous instruction word). This means two bits are missing from the last word; the instruction encoding is designed so that among the 8 expressible instructions for this last slot are `;` (return), `.` (nop), `dup`, `+`, and `unext` (which loops back to the beginning of the instruction word a number of times stored in the R register).

In this way, you can always NOP out the truncated instruction slot if you can't do anything useful with it, but you *can* fit many of the most common instructions — including particularly the ones that are most likely to be useful at the end of an instruction word. If you can do this ¾ of the time, you can fit 15 instructions into four 18-bit

words, an average of 4.8 bits per instruction — and, as I suggested earlier, typically you need about two instructions per computational operation, giving 9.6 bits per computational operation, not counting jump targets.

You could use a similar approach with 32-bit words of bytecode on a 32-bit or 64-bit machine. If each opcode is 6 bits, for example, you can fit 5 whole ones and one 2-bit truncated one into a 32-bit word, or 4 whole ones and two 3-bit truncated ones.

However, jumps will use up the rest of the instruction word; the above **repr** example code contains 99 bytecodes, of which 4 were `FOR_ITER` or `JUMP_FORWARD`, for an average of about 24 bytecodes between jumps. This is probably roughly typical, or slightly high, so a substantial fraction of words will be taken up with such things.

I'm not counting method invocation as a jump (though it is on the F18A), because I propose to carry it out in a different way, as explained below about "Facets and Dispatch".

Type tagging

For a Pythonish language, we really need some kind of dynamic dispatch that allows us to use the same bytecodes to operate on native integers as on, for example, rational numbers. One way to do this — the approach CPython takes — is to make integers heap-allocated objects too. But it really helps performance, not to mention reliability and timing data leaks, if ordinary integers don't need to be stored in memory like that.

The standard approach to support runtime polymorphism between integers (held in registers) and pointers is to use one to four bits of the address word as type tags. On byte-addressed machines with four-byte alignment for objects, the lowest two bits of a valid object pointer are always 00, so you can set them to, for example, 01 to indicate integers. Then

64-bit machines with byte-addressed memory have

Facets and Dispatch

Constant literals

Static Checking

Append only unique string pool

Kragen Javier Sitaker, 2016-07-27 (2 minutes)

A couple of systems I've been dealing with recently involve reading in a bunch of strings (up to a few million) as fast as possible, storing them in minimal space, and then retrieving them by index. It may turn out in these cases for space reasons to be advantageous to deduplicate the strings, but we can't afford a lot of hashing or hash search time.

The most space-efficient solution to the problem (without resorting to compression) is just to concatenate the strings with delimiters in between, or better, preceded by a variable-length count. Then, retrieving string i requires iterating over the i preceding strings.

That's unacceptably slow both for indexing and for searching for duplicates. If you store a separate array of the indices of the starts of the strings, you can quickly index, but on a 64-bit machine, that array may be rather large; it may be more practical to store the start index of, say, every 8th or 16th string, and then, in a separate array of 16-bit values, the lengths of all the strings. These lengths only cost one more byte per string than inline delimiters, make the system 8-bit clean, and allow for strings up to 64KiB. Now we have constant-time indexing.

Finding duplicate strings requires some kind of additional index, of which a hash table is the simplest. It has the problem that it potentially needs a lot of space if it's full of pointers to strings, and I don't have any particularly clever solution to that, but it shouldn't use much extra time if collisions can be kept low enough; in particular, you can compute the hash function as you're copying the incoming string into the place it will be occupying in the concatenated strings if it turns out not to be a duplicate. For very long duplicate strings, this copy will result in extra memory bandwidth, but for short strings and non-duplicate strings, it won't.

A 7-segment-display font with 68 glyphs

Kragen Javier Sitaker, 2017-02-21 (4 minutes)

Seven-segment displays are easily salvaged from lots of electronics. They are somewhat limited in what they can display, but there are 128 possible glyphs, not counting the decimal point which usually accompanies them. Many of them are recognizable letters or punctuation.

The most popular 7-segment LED display on Digi-Key right now is http://www.digikey.com/product-detail/en/kingbright/ACSC56-41CGKWA-F01/754-1047-1-ND/1747764, a Kingbright 2.1V 20mA (pulsed to 150mA in 100µs pulses) common-cathode slightly slanted green LED display with a decimal point, with the totally ridiculously high price of US$2.70. Its datasheet "numbers" the segments as follows:

```
  a
 --
f|g |b
 --
e|  |c
 --
 d  DP
```

with the totally absurd pinout 7, 6, 4, 2, 1, 9, 10, 5, with the last being DP.

If we make a the MSB of a 7-bit word, then the standard glyph for 0 is 0x7e, with 0x7f being 8. The numeric weights in hexadecimal are as follows:

```
  40
 --
2|1 |20
 --
4|  |10
 --
 8
```

A more complete font looks like this:

```
' ' 0x00                          '⌝' 0x60
'-' 0x01                          '⊃' 0x61
''' 0x02    '"' 0x22    '⌝' 0x42    'ⁿ' 0x62
',' 0x04                '⊂' 0x43    '°' 0x63
'r' 0x05
                                  '?' 0x65
'|' 0x06                'Γ' 0x46
'⊢' 0x07    'µ' 0x27     'F' 0x47    'P' 0x67
'_' 0x08
'=' 0x09                '≡' 0x49    '⊇' 0x69
```

```
                    '⊆' 0x4b    'º' 0x6b
'ㄴ' 0x0c
'c' 0x0d    '¿' 0x2d            '2' 0x6d
'L' 0x0e            '[' 0x4e
't' 0x0f            'E' 0x4f    'e' 0x6f
'i' 0x10    '1' 0x30            '7' 0x70
'¬' 0x11    '⊣' 0x31

            '4' 0x33    'ς' 0x53    'q' 0x73

'n' 0x15            'ñ' 0x55
                                '∩' 0x76
'h' 0x17    'H' 0x37            'A' 0x77
'ㅣ' 0x18                        ']' 0x78
                                '3' 0x79

            'y' 0x3b    '5' 0x5b    '9' 0x7b
'u' 0x1c    'J' 0x3c    'ū' 0x5c
'o' 0x1d    'd' 0x3d    'ō' 0x5d    'a' 0x7d
            'U' 0x3e    'Ḡ' 0x5e    '0' 0x7e
'b' 0x1f    '∀' 0x3f    '6' 0x5f    '8' 0x7f
```

I've tried to omit duplicates here. These 68 glyphs don't include all the letters in even the English alphabet (missing are 'k', 'm', 'v', 'w', 'x', 'z', and very sadly 's'), but they include a fairly complete repertoire of logical operators (at least if we interpret set arithmetic as logic) except for ∃. They include a perhaps unreasonable number of bracketing characters.

The absence of 's' and 'w' eliminates many of the most common English words: 'is', 'was', 'with', 'have', 'this', 'his', as well as most plurals. 'm' also eliminates 'from'. So you can't use this font to write in English, unless maybe you use 'ς' for 's'. You can't even write "sin" and "cos".

Many old typewriters didn't have separate characters for "l" and "1", or "0" and "O"; the number row started at "2" and ended at "9". Due to typewriter legacy, even today, we often use the same character "'" for "‘" and "’", and the same character '"' for "“" and "”", and the same character "-" as a hyphen, minus sign, em dash, and en dash. If you use the same approach here, allowing the "ς" and "2" glyphs to double as "s" and "z", then you get back trig operations and most common English words. The most common ones missing are "was with have from which we were would will what who more them some him two time my like me now".

These glyphs do not include any arithmetic operators other than '-'. Some calculators use 0x05, 0x21, or 0x25 for "/" for a fraction bar.

For the more limited purpose of rendering decimal or hexadecimal digits, you want the list {0x7e, 0x30, 0x6d, 0x79, 0x33, 0x5b, 0x5f, 0x70, 0x7f, 0x7b, 0x7d, 0x1f, 0x0d, 0x3d, 0x6f, 0x47}.

Topics

Audio logic analyzer

Kragen Javier Sitaker, 2019-11-12 (3 minutes)

Suppose you want a logic analyzer, and you have electronics, but you don't have a screen; you only have a speaker or headphone jack and perhaps an LED or two. What can you do?

It seems sensible to map the time domain to the time domain. (However, you will often want about six orders of magnitude slowdown: a logic analyzer needs to be measuring signals of at least 20 MHz, and the humans can only hear signals up to about 20 Hz. Then you can loop the capture if desired.) Then what do you map the different logic channels to?

Probably the most sensible thing to do is to map them to different pitches in the same octave, synthesizing those pitches with rich harmonic content in order to make the perception of both pitch and envelope more precise. Emphasizing onsets with an attack-decay envelope, or the variation in harmonic content that comes inevitably from Karplus–Strong or other waveguide synthesis or that can easily be produced with FM synthesis, might help with some kinds of debugging.

Unfortunately the choice of pitches has a tradeoff between interpretability and aesthetic quality: dissonant pitches are easier to distinguish, particularly if they happen to start and end simultaneously, which will happen frequently on a logic analyzer. Additional features that may help to distinguish the notes might include different speeds, depths, and phases of vibrato, and the kind of flanging effect produced by the beating of the harmonics of nearly-equal-delay strings, as in a piano or a 12-string guitar.

(A counterintuitive feature of modern microcontrollers is that even low-end microcontrollers are more than powerful enough to do real-time multichannel Karplus–Strong synthesis with all-pass filters for variable fractional-sample delays, and additionally they can do digital logic analyzer data acquisition at megasamples per second.)

You probably need some way to configure a Boolean function to trigger a capture. Since you're fiddling around with wires anyway in this scenario, the simplest approach is to use jumper wires to hook up some of the input lines to particular pins — some designated such that their conjunction will trigger a capture, others designated such that any of them will inhibit it. This is not universal but might be enough. However, here in CMOS land, we need to hook those input pins up to *something*; probably the best approach is to just enable pullups or pulldowns and hope that doesn't disturb the DUT too much.

Antialiased line drawing

Kragen Javier Sitaker, 2018-11-13 (updated 2019-09-01) (4 minutes)

In using matplotlib to do a series of plots, I've found a number of annoying aliasing phenomena.

One phenomenon is that, although the edges of lines and markers are antialiased, the antialiasing is relatively soft. So the lines still contain substantial energy above the Nyquist frequency of the display. When a single line is drawn, this is rarely important, but when many parallel lines are drawn, even if they are perfectly vertical and equally spaced at non-integer pixel spacing, the aliased frequencies can be visible and indeed produce a dominant moiré pattern over the whole area.

Completely eliminating this phenomenon with even a single hatching pattern would require bandlimiting the line's pixel image to strictly below the Nyquist frequency for the display, and of course a strictly bandlimited signal necessarily fills all of space — worse, a bandlimited impulse is a sinc, which drops off in intensity fairly slowly with distance, only inversely proportional to the distance. But it might be reasonable to touch, say, a swath of 8–16 pixels along each edge of the line, rather than 2.

Eliminating moiré for *multiple* hatching patterns would require combining the patterns linearly, which is to say, without opacity. Although this departs from the historical practice developed from pen-and-ink graphics, experience shows that this is a very useful way to plot data on, for example, an oscilloscope display, but it may not be entirely practical for all kinds of data graphics. However, there's a whole range in between, easily accessible in a system that uses premultiplied alpha. RGBA(0, 0, 128, 255) is pure opaque dark blue; RGBA(0, 0, 128, 0) is perfectly transparent luminous dark blue with no opacity; and RGBA(0, 0, 128, 128) can be viewed equally validly as half-transparent bright blue or as a partly luminous, partly opaque dark blue. Indeed, that color is representable even in a system where alpha is not premultiplied (it's RGBA(0, 0, 255, 128)) but other, brighter colors are not.

Note that in this case you want to be able to represent not only overunity brightnesses but also negative brightnesses if you want to plot dark lines on a light background.

The other phenomenon is that, although my LCD uses RGB subpixel ordering, and my font rendering takes advantage of it, matplotlib does not. This results in wasting something like half of my display's horizontal resolution, two thirds for dim blue-tinted graphics. This is really frustrating when I'm trading off legibility for data coverage.

LCD subpixel ordering is not the limit of subpixel antialiasing, either, and I think that even the soft antialiasing matplotlib uses provides visually-subpixel positioning of the line.

Matplotlib of course does not insist on drawing one-pixel-wide lines. You can get it to draw lines several pixels wide. It's just that the particular line profile it uses is a slightly antialiased boxcar: a constant opaque color inside the line, dropping off to perfect transparency outside it. You could easily imagine a better

compromise between precision and visibility — for example, a strong thin line with a diffuse background around it, possibly in a contrasting color, making it easy both to find the line and see its overall shape and to see its precise value.

Do visually expanding images evoke an orienting response, or the startle response, and what does that mean for ZUIs?

Kragen Javier Sitaker, 2016-06-03 (14 minutes)

In the sci-fi user interface criticism blog [???] the guy complains that it's really bad user interface design for a HUD in a flying machine to have things expand in place, because it triggers a human "startle response", which stresses people out, makes them blink, and distracts them.

Presumably the underlying phenomenon here is that if something is expanding rapidly in place in your visual field, it's usually an object flying rapidly at your face, which means it could hit you soon.

I was alarmed and concerned, because I've been playing a bit with ZUIs, and in ZUIs it's really common for things to expand in place. I started thinking of workarounds: could we maybe zoom into a thing by first zooming in on a point to the right of the screen, then a point to the left of the screen, thus avoiding this response?

But does this visual "startle response" to zooming in exist at all? If so, will it cause problems? Or is the related "orienting response" more relevant? Here's a cursory literature review.

Relevant literature

The Wikipedia article on "startle response" says:

> In animals, including humans, the startle response is a largely unconscious defensive response to sudden or threatening stimuli, such as sudden noise or sharp movement, and is associated with negative affect.1 Usually the onset of the startle response is a startle reflex reaction. The startle reflex is a brainstem reflectory reaction (reflex) that serves to protect vulnerable parts, such as the back of the neck (whole-body startle) and the eyes (eyeblink) and facilitates escape from sudden stimuli. It is found across the lifespan of many species.

Startle and Surprise on the Flight Deck, Rivera et al., 2014. This is a five-page paper on the difference between the "startle reflex" and the "surprise emotion". It says that startle was "studied extensively in the 1970s and 1980s", but refers primarily to the acoustic startle response, although it says, "The startle reflex can be elicited through auditory, visual, or tactile stimuli," citing Carlsen et al. 2008, Davis et al. 1982, and Yeomans et al. 2002. With regard to effects we might care about in ZUIs, it says, "startle has been found to impair information processing on mundane tasks," and "may induce brief disorientation and short-term psychomotor impairments which are likely to lead to task interruptions, or brief confusion," and that "after startle", "decision making can be significantly impaired, especially higher-order functions".

It does mention ways the startle response can be evoked visually: sudden illumination of flight crews by lasers, for example.

The "Startle Reflex" article in the Encyclopedia of Autism Spectrum Disorders, by Sterling, defines it as an "automatic response to the sudden onset of an acoustic, visual, or tactile stimulus… that

varies systematically with the individual's emotional state… characterized by a fast series of muscle contractions around the head, neck, and shoulders;" this says very little about what kind of stimuli will cause it, other than "sudden", or what kinds of cognitive effects it might have.

Human On-Line Response to Visual and Motor Target Expansion, Cockburn and Brock 2005 or so, says that expanding mouse targets in place as the mouse approaches them is "visually appealing" but also "improves acquisition performance". Their main result is that it's easier to click on things when they expand when you move the mouse toward them, and that this is mostly due to the visual feedback, only slightly due to the larger click target. While this is basically not about startling users at all, but rather about how long it takes to click on things when they're expanding (related to Fitts' Law), it provides a sort of useful negative evidence — in their experiments, users were able to click on things faster when they expanded in place, while if expanding stuff in place was invoking a strong "startle reflex", you'd expect to see their performance worsen. But maybe they didn't expand fast enough or far enough, or maybe the performance improvement would have been even greater without the "startle response" confounding it.

The Wikipedia article on "fear-potentiated startle" mentions bright light as a stimulus that elicits "startle", and says that the "startle" is stronger when the organism is afraid, or when the person is traumatized or not depressed, and mentions some symptoms of "startle": blinking and faster pulse. However, apparently, usually the experiments use loud noises.

The Uncanny Valley in Games and Animation, by Tinwell, p.106, section "Lack of Visual Startle Reflex and Psychopathy," says that we make surprised faces when "we experience a sight or sound that frightens or surprises us", except for psychopaths. It's talking about things like "seeing a shadow when we thought we were alone," though, not seeing windows expand on a screen, and it doesn't mention cognitive effects. The author is bringing this up because apparently people who act scared or surprised without showing fear "in the upper facial region" are creepy ("uncanny") and that maybe this is a reason animations can be creepy.

Boo! Culture, Experience, and the Startle Reflex, by Simons, 1996, is a 288-page book about the "startle reflex". It goes into quite a bit of philosophizing about the relationships between culture, biology, and psychology, saying things like, "Being startled changes… one's relationship with the entire experienced universe," and "Pythagoras… showed that the soul is mathematical."

The author is a collaborator of Ekman and Friesen who himself did original research on startle some years back, using pistol sounds.

It explains, "The subject of the book is a more general one: (1) How one's experience of being in the world is shaped by neurophysiology and how it is shaped by prior experience, beliefs, values, and social condition, and (2) how these different types of shaping influences might be consid- ered jointly in single explanatory formulations."

It gives some more detail on what the startle response *is*, exactly (p. 9):

The usual human startle response is precisely the set of behaviors that would be

maximally effective in minimizing the chance of a fatal encounter. The response includes both physical events and alterations in attention, thought, and mood. Instantaneously and without reflection, forward motion is checked. The raised foot is arrested or drawn back and the upper limbs are drawn in to safety. Visual attention is locked onto the eliciting stimulus, whatever had been in consciousness is obliterated, and the mind is filled with one thought: "Snake!" Startling stimuli other than snakes elicit similar immediate patterned rapid-avoidance behaviors and similar redirection of attention.

In the context of ZUIs, redirecting your attention to what you're zooming into might be *good*, and that would be consonant with the positive results Cockburn and Brock got from inflating click targets.

He confirms the 14-ms number Sourakov (the butterfly dude) cites for human startle response time, but for tightening jaw muscles, not blinking.

He cites "Hoffman, 1984, p.275", which turns out to be "Methodological factors in the behavioral analysis of startle," as a paper that mentions a "startling sight." His Table 1.2 on p.14 lists startling stimuli; the visual items include "dangerous or appalling sights" ("snakes and creepy-crawlies, other dangers, appalling sights"), "bright lights", "sudden motion", "great beauty", and "cessation of a stimulus". Later (p.21), he reports on visual stimuli that startled his informant Barbara Haldane:

I mentioned before my startle reaction to the sight of a large spider (or a picture or drawing of one); other large images of things with spindly legs, such as ants and other insects, produce a similar but less-violent startle reaction.

A real snake (but not a picture of one)…

As I told you, the unexpected sight of a human skull--of nearly life-sized or larger proportions, anyway--induces a shock in me … especially if it has dark eye-sockets.

The sight of a larger-than-life human face looking directly at me (at the camera, in the case of a photo) has a similar shock value. I recall one instance of being quite unpleasantly startled by the face of Sophia Loren on a magazine cover, and more than once by an ad in a magazine featuring eyes (larger than life) looking directly at the viewer. (Both eyes usually have to be present — one big eye doesn't have as much effect.) [T]hese reactions are invol- untary and uncontrollable unless the sight in question is antici- pated, and even then I am apt to experience an internal moment of panic.

And his hyperstartler informant Gould startles easily with a variety of visual stimuli, including boys jumping out at her at a ranch, her children stepping out into the hall in front of her, a classroom of her students having turned their desks around while she wasn't paying attention, and putting on the wrong kind of glasses.

The exaggerated startle reaction he reports of Gould, in which she screams for a while, falls to her knees, and throws whatever she's holding, would certainly be a UX problem in a ZUI; it would likely break her phone. However, it seems to be mostly related to seeing unexpected things, not to a lower-level stimulus such as a thing expanding in her field of vision, regardless of whether it's expected or not.

Emotion, attention, and the startle reflex, by Lang et al. in 1990, is a theoretical model of emotion in general, based on the "startle reflex", which is an intellectual overreach if I ever heard of one.

Irrelevant literature

Visual Pathways Involved in Fear Conditioning Measured with Fear-Potentiated Startle: Behavioral and Anatomic Studies, Shi and Davis 2001, startled rats with sounds or electric shocks but *conditioned*

them to associate the "startle response" with visual stimuli. Then they injected different drugs into different parts of the rats' brains to see which parts were involved in the association. This paper doesn't use an innate visual startle response or human subjects, so it is of no interest.

The pupil as a measure of emotional arousal and autonomic activation, Bradley et al. 2013 had people look at pleasant or unpleasant pictures, measuring their emotional response to the pictures by their pupil diameter, skin conductance, and pulse. They also found that people's pupils contracted even more when the pictures were bright than when they were unpleasant. This came up because they startled some people, but not others, with loud noises before showing the pictures. However, they didn't report on the results of this part of the experiment in the paper!

Postural and eye-blink indices of the defensive startle reflex, by Hillman et al. 2003, reports on an experiment where they startled 24 volunteers with loud noises through headphones and measured how much they blinked and cringed, rocking first forwards and then backwards. Their results were that people who blinked more also cringed further backwards.

A Double Dissociation in the Affective Modulation of Startle in Humans: Effects of Unilateral Temporal Lobectomy, by Funayama et al., 2001, found differences in the "startle response" in people who had had one of their temporal lobes surgically removed. They were startling the subjects with loud noises as a way to measure the emotional effect of looking at pleasant or unpleasant pictures or being told they would be electrically shocked. Their results are somewhat involved and they draw a bunch of conclusions about the role of the amygdala in fear that I don't care about.

Perceiving Threat In the Face of Safety: Excitation and Inhibition of Conditioned Fear in Human Visual Cortex, by Miskovic and Keil, 2013, startled 29 subjects with loud noises that the subjects could predict by the speed a light flickered at.

Greater general startle reflex is associated with greater anxiety levels: a correlational study on 111 young women, by Poli and Angrilli, 2015, startled young women with loud noises in both ears after questioning them about how anxious they felt, finding that more anxious women blinked more (but only with their left eyes) and hated the noises more. As background, it mentions that old people and men startle less.

Extraordinarily Quick Visual Startle Reflexes of Skipper Butterflies (Lepidoptera: Hesperiidae) are Among the Fastest Recorded in the Animal Kingdom, by Sourakov, 2009, is about visual startle reflexes in butterflies. I think butterfly eyes and visual cortices evolved separately from our own, so I doubt that conclusions about startle reflexes in butterflies are applicable to humans. It does, however, mention that loud noises can make people blink within 14 ms, puffs of air can make us blink within 30–50 ms, but these butterflies jump into the air in less than the researcher's camera's exposure time of 17 ms when visually startled by the flash; however, it claims that this is "twice as fast as the fastest startle reflex of humans", so, I don't even know.

Hand drawn font compositing

Kragen Javier Sitaker, 2018-10-28 (2 minutes)

I thought it would be fun to hand-draw a font on paper and scan the paper, but producing a TrueType font from this in the usual way then requires a certain amount of manual work, converting it to Béziers and whatnot. But, in a sense, you don't really need all that manual work; the input is pixels, and the output is also pixels, and the output is a sort of pasteup of the input.

Minimally you do need some way to identify the location and orientation and size of each character in the font on the page, which is best done with some kind of interactive UI. And you might want to separately indicate the character cell and the bounds of the drawn character — either because, in your drawing, some descender or something impinged upon the character cell undesirably, or because you have some kind of swash protruding.

Leaving aside the UX details of such an interface for now, there's the question of how to do the compositing of the different characters to produce the rendered image. Assuming you're drawing on white paper, you'd like to threshold the background paper to pure white, and treat that as transparent. So if you have overlapping bits of letterforms, you'd like to composite them in something like logical-AND fashion:

A	B	A & B
0	0	0
0	1	0
1	0	0
1	1	1

Now, it might be a reasonable thing to do to actually do this in binary, using oversampling. (Maybe you do 2× oversampling in both X and Y, so that each 32-bit word represents the top or bottom half of 16 different pixels; once you're done with compositing using &, you can use parallel population-count on the subpixels to decide on the grayscale value. The apparent efficiencies of this approach, with an average of 8 antialiased pixels per word instead of 1 or 4, are somewhat compromised by the amount of bit-shifting required.) Alternatively, though, you could use grayscale or even RGB representations directly. And in that case, clearly the compositing operation you want is pointwise *multiplication* followed by rescaling the result.

Topics

Linear trees

Kragen Javier Sitaker, 2016-05-19 (updated 2016-05-20) (6 minutes)

So I've been thinking a bunch lately about the Z-machine's object-tree memory model for embedded systems like the Arduino, as an alternative to the usual C approach of nesting structs and arrays inside other structs and arrays.

There are a couple of problems with the usual Lisp or ML memory model, where all values are either pointers or fit into pointers, and can be referred to from any number of places. One problem is that you almost need a garbage collector, which means that you can only use a fraction of physically available memory for your data; a garbage collector that collects garbage too often will use up the vast majority of your system's runtime. This is a big problem if you have 2048 bytes of memory available. Another problem is that the garbage collector imposes relatively large pauses on things — when you try to allocate and the GC needs to collect first, you get a pause, which can be tens of thousands of instructions long, even if you only have 2048 bytes of memory. A third problem is that the conditions under which your allocation can fail are relatively poorly defined; fragmentation and tenuring, among other things, can keep pieces of memory unavailable that ought to be available, causing allocation to fail unpredictably. A fourth, comparatively minor, problem is that the pointers themselves occupy a lot of memory space, and they are usually a relatively inefficient encoding of the facts about the world with which the program must grapple.

The more subtle underlying problem is that, in some sense, if you're allocating memory at run-time instead of compile time, it's probably because you didn't know how much memory you were going to need when you wrote the program. That, in turn, means that the program could need more memory than is physically present. And that's true even if you don't use a garbage collector.

In desktop and server applications, where programs have error-handling options that include popping up a dialog box with an error message, notifying a user that they are exiting, paging a system administrator, shedding load by dropping network requests without answering them, and logging error messages in logfiles, the occasional failure is accepted as a fact of life.

Embedded applications are different: their options for handling failure are often limited to blinking an LED and rebooting. Ideally you would like your jet engine, robot arm, chemical plant, or antilock braking system to simply not fail, rather than just having ways to report the failure gracefully.

C has other options. It inherits from COBOL, by way of Algol, the possibility of hierarchically composing structs and arrays out of primitive types and other structs and arrays; no pointers are necessary. C code for life-critical embedded systems is usually supposed to obey a set of rules called MISRA, which, among other things, entirely forbids the use of dynamic heap allocation.

However, C code to handle things made out of structs and arrays with no pointers accommodates any kind of polymorphism only awkwardly, and consequently exhibits very poor generality.

Common Lisp includes generic functions like `concatenate`, `append`, `map`, `remove-if`, `reduce`, `every`, `some`, `length`, `reverse`, `search`, and `equal`; the C++ STL includes generic algorithms like `copy_n`, `swap_ranges`, `nth_element`, and `set_intersection`; Python code has at its disposal generic dictionaries, lists, heaps, and sets.

It would be very desirable to program our embedded systems at a similarly high level of abstraction and generality without paying the heavy memory-efficiency and reliability costs imposed by the Lisp memory model.

The Z-machine object containment tree seems like a possible candidate. Each object contains three pointers: its parent, its first child, and its next sibling. (In the Z-machine itself, these were 16-bit object indices; on the Arduino, 8 bits each would make more sense. Also, it might make more sense for only active cursors into the object tree to carry the parent information, rather than every object.) Rather than destroying or creating objects, including by copying, our algorithms can only move them around and mutate them.

Despite this, most of the Common Lisp generic functions immediately make sense in the context of this rigid object tree. It's just that, unlike most of their Lisp antecedents, they destructively consume their inputs, and in some cases need to be directed as to where to place their output. The sorted set-arithmetic functions in particular, except for symmetric difference, probably reduce to a single `set_filter(comparator, targets, input, output)` subroutine which moves all the objects from `input` that are equal to an object in `targets` into `output`.

The hierarchical structure might prove valuable for persistence support, where it could segregate persistent from nonpersistent objects.

I suspect that this is related to linear or affine typing, as used in Rust, but I don't understand them well enough to really know.

There is a thing wrong with all of my analysis above. It may be only slightly wrong, but enough to make a difference. It doesn't really account for function call stacks.

In the absence of recursive functions (and they should certainly be absent if you want high assurance of no stack overflows) we could certainly statically allocate the activation records of each function, which would ensure no stack overflows. But this is probably much more costly than necessary; functions overlay one another's stack frames in a guaranteed-safe way (modulo uninitialized variables and taking the address of local variables) and give a much tighter memory-usage bound.

Can we extend this property in general?

Topics

Polycaprolactone

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

ShapeLock is actually polycaprolactone, I think, an extremely shatterproof biodegradable, bioimplantable, anti-static (? or is that only Mater-Bi?) thermoplastic with a melting point around 60°C and a relatively low price. It's weak, though, and quite viscous when melted.

Tradenames are Mater-BiZ (a mixture of polycaprolactone and starch), Anderson Andur 6 APLM, Boltaron 4300, and Dow Tone P-767 or P-787. See http://www.ides.com/grades/Boltaron_grades.htm and related pages.

There is some pricing in the RepRap blog comments: http://blog.reprap.org/2005/12/polymorph-and-polycaprolactone.html says "$5.30-3.50/lb for CAPA 6800". It also gives the name "CAPA 6800 polycaprolactone (2-Oxepanone, homopolymer; molecular weight 80,000, CAS number: 24980-41-4)".

The blog post suggests Solvay Interox Ltd. as a supplier. In early 2008, they were sold to the Perstorp Group of Sweden. CAPA was Solvay's brand. Now it is http://www.perstorpcaprolactones.com/; they claim to be a "global supplier".

http://reprap.org/bin/view/Main/Polymorph says Solvay's product cost US$9/kg in 20kg or 500kg bags.

By comparison, Forrest Higgs says:

> Right now you can buy HDPE filament for about $4.50/lb. ABS costs about a dollar per pound more, if I remember correctly. That means that the filament to make the printed parts for a Darwin will cost you about $12.50 while for a Tommelise the cost will be closer to $30.

There's another blog post on the topic at http://createdigitalmusic.com/2006/08/29/prototyping-custom-gear-friendly-plastic-aka-shapelock/ that says it's hard to find the stuff in Australia.

Someone suggested Consilium Designs, an eBay merchant that sells many specialty substances. http://www.mutr.co.uk/ is another UK company that carries essentially the same items.

According to Perstorp's datasheet, their product crystallizes at 25°C, has a glass transition temperature at 60°C, and has 77 joules per gram heat of fusion, more or less. And it supercools. Yield stress is around 16±1MPa, modulus is around 470±30MPa, and strain at break is >700%.

When melted, the higher molecular weight polycaprolactones are 4x as viscous as the lower molecular weight ones, but they all decrease in viscosity by another factor of 6 or so when heated to 150°C.

It's very permeable to CO_2, water, and oxygen.

One person reported that polycaprolactone is better than HDPE for FDM accuracy at great length; it warps less, has less "die swell" (that is, the molten filament isn't much bigger than the extruding hole), sticks to more things, and is "more compliant" (??). But it has a lot of other problems. http://hydraraptor.blogspot.com/2008/03/chalk-and-cheese.html

Stuff I've posted to kragen-tol over the years about post-HTTP

Kragen Javier Sitaker, 2014-02-24 (12 minutes)

I've argued that we need a browser that supports accessing resources stored in decentralized content stores like Tahoe-LAFS or Git, rather than named according to a path defined by the administrator of a particular domain name over time. I haven't done a very good job of gathering my thoughts on the matter into one place yet.

This all seems a little silly, given that other people have contributed so much more to solving this problem than I have, but there may be one or two things in here that aren't currently easy to find, but that are important.

I've only dug through the archives back to 2000. There might be stuff in 1998 or 1999 that's relevant, but surely not very important.

Reasons why

"What's wrong with HTTP?"

In this essay, the first of a pair on browser apps, I explore how they are better than traditional desktop apps in some ways, but worse in others. Some of the disadvantages of browser apps are deeply rooted in the use of HTTP URLs for naming. In the second essay, I will present a design sketch for a new platform, a replacement for HTTP combining both styles' advantages.

I still haven't published the second half, and it needs thorough revision now.

"The equivalent of free software for online services"

Explains why it's crucial to implement communication systems as cooperating software running on users' computers, rather than on centralized servers.

So people use free software because of its guaranteed low cost, because it does what its users want, and because it's trustworthy. And they use web services because they get low system administration costs, they can use huge databases without downloading them first, they can get software updates quickly, they can do very-CPU-intensive things, and they can collaborate with their friends easily. How can we get both of these sets of advantages at once?

I think there is only one solution: build these services as decentralized free-software peer-to-peer applications, pieces of which run on the computers of each user. As long as there's a single point of failure in the system somewhere outside your control, its owner is in a position to deny service to you; such systems are not trustworthy in the way that free software is. ...

So we need a platform, something like a web browser, that supports a universe of constantly-changing code written by a multitude of authors, which migrates to where it's being used, and simultaneously supports individual control over what version of the code is running on your system and no-hassle updating when someone else has a change you want; that replicates your data transparently to other machines so that you don't have a single point of failure, but without allowing the owners of those other machines to spy on you or corrupt your data; that runs programs in a high-level language; that supports conflicting updates to different replicas of the data and allows a human being to resolve the conflicts; and that makes it easy for you to share particular bits of your code or data with anyone, everyone, or no one. Maybe we could even start with a web browser and add the other stuff to it.

If we don't build such a platform, we will eventually lose the advantages of free

software, because we will use web services instead.

There's actually a lot of detail in this essay about specifically how you could structure such a system.

"Why I do not want to work at Google"

Google has an orientation that is opposed to my agenda. ...

I imagine a different future, where if Alice wants to talk to Bob and Bob wants to talk to Alice, there's no unaccountable intermediary that can interfere with their communication, whether they're speaking text, or video, or 3-D models, or simulation. If Alice's email gets marked as spam, Bob ought to be able to find out why — and fix it! I imagine a future where every human being can participate in creating the culture they live in, without needing permission from anybody, and without fearing repercussions. ...

I believe that warehouse-scale client-server computing will, in the end, undermine the kind of democratic freedom of communication that we need to deal with today's global menaces. It's more practical than peer-to-peer computing at the moment, but that pendulum has swung back and forth several times over the decades. (Some of my friends were among the first employees of a hot cloud-computing startup, in 1964, called Tymshare.) The proper response to the current impracticality of decentralized computing is not to sigh and build centralized systems. The proper response is to build the systems to *make decentralized computing practical again*.

Things contributing to building the solution

There's a lot of software out there now that wasn't there when I wrote this stuff; I should probably make a list of it here too. See above, too, the item about "The equivalent of free software for online services."

"Imagine decentralizing Wikipedia with Codeville"

Codeville was an early decentralized version control system, like Git or Mercurial, that didn't take off. Functionally the systems are equivalent: they replicate the entire version history to every user and provide hash-based retrieval.

So support for individual points of view amidst general disagreement is one of the benefits of del.icio.us over dmoz or Yahoo, and it's built into the architecture of the system --- it's not just a social practice. Could Wikipedia's architecture change to support divergent points of view better?..."arch", darcs, monotone, Codeville, git, and other decentralized version-tracking systems aim to support a wider array of development models; in particular, they aim to allow each person's tree to stand alone as a first-class citizen, easily sharing its changes with other similar trees.

Imagine that we applied one of these systems to Wikipedia. We would have several benefits: tolerance of controversy, disconnected operation, higher availability, and potentially organizational decentralization.

We could tolerate controversy better because Holocaust deniers would have their own version of Wikipedia, which they could modify to their heart's content. This would reduce their desire to modify the Wikipedia that everyone else reads, but it would not eliminate it.

"DHTML persistence: a design for a generic Ajax server-side"

Probably the first essay I wrote advocating what we were doing at KnowNow in 2000, which kind of went mainstream in 2004 with Gmail and 2005 with Google Maps: putting all the application logic on the client side in JavaScript, relegating the server to basically being a dumb data store. Once you do this, of course, you no longer need a server as such; you need a dumb data store, which can be provided by

a peer-to-peer network — but this essay doesn't talk about that at all.

I'm not convinced that I actually achieved a usable protocol design here.

In my view, the most sensible thing to do is to write the application entirely in JavaScript from the beginning and run it all on the client side. Doing this prevents you from having to rewrite bits from time to time, and puts the application code on the machine of its user, who can then use bookmarklets and Greasemonkey to customize its functionality.

"Decentralized chat using CouchDB"

I was just chatting with Noah on IRC about how IRC sucks and we need to replace it and whether we could do that using CouchDB.

More broadly, what's needed for decentralized secure chat, which is to say, pub/sub, or event notification. Pub/sub is one of the fundamental services needed for distributed, including decentralized, applications.

CouchDB is one of the current systems that contemplates Lotus-Notes-style mobile-code secure applications, which it calls CouchApps. Unfortunately, I think the discussion that followed this email showed that it's not capable of providing the kind of support for secure collaboration that we need — its security model is too simple.

"distributed posting list joins"

One of the hardest problems in decentralized systems is how to query a decentralized database with acceptable efficiency. In this post, I finally found a solution that allows you to build a *distributed* if not decentralized full-text web search engine. This followed some work in http://lists.canonical.org/pipermail/kragen-tol/2004-February/threaod.html.

"rumor-oriented programming"

Suppose we want to build a distributed application with automatic change synchronization. Here's a persistence system with coordination functions somewhat similar to mod_pubsub or Linda, but specifically designed for replicating the state of an application.

I actually wrote some things kind of like this, but never built the full system described. In fact I never finished describing it :(But it's kind of like CouchDB or Meteor.

"Peer-to-peer overlay networks are a bad idea on a DSL-based internet."

Peer-to-peer overlay networks are inefficient on ADSL networks. ADSL networks are almost twice as efficient as SDSL networks. Better alternatives require redesigning the physical layer.

"mailing lists, blog posts, and Git: what to do next with kragen-tol?"

Lamenting that neither Git nor the Web provide distributed autentication of publication date, which is a thing I want for kragen-tol, which is why kragen-tol is still a mailing list.

"web services, operations as a strategic advantage, and decentralization"

Suggesting that if we can decentralize web services onto individual

users' machines, then maybe we'll be able to reduce deployment headaches. In retrospect, I think this is kind of a dead end — instead we have devops — but it contains the concept.

Just because the software runs on its users' machines doesn't mean it can't be providing a networked service; consider BitTorrent or Skype or, for that matter, Sendmail, ircd, or INN.

"the end-to-end principle in human society: scholarly writing and freedom of speech"

Describes web browsers as "mere conduits" for information; suggests content-centric networking.

"offline web reading"

Nothing earthshaking but does mention I was able to use Google Maps offline with WWWOFFLE because of its RESTian architecture.

Polynomial-spline FIR kernels by integrating sparse kernels

Kragen Javier Sitaker, 2014-04-24 (12 minutes)

I think I have a method for reducing the computational expense of a large and interesting class of FIR filters by an order of magnitude or so, but I haven't tried it out yet, and it seems like the kind of thing people would have tried by now, so it probably either won't work or is already known.

In my case, this questionable insight came out of, among other things, considering how to write timesheet software using functional reactive programming, sweating through the night in the Buenos Aires heat wave and blackouts, and considering whether it's possible to approximate dense FIR kernels by convolving multiple sparse FIR kernels together.

I've tried to write this with some humor, although I think the result is basically that I sound insane. Hopefully that provides some entertainment. Don't take it too seriously.

Background

(This section is basically me regurgitating shit from Wikipedia and dspguide.com, so feel free to skip it if you know DSP. Or, better yet, read it and correct me.)

FIR filters are common tools in DSP because they can easily be designed to get zero-phase high-performance filters: you take the inverse FFT of your desired frequency response, giving you the impulse response, which you window to give it compact support without fucking up the frequency response too much, and that gives you the weights for your filter. (Not the only method, but a common one.)

However, in many cases, you end up needing tens, hundreds, or even thousands of multiply-accumulates per sample. As a result, we often use IIR filters to get better efficiency, even though we don't have a general theory of how to design IIR filters.

The moving-average filter

The moving-average filter is a special case of a FIR filter: all the weights within its support window are equal, so its impulse response is a pulse, like one cycle of a square wave. It's used for a couple of reasons: (1) it's optimal in minimally degrading time-domain step response while rejecting high-frequency noise, and (2) it's highly efficient.

If you implement it in the general FIR fashion --- multiplying each of the last N input samples by a weight, then adding them --- it's not any more efficient than any other FIR filter with the same support. But you can implement it much more efficiently than that, because composition of time-invariant linear operators is commutative.

Specifically, the impulse response of the moving average filter is the integral (or prefix sum) of a very sparse kernel: a single positive impulse at the beginning of the window, and a single equal negative impulse at the end. Integration (or prefix sum) is a time-invariant

linear operator, as is convolution with a given kernel. So what you do is that you first convolve the input signal with the derivative (or finite forward difference) of the desired impulse response, which requires only two multiply-accumulates per sample, since that derivative is so sparse; then you integrate (or prefix-sum) the result of the convolution; and the commutative property guarantees you that the result is the same. So you get by with two MACs and an addition per sample.

(Actually, because the two impulses are equal in magnitude, you can wait until the very end of the process to multiply by the weight, giving you three additions/subtractions and a single multiply per sample. Sweet.)

Polynomial splines

A spline is when you approximate a function by breaking it up into chunks along the X-axis and approximate each chunk with a different polynomial. Typically the polynomials produce the same value at the points where they join up, the "knots", which is to say, the spline is at least continuous, and usually has a continuous derivative too. (Normally you have the constraint that a spline made out of Nth-order polynomials has continuous derivatives up to order N - 1.)

Typically you can get a pretty good approximation of an analytic function with second- or third-degree polynomials, and without all that many of them. This is a lot less computation than using a high-order approximating polynomial, and as a scrumptious bonus, it also avoids Runge's phenomenon. So this is actually the approach used by a lot of math libraries these days.

(This suggests that the Difference Engine could have been quite a bit smaller if equipped with a facility to reload the highest-order difference from a table periodically, at knots; it could perhaps have used three or four columns instead of eight.)

Efficiently approximating FIR kernels with splines

The standard efficient method for computing the moving average filter can be generalized to a wide class of FIR kernels, producing a worse but still very substantial computational speedup.

Step function OTFs

A moving average filter is of the family of step functions: piecewise constant functions. That's why its derivative (or forward difference) has such sparse support.

But you could in principle compute a convolution with any piecewise constant OTF by convolving with the derivative and then integrating.

Step functions and splines

If you integrate a piecewise-constant function, you get a continuous piecewise-linear function; if you integrate that, you get a continuous piecewise-quadratic function with a continuous derivative; and if you integrate that, you get a piecewise-cubic function with continuous zeroth, first, and second derivatives. Which is to say, you get a polynomial spline.

If it happens that your desired impulse response can be

approximated by an Nth-order spline with a small number of points, then you can fit that spline to it; take the N+1th forward difference to get a sparse kernel; apply that sparse kernel to your input data; and integrate its output N+1 times to get the filtered output.

For each sample, this requires one multiply-accumulate per spline knot plus N+1 additions for an Nth-order spline.

Desired frequency response containing no low frequencies

This section is incomplete.

This is going to suck if your desired impulse response is very wiggly, though, because I think that in general (certainly with a second-order spline), you'll need two knots for each oscillation. If the wavelength of your oscillations is only like six or eight samples, then you're not going to be saving much.

I think, based on basically no experience, this kind of wiggliness often shows up because you're trying to put together a high-pass or bandpass filter, and so all your low frequencies are zero. Which is to say, your desired frequency response is the convolution of an impulse at some high "base frequency" with some window function giving the shape of the frequency response above that frequency.

If you shift the window function down closer to zero, you'll reduce the wiggliness a lot, and you'll be able to get by with a lot less knots.

So what good is that? You'd have to somehow shift the signal down in frequency, and then back up. RF circuitry does this kind of downconversion all the time by just multiplying the high-frequency signal by a reference signal at a nearby frequency, thus producing sum and difference frequencies[1], typically much lower (either near zero, "baseband", or in some lower but still RF band, "intermediate frequency"). This is easy enough to do (it requires one multiply per sample, not even a multiply-accumulate). But I have the impression that this kind of downconversion and upconversion requires high-pass or bandpass filtering before and after, which seems to be begging the question, so I suspect this may be making the problem harder rather than easier. (Maybe you can use an inverted low-pass filter for your high-pass filtering? That shouldn't run into the wiggliness problem, although you want to do the inversion separately from the spline approximation.)

[1] If this is puzzling, remember the sum and difference identities from trig class. Or re-derive them from Euler's Formula.

Anyway, if you somehow manage to frequency-shift your input signal down to baseband, then you can use a much less wiggly filter kernel on it, and then multiply it by a carrier wave to upconvert it back to its original frequency.

Another incomplete approach for kernels containing no low frequencies

Another possibly valid approach for wiggly kernels: note that N cycles of a sine wave are the convolution of a comb filter with N impulses spaced one cycle apart with a kernel consisting of a single cycle of the sine wave. You can thus convolve a kernel consisting of N cycles of a sine wave with your signal (as if that were a useful thing to do, but bear with me) by first convolving it with the comb filter, then with the single cycle, for an almost N-fold reduction in

computation if the number of samples per cycle is large, or an almost samples-per-cycle-fold reduction if N is large.

If you want instead to shape the sine wave with some kind of envelope, you could make each impulse in the comb a different height, but that is going to give you discontinuous derivatives and totally fuck up your frequency response; those discontinuous derivatives are almost like impulses in their wideband-noise nature. You can do better by making your second kernel be, rather than a *single* cycle, *two* cycles, but windowed with a triangular window. This way, in between the comb points, you're linearly interpolating between two sine waves with different amplitudes.

Getting back to the wiggly kernel, I think you can approximate it as such an amplitude-modulated sine wave, with the frequency of the sine being the "base frequency" I mentioned earlier.

So how does this save you work over the spline approach? Well, I think you can use the spline approach to do the N-points modulated comb filter in a lot less than O(N) work by round-robining among a bunch of different intermediate signal buffers, one for each cycle per sample. But I haven't worked out the details yet, so I'm not sure it will work.

Related work

I wrote the above while my internet connection was off, so I couldn't search to see if anybody had already done this.

B-spline image interpolation might appear to be related, but it is different. This is a common algorithm for image interpolation (upsampling, resolution enhancement) aka cubic B-spline interpolation, where you construct a bicubic B-spline patch between adjacent pixels in order to approximate the values between the pixels. It turns out that you can do this by applying a FIR filter to the image; that is to say, the interpolated pixels of the upsampled image are a linear function of the neighborhood pixels of the original image, even though the splines are nonlinear. This, approximating the ideal image with a spline, is a very different concept from approximating the FIR kernel itself with a spline.

"Kernel B-Splines and Interpolation", by Bozzini, Lennarduzzi, and Schaback, 2005, appears to be about a variant of the image interpolation problem (interpolating an unknown function between some set of known points).

There's a substantial body of theory interpreting sampled signals as ways of representing splines rather than bandlimited sums of sinusoids; the methods mentioned above belong to that theory. The approach I'm discussing here does not, I think, belong to that family of methods, but I'm not very familiar with the theory of spline image processing. So maybe it's in there somewhere.

10tcl ui

Kragen Javier Sitaker, 2019-12-06 (17 minutes)

I was talking with the entity known as The Doctor. They mentioned that they really liked the idea of having a tiny programming language in your boot ROM, but had found the Forth in OpenBoot to be fiddly, requiring a lot of effort to do simple things like changing the MAC of a Sun NIC.

Usually what I've done with the boot ROM is to boot, though, maybe occasionally from alternative boot media. I found that to be kind of fiddly in OpenBoot too. (I also wrote a graphics demo in OpenBoot on an OLPC, but because I couldn't figure out how to abort back to the interpreter, my first infinite loop ended the experiment†.)

Tcl

This reminded me of Yossi Kreinin's wonderful 2008 essay I can't believe I'm praising Tcl, about why Tcl is a terrible programming language but a good command language:

> Well, in Tcl that's as simple as it gets. Tcl likes to generate and evaluate command strings. More generally, Tcl likes strings. In fact, it likes them more than anything else. In normal programming languages, things are variables and expressions by default. In Tcl, they are strings. `abc` isn't a variable reference – it's a string. `$abc` is the variable reference. `a+b/c` isn't an expression – it's a string. `[expr $a+$b/$c]` is the expression. Could you believe that? `[expr $a+$b/$c]`. Isn't that ridiculous? ...
>
> And the nice thing about my retarded debugger front-end is that it looks like shell commands: `blah blah blah`. As opposed to `blah("blah","blah")`. And this, folks, is what I think Tcl, being a tool command language, gets right. ...
>
> And eventually, simple commands become all that matters for the [interactive] user, because the sophisticated user grows personal shortcuts, which abstract away variables and expressions, so you end up with `pmem 0 bkpt nextpc` or something. *Apparently, flat function calls with literal arguments is what interactive program usage is all about.* ...
>
> I have a bug, I'm frigging anxious, I gotta GO GO GO as fast as I can to find out what it is already, and you think now is the time to type parens, commas and quotation marks?! Fuck you! By which I mean to say, short code is important, short commands are a must.

Tcl is also, it bears mentioning, quite a bit saner than bash as a programming language.

In Tcl, `foo -x $bar -y $baz` invokes `foo` with four arguments: the string `-x`, the value of `bar`, the string `-y`, and the value of `baz`. The equivalent command in bash sometimes does this and sometimes calls `foo` with some other random number of arguments, depending on what is in `bar` and `baz`.

In Tcl, if your code has an error, your program will stop there with a backtrace (possibly popped up in a Tk window, if you're into that kind of thing), while in bash, it will probably continue as if nothing untoward had happened, unless you're running with `set -e`, which will crash perfectly working programs with some older versions of sh, because sh commands indicate failure in the same way that sh boolean expressions indicate falsehood: by returning nonzero. And not only won't `set -e` give you no backtrace, it will give you no error message at all --- you may not notice that anything has gone wrong.

And Tcl supports not only lists, which bash sort of does, but also nested lists and associative arrays ("dicts" or "hashes"), although like

Perl 4 and Awk, the associative arrays are not first-class.

(Tcl's nested lists are kind of shoddy, but they do exist. An unusual thing about them that they sort of share with bash lists is that a list of one string is the same as that string; a string is a single-item list of itself, in the same way that Python uses single-character strings to represent characters, or Octave uses 1x1 matrices to represent scalar numbers. So you can't distinguish between the string `squizz` and a list of one item that contains a list of one item containing the string `squizz` .)

Also, in Tcl, you can define subroutines that return values, including nested lists. In bash instead your subroutines can just write bytes to their output channel, which by default displays the result on the terminal.

Like Bash, Tcl unfortunately doesn't support named arguments or any other kind of name-value-pair interface that would make it reasonable to preserve backward compatibility, except by using some ad-hoc command-line parsing like Tk does:

```
button .x -text foo -command {puts bar}
```

One way bash usability beats the *shit* out of Tcl usability, though, is in tab completion, which in modern bash setups is fairly context-sensitive, understanding the syntax of most commands well enough to complete the appropriate kind of thing for the context you're in, most of the time; so, for example, `sudo` will tab-complete to available commands, `sudo apt` tab-completes to the 11 `apt` commands, and `sudo apt install` tab-completes to the available `apt` packages (!).

This is a huge timesaver; modern IDEs implement something similar, with dropdowns, by using static typing information which isn't present in Tcl, or for that matter bash. IPython does it without static typing information but only for properties of a variable that's already defined. Fecebutt and Slack provide dropdowns with substring search when you start to @mention somebody in a text box.

Tab completion is extremely useful for navigating hierarchies; for example, when you're booting, there's often a hierarchy of possible boot media --- USB vs. hard disk vs. network, different USB mass storage devices, different partitions on the mass storage device, different files in the filesystem, etc. Or, when you're debugging, you may have nested structs, or arrays of structs, or linked structs, that you maybe want to examine pieces of; or you might have nested dicts ("objects" in JS) with arbitrary sets of names. In Tk you have a hierarchy of widgets. (Though I think IMGUI is probably a better design than Tk on modern fast machines; see IMGUI programming compared to Tcl/Tk (p. 2333) for thoughts on that.)

Noun-verb ordering rather than Tcl's verb-noun?

Verbs act on nouns. Yossi's `pmem 0 bkpt nextpc` is a verb `pmem`, print memory, that acts on CPU 0 and, I think, prints out its breakpoints and next program counter value. `mv Un_Yanqui_Enseñando_Dichos_Argentinos_a_otro_Yanqui-hBhrHaoYONs.mp4 humor/.` is a verb `mv`, move, that acts on a video named by the first argument,

moving it into a named directory.

Verbs and nouns have some type-compatibility requirements, so if you know one of them, you can narrow down the candidates for the other, making it easier to choose. `mv` above only acts on filenames, and if it's given more than two arguments its destination argument needs to be a directory, while `mpv` only acts on *some* filenames, those that name directories or video or audio. `pmem` presumably only acts on CPUs for its first argument.

If you have more verbs than nouns, tab completion is probably easier if you specify the noun, or *a* noun, first. If you have more nouns than verbs, tab completion is probably easier if you specify the verb first. So, for example, my /usr/bin directory has 4652 verbs in it, most of which are only applicable to a few kinds of nouns, but none of my own directories have that many nouns in them. `tiff2bw` is only applicable to TIFFs, `pdftotext` is only applicable to PDFs, and `avrdude` is only applicable to AVR flash memory images. So probably a noun-verb order would be more usable.

In either case, there's the possibility of needing a space-filler of whichever syntactic category comes first. If I don't want to do any particular operation on some file, just see it, I still need to invoke Unix `cat` or `less` or `xdg-open` or `ls`. Similarly, in Smalltalk, verbs that don't really operate on any object have to get arbitrarily attached to some class as class methods.

If you have a lot of nouns --- or for that matter verbs --- you probably want a better way of choosing one than reading through a list of all of them or typing a memorized name. As alluded to above, a hierarchy is one possibility, while search (for example, using substrings, as in Fecebutt, or arbitrary database queries) is another. Bash tab-completion does a prefix search which doubles as hierarchy navigation. But bash tab-completion is copied from csh and tcsh, which come from a time when avoiding process context switches was an important consideration (so, for example, csh completions were triggered with ^D!) and terminals were commonly 2400 baud --- 3 lines of text per second. Most modern computer systems have much larger display bandwidth, often in the gigabits per second, and can thus afford to be more proactive about presenting candidates.

Most OO and OO-influenced programming languages put object properties (forming, sometimes, a hierarchy) and operations (verbs) in the same namespace; Smalltalk uses the same syntax for `anArray size`, which returns a number, and `anArray inspect`, which opens an inspector window; or for `anArray at: 3` and `anArray at: 3 put: 4`; and, in Python or JS, `foo.bar` can be either the instance variable `bar` or a method `bar` of the object `foo`, although they do distinguish between merely *reading* the property and *invoking* an arbitrary operation.

Making such a distinction, like the HTTP distinction between GET and POST, is crucially important for tab completion: if evaluating `foo.bar` can cause serious side effects, you don't want the UI to do it peremptorily. But, of the things that *can* be evaluated without serious side effects, you would like to maximize the number that the UI can look at peremptorily.

Another usability-maximizing design feature (missing from Tcl! but not from bash!) is being able to write to things in a way consistent with reading them. That is, if reading `foo.bar.baz` gives you 3, it is often useful to define `foo.bar.baz <- 3` or something similar as a way to

establish the same state of affairs in the future. It's much worse for usability to have to wander around looking for an operation on `foo.bar` or perhaps even `foo` that has the effect of changing `baz`.

An excellent example of the utility of writability and hierarchies was The Doctor's original example; under Linux:

```
$ cat /sys/devices/pci0000:00/0000:00:1c.0/0000:01:00.0/ieee80211/phy0/macaddress
00:24:2c:97:d8:58
```

Sadly, this kernel does not provide the ability to change the MAC address by writing to that pseudo-file.

Most of Yossi's hardware-debugging example from before could quite reasonably be implemented as a mere object graph like this, with custom getters performing the operations he'd decided were safely side-effect-free. (He mentions in the article that reading memory-mapped I/O regions wasn't always safe, which is a pretty common situation in device drivers.) Occasionally you'd maybe need to apply a verb to it. Here's a fragment of a recent GDB session as I was tracking down a bug, a fragment which consisted almost entirely of such navigation:

```
(gdb) p symbol
$1 = (HCFChoice *) 0x1e
(gdb) frame 1
#1  0xb79ecacd in collect_nts (grammar=0x83e92e0, symbol=0x83e9258)
    at build/debug/src/cfgrammar.c:121
121         collect_nts(grammar, *x);
(gdb) p symbol
$2 = (HCFChoice *) 0x83e9258
(gdb) p *symbol
$3 = {type = HCF_CHOICE, {charset = 0x83e92b0, seq = 0x83e92b0,
    chr = 176 '\260'}, reshape = 0xb79f0202 <h_act_first>, action = 0x0,
  pred = 0x0, user_data = 0x4c3b433d}
(gdb) p *symbol->seq
$4 = (HCFSequence *) 0x83e92c0
(gdb) p **symbol->seq
$5 = {items = 0x83e92d0}
(gdb) p (*symbol->seq)->items
$6 = (HCFChoice **) 0x83e92d0
(gdb) p (*symbol->seq)->items@10
$7 = {0x83e92d0, 0xb7f89450 <main_arena+48>, 0x3c, 0x11, 0x1e, 0x0, 0x41,
  0x29, 0x0, 0x83e431c}
```

You could imagine this whole transcript collapsing down to `stack.1.symbol.dest.seq.dest.dest.items dump 10`, or even `stack.1.symbol.seq.0.items d 10`.

Similarly, most of the booting I do could be accomplished by navigating through a device tree and finally applying a "boot" verb.

A thing that is mentioned in this transcript, but missing from my commands and from bash, Forth, and Tcl, is GDB's ability to refer back to previous results; for example, instead of `p **symbol->seq`, I could have written `p *$4`.

This kind of navigation does not entirely replace the need to pass string --- or other! --- parameters to verbs.

GUIs

Noun-then-verb interaction is of course entirely standard in GUIs; even SKETCHPAD had you select onscreen objects with the light pen before applying actions to them by flipping switches. It's still uncommon in command-line interfaces.

10tcl

Originally I was thinking of something fairly traditional: a simple Lisp dialect, but with more Tclish syntax, in which symbols and lists are quoted by default and require some kind of explicit sigil to unquote them --- perhaps "," rather than Tcl's "$" --- and in which the outermost parentheses are unnecessary. And called "10tcl" as in "tentacle". And maybe with dicts, like Clojure. But then I started thinking about how to handle tab completion, and the noun-then-verb thing popped up, and the RESTish distinction between properties and verb invocations.

This suggests a connection with Darius Bacon's language Cant, a dialect of Scheme in which the basic procedure-definition system includes a pattern-matching system, so that it is easy to define a procedure which returns `#no` if invoked with the argument `.interactive?` and a different form if invoked with two arguments the first of which is `.pick-move`:

```
(make greedy-player
  (to ~.interactive? #no)
  (to (~ .pick-move board)
    (for min-by ((move board.gen-legal-moves))
      (greedy-evaluate (update move board)))))
```

Specifically, you could imagine that invoking `sys.class.block.sda1 boot` would invoke the procedure denoted by `sys.class.block.sda1` with the symbol `boot` as its single argument. This is the same as Tcl as far as it goes, except that `sys.class.block.sda1` is actually an expression interpreted as it would be in Python or JS: as a series of property accesses. But a facility for defining actors like the Cant `greedy-player` above would make it convenient and idiomatic to define entities that responded to such invocations.

However, a significant difference is that these 10tcl objects *additionally* have properties which can be, by convention, safely enumerated and read; they might be a statically determined set or a set computed by arbitrary code invoked at runtime, like Python `__dir__`, `__getattr__`, and `__getattribute__`. That is, like JS or Python functions, 10tcl objects can have *both* behavior *and* attributes.

As in Tcl, the first word of the command is evaluated under different rules than the rest of it: namely, the first word is *evaluated* (rather than used to look up a proc, as in Tcl), while if there is more to the command, it is *quasiquoted*.

The grammar might look something like this:

```
command ::= expr (hwsp quasiquoted)* newline
hwsp ::= (' ' | '\t')*
expr ::= '(' command ')' | name | expr '.' name | number | obj
quasiquoted ::= '(' command  ')' | name | number | ',' expr | obj
```

Here "obj" is intended to represent things like lists and dictionaries, whose syntax I haven't thought about yet.

I think the Common Lisp, Forth, and Scheme approach of defining new control structures through compile-time metaprogramming is probably better than the Tcl and MACLISP approach of defining them through fexprs, partly because you can inspect the results of the compile-time metaprograming more easily.

Footnote

† It turns out that to interrupt an infinite loop in OLPC Open Firmware/OpenBoot, the answer is that the DEL key or the key with a rectangle on it in the upper right will abort, although after that you have to type `enable-interrupts` to run it again, except on later models of the XO.

Could you do DDS of comprehensible radio signals with an Arduino?

Kragen Javier Sitaker, 2017-03-31 (4 minutes)

Could you do DDS of comprehensible radio signals with an Arduino? Maybe with some filtering.

You can spit out data words with bitstreams at the full clock rate with the SPI controller (and some trickery), which is a square wave of up to 8MHz. You can get 10MHz (20mbps) if you use a 20MHz crystal.

AM radio is 525 kHz to 1705 kHz with like a 10kHz bandwidth. FM radio is 88 to 108 MHz with like a 200kHz bandwidth and ±75 kHz deviation.

The mechanisms for these two bands would be quite different.

For AM, we would be synthesizing more or less the frequency we actually want, but with different amplitudes (and unwanted harmonics). A 530kHz cycle is 1.89 µs, about 30 bit times. That should give us something like 10 or 15 distinct amplitudes, maybe 4 bits. Not as good as magnetic tape, but probably enough for comprehensibility.

For FM, we can't hope to get close to the actual carrier frequency; instead, we can hope that our square waves are square enough and well-timed enough to have harmonics up there. We may be able to improve the situation by reshaping them (say, with a Schmitt trigger) to sharpen the edges. At 8MHz, though, you can't get very narrow variation of frequencies. At 4MHz, your 23rd and 25th harmonics would be within the FM band. But I'm not convinced you can do an adequate job unless you're actually bending the Arduino's own clock.

Bending the clock might not be that hard, though, especially if we're running on the internal 8MHz RC oscillator for a change. Keep in mind we're looking for a deviation of less than 75kHz out of about 100MHz: 0.075%. And it doesn't even have to be very linear. It just has to be roughly controllable.

(The numbers hereafter are from the ATtiny2313 datasheet.)

The OSCCAL register on the ATtinies can adjust the internal oscillator speed, but only by increments of about 1% (about 2% at the high end of the frequency range) which would take you to an entirely different radio station. However, the oscillator frequency also varies with Vcc in a much more subtle fashion. So maybe by putting a resistor on the Vcc lead we could vary the Vcc between, say, 1.8V and 5V, by varying the current drawn by the chip and therefore the voltage across the resistance. The voltage coefficient of frequency varies on both sides of zero over the voltage range, but it seems to be usably large in many places. For example, going from 2V to 2.5V, eyeballing the chart, it looks like the frequency at 25° declines from about 8.02MHz to about 7.99MHz, a 30kHz variation (0.375%), about 60Hz/mV (0.00075%/mV). This means that by varying the voltage by 100mV we can vary the frequency over the appropriate range.

Active supply current Icc increases with Vcc; over that range, it

varies from 1.3 mA at 2V to 1.8 mA at 2.5V, supposedly. Idle supply current is about 0.3 mA to 0.5 mA over that range, so you can generate a proportionately large variation in current just by executing instructions. If we want 1mA to vary our current by 100mV, then we want about 100Ω of resistance.

We can't be sourcing 20mA of FM signal, because the resulting current and thus voltage and thus frequency variation would overwhelm the signal we are trying to generate. We might be able to sink it, though, with the output load being connected between an output pin and Vcc.

Scott Harden reports that he is able to get good results transmitting 1MHz square waves with a class-C amplifier consisting of a 2N7000, a resistor to Vcc, a couple of coupling capacitors, and modulating the signal into the transistor's drain below the resistor with an audio signal. But he was just generating square waves. If I understand it right, this seems like it might be a useful alternative to direct digital synthesis, maybe using a filtered PWM output.

Better be weird

Kragen Javier Sitaker, 2019-06-17 (updated 2019-06-24) (9 minutes)

(Revised from some comments I posted on the orange website.)

Why is it crucially important, as Feynman thought, to disregard others' opinions in order to be productive? In his case, part of the problem was that he was suffering from a fear of failure due to others' high expectations of him. He was so worried about looking foolish that he couldn't play with new ideas in the way that made him productive. But there's a deeper and broader reason, one that goes far beyond performance anxiety.

In fields like art, programming, and physics, you'd *better* be doing something *weird*. If you're doing something *mainstream*, the same thing thirty other people around the world are doing, you're all competing to make the same thing — paint the same painting, write the same text editor, prove the same theorem about black holes. Twenty-nine of you are going to get scooped by whoever is the hardest-working, the smartest, the best-supported institutionally, or whatever combination of those turns out to be the deciding factor. Your chance of being in that 97% who have totally wasted their efforts? 97%.

And if you're doing something *really* mainstream, like writing the next big client-side JavaScript framework, the one that will replace React, watch out! Your chances are a lot worse than that, because there are *hundreds of thousands* of people who fight with React every day and are frustrated with its shortcomings. Your chances are literally millions to one, unless you work at Microsoft or Google and have management support to beat those Facebook fuckers.

But if you're doing something offbeat, working on a problem† that's mainstream enough to be interesting if you're successful but not mainstream enough that dozens of people are already spending their weekends trying to solve it, you have a much better chance of finding a niche for your project. Maybe it's non-mainstream because people take for granted that it can't be solved (in which case they might be right, as with the reactionless drive — the objective here is to be weird in your *project goal*, not your *epistemology*); maybe because they don't understand why it would be important to solve it ("Where's the market?"), and you do; maybe, as with OpenSSL, it's an important problem, but there's no way to get paid for solving it.

A thousand hackers writing a thousand versions of the same library in the same way are only epsilon more productive than one hacker. A thousand hackers writing a thousand different libraries are almost a thousand times as productive.

Winning the lottery? Well, that's pretty much out of your control — but if you do decide to waste your money on the lottery, don't pick a number lots of other people are picking. Then you'll have to split the already-improbable winnings N ways.

But what if you're determined to solve a mainstream problem anyway, one where a thousand people are also trying to solve it? Then you need all the *outcome* variance you can get! If, of those thousand hackers, 500 are using a very conservative approach that is guaranteed to solve the problem with some quality metric 10 ±1 in 26

weeks ±2 weeks (these being the standard deviations, not some kind of 95% confidence interval), while the other 500 are using all kinds of wild approaches that give them quality metric exp(ln(4)±ln(4)) in time exp(ln(52)±ln(4)) weeks, it's pretty much guaranteed that the "winner" is going to be someone with a totally insane approach that hacked together a library with quality 49 in only 14 weeks. It's not going to be one of the 26-week plodders, because 14 weeks is 12 standard deviations out on their distribution (vs. 0.95 out on the crazy hackers' distribution), and quality 49 is 39 standard deviations out (vs. 1.3 out on the crazy hackers' distribution).

In fact, it's even worthwhile to sacrifice *expectation* to get higher *variance* in these situations. If your only hope of winning is to beat everyone else in a single round, you should do whatever will increase your minuscule chance of a home run, regardless of how it affects your chances of striking out.

It's still not socially optimal for people to behave this way — note that here you have 1000 hackers whose aggregate productivity is only about 20× the productivity of an average plodder — but if you've gotten suckered into competing for a mainstream niche, that's the way to play the game.

All of the above is for the simplified situation where you're working on a project by yourself. In a teamwork situation, the relevant actor is your team, not you individually. Do not write your code in Clojure if the rest of the team is working in Ruby. Do not try to solve only problems that nobody else on the team thinks are important.

And this advice definitely does not apply to a situation where doing the same thing someone else already did is valuable. If you're making a sandwich, there's no reason it needs to be different from the sandwich someone else is making across the street. They're two different sandwiches. If someone eats the sandwich across the street, it's gone and it can't feed your customer. They're going to be happy if you make them a sandwich they like, even if it's a little worse than the sandwich across the stret; even if there are many just like it, this sandwich is theirs. This is very different from the situation in software, where one sandwich feeds everybody in the world at once, except people with celiac disease. Nobody is going to be happy that you wrote a web browser from scratch for them instead of just installing Firefox. Web browsers are winner-take-all. Sandwiches aren't.

You might think that after you work through a few iterations, the distribution would start to approach a standard normal distribution, and the mean would start to matter more. But this isn't the case as often as you might think. If you're hacking on free software, as you should be, then after the first iteration, everyone can start using the clearly-much-better thing that is already working, rather than wasting months finishing their own inferior versions. And the person who wins the race that time around may not be the same one who won the first time.

The other thing is that there are distributions like the Cauchy distribution that are so heavy-tailed that they don't even have a mean, or even a variance. The Law of Large Numbers doesn't apply to them at all! And even for more ordinary heavy-tailed distributions that do have means, like the lognormal distribution (relevant here

since it's empirically the distribution of how much we misestimate tasks by) the Law of Large Numbers takes a lot more than "a few times" to start making the distribution of the sum look normal. Try it! Pop open Jupyter and convolve the lognormal distribution with itself a few times! How long does it take before it even starts to look Gaussian? How long does it take before it still looks Gaussian in a log-linear plot?

On the other hand, if you took my first piece of advice and you're working on something sufficiently weird, you no longer need to worry about increasing your variance further to beat the pack. There is no pack. Instead, anything you achieve will be a positive contribution; so, instead of grasping at straws to avert the almost-certain failure of competitors in a winner-take-all game, try to maximize your *expectation* of performance. That might mean increasing variance or it might mean decreasing variance, and it might depend on your utility function as well as the objective probabilities.

† I recognize that a painting is not "solving" a "problem", but many of the same principles apply.

Macroscopic capacitive DLP

Kragen Javier Sitaker, 2019-04-08 (1 minute)

I was writing in Paper/foil relays (p. 3273) about macroscopic electrostatic relays made from paper and graphite. Metal foil is another potential material for such devices, which deflect an insulator bearing conductive contacts using the electrostatic force on a conductive plate mounted on the insulator. Metal foil can also be mirror-reflective, which means that by deflecting it in this way, you can also redirect light. Indeed, as described in Caustic business card (p. 255), even submicron deflection of the foil surface can be sufficient to produce visible reflection effects nearby. You could produce such deflections fairly quickly and with fairly low voltages.

Topics

Parametric polymorphism and columns

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

In a relentlessly monomorphic language with good type safety, you could imagine reducing the size of object pointers to the size needed to distinguish the members of their class. If there are never more than 16 Rectangle objects, for example, you don't need more than 4 bits to identify a Rectangle; you can store their xmin, ymin, xmax, and ymax attributes in arrays of size 16. This is actually a practical thing to do in Verilog, where you actually can have a 9-bit variable (as opposed to a 16-bit one).

Now, maybe your Rectangle object is instead actually made of Point objects ul and lr. If you want to pass the ids of those Point objects to Point functions, you have two options:

• The Fortran option: make the x and y attribute arrays of the Point class explicit parameters to the Point function.
• The Smalltalk option: store all the Point attributes in the usual Point attribute arrays, then put the ids of the Points in question into ul and lr.

So far so good, although in #2 maybe you are spending more space on the Point pointers than on the Rectangle pointers.

Okay, now here's a thing that bothers me. What do I do if I want parametric polymorphism? Consider the case of an 'a list made out of car and cdr attributes, where the car has type 'a and the cdr has type 'a list, and where maybe we use -1 or something for a null cdr. Can I write a polymorphic list length function?

I have somewhat corresponding options.

If I have a Rectangle list type, for example, its car array can be of 4-bit Rectangle ids, in an alternative analogous to #1. But the length function doesn't actually use that array at all; it only needs the corresponding cdr array. So that works fine. In an alternative analogous to #2, I store all types of 'a list in the same car and cdr array, so the car array needs to be wide enough to accommodate pointers to any object type.

Agenda hypertext

Kragen Javier Sitaker, 2018-07-14 (updated 2018-07-15) (2 minutes)

Lotus Agenda was an interesting program that you could use for organizing research notes, tracking expenses, scheduling appointments, and the like. It gave birth to the "Personal Information Management" or "PIM" category of software, but it's more flexible than the other programs in that category.

An unusual thing about Agenda is that it mostly managed text, but at an intermediate granularity, roughly the granularity of a sentence. Each "item" was categorized into some set of "categories", which were like tags, but were mostly implicitly applied based on matching words in the text. The item-category association could have an associated value, sort of like a spreadsheet cell, with items being the rows and categories being the columns.

You could have several different views of your items, selecting which categories you wanted to display as columns, which you wanted to use to divide the view into sections, and which you wanted to add section totals to.

Web browsers allow you to navigate and organize text at the level of pages, while word processors and text editors allow you to navigate and organize text at the level of letters. Agenda was born about the time of Hypercard, long before hypertext became popular, but I've been thinking it would be interesting to have a hypertext system that worked at the intermediate level where Agenda did.

The key questions here are:

- Do links lead to views or to items?
- Are they transclusion links, explicitly activated links, or some of each?
- Are they only embedded in items, or can they also be tag-values?
- Are categories different from items, or is there just a single type of data that embraces both? An item belonging to a category can clearly be represented as a link, of course.

Midpoint method texture mapping

Kragen Javier Sitaker, 2019-06-01 (3 minutes)

I was thinking about Zdog and my similar `<canvas>` hack the other day for Dercuano drawings (p. 64), and today watching Κορη play a slightly-3D game, it occurred to me that a little bit of texture-mapping would go a long way to help the illusion of depth.

But both my hack and Zdog are based on, basically, spheres. How do you texture-map a sphere? The mapping from screen space to texture uv-coordinates has a couple of singularities (where the line of sight is tangent to the sphere) and so can't be reasonably approximated with a polynomial; Babbage's Method of Finite Differences is out of the question.

Consider the plane that includes the viewpoint and a scan line on the screen. The intersection, if it exists, between a sphere and this plane is a circle; along that circle we will find the points on the sphere that are visible in that scan line. If we consider only orthographic projection for a moment, we can use the standard midpoint algorithm for rasterizing circles to find the coordinates of the points in this circle. We may be able to use texel-sized steps if the sphere is close enough.

If we're using a solid texture, that's all we need — we apply the texture function (suitably strength-reduced) to the coordinates and get the colors to paint, but if we're using a flat texture, we may need to map from 3-D space to the texture's uv-space. Ideally we can use a polynomial fit (again, strength-reduced) to map into that space.

Adding perspective back in is a matter of stretching the middle of the scanned texture pixels while compressing the ends, some all the way to zero. We should be able to do this with a simple polynomial approximation, probably cubic, of the transformation from the orthographic view to the perspective view.

Actually, though, can't we do this all the way through? The transformation from screen pixel space to texel space has two singularities in it, but the inverse transformation, from texel space to screen pixel space, is singularity-free and actually relatively calm. Perhaps we can just walk along the texels on the appropriate path along the sphere's texture map, with a stride size small enough to transform at least two texels to every screen pixel, transforming each one to screen space and painting it into a screen buffer. A strength-reduced cubic spline should be perfectly adequate.

Maximal-flexibility designs for printable building blocks

Kragen Javier Sitaker, 2019-04-20 (18 minutes)

I played Minetest a lot for a while (see Why Minetest is so addictive (p. 1781)) and I've been thinking a lot about lego-like construction sets and Minecraft voxels, in particular the voxels used for flowing water and lava, which have varying heights. More like real-world sand, Minetest water or lava (and, I assume, Minecraft water and lava) has a certain angle of repose; if you have a water source on top of an otherwise flat surface, the water forms a very obtuse cone around it, out to a certain maximum radius. The water height within any given voxel is an affine function of X and Y, and the water heights in adjacent voxels are equal along their common edge, at least in equilibrium. The result is that you can get a smoothly sloping surface, with a crude approximation of curvature, out of a finite number of distinct voxel types.

This led me to thinking of 3-D printing and marching cubes or marching tetrahedra. If you wanted to print out cubical building blocks that snapped to a voxel grid to do this kind of smoothly sloping heightfield, you'd need to quantize the height at the points of the X-Y lattice; the minimal number of heights would be 2, and this yields five types of building blocks, with empty and full corners expressed in the order (0, 0, 0), (1, 0, 0), (1, 1, 0), (0, 1, 0), (0, 1, 1), (1, 1, 1), (1, 0, 1), (0, 0, 1): FFFF FEEE, FFFF FFEE, FFFF FFFE, FFFF FFFF, and EFFF FEFF. Here a "full" corner has material inside the cube touching the corner, though possibly only in some directions, while an "empty" corner has no material around it, and indeed no material anywhere nearby. The intended shape is something like the convex hull of the "full" points.

The fourth block is just a cube; there's a sixth "block" EEEE EEEE that is just empty space and thus doesn't need to be printed. FFFF FEEE, FFFF FFEE, and FFFF FFFE are different kinds of ramped surfaces, two with three √2 edges forming a slanted triangle, and one in the middle with two √2 edges and two 1 edges forming a slanted rectangle, all three with 1-1-√2 triangles on some vertical sides. The final block, EFFF FEFF, is missing two opposite corners, so all six of its paraxial faces are right triangles; it's a triangular antiprism, and it isn't needed for heightfields. These five blocks can be rotated and somehow stuck together at grid nodes to approximate any surface mesh produced by marching cubes, rounded to the nearest grid node.

If we're looking for maximal expressiveness with minimal inventory, the many symmetries of the cube are helpful; four of these five blocks are asymmetric and can be oriented in different ways to produce different shapes. (FEEE and FFFE have 8 meaningfully different orientations, while FFEE has 12. EFFF FEFF only has 3.) This rotational symmetry dramatically increases the expressiveness of this five-block vocabulary.

Or so I thought. But that's only 1+8+8+12+3+1 = 33 total voxels that can be formed, which is actually still short by a factor of 8 from

the 256 I'd expect. I realized I was missing FFFF FEFE, which can be realized as a ridge, a valley, or a saddle, but in any case has 12 distinct rotations. And EFFF FEFE, and some others. I should probably write a program to make a full inventory.

But this led me to the conclusion that perhaps, even though the cube's 24 orientations mean that any individual block can be oriented in the voxel structure in up to 24 different ways, its 8 vertices, which give 256 different possible voxels, are a difficulty. Still, five blocks (FEEE, FFEE, FEFE, FFFE, and FFFF) are sufficient for heightfields, which are sufficient for arbitrary shapes that aren't thinner than two voxels.

Hill's polyhedron, an irregular tetrahedron into six of which you can slice a cube, is an immediately promising alternative polyhedron. As it's a tetrahedron, removing any of its vertices leaves it empty, so you don't need a potentially large selection of them. As a bonus, you can assemble it into cubes and also a number of the pieces I described having to print separately above. I don't think it covers all the possible heightfields described above, though, because its faces are $1\text{-}1\text{-}\sqrt{2}$ and $1\text{-}\sqrt{2}\text{-}\sqrt{3}$, so it doesn't have the $\sqrt{2}\text{-}\sqrt{2}\text{-}\sqrt{2}$ equilateral triangles that result from cutting off cube corners.

Another alternative for approximating marching-cube surface meshes is to approximate just the surface, rather than voxels bounded by the surface, using flat triangles connected at the edges. $1\text{-}1\text{-}\sqrt{2}$ triangles are adequate for square faces and half-square faces; $\sqrt{2}\text{-}\sqrt{2}\text{-}\sqrt{2}$ triangles provide the cut-off corners; and $1\text{-}\sqrt{2}\text{-}\sqrt{3}$ triangles provide the remaining cutting planes.

Other tilings of 3-space ("honeycombs") may also offer good tradeoffs. Although the close-packings of rhombic dodecahedra and cuboctahedra aren't particularly promising in themselves, the duals of these packings packing consist of tetrahedra and octahedra. With tetrahedra and half-octahedra, you could build a version of these packings that can be truncated at a wide variety of planes.

Octahedra have the same set of 24 rotations as cubes (it's actually called chiral octahedral symmetry; its point group is the symmetric group S_4) while tetrahedra have 12 (A_4, the alternating subgroup of the symmetric group S_4). So an asymmetric octahedral piece could have as many as 24 usefully different orientations, and an asymmetric tetrahedral piece could have as many as 12.

I'm having a hard time visualizing the close-packings at the moment, but I think each face in the octahedral-tetrahedral honeycomb is shared between a tetrahedron and an octahedron. If that's the case, a single asymmetric octahedron and eight asymmetric tetrahedra would have $12^8 = 430$ million usefully distinct configurations; by the time you have the six octahedra and eight tetrahedra necessary to surround a point in space, the configuration space is unbelievably huge.

Stud patterns

Returning to a cubic honeycomb for the moment, two square faces can be joined together in any of four orientations; if we want all such faces to be compatible with all other faces, the simplest option is to make them all identical. But they must be symmetric under not only those four rotations, but also some kind of half-turn around an axis in the plane of the face to bring a face around to face another identical

face; that is, the three-dimensional contour of the face itself must possess chiral octahedral symmetry. It could, for example, possess male organs at 1 o'clock, 4 o'clock, 7 o'clock, and 10 o'clock, and corresponding female organs at 11 o'clock, 8 o'clock, 5 o'clock, and 2 o'clock. Indeed, fully an eighth of the face could be devoted to each such organ. But how should these organs interlock?

Thinking about legos (in particular, Lego-brand legos versus inferior underdog knockoff legos like the "Loc Blocs" I had as a kid), I had an epiphany: the very short insertion distance of Lego-brand studs is a natural optimization result for such frictional connections. The strength of the two-piece assembly is proportional to the frictional force (in one direction, it is precisely the frictional force), while the energy to assemble or disassemble it is jointly proportional to the frictional force and the insertion distance. (In fact, it is their product.) The impact energy the two-piece assembly can withstand without coming apart is also, in one direction, the energy to assemble or disassemble it, so lower assembly energy means lower impact resistance, but it need not mean lower strength. That strength can be arbitrarily high despite arbitrarily low assembly energies, at least in the limit of arbitrarily rigid material shaped with arbitrarily tight tolerances. The Lego company's tolerances are around 2–10 microns.

Roughly approximating, Lego-brand studs are inserted to about half a millimeter with about 5 newtons of force, so an 8-stud brick needs about 20 millijoules to assemble or disassemble.

PLA

This is reassuring for the prospect of 3-D printing building blocks using PLA, which is somewhat weaker and enormously more rigid than the when assembled ABS used in Lego-brand legos, or even the shitty polystyrene used in "Loc Bloc" brand legos. The consequence is that PLA has dramatically less impact resistance than ABS, and also can store dramatically less elastic energy when pieces are snapped together.

Typical RepRap-style FDM has curious precision characteristics: an error of some 100 μm horizontally (in the X and Y directions) which can sometimes be reduced to 50 μm or less, but typically a worst-case error of 150 μm or more in the Z direction, due to quantization to typically 300-μm layer height to avoid unreasonably long printing times. These impose a minimum scale on interference-fit parts which depends on the geometry: the parts need to stretch or squish or bend by at least the dimensional error when assembled in order to have any contact at all in the dimensional-error worst case. Ideally, they need to deform by an amount that is large relative to the dimensional error, so that the dimensional error won't result in dramatic variations in assembly/disassembly force (and assembly impact resistance), as it does with many kinds of poorly made construction sets.

I don't remember what PLA's elongation at break is, but let's suppose it's around 1%, similar to steel's yield strain. (Nylon is around 30%, and ABS is substantially less.) That means that a simple mortise-and-tenon joint with a deformation of 300 μm needs to be at least 30 mm wide in the deformed dimension! A simple mortise and tenon is not far from the geometry certain Lego-brand legos use, in particular the one-unit-thick plates. Such a geometry will not work

with RepRap-printed PLA until you reach pieces 1000 times the volume of Legos.

Prong clips

However, cantilever beams as used in many molded-plastic snap joints should work. 1% elongation means that you can bend a uniform-thickness strip of it in a circle of whose diameter the strip thickness is 1%: 100 mm diameter if the strip is 1 mm thick, for example, or 30 mm diameter if it's 300 μm thick, or 10 mm diameter if it's 100 μm thick. Cantilever beams get slightly better performance than that using a linear taper to get a uniform stress distribution, but it's not too far; so a 300-μm-thick uniform-thickness PLA cantilever beam can deflect by 300 μm without breaking if it is at least 9.5 mm long.

This is objectionably long, but it need not protrude by 9.5 mm; it can be recessed and zigzag as desired, in ways that are impractical in molded parts, reminiscent of coil springs but potentially much more sophisticated.

I don't know PLA's Young's modulus, either, but an old snapshot of Wikipedia gives polystyrene's Young's modulus as 3–3.5 GPa, which is probably in the ballpark; the plastics feel about equally stiff, although PLA is much more fragile. This suggests that if that 9.5-mm strip is 1 mm wide and 300 μm thick, bent into a circular arc with a surface strain of 1% and thus an average strain of 0.5%, it's under a total force of about 4.5 N, half tension and half compression, working over lever arms which vary proportionally with the stress and so average about 100 μm; this means the force to deflect the beam by that much is about 45 millinewtons.

Calculating this force in another way, the specific energy of (my guesses about) PLA amounts to stretching it by 10 microns per millimeter, requiring 30 MPa of stress; ½ 30 MPa 10 μm/mm = 0.15 J/mℓ, so PLA can tensilely store 0.15 J/mℓ, or half that in the beam-bending case, 0.075 J/mℓ. This strip is 0.00285 mℓ, so that works out to 214 microjoules. If that's built up over a deflection of 300 μm, the average force should be 713 millinewtons, with a peak force of 1.4 newtons. So I biffed a calculation somewhere.

By sticking a hook on the end of such a clip, we can amplify this force with an inclined plane, but probably only by a factor of two or three — at some point the frictional force will get out of control and the thing will just break instead of sliding in and out as desired. (The hook does have the major advantage that you can make it easier to assemble than to disassemble — same energy, but lower force.) The solution is probably to put many such thin strips in parallel like the pages of a book.

Suppose you have a 3-mm-side square hole to work with. You can have two parallel prongs that fit into it, each tipped with a hook, each of whose shafts consists of many 3-mm-wide, 300-μm-thick strips with 150-μm-wide spaces between them. The shafts deform by 300 μm upon insertion, coming into near contact (100 μm of space left in case the fabrication comes out too thick) and snap back by 150 μm upon full insertion. This gives us 2.6 mm of space to divide among these strips, meaning that there can be about 3 of them in each prong — 433 microns rather than the 450 described above, so only 283 microns of thickness in each strip. And these strips are being bent

S-curve-style rather than cantilever-style, since their ends are not free to rotate relative to one another (unless we want to try for a living hinge pivot, which seems inadvisable) so the prongs need to be about 13 mm long, which could quite reasonably be half recessed without even zigzagging.

The hook ramps can reasonably give a 2:1 mechanical advantage for insertion (600 microns deep for 300 of deflection) and a 1:2 mechanical disadvantage for removal (75 microns deep for 150 of deflection), so that the removal force is four times the insertion force, plus friction. Most of the 3-mm-wide hole can be oversized so as not to contact the hooks until they are almost at depth, so only the last 675 microns of movement have friction. The prong tips are 3 mm (almost) by 1.3 mm, so they are quite robust relative to the 300-micron-tall hook on their side.

Better than prong clips

But there's no reason to put the springs outside the building blocks in long prongs like that where they're vulnerable to breakage. Nearly the entire volume of the building block can be devoted to spring flexures that permit hooked studs on the outside to move or help capture inserted studs.

But you only have a sixth of the block to devote to the springs for each face, assuming you have connectors on all six faces. (It might be better to default to connectors on three or four faces for most projects, both in order to ease assembly and in order to ease printing; passive recesses can frictionlessly accommodate excess male stud prongs). If you want to be on the order of the Lego-brand assembly energy per face, which I estimated above at 20 millijoules, the one-sixth of the block devoted to that face needs to contain 0.27 mℓ, so the block as a whole needs to contain some 1.6 mℓ of PLA. If it needs to be 25% empty space, it needs to occupy at least 2.13 mℓ. Probably it's best to use a large safety factor and allocate, say, 8 mℓ per cube, which is precisely 20 mm on a side. This is significantly coarser than Lego-brand resolution, but not outrageously so; far better than we have any right to expect, actually, given the outrageously inferior qualities of PLA for this sort of thing.

Maybe the studs (or stud parts, since they ought to have opposing motion in order to grip locally rather than globally) should have motion that isn't purely parallel to the surface of the block, so the inclined-plane effect is larger than you'd expect from the shape of the hooks.

Minimal distributed streams

Kragen Javier Sitaker, 2018-04-27 (5 minutes)

I want a Wiki thing that provides some kind of knowledge ratchet for the things I work on in my spare time. In particular, I want to be able to write things on my cellphone (including calculations) and not lose them or have them inaccessible from another cellphone or computer.

The absolute minimal mechanism for this is some kind of text formatter that supports wiki links and some kind of sync protocol. The simplest feasible sync protocol is probably something like this, with each speaker uttering an append-only numbered sequence of lines:

"Give me any lines from Bob in the range 206–215."
"Bob line 206 is wejgoiewjgojagoijg."
"Bob line 207 is 302t020ujgs."
"Give me any lines from Alice in the range 201–211."
"Alice line 201 is jw0t23it20s."

This requires some kind of out-of-band mechanism for noticing that the connection has been established, or deciding when to make the request, and it doesn't have any "now you are up to date" indicator or any way to indicate failure. However, it doesn't leave the door open for unbounded quantities of future messages, all the messages are idempotent, it's convergent when messages are lost or when individual nodes fail or are restarted, and it doesn't require any session state. And it works as publish-subscribe as well as fetch-store. (You could even add sender-side message filters.)

It doesn't accommodate new speakers at this level of the protocol. Much. I mean normally you would only ever send a requested line but I guess you could make an exception.

Making this work offline on a cellphone is easiest in a browser app in JS. This suggests that maybe the server should be JS too, probably using Node. If I want to run it on adjuvant, though, which is probably a decent idea for prototyping, a CGI program is probably better. (Adjuvant doesn't have working TLS at the moment, though. I could probably fix that.)

You could require that the channel names ("Alice", "Bob") be public key hashes and that the lines each be signed. This probably isn't necessary for an initial prototype.

A browser app can itself be cached with a cache manifest, but it needs some way to store the data being synchronized. LocalStorage is the easiest and gives 5 megacharacters; WebSQL on Mobile Safari gives another 5 megabytes, and IndexedDB also works on Mobile Safari and supposedly gives 50 megabytes. On my browser, using the Browser Storage Abuser, it claims to have gotten 910 MB, but half the time it doesn't load at all. And it seems to be persistent after a month and a half, which is probably long enough to reconnect to the internet at least once.

Text formatting with wiki links could be something along the lines of

```
input.replace(/&/g, '&amp;')
```

```
    .replace(/</g, '&lt;')
    .replace(/"/g, '&quot;')
    .replace(/\n\n/g, '\n<p>')
    .replace(/\[(.*?)\]/g, '<a href="$1">$1</a>')
```

although obviously you could go quite a bit further with real Markdown or something. Markdown is not ideally suited for Wiki markup but it can work.

You need some kind of interface for handling update conflicts.

IndexedDB is the tricky bit here. With IndexedDB, I can quite reasonably store 50MB of text — perhaps compressed, so more like 150MB. But IndexedDB is not a very stable interface, and it's kind of complicated. Firefox by default treats it as a cache; specifying `{storage: "persistent"}` requires using an interface that is incompatible with Chrome and probably Safari. Worse, when Firefox evicts, it evicts the entire origin; there's no way to ask that it please save a little bit of data. (Although maybe a cookie or something would work.) And the callback approach recommended in MDN doesn't work in Chromium. (Oh, wait, it does. You just have to add the callbacks early enough, and subsequent opens are blocked until the earlier ones are closed.)

The IndexedDB interface is, like, you open a database, and it gives you a database-opening callback during which you can create and delete tables ("object stores"). Then once it's open, you can open a transaction on it, and in the transaction you can execute get, put, and delete on the tables. All of this is hidden behind an event-driven interface. In some browsers you can do this:

```
try {
  let db = await indexedDB.openDatabase('db')
    , tx = db.transaction('store')
    , store = tx.objectStore('store')
  ;
  await store.put('value', 'key');
  console.log('Put is totally done');
  await tx;
  console.log('Committed');
} catch (ex) {
  console.log(ex.message);
}
```

But I'm not sure the iPhone browser I want to use is among them.

The future of the human energy market (2014)

Kragen Javier Sitaker, 2014-04-24 (19 minutes)

In 2013, a momentous, revolutionary change, decades in the making, came to pass, almost unnoticed. Silicon solar photovoltaic energy became cheaper than coal in much of the world. Consequently, the majority of world marketed energy will be solar by around 2020–2026, and the problems humanity has to face will be completely different thereafter. Many things we think of as problems today will no longer be problems, and many things we don't think of as problems yet will be problems.

What does it mean for the cost to be lower?

The cost of energy, particularly for power plants, is tricky to calculate because the investments are long-term and often have unforeseen consequences. But energy utilities do these calculations on a regular basis, depreciating investments in physical generation infrastructure over XXX years and including cost of labor and fuel.

By these calculations, XXX in many parts of the world, utility-scale solar photovoltaic energy is now cheaper than fossil-fuel energy. This is new as of 2013. It was never true before.

The major reason for this has been the precipitously dropping price of silicon photovoltaic cells, due to an explosion of new low-cost photovoltaic manufacturers in China.

In the case of solar energy plants, the fuel is free; the vast majority of the cost of the energy is just the cost of building the plant, much of which is the cost of the solar cells that went into it.

One of the significant expenses in photovoltaic cell production is energy. But cheaper photovoltaic cells will lower the price of solar energy, which will lower the price of photovoltaic cells further. The ultimate limit is the cost of the raw materials and the depreciation of the capital equipment needed to produce the cells in a lights-out plant. As explained below, the cost of the raw materials is extremely low.

Some people have published calculations claiming that the embodied energy of photovoltaic panels — that is, the amount of energy consumed in their production — is greater than the amount of energy that the panels produce over their lifetime, and therefore using fossil-fuel energy to produce panels is just a waste. This was probably correct up to the 1980s, but the current energy payback time on photovoltaic panels is probably around one year, while the panels are designed to last 30 years, but in practice usually last longer.

What are the ultimate and practical limits to solar energy?

The "solar constant", the amount of sunlight that reaches Spaceship Earth, is about 1400 watts per square meter above the atmosphere. At ground level, it's about 1000 watts per square meter, due to clouds,

dust, and air absorption at some wavelengths. But that's a square meter at right angles to sunlight, not parallel to the ground. Tropical latitudes receive more sunlight because they're closer to being at right angles to the sun, while areas near the poles receive the least.

The total amount of sunlight striking the earth is XXX

Total world marketed energy consumption is XXX

You could imagine that even if the total amount of energy available is very large, limitations on manufacturing capacity or raw materials will limit us to harvesting a small fraction of it, as they have for the past several million years.

Indeed, many solar energy technologies do have some limitations. Thin-film panels invariably need indium, gallium, or both, although in small amounts; these metals are already more precious than silver, and they're mostly produced as a byproduct of zinc mining, so their supply is very inelastic — the prices will have to go up a lot more before people start opening indium and gallium mines. (Substantial amounts of indium could be recovered from discarded LCD panels if they can be efficiently separated from the garbage stream.) And germanium and other exotic semiconductors used in high-end multijunction solar cells are also rare.

But silicon photovoltaic cells, the current mainstream solar panel technology, do not suffer from these problems. They are principally made of silicon, with aluminum conductive traces, and then doped with trace amounts of group III and V elements such as phosphorus and arsenic — all among the most common elements in Spaceship Earth's crust. Given sufficient energy and equipment, you could make silicon photovoltaic panels out of almost any random rock, although perhaps at a somewhat higher cost than using the currently popular ores.

Entire panels contain some additional elements: aluminum frames, copper or aluminum wires, and tempered glass, which is made from calcium, silicon, sodium, and oxygen, using fairly inexpensive processes.

There's still the risk that, even if the raw materials intentionally included in the solar panels are cheap, the capital equipment needed to convert them into solar panels might be expensive. For example, parts of the manufacturing process involve melting silicon, which requires very high temperatures, and typically platinum-iridium crucibles. Even if silicon is abundant, platinum and iridium are not. I don't know enough to know if this risk will materialize, but if it does, there is a lower-tech alternative: concentrating solar power.

The first solar power plant was built in 1908 (XXX?) in Egypt, and used trough-shaped mirrors to focus sunlight on pipes, boiling water to drive a steam engine. This project ended when abundant oil was discovered in the area, providing a cheaper source of energy, but now that we've used up most of the oil, there are a number of similar projects.

Steam engines do not need any scarce materials, either in the finished engine or the factory to produce it, although they can be substantially more efficient, up to 40%, if made using modern alloys. And the mirrors for a concentrating solar power plant can be made from aluminum and glass. Current mirrors are made using a vacuum-deposition process which makes them almost as cheap as plain glass. It's also possible to use Fresnel lenses molded from cheap

transparent plastic.

CSP doesn't gather sunlight on cloudy days, but it has the great advantage that it is practical to use it to produce electricity at night, by storing the gathered heat in tanks of molten nitrate salts.

An in-between option is what the famous Solyndra was pursuing: by concentrating sunlight with mirrors or lenses, you can use a tiny fraction of the photovoltaic cells that you'd need to gather the same power directly from the sun, which in today's world may allow you to use high-end multijunction cells with up to 40% efficiency, but in a hypothetical world where platinum shortages limited photovoltaic production, could substantially increase the installed power. Solyndra went bankrupt because, at the moment, simple photovoltaic cells are too cheap to compete with using complicated machinery that needs to make back R&D costs.

How fast is adoption growing?

Utility-scale solar photovoltaic installed capacity is currently doubling every year in the US; recently worldwide capacity was doubling every 22 months, but in early 2013 I saw figures that said the doubling time had shortened to 8 months, presumably as a result of the much lower costs.

I don't have any numbers for non-utility scale solar (e.g. on rooftops) or other forms of solar energy (e.g. thin-film solar and concentrating solar power), but I think it's safe to say that, for now, utility-scale silicon photovoltaic has won the race and will remain the cheapest way to harvest solar energy for the foreseeable future. The other forms are much smaller.

Specifically, Intersolar reported in July that new solar energy installations (worldwide, I presume) would go from 30 GW of new installed capacity in 2013 to 100 GW in 2014. This represents a doubling time of 8 months.

My prediction that this exponential growth will continue for another decade and beyond is apparently a lunatic-fringe opinion; everybody else I can find making plans or predictions about solar-energy growth rates seems to be expecting something more like linear growth, to a double-digit percentage of electric power supply only by the mid-2020s.

What human problems exist because of energy scarcity?

Water shortages

Much has been said about the worldwide shortage of fresh water, with predictions of wars being fought this century over it. But salt water is abundant, and production of fresh water from salt water can be carried out straightforwardly with large energy inputs: either via distillation, the traditional way, or by reverse osmosis, which uses less energy. XXX Reverse osmosis plants do require significant investment in equipment, but the majority of the cost of their water is the cost of the energy they consume; and they are already cheap enough to produce water to irrigate farmland, water pure enough that it can reverse the problem of progressive salinization that has desertified many previously-fertile lands that have been irrigated by

slightly salty water.

In short, fresh water is only scarce because energy is scarce. Abundant energy will eliminate water scarcity and the risk of water wars, except perhaps for landlocked countries.

Expensive aluminum

Since Andrew Carnegie and his competitors exploited the Bessemer process to make steel the mainstream material in the late 19th century, our society has been girded with steel: steel railroad tracks collapsing the price of transport, steel rebar holding our buildings and bridges together, steel boats carrying our goods from port to port, steel automobiles ferrying us from steel-framed building to steel-framed building, where we can be shot by people with steel guns.

But the Hall-Héroult process, discovered in Carnegie's heyday, made aluminum (previously a precious metal) into a lightweight, inexpensive substitute, and it's displaced steel in some uses: airplanes, drink cans, bicycles, engine pistons, and so on. It's lighter than steel for the same strength, and it doesn't rust. Aluminum, however, is still more expensive than steel per pound and even for a given strength, so we continue using steel.

Most of the cost of the Hall-Héroult process, though, is the cost of the energy it consumes to electrolyze the molten aluminum ore, an ore which is abundant. Abundant energy will make aluminum abundant too, and it will displace steel in most applications; it will even displace plastic in some.

Climate control

Many of today's buildings, especially here in Argentina, are expensive to inhabit because they were built in an age of energy abundance — from the 1940s to the 1970s — and so are built with little concern for efficiency of climate control, since operating air conditioners was cheap at the time. Many other buildings, like those in the world's slums, are unpleasant and dangerous to live in because they don't have adequate air conditioning or heating, and are not built with sufficient resources to enable passive climate control. (Vinay Gupta's Hexayurt design is a possible alternative that provides passive indoor climate control with much less resources than traditional designs such as meter-thick adobe walls.)

Abundant energy makes it possible to heat and air-condition easily.

Energy production centralization

Current electrical energy production is carried out in centralized power plants, either because it's hydroelectric and therefore not portable, because it's steam and therefore experiences great economies of scale, or because it's nuclear and therefore is dangerous to distribute widely. About a third of it is then lost between the power plant and the consumer, and sometimes inadequate infrastructure maintenance results in widespread power outages, which are deadly. This is okay if you have good governance, but in places with shitty governance (like any slum, war zone, or refugee camp), it sucks. It also sucks if you have shitty self-discipline and blow your paycheck on smack and booze instead of paying the electric bill.

Photovoltaic panels are portable, do not experience economies of scale in use, and are not particularly dangerous. They can

substantially ameliorate the problems of inadequately maintained electrical transmission and distribution infrastructure, fragility in the face of attack, and poor governance.

Limited transportation

Much of the cost of transportation, especially air transportation but even bus transportation, is the cost of the energy needed. This cost makes traveling an unachievable dream for much of the world's population.

Airplanes, intercity buses, long-distance trains, and ships universally use liquid fuel rather than batteries because of its much higher energy density. This has led to suggestions that solar energy cannot replace fossil fuels for transport. This is a mistake. Liquid fuels can be produced synthetically from CO_2 and water; it just takes energy, and it's an inefficient process, so it won't happen until electrical energy is *much* cheaper than fossil-fuel energy.

Climate change

Global warming is caused by releasing fossil fuels into the atmosphere, either burned or unburned, and by releasing carbon dioxide from calcite in the production of cement. With sufficiently-cheap energy, cement production can be reoriented to magnesium cements derived from seawater with no carbon emissions, and we can build plants to actively remove carbon dioxide from air, either to sequester it back underground or to reduce it into combustible material, as suggested in the previous section.

What new human problems will exist because of energy abundance?

Dependence on energy suppliers; concentration of power in the hands of those who control energy production.

Pollution.

Lack of menial labor.

What new human problems will exist because of solar photovoltaic energy?

We can expect that a greater and greater proportion of our land area will be consumed by solar panels, because building them on land is easier than building them at sea. At first, much of this will take place in deserts, but eventually anyplace that gets sunlight will be fair game.

Calories are a measure of energy; a food calorie is about 4200 joules. The price of a joule in the form of food is similar to its price in the form of electricity. But solar panels are reducing that price, and they turn a larger fraction of sunlight into usable energy than natural photosynthesis does. Typical silicon solar cells convert 16% of incident sunlight into electricity, while the most efficient plants convert 7% of incident sunlight into biomass energy XXX, which then must be burned in a heat engine to recover some 2.8% of the original energy. So in the limit, an acre of solar cells will produce some five times the usable energy of an acre of sugar cane.

So we can expect food crops, as well as nature reserves, to compete with photovoltaic cells for land once the tropical deserts are used up.

However, even with yearly doubling times, that won't happen until the 2030s. Before that, it will probably make more sense to plant crops in the shadows of solar panels. (Current practice, which I hope stops, seems to be to concrete over the entire area to be populated with solar panels.)

Historically, we have carried out only fairly small-scale semiconductor fabrication, because it's an expensive process and because integrated circuits can be very useful while still being small. XXX These small-scale processes nevertheless produced staggering amounts of toxic waste, contaminating numerous sites around the world. To convert the world energy infrastructure to photovoltaic, we will produce semiconductor wafers by the hectare, with a correspondingly large possible increase in toxic waste.

While we won't have water wars, we probably will have wars for access to tropical areas with low cloudiness, such as the Sahara and the Atacama.

It hardly seems worth mentioning, but the Economist predicts that European utility companies may go bankrupt when solar energy lowers the price of energy below the cost of operation of their existing fossil-fuel and nuclear plants; as a result, their market capitalization has already dropped by half a trillion dollars. (!)

How is this practically different from biomass or agriculture?

As I mentioned above, current solar panels can collect some five times the usable energy from sunlight that biomass and agriculture do.

How will solar abundance be distributed?

More tropically. England's kind of fucked, as eloquently calculated by David MacKay in Sustainable Energy without the Hot Air, while North Africa is sitting on a gold mine — but geopolitically lacks the power to keep it from being exploited by other powers.

XXX

Should we conserve energy?

Yes, both because right now much of our energy produces CO_2 by burning fossil fuels, causing global warming, and because energy is expensive. Miners and drillers die to bring coal and uranium to your power plants and gasoline to your cars.

Should we make long-term investments to reduce energy usage?

No. Marketed energy will become abundant in the mid-2020s. An efficiency investment that saves a dollar a year now will turn into saving an inflation-adjusted dime or penny a year then.

Some people will do it anyway. Here in Buenos Aires, I hear people making arguments about how conserving fresh water is important, while the Rio de la Plata a couple of kilometers away discharges 22000 cubic meters per second of fresh water into the salty Atlantic (which is to say, 600 000 liters per day per inhabitant of Buenos Aires), and every construction pit in the city needs a sump

pump to constantly pump fresh groundwater out into the street. They seem to be inspired by the virtue of asceticism more than any actual knowledge about the issues.

But in an energy-abundance regime, it will make as much sense to try to conserve electricity by not using it as to try to conserve sunlight by sitting in the shade instead of out on the beach.

How, where, and by whom are panels made today?

Fast message router

Kragen Javier Sitaker, 2017-06-15 (updated 2019-07-23) (15 minutes)

Suppose you have a bunch of small processes, like the size of httpdito (which uses 12k or 16k of memory maps XXX no it has more memory maps than that), running and sending requests, responses, and change notifications to each other. How fast could they reasonably do this?

I wrote this test called syscallovh.c to get a ballpark:

```
char c[s];
int fd = open(devzero, O_RDONLY);
if (fd < 0) {
  perror(devzero);
  return 1;
}

for (int i = 0; i < n; i++) {
  read(fd, c, s);
}
```

It finds that, on my current laptop (Intel(R) Pentium(R) CPU N3700 @ 1.60GHz under Linux debian 4.4.0-21-generic), a system call takes about 300 ns, and bulk-copying bytes into userspace takes about 171 ps per byte, or, let's say, 175 ns per kibibyte. This suggests that, to keep the system call overhead under 10%, we need IPC message buffers to usually be in the neighborhood of 16 kibibytes or bigger. Such a bufferful of data should take 300 ns + 16 * 175 ns = 3.1 µs to process.

The sample CoAP request from Appendix A of RFC 7252, the CoAP RFC, is 16 bytes long (0.01 GET /temperature MID=0x7d34) and it receives an 11-byte response (2.05 Content "22.3 C" MID=0x7d34), so sending it through a Linux system call by itself incurs about 100× overhead: 300 ns for the system call plus 2.7 ns to transmit the actual request, plus a comparable amount of work for each of the three steps where the server receives the request, the server sends a response, and the client receives the response, a total of 1.2 µs. A buffer of 1024 such requests or responses, by contrast, would require 3.1 µs, or 3.1 ns per request — 12.4 ns per request for the full request-response cycle. This would allow my four-core laptop, naïvely, to handle 32 million request/response pairs per second, or 500 000 request/response pairs per 60Hz screen refresh.

As some kind of comparison, on a machine similar to this, httpdito can serve (and ab can measure) an HTTP request in about 50 µs, which takes about 2700–3200 instructions in the spawned child process and 29 instructions in the parent process, plus some unknown amount of work in the kernel on its behalf, which is actually the great bulk of the execution time.

As another comparison, here's the usual dumb fibonacci microbenchmark:

```
fib(n) { return n < 2 ? 1 : fib(n-1) + fib(n-2); }
```

On my laptop, this takes 920 ms to calculate that fib(40) is 165580141, running 2,288,656,125 instructions (2.49 billion per second), which works out to 5.6 ns per leaf call. There are almost exactly twice as many total calls as there are leaf calls, so this is 2.8 ns per function call and return, or 6.9 instructions per function call and return.

This is probably an unusually serial benchmark. One core of the machine can presumably run about 4 billion instructions per second with more typical levels of ILP, giving these crude ballpark numbers:

task	ns	insns	reqs	insns/req
syscall/ret	300	1200	0	1200/0
4 syscall/rets	1200	4800	1	4800
httpdito HTTP txn	50000	200000	1	200000
1024-req buffer 4 syscall/rets	12400	49600	1024	48.4375

#+TBLFM: $3=$2*4::$5=$3/$4

(It's amusing that the kernel is presumably running about 200 000 instructions while being scripted by httpdito running about 3000 instructions.)

Perhaps for messages sent over a network, this enormous microsecond-scale overhead of computation per request/response pair is unavoidable, but for processes on a single machine, it seems like it should be avoidable. A message broker that accepts buffers full of messages from other processes, copies the messages around appropriately to other processes, and sends the buffers off to the other processes should be able to cost somewhere between the 48 instructions per message that copying them minimally costs and the 4800 instructions per message that the kernel charges us for more or less the same job. If we could manage 512 instructions per message, for example, that would be 128 ns, several times faster than doing a couple of system calls per message. This would scale down to pieces of work as small as 32–64 function call/return pairs, and be efficient for pieces of work as small as 512 call/return pairs.

(Even across a network, if each node has a message broker talking to other message brokers across the network, it may be feasible to reduce the overhead; alternatively, zero-copy networking hardware may be able to store incoming packets directly into the message buffers of waiting processes.)

For communications topologies that change much less often than messages are sent over them, such as with flow-based programming, Unix pipelines, or farming work out to worker threads, no message broker would be needed to amortize per-system-call overhead over many messages.

What might such a protocol look like?

You probably want the messages to have an 8-byte-aligned fixed-length header with a length field counted in 8-byte units, rather than the bytes used by 0MQ and CoAP. You need to be able to have thousands of outstanding requests at a time, which probably requires you to be able to accept results out of order. You probably want your header fields to be either single bits or entire bytes in order to avoid the need for extra shift instructions.

You probably don't want per-message authentication and

encryption, not only because it impedes routing but also because it takes too long. In The security impact of a new cryptographic library in 2012, Bernstein, Lange, and Schwabe report that NaCl can run 80 000 public-key authenticated encryption or authenticated decryption operations per second an a 6-core 3.3GHz AMD Phenom II X6 1100T, which is presumably in the ballpark of 750 000 instructions per operation. The paper mentions a faster interface consisting of crypto_box_beforenm, crypto_box_afternm, and crypto_box_open_afternm, which allows you to amortize the expensive public-key operations across many messages to or from the same correspondent.

However, even the ChaCha20 stream cipher used by NaCl needs 5.6 clock cycles per byte for a 64-byte message on an AMD Ryzen 7 1700 at 3GHz, working out to 128 ns per message. So per-message authentication and encryption could conceivably be affordable, but it will probably use more CPU time than the message routing would.

It's crucially important that, if there are message brokers, whatever transformation they must do need not examine every byte in the message, including in particular breaking the 8-byte alignment guarantee as they copy the message from an input buffer to its appropriate output buffer or buffers.

Messages should probably normally be in the range of 16 bytes (smaller messages will have space only for the 8-byte header!) to 512 bytes (significantly larger messages will probably gain no further efficiency), with 128 bytes being the normal case. A single-byte length field would support messages up to 2048 bytes.

So, a single message might contain a datum of a level of detail such as the following:

- the above example request or response about temperature
- a 512-byte disk sector (although maybe in the age of 3D XPoint memory, user processes should be interacting directly with durable memory rather than indirecting their access to it through kernels and servers)
- a 16×16 pixel RGBA tile (1024 bytes)
- part or all of a scan line of pixels (2048 bytes in RGBA is 512 pixels; in 16-bit RGB, it's 1024 pixels; in 8-bit grayscale, it's 2048 pixels; in 1-bit monochrome, it's 16384 pixels)
- a rendered glyph from a font (some of the glyphs on my screen right now are 20×34, 12×17, 7×9, 12×9, and 7×7, thus ranging from 49 pixels up to 680 pixels; some mainstream fonts have glyphs as small as 5×7, and I've designed a proportional 6-pixel-tall font with some 2×6 glyphs)
- a millisecond or two of PCM audio; at DAT quality this is 192 bytes
- a drawing command
- a Merkle tree node with 4–32 SHA-256 hashes
- 32 single-precision floating-point numbers from one column of some table
- a touch, keystroke, or mouse event
- a SQL query
- a SQL table row
- the log message for an HTTP request
- a Redis query or response

• a line of text (but ideally not a letter, word, paragraph, page, or document)
• a 128-node binary DAG with two bytes per node and 128 implicit leaf nodes
• an AST of some 64 nodes with up to 192 implicit leaf nodes
• the bytecode for a method to be compiled or the machine-code compilation result
• a B-tree node containing 32–128 child node pointers, 64 bits each, with or without keys
• an SNMP request or response
• a Git commit, but probably not an entire Git commit history.
• a Git tree entry such as "100755 blob b734283e0473b9d77f07efee066f1486a1c5a37f wifiscan.py", but probably not an entire Git tree.
• a Tweet
• an SMS
• a financial transaction
• a stock price update
• a compilation command

It probably makes sense to layer some kind of application-layer protocol defining semantics (routing, failure recovery, naming, request-reply, publish-subscribe, caching) on top of a base data representation layer.

Many-output computations

Thinking about how to wedge a "give me the 16×16 RGB tile (768 bytes) at (112, 144) from frame 1832 of foo.mp4" service into a cached RESTful architecture makes me question the idea of caching individual message responses to achieve efficiency. Computing the tile in question, or even an approximation of it, is going to require decoding a potentially large area of the previous several frames, possibly up to a few seconds' worth of video. I'm not sure if it's feasible to break that computation down into pieces whose outputs would fit into a single 2048-byte message so they could be cached, but it certainly isn't the easiest way to bring existing video decoders into the system.

However, if instead of "give me the 16×16 RGB tile (768 bytes) at (112, 144) from frame 1832 of foo.mp4", you instead request "please store the next few frames following frame 1770 of foo.mp4 at /some/place", the video codec could issue a few hundred thousand PUT requests to store its output, and then we could fetch those outputs.

A similar kind of thing happens with, say, a drawing that gets rendered to a high resolution set of pixels — in the extreme case, the drawing is some view of the OpenStreetMap database. If we move one of the lines in the image, naïvely, that invalidates every tile of the cached image. To avoid invalidating the whole cached image, you need some kind of intermediate layer that efficiently partitions the drawing elements into those that affect different bounding boxes, then makes the individual pixel tiles depend only on the subset drawn within their bounding box. This seems feasible, but still tricky.

High-bandwidth computations

Copying a byte into or out of a user process may take only 171 ps of

one core, which suggests that you could do 23 gigabytes per second on this laptop, or 11.7 gigabytes per second out one process and into another. That's pretty decent bandwidth; 1920×1080×60Hz×4bytes is only 498 megabytes per second. But that bandwidth gets divided by the number of intermediary processes it ends up flowing through.

Still, this seems like it should be okay.

Low-latency computations

One of my examples above is "a millisecond or two of PCM audio". For media playback applications like watching a movie with bae, fairly high latency is acceptable as long as you have enough buffer to even out the jitter. But, if you're building a synthesizer out of a bunch of processes piping PCM audio to each other, even 10 milliseconds of audio latency is intolerable.

Buffering a millisecond of audio is not bad. Earlier today I wrote a softsynth in C++ to make the sound of the synthesizer in Eurythmics' *Sweet Dreams*. It has 29 very-low-level processing nodes in an 11-level-deep DAG, all of which are stateless and use continuous time. If they were being called upon to generate a millisecond of audio (192 bytes at DAT quality) we would expect sending that millisecond to require 300 ns + 192 * 171 ps = 330 ns at each node, plus another 330 ns on the node that received it; all 29 would take a total of 19 µs of system call overhead. The current C++ implementation spends about 20 µs generating that millisecond of audio, but 90+% of that is in method invocation overhead (including virtual method dispatch), because each node is generating a single sample instead of 48 samples.

(Some of the nodes are invoked more than once; there's a seven-node sawtooth C3 note subgraph that's used at two different times by the flanger, and a five-node triangle-wave C2 note subgraph that's both used to amplitude-modulate the flanged signal and added to the final mix, and the identity function is a single node that's used in six places. So this count of 29 is slightly low. Compiling the node graph into JS reveals 45 operations, but 15 of those are the identity function and could perhaps be skipped; another couple are redundant constant evaluations. So I think 29 is in the ballpark.)

So this approach, with a single millisecond of latency, would impose an order-of-magnitude overhead on soft-real-time audio-processing applications, but would still be almost two orders of magnitude more performant than necessary in this case.

In fact, it would not even be fatal if these messages were enqueued in a message broker between each node behind a 16-kibibyte buffer of other data. If each of the 9 levels of the tree cost 3.1 µs of bufferbloat, the total would be 27 µs of message-broker bufferbloat latency, less than the 39 µs of CPU usage to get all those tiny messages in and out of all those tiny processes; the total would be 66 µs, or 6.6% of the millisecond.

Everything is money?

Kragen Javier Sitaker, 2019-08-31 (4 minutes)

A remark overheard at the end of a math lecture, when the students were complaining about having to use different programming languages in different math classes (R, Octave, Python): "Everything is money." This was intended as an explanation for why essential free-software libraries for certain algorithms were not available in some of these programming languages, ruling those languages out for classes that needed to use those algorithms.

This struck me as profoundly short-sighted and unaware of the history of free-software development, particularly coming from a professor who shall not be named but who can trace their academic lineage back to Lagrange. When Euler and Lagrange were inventing the variational calculus in 1754 to 1756, Euler was indeed being paid — he was the director of mathematics at the Prussian Academy of Sciences. But spending some of his professor time on reading letters from Lagrange was entirely his own decision — not only did the providers of funding not know that Euler was doing this, but under the basic norms of Prussian academic freedom later codified by Humboldt, they did not have the right to know or to veto it. Moreover, Lagrange was not being paid for this; he did get a position as Sostituto del Maestro di Matematica for the Piedmontese army in 1755, but there he was being paid to teach calculus and ballistics to military artillery engineers.

The variational calculus wasn't published until 1762, at which point it was published by the Turin Society (*Societas Privata Taurinensis*), which Lagrange established with his students in 1757, and which today is the *Accademia delle Scienze di Torino*. It was initially established as a private club, but before the publication of the variational calculus, it had gained royal patronage from Victor-Amadeus in 1759, making it the Royal Turin Academy of Sciences (*Société Royale des Sciences de Turin*).

Much of the history of mathematics, academia in general, and free software is like this. If you want to know why a theory was developed or why a book or free-software library was written, it is only minimally informative to investigate who was paying for it and what they wanted to fund. Instead you should look for what interested the individual people who developed or wrote it, what other scholars they were in touch with, and what ideas they were influenced by.

Sometimes the *absence* of free software or research can be explained by funding. Snapshots in free-software filesystems don't exist because NetApp funded patents to stop them during many years. High-quality free-software mixed-integer linear programming solvers don't exist because researchers use CPLEX, Gurobi, Xpress, or SCIP — see Some notes on the landscape of linear optimization software and applications (p. 1285) for the whole sad story. There's no decent free-software spreadsheet for Android because people just use Google Sheets. Little public-domain research exists on isotopic enrichment because the US and Israel have funded wide-ranging efforts to prevent it, to the point of releasing industrial-sabotage

viruses into the wild and assassinating researchers.

Wikipedia, of course, is the first place any student of mathematics goes to learn about any mathematical concept. Wikipedia is written and edited by people who do not get paid, except in a minority of cases usually considered vandalism.

So, not everything is money, I think.

CCD oscilloscope

Kragen Javier Sitaker, 2017-06-20 (updated 2017-07-04) (7 minutes)

I've been trying to figure out how to build an oscilloscope from e-waste (see files TV oscilloscope (p. 1253), VCR oscilloscope (p. 213), Laser printer oscilloscope (p. 449), and Disk oscilloscope (p. 713)). The difficulty is that a basic oscilloscope has frequency response up to 20MHz, which means that if you want to digitize the signal you need a sampling rate of at least 40 megasamples per second, and such fast analog-to-digital converters (ADCs) are hard to come by. To display it without digitizing it, you would need some kind of display device with response up to 20MHz, like an analog oscilloscope tube, which is challenging to construct and very rare to find in garbage streams, especially intact.

I finally have an answer that I am confident will work: use a laser to store the analog signal on a CCD long enough to digitize it with an easily-available low-sample-rate ADC. Discarded flatbed scanners contain linear CCDs, which are already connected to moderate-speed ADCs; discarded laser printers contain lasers connected to scanning mirrors. Point the laser at the CCD and modulate the laser brightness with the signal you want to measure as it passes across. Then you can digitize the signal from the CCD at a lower speed in the usual way.

Let's consider a garden-variety 22ppm A4-size landscape-mode 600×600dpi printer laser assembly. A4 paper is 210 mm × 297 mm, so the paper moves at minimally 22x210 mm = 4.62 meters per minute, or 77 mm/s. 600 dpi is 23.6 "dots" per mm, so the printer must scan at a bit over 1800 scan lines per second; if it uses a 6-sided spinning mirror, that's 300 revolutions per second, or 18000 rpm, which is a pretty high speed.

(And it seems like a pretty average speed. The Samsung M2020W costs AR$2139 = US$134 and is 20ppm with fake 1200dpi in portrait mode; the HP Wifi Pro M12 costs AR$2900 = US$181 and is 18ppm A4 with 600dpi in portrait mode; a Xerox Phaser 3020 costs AR$1900 = US$119 and is 20ppm A4 with 600dpi, but I can't tell if that's landscape or portrait.)

For a laser printer, the laser doesn't need to be linear (it's either on or off for each pixel) but it does to be modulated at a pretty high speed. Each of those 1800 scan lines is, hypothetically, 297 mm long, with 7000 pixels per scan line. (In portrait mode you need more scan lines, but they are shorter, for the same number of pixels per page and per second.) This means the laser needs to be turned on and off at a bit over 12 MHz to meet the 600 dpi spec, but possibly 12MHz is already past the low-pass 3dB point of the electronics hooked up to it. However, laser diodes that can be modulated at many tens of MHz are easy to come by, and can be tested using a garden-variety photodiode and existing known-good oscilloscope.

A 6-sided mirror sweeps the laser across some 120 degrees in each scan, which are linearized by some weird one-dimensional optics in the laser assembly. They are linearized over a much longer region than the CCD from a scanner, which is typically as small as possible to cut down on silicon wafer costs, but which has its own set of optics to focus an image from typically the width of A4 or A3 paper onto it.

Although it limits bandwidth, these two complementary sets of optics could be left in place with a sheet of paper between them as a diffuser, but maybe you could get better performance (lower "dark current" due to stray light) if you could eliminate them and just scan the reflected laser directly across the CCD, maybe using a mirror and a second laser at a different angle to cut the sweep angle down to 30°, and compensate for the temporal nonlinearity across the CCD in software. This allows you to scan the laser across the CCD several times (such as four, in this example), which keeps the CCD's spatial resolution from being the limiting factor on the bandwidth.

The number of points you can sample from the captured analog signal on the CCD presumably depends on the resolution of the original scanner, but even a shitty scanner is 300 dpi, which across a 210 mm A4 page gives you 2480 pixels. A normal scanner is four times that; a high-end scanner is eight times that. 2480 samples is several times what you need for a decent DSO.

I think there may be some "dead time" during which it is impossible to capture the signal, either because the scan angle is too large for the CCD or because the laser is hitting the corner of the mirror or because the CCD is going through some kind of reset process between frames or something. There is definitely "dead time" on the laser end of the process, at least in the printers I've disassembled, where the laser is directed elsewhere than through the optics onto the page for part of the scan, thus getting lost.

Any other kind of camera would also work for converting from spatially modulated light (integrated over some frame time) back into a signal temporally modulated slowly enough to be easy to digitize. It's just that the CCD from a scanner is high-quality (typically more than 8 bits per pixel) and has a lot of pixels already in a line.

If no lasers are available, a possible alternative is to use an LED viewed through a spinning mirror and focusing optics, i.e. take a picture of the spinning mirror in which the LED is reflected with a camera. Many LEDs have relatively low junction capacitance and consequently can respond far more rapidly than they really need to for their intended use.

If no mirror is available either, it may be possible to do the job by spinning the camera (relative to the LED) instead, although this involves potentially tricky electrical connections to the rapidly spinning camera or LED. To avoid that problem too, you could nutate the camera or LED rather than rotating it, although that seems likely to be mechanically tricky and will also require trickier time base correction.

Writing math in Unicode with the Compose key

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

I can write quite a bit of math in a quasi-reasonable way with Unicode combining characters. For example:

This one uses COMBINING OVERLINE; xterm supports this, but Emacs, gnome-terminal, and Firefox 2 don't:

$z\bar{z} = x^2 + y^2 = |z|^2$

Using • for the compose key, I type this as `zz•^__ = x•^2 + y•^2 = |z|•^2`.)

This one totally abuses it, and it doesn't look that great in xterm either:

$\sqrt{a^2+b^2}$

That's `•sqa•^__•^2•^__+•^__b•^__•^2•^__`, which is kind of a pain, but still kind of cute.

This uses superscript and Greek characters:

$\theta = \tan^{-1}(b/a)$

That's just `•*u = tan•^-•^1(b/a)`. My Greek bindings, which are based on the standard Greek keyboard layout, are adequate for math, but not for typing Greek, because they don't include accents. And, as you can see, typing things like $x^{32^{07}2}$ is a bit of a pain.

There are logic characters:

$\forall x \in \mathbb{Z}: \exists y \in \mathbb{Z}: y > x$

`•AAx •in • Z: •EEy •in • Z: y > x`

$\forall x, y \in \mathbb{Z}: x < y \vee x = y \vee x > y$

`•AAx, y •in • Z: x < y •\/ x = y •\/ x > y`

Definition of XOR:

$x \oplus y = \bar{x}y + x\bar{y}$

`x •(+) y = x•^__y + xy•^__`

Or in different notation:

$x \veebar y = \neg x \wedge y \vee x \wedge \neg y$

`x •\_/ y = •-,x •/\ y •\/ x •/\ •-,y`

I'm not sure if this is any clearer than the C:

`x ^ y = ~x & y | x & ~y`

And I can write:

$f \circ g = \lambda x.f(g(x))$

`f•o*g = •*lx.f(g(x))`

Also I have a keybinding for the vector arrow, even though its rendering is pretty suboptimal in every piece of software I have handy:

$\vec{F} = m\vec{a}$

`F•^> = ma•^>`

An example from the Zeldovich HiStar paper:

$L_1 \sqsubseteq L_2$ iff $\forall c: L_1(c) \leq L_2(c)$.

`L•_1 •[= L•_2 iff •AAc: L•_1(c) •<= L•_2(c)`

Electric hammer

Kragen Javier Sitaker, 2018-07-02 (updated 2018-07-05) (14 minutes)

A hammer is a simple machine; you apply energy to it over a long period of time, and upon impact, all that energy is released in a short time. As an example, you might swing a 2kg hammer in a 3m-diameter circle at 2Hz, which works out to 9.4 m/s and 89 J, and it might take you 500ms over 2.4 m for the whole swing, thus an easily human-achievable 37 N and 178 W (though at least the power must vary, increasing as it does from zero); upon impact, this energy is released within, say, a millimeter, which is about 200 µs, 450 kW, and 89 kN. So in effect you have a mechanical advantage of about 2400 — your 37 N applied over 2.4 m is amplified to 89 kN applied over 1 mm.

Correspondingly, your 178 W is amplified by 2500 to get 450 kW, because it's released over 1/2500 the time.

Springs can be used in a somewhat similar way, and also in reverse, which is a thing we don't usually do with hammers. Springs have the feature that the input force and distance are always the same as the output force and distance, but the input and output power need not be. A bow, slingshot, or onager is the hammer-like approach — you apply a small power over a long period of time to charge up the spring, then release the energy over a short period of time. Applying the same principle in reverse, you can wind a watch, applying a large power over a short period of time, and then let it run down, applying a small power over a long period of time.

A traditional simple machine like a lever doesn't have the variability in time that hammers and springs do — the instantaneous power in is always equal to the instantaneous power out. A rough electrical equivalent of the lever, if we disregard dc, is the transformer — the input voltage can have whatever relationship to the output voltage, but the power in is equal to the power out.

Capacitors and inductors can be used like springs or hammers in the electrical world. You can add energy to either one slowly over a period of time, then release it over a short period of time; in the case of the inductor, the voltage is arbitrarily different from the original voltage, while the current changes continuously, while in the case of the capacitor, the current is arbitrarily different form the original current, but the voltage changes continuously. As one example, engine spark plugs are fired with ignition coils that work this way, and flashtubes are fired with capacitors that work this way. Some spot-welding machines also use either capacitors or inductors in either of these two ways, and of course ordinary switching power supplies use inductors precisely in order to change voltages. And it's easy to provoke accidental, and dangerous, energy releases from either kind of device. Heck, I just spewed sparks of vaporized copper into the air when I plugged in my power strip because it has a wall-wart plugged into it.

In this process, the non-ideal properties of the various devices, including even switching elements, come into play. The ESR and ESL of capacitors limits how quickly they can discharge (or charge), their leakage current wastes energy, and the ESR also causes energy

losses during both charge and discharge; parasitic capacitance of inductors limits how quickly they can store or release energy, and their ESR causes energy losses during the whole time they are storing energy. The limited energy density of either device also

For capacitors, the resistive losses are concentrated in the high-power part of the cycle, because they are quadratic in current. Consider charging a 1µF 1Ω capacitor with a constant-current source to 1 V over 1 second and then discharging it, also at constant current, over 1 millisecond. You charge it at 1µA, eventually depositing 1µC in it, dissipating 1pW and thus finally 1pJ in its ESR (and 1µJ in its dielectric). When you discharge it at 1 mA, it's dissipating 1µW, a million times as much, and finally 1nJ, a thousand times greater.

For inductors, instead, resistive losses are concentrated in the low-power part of the cycle. If you spin up a 1mJ 1Ω inductor with a constant-voltage source to 1 A over 1 second, then discharge it through a constant-voltage load in 1 ms, your current rises linearly from 0 A to 1 A, and the resistive loss rises quadratically from 0 W to 1 W over that second, dissipating a total of ⅓J. During the discharge cycle, it drops again from 1 W back to 0 W, playing the same curve backwards but a thousand times faster, and so dissipating only ⅓µJ.

So I was wondering about the limits of this kind of thing.

The Pulse Electronics PA4309.105NLT unshielded drum-core inductor is 1mH (±20%), 1.08 A, and 3.915Ω; it's 7mm × 12.8mm × 12.8mm. At its full current, it stores 0.58 mJ and dissipates 4.6 W, which I guess means it only stores about 127 µs worth of power, about 0.5 J/liter. I don't know what its self-resonant frequency or parasitic capacitance are, but Pulse measures the inductance at 100kHz, so I'm guessing it's at least 1MHz. So you can probably get a boost or dropdown of up to about a factor of 100 or 200 higher or lower voltage and power out of these inductors, with microsecond-scale spikes of a few hundred watts and volts.

Their PA4309.104NLT is 0.1mH (±20%), 3.5 A, and 0.405Ω, and is the same size. It can store 0.61 mJ, almost the same as the previous one (which makes sense, since all that's changed is the wire!) and dissipates even more, 5.0 W (which, again, makes sense).

The PA4309 series goes down to a 1µH 20A 19mΩ inductor of the same size, which is slightly higher power (7.6W) and lower energy (0.2 mJ).

So it seems like, for energy-storage purposes, the power, energy per unit size, and cutoff frequency don't really vary with inductance, at least within a given core material and size.

Capacitors can handle much longer energy storage (going beyond microseconds up to seconds, hours, even longer) as a result of us having much better approximations to perfect insulators than to perfect conductors, at least around our normal temperatures. They're also much denser.

A random capacitor I have lying around (in a broken CFL bulb) is a can 8mm in diameter, 17mm long, 3.3 µF, 400 V. This works out to 264 mJ in 0.854 mℓ, 309 J/ℓ, 600 times denser than the inductors I was looking at. I don't know how fast it can discharge and whether it's electrolytic (as it appears) or polyester (it says "PET" all over one side). But I think electrolytics are good up to about 10kHz or so, so it might not be able to do under 100 µs or so. In the CFL, it's being used to smooth the ripple in rectified 50Hz ac.

A random inkjet printer board I had sitting around has a Nichicon supercapacitor on it: 8mm diameter, 20mm long, 2.7 V, and an astounding 2.2F, which works out to an astounding 7.3 J in 1.0 mℓ, and thus 7.3 kJ/ℓ. However, supercapacitors have high ESR and much lower capacitance over short timescales.

Checking out datasheets and stock at Digi-Key, the Nichicon JUWT1105MCD costs 92¢ down to 30¢ (quantity 5000). It's a 1-farad 2.7V 6.3mm-diameter 10.5mm-long EDLC rated at 4Ω ESR at 1kHz. The datasheet lists a 4Ω "DCR", but I don't know what that is. The capacitance rating is based on discharging in, I guess, 270 seconds after a 30-minute (!) charge cycle. (See Capacitors: some notes on tradeoffs (p. 134).) This works out to 0.33 mℓ, 3.6 J, and 11.1 kJ/ℓ. The datasheet gives 4Ω ESR at 1kHz, so its maximum energy output at around that timescale would be into a 4Ω load, which would work out to 460 mW.

Another inkjet printer power supply has an electrolytic that is 16mm in diameter, 35mm long, 50 V, and 2200 µF, which works out to 2.75 J in 7 mℓ, 390 J/ℓ.

At the other end of some kind of scale, I have a microwave oven capacitor which is 25 µF and 450 V, 50 mm diameter and 70 mm long, 137 mℓ, 2.5 J, 18 J/ℓ. This is presumably designed for high currents and low ESR, although its extensive surface markings do not provide any indication of how high and how low.

Comparing to batteries, a lead-acid Yuasa GYZ16H holds 16 amp-hours at nominally 12 volts (690 kJ), is 150 mm × 87 mm × 145 mm (1.89 ℓ), weighs 12.4 lbs (5.6 kg), and can deliver 240 amps (nominally 2.9 kW, but I bet the voltage dips) to start your motorcycle. This works out to 365 kJ/ℓ or 120 kJ/kg, orders of magnitude better than even the supercapacitor. Li-ion and Li batteries are even better, and combustible fuels are orders of magnitude better again.

Murata has a line of "GR7" ceramic capacitors specifically optimized for camera flashes, the largest of which (GR731CW0BB473KW03#) is 3.2 mm × 1.6 mm × 1.8 mm. These are ceramic capacitors rated for 350VDC, 10nF to 47nF, with 50mA max discharge current, which works out to at least a megavolt per second, except that its capacitance droops below 50% at full rated voltage, so it's more like two megavolts per second. The power output of this device is an astounding 17.5 watts, but its energy content is only 2.2 mJ, which works out to 234 J/ℓ. I don't know what their ESR or ESL is; the datasheet lists their "dissipation factor" as 0.025 max at 1V and 1kHz.

Most promising are tantalum capacitors like the AVX TAJB226M010RNJ, which costs 69¢ in quantity 1, 23¢ in quantity 1000. It's 3.5 mm × 2.8 mm × 2.8 mm, 22µF, 10V, has an ESR of 2.4Ω at 100kHz, and has a leakage current of 2.2 µA. This works out to 2.2 mJ, 27 µℓ, and a rather poor 80 J/ℓ. The leakage current will steal 100 mV/s, so these are only good for storing energy for timescales of up to a minute or two. Discharging through a 2.4Ω load, it can theoretically deliver 2100 mA and thus 20 W.

So, suppose I want to dump 1000 J into a spark that lasts 1 ms — a rather high power of 1 MW. If electrolytic capacitors are my medium of choice, I need 3.2 ℓ of electrolytic capacitors! If I were to use tiny ones like the one from the CFL, I'd need 3800 electrolytic

capacitors. Using the bigger one from the inkjet, I'd need 360 capacitors, totaling 2.5 ℓ.

(Putting this power into context, arc welding on steel commonly uses a spark of 40 V at 150 A, melting a weld puddle a few millimeters across, which works out to 6 kW. This spark would generate heat 167 times as rapidly.)

Supercapacitors are apparently capable of discharges over a timescale of milliseconds, but their ESR is too high; using the one whose datasheet I examined above, you'd need 2.2 million capacitors, containing a total energy of 7.9 MJ, to get an instantaneous 1 MW out of them. Also it would cost you US$650 000 and they would occupy 720 liters.

Using Murata's camera-flash capacitor, on the other hand, you could get 1 MW out of only 57000 capacitors, which is actually a more reasonable quantity than it sounds like — the capacitors are tiny, so it's only 530 mℓ. But the total energy capacity would be only 126 J, which is an eighth of what I specified above, even if it is a bit larger than the literal 89J hammer blow I started the explanation with. To get to 1000 J you need 450 000 capacitors, but they "only" occupy 4.2 liters. I don't have the price handy but I imagine it would add up to around US$45000.

The AVX tantalums seem like perhaps a better balance: they hold the same 2.2 mJ as the ceramic capacitors, but can deliver a higher maximum discharge current despite the lower voltage, so the output power ends up being almost the same. Unfortunately, they occupy even more space and are probably more expensive.

How can we do online pitch detection?

Kragen Javier Sitaker, 2018-04-27 (updated 2018-04-30) (6 minutes)

These are my notes on pitch detection algorithms for three DSP projects I want to do: the Magic Kazoo, the R2D2 Light Switch, and Ultranarrowband Speech.

The projects

The Magic Kazoo is a synthesizer the size of a regular kazoo that you play mostly by holding it in your mouth and humming into it. It does live looping, sampling, synthesis of a variety of instruments, rhythm accompaniment, harmony, and autotune.

The R2D2 Light Switch is a light switch that you control by whistling at it to turn lights in your house on or off, or possibly dim them, change their color, or activate disco dancing strobe mode. Instead of running regular speech recognition algorithms which require a lot of processing power and are easily confused by background noise, I'd like to use a small number of chirp-based whistle signals, maybe with analog components to control brightness.

For the Magic Kazoo, I want to be able to do pitch detection on a distorted human voice, vastly outweighing any noise, with very low latency, like, under 10 ms, with relatively low computational cost, like under 50MIPS. For an R2D2 Light Switch, I want to be able to detect whistled pitch patterns even in the presence of substantial background noise, but I can tolerate latency up to maybe 200 ms, and it would be reasonable to use gigaflops if necessary. For Ultranarrowband Speech, pitch estimation is a necessary element, and it operates under fairly strict latency constraints (traditionally up to some 40 ms).

Why does the Kazoo need so little latency? Brandt and Dannenberg around 1997 say: "There do not seem to be published studies of tolerable delay, but our personal experience and actual measurements of commercial synthesizer delays indicate that 5 or maybe 10 ms is acceptable. This is comparable to common acoustic-transmission delays; sound travels at about 1 foot/ms."

Such low latency is particularly challenging because human voice pitches are often as low as 100Hz or even lower, which means 10 ms is a single period. Worse, the precision needs to be pretty high; if we autotune, we can afford up to a quarter-step of pitch error, which is about 2.9%. At 44.1ksps, 100Hz is a period of 441 samples, so the period estimation can be off by only up to about 13 samples. This is definitely doable with either zero-crossing detection (with a sufficiently amplified waveform) or various kinds of autocorrelation-based measures (with low distortion).

Ultranarrowband Speech is an effort to develop a comprehensible speech codec below one kilobit per second. However, I have recently learned that such algorithms already exist, like David Rowe's Codec 2, which manages comprehensible speech at 700 bits per second.

The algorithms

Zero-crossing counting

Simple counting of zero-crossings, on the raw waveform or on variously filtered versions, is the simplest thing to try. But to achieve the kinds of latency we're talking about here, we need to use the lapse between the zero-crossings, not the number of zero-crossings during some predefined interval. Perhaps the median lapse during the last 10–20 ms or so would be the best measure to use for this.

The downside of counting zero crossings is that you discard almost the entire wave, and that wave has a lot of information about the current phase which it would be better not to discard.

Quadrature encoding with the derivative

Another approach that has occurred to me is to use the instantaneous amplitude and derivative to estimate a phase quadrant, which you can use like a quadrature encoder to count revolutions. It also gives you phase information twice as often as simple zero-crossing counting.

Phase-angle tracking with the derivative

Going further in that direction, you could imagine estimating a phase angle, and timing the first time the phasor reaches a given phase angle during each cycle. At each new angle, you can measure the time lapse since it reached that angle during the previous cycle.

Measuring the derivative can be done in a variety of ways, but it's important to keep in mind that the derivative is proportional to the frequency, among other things. So you have to multiply the derivative by something to get the phasor to follow a roughly circular pattern near your desired frequency (say, within an octave or two of it). As long as you're privileging a certain octave, you might as well run some degree of low-pass filtering over it as well — for example, differencing the latest sample from a simple moving average over the last N samples, or differencing a shorter moving average from a longer one. The width of these moving averages provides a crude low-pass filter, and the lag between their centers provides a high-pass filter.

Particle filters

Another approach is to maintain a variety of hypotheses in memory about what the waveform is doing, updating the probability of each one in a Bayesian fashion after each sample, then resampling the population of hypotheses according to the implicit distribution.

The hypotheses can be things like "repeating the wave N samples back with M amount of Gaussian noise" or "silence" or "a new wave with a period around P Hz".

Autocorrelation

This is sort of the gold standard. If you're working on a 10-ms window at 44.1ksps, you need 441*440/2 = 97'020 multiply operations, most of which are multiply-adds. You could maybe do this every millisecond, which ends up as 2200 multiply-adds per sample, 2.2 million per second. Then you need a bit more work to look at the autocorrelation spectrum and pick out the peaks. This is probably too slow to do in real-time on many processors, but it's an easy first thing to try, and provides a basis for comparison for other algorithms.

Cross current zone melting

Kragen Javier Sitaker, 2016-10-06 (1 minute)

In additional to the usual countercurrent configuration for minimal heat loss and the cocurrent configuration occasionally used, a recuperator-type heat exchanger may be arranged in a cross-current configuration for process intensification, where you have alternating layers of pipes in the X and Y directions. (A rete mirabile is a much better way to do high-density heat exchange, but that is a different topic.)

This cross-current configuration is optimal, however, for a different purpose: rapid zone melting. Although I suspect that the speed of zone melting is limited by crystal growth speeds, maybe you can still do it faster by doing it in thin pipes (made of a material that doesn't dissolve significantly in the material you're trying to purify, of course). You can run hot coolant through only one or two cross-current pipes above and below the layer of the material being purified to melt it in a narrow region, while perhaps simultaneously running cool coolant through other adjacent pipes to intensify the temperature gradient.

By switching between pipes, it should be possible to rapidly move the molten zone along the material being purified.

The Magic Kazoo: a synthesizer you stick in your mouth

Kragen Javier Sitaker, 2017-04-04 (updated 2019-05-12) (6 minutes)

I thought I must have written about this in detail elsewhere, but I can't find it.

I propose the Magic Kazoo, an electronic musical instrument. You use it by putting it in your mouth and singing into it; the pitch, volume, airflow, and tonal quality of your voice, together with buttons on it, control a synthesizer running on one or more microcontrollers to produce music emitted from a built-in speaker. With live looping, you are a one-man band.

Real-time audio synthesis is no longer power-hungry

Modern microcontrollers — even MSP430s and AVRs, but especially the ARM Cortex-M series — are powerful enough to do real-time audio synthesis easily, even running on tiny batteries. We should expect the vast majority of the power consumed by the Magic Kazoo to be the power dissipated in its speaker.

Pitch detection can be super simple; amplitude detection may be harder

Your voice recorded on a microphone that is actually inside your mouth is enough to saturate just about any normal microphone, and it's reasonably sinusoidal, so you can get the frequency just by counting zero-crossings. You can't get the amplitude in the usual way, because it's totally saturated and does a pretty good impression of a square wave. You may still have 200–500µs or so in between saturated positive and saturated negative, though, and the slope in that 500µs (or equivalently its length) kind of tells you what the amplitude of the whole sine wave would be if you could record it.

Given that, you can detect sound onsets with amplitude, measure the frequency with time between zero crossings, round to the nearest halfstep, and control a softsynth. Maybe you can use the inferred volume contour of the sound to give you further control over the sound.

Even ceramic capacitors might be adequate microphones in such extreme circumstances

(The power of the sound is such that you might be able to use things that you wouldn't normally use as microphones. Like high-barium-titanate ceramic capacitors, which are a lot cheaper, and which can sometimes generate over 100mV piezoelectrically, or even over two volts when Dave Jones bangs them on wood like drumsticks .)

Interfaces to the outside world

Aside from the speaker, it has a headphone jack.

Should air pass through it?

Since you can breathe through your nose, it doesn't need to have air pass through it, and if you take that option, you can make music for yourself or a headphone listener by humming quietly. This does remove the possibility of controlling a dimension of the music with airflow, though.

Sliders, knobs, and buttons

In addition to the continuously-variable frequency and amplitude inputs from your voice, the possible continuously-variable spirometry input, and the possibility of maybe detecting other aspects of your vocal-cavity resonances, the Magic Kazoo probably needs some further controls. The variety of things you *might* want to control are endless: adjusting the volume, selecting from thousands of existing instrument sounds, recording a pattern to loop later, enabling or disabling existing patterns, starting or stopping a canned beat-box rhythm, adjusting tempo, and any of the endless variety of effects pedals out there; and if you're using it to construct your own virtual instruments, you could start with adjusting attack, decay, sustain, and release, recording samples, autotuning them, and then selecting what part of the sample gets used, generating sounds from systems like Karplus-Strong and FM synthesis, and so on.

There is, however, a very limited amount of space available on a kazoo-sized thing for the full set of controls you might want on a digital audio workstation, and even less screen space for feedback. I have this little 8-color ballpoint pen here that's about the right size; as mentioned in A phase-change soldering iron (p. 2270), it's 17 mm in diameter and 130 mm long. The eight colors are selected by eight sliders somewhat like the digit inputs on a Curta calculator, which slide about 25 mm; things that are more closely spaced than that probably aren't too practical, and even those might be pushing it — I can't move two adjacent sliders at once because my fingers are too big. So controls need to be at least 13 mm apart to be simultaneously operable.

For such a device, there are strong incentives in favor of capacitive touch sensing instead of physical buttons: moving parts break, especially on instruments played by children; physical buttons tend to let water in, which is a problem for an instrument normally partly immersed in saliva; the higher parts count and extra assembly steps for physical buttons raise the cost; and physical buttons are generally limited to detecting contact or non-contact, with no analog levels, until you go to potentiometers (which really exacerbate the other three factors). But normal touch sensing is kind of a no-go for a musical instrument, because it generally requires looking at the thing and responding to what you see, which adds far too much cognitive latency. It's *really* important to be able to find controls with your fingers before you activate them.

A possible solution is to expose the touch surfaces through holes in a touchable template, which allows you to find the "button" or "slider" hole you want by feel alone, then use a bit more pressure to squeeze your finger skin through the hole so it touches the surface.

Mechanical buck converter

Kragen Javier Sitaker, 2016-06-20 (5 minutes)

Springs apply a force that increases as they are deformed from their equilibrium form. To compensate for this, old clocks and crossbows use the horological fusee to compensate.

But, in electronics, to compensate for the similarly variable voltage from batteries and especially from supercapacitors, we use buck converters instead. Buck converters periodically dump a pulse high voltage into an inductor, which ramps up current rapidly in response, and then ramps down (perhaps more slowly) when the high voltage is disconnected. The roughly constant but oscillating current through the inductor is used to charge a capacitor, whose voltage oscillates slightly as the current rises above and falls below the current drawn by the load in parallel with it. The voltage on the capacitor is used to control the pulse width.

The mechanical equivalents of inductors and capacitors are springs and masses, but there is a duality; interchanging current and voltage, and inductance and capacitance, you get a new circuit that functions similarly.

In this case the particular analogy I was thinking of was attempting to maintain a constant but smaller force (analogous to voltage). If force is voltage, then velocity must be current, right? Because the thing you multiply force by to get power is velocity. So the component analogous to a resistor would be a dashpot, as expected: velocity proportional to force. The component analogous to an inductor, with the force proportional to the derivative of velocity (acceleration), must be a mass. And so a capacitor must be a spring, with the velocity proportional to the derivative of force, which is to say, the position is proportional to the force. So far, it all checks out.

So periodically we allow velocity to flow briefly from the mainspring to a mass, such as a flywheel, for example through a freewheel clutch mechanism (analogous to a diode). Then we use this flywheel to energize a spring, such as a torsion bar, connected to a load. The torsion bar is maintained at a roughly constant but slightly oscillating torsion as the flywheel is accelerated by the mainspring, then left to slow down under the influence of that torsion bar or whatever. And then we use the total force in that spring to control the duty cycle with which energy is dumped into the flywheel, by applying and removing a brake (a clutch, really, connected to a fixed shaft that cannot rotate) from the driving side of the freewheel.

It's easy to imagine two rotating actuators, one attached to the flywheel and the other attached to the load, whose difference measures the spring force in the torsion bar, like the pointer of a torque wrench. And you could imagine these two things engaging and disengaging the clutch once per revolution. You probably want those revolutions to be pretty slow, like under 1 Hz, to get acceptable clutch life. You could achieve this either with a large flywheel or by gearing down the relative motions of these timing devices.

So this gives you an efficient, if probably unreliable, kind of continuously variable transmission, with a built-in governor that produce a constant output force (torque), regardless of how fast the

output is rotating, as long as the input force is equal or greater.

As an alternative feedback mechanism, you could control the duty cycle of the clutch to obtain a constant output velocity rather than a constant output torque, for example using a centrifugal fly-ball governor.

If we run this the other way around, we have a mechanical boost converter instead. In this configuration, the input shaft is allowed to freely spin up a flywheel, which is at times not connected to any load. Periodically, however, a clutch is engaged, connecting the flywheel to a freewheel which winds up a spring. A second freewheel keeps the spring from unwinding while the drive clutch is disengaged.

When the clutch is engaged, the flywheel can decelerate much faster than the input drive, providing much greater force. If the force required is much greater than the force provided by the input, the clutch will be disengaged most of the time, while if it is almost the same, the clutch will be engaged most of the time.

All of these contrivances seem to me perhaps foolish compared to the reality of continuously variable transmissions achieved by existing methods.

In the world of hydraulics, the boost converter is well known in the form of the hydraulic ram; I suspect that pursuing the analogy further is likely to be fruitful.

Complementary goods in home economics

Kragen Javier Sitaker, 2017-07-19 (3 minutes)

Suppose you have a budget of US$1000 to spend on two complementary goods, A and B. The benefit you get from the combination is jointly proportional to the quantity of A and the quantity of B that you purchase. Then you should spend US$500 on A and US$500 on B, because if x is the amount you spend, your benefit is proportional to x(US$1000-x), whose maximum is at x=US$500. Note that this doesn't depend on the unit prices of A and B!

And it only depends a little bit on constant offsets, for example if spending x on B gets you 10 + x/$15 units of B; you can simply impute the cost of the constant offset to your budget and spending on B, in this case pretending that you are spending US$150 more on B than you really are, out of a total budget of US$1150. (So in that case you want to spend US$575 on A and US$425 on B.)

You'd think that if there are three analogously complementary goods involved, you should probably spend equally on each of the three. And yes, it turns out that although xy(1-x-y) blows up to positive infinity in several different directions, its only maximum for positive x and y is at x=y=(1-x-y).

I think this reasoning is applicable fairly generally in home economics, although you have to contend with diminishing returns as well.

For example, spending US$1000 a month in rent and maintenance costs on your apartment implies that you should probably also spend US$1000 a month to decorate it, or whatever else makes it enjoyable. If you're spending more than that on decoration, maybe you would enjoy it more if you moved into a bigger apartment and spent a bit less on decoration; and if you're spending less than that on decoration, maybe you should move into a smaller apartment so as to have more money to make it habitable.

Here I'm assuming that "maintenance" costs like cleaning and repairs, as well as your rent, scale proportional to the size of the apartment (adjusted by some quality factor), but there are cases where this is backwards — some kinds of maintenance, like repairing damages from a leaky roof, are a matter of wasting money as a result of renting a low-quality good. In those cases, it would be more intelligent to rent a higher-quality good instead of wasting money on maintenance.

Does this mean that spending US$500 a month on car payments (or the time-adjusted equivalent in up-front costs) implies that you should probably also spend US$500 a month on mileage-proportional costs such as fuel, oil changes, and maintenance?

Having a nicer, faster, or more efficient car means that time you spend in the car is more pleasant, and you can travel proportionally further in the same time. But if that expense means that you don't have enough money to pay US$500 a month in variable costs, maybe you would get more value out of a cheaper car that you could afford

to drive more.

But maybe you have a lot of money and not that much time to spend traveling in the car.

Sparse sinc

Kragen Javier Sitaker, 2019-09-15 (10 minutes)

Is there a reasonable way to approximate a low-pass time-domain sinc filter with a sparse filter cascade, in the sense described in Sparse filters (p. 834) and elaborated, for example, in Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547)?

A sinc consists of two sine waves of the same frequency, 180 degrees out of phase, joined with a kind of parabolic lump in the middle (the "main lobe"), and with an overall hyperbolic envelope: go twice as far out and the oscillations are half as high. A sort of important thing is that the zero-crossings are at perfectly regular intervals, except that there's one missing in the middle, in the center of the parabolic lump, which is instead the maximum of the whole function.

Most commonly, instead of convolving with the full sinc function, which has annoyingly long support, we convolve with a windowed sinc function, whose amplitude diminishes considerably more quickly.

A couple of different ideas occur to me for how to do this.

Beating frequencies with a Gaussian window

If we want a sine wave to go through a 180-degree phase shift, a simple way to get this is to generate a beating signal by adding two sine waves at frequencies above and below it. For example, if we want a 22,050-Hz sine wave to switch polarities 100 times a second, we can add equal-amplitude sine waves at 22,000 Hz and 22,100 Hz. If we put a tight window around a zero-crossing of the phase, we can attenuate the signal sufficiently that only a single crossover has a significant amount of energy.

Image filtering with an approximate Gabor wavelet or Morlet wavelet using a cascade of sparse convolution kernels (p. 547) shows how to put a Gaussian window on a sine wave by composing a feedback comb and a feedforward comb, and by adding two different windowed sine waves you can get much of the tails of a windowed sinc. For better or worse, the amplitude will diminish in the tails as $\exp(-x^2)$.

This doesn't provide the lump in the center, but perhaps we can get a reasonable lump out of a simple (non-oscillating) Gaussian and add that in.

The above gives us about 15 additions and subtractions per sample.

However, I think the envelope of this approach will be too far from correct, because the sidelobes immediately next to the main lobe will have amplitudes that are too small.

This approach is particularly interesting for a slightly different application: as an ideal *bandpass* filter has a frequency response of a symmetrical low-pass boxcar convolved with an impulse at its center frequency, it has a time-domain response of the low-pass boxcar's sinc *multiplied pointwise* by a sinusoid at the center frequency. Where the

sinc crosses zero, the center-frequency sinusoid reverses phase. So the beating trick can be used to get some of those sidelobes.

Summing a bunch of in-phase Gaussian-windowed oscillations

Suppose that, instead of trying to generate a beating frequency and then window it, we start with a single Gabor kernel (a Gaussian-windowed sinusoid) of, say, an eighth of the overall window width. Then we build up the overall hyperbolic envelope by adding delayed and amplified copies of the thus-windowed signal, careful that the delays don't put the various copies out of phase (except in the middle). Perhaps six or eight copies should thus be adequate to get a good approximation to the overall hyperbolic envelope, and then, as before, you need to add in the central lump.

The copies on opposite sides of the central lobe are the same amplitude, so you can sum them first and then multiply them by the amplitude; with this approach, eight copies will require four additions and four multiply-accumulates, all starting from the same windowed sinusoid.

With this approach we should need about six adds and subtracts to get the initial windowed sinusoid, six adds and subtracts to get the central lump, and four additions and four multiply-accumulates to put the whole thing together: 20 operations in all.

Summing exponentially-decaying oscillations

The things above all work using Gaussian-windowed oscillations, but while a real sinc decays as $1/x$, the Gaussian decays as $\exp(-x^2)$, which is a lot faster. In between, we have exponentially-decaying oscillations, such as those proceeding from the feedback comb filter

$$y(t) = x(t) - ky(t-s)$$

where $0 < k < 1$. Maybe such a decay could produce one of the tails of the sinc filter efficiently, with a slower decay than the Gaussian and potentially a much sharper onset, although you might want to tone that down a bit in order to reduce discontinuities.

A feedforward-comb trick similar to the trick used to get Gaussian-windowed oscillation can cut this exponential off after some number n of oscillations by composing with a filter something like this:

$$y(t) = x(t) - k^{2n}x(t-2ns)$$

This will inevitably have some rounding error, but the rounding error will decay exponentially thereafter, so it shouldn't be a major concern in this application. This allows you to put together the tail out of a piecewise-exponential decaying oscillation, although you can't derive each piece from the same exponential the way you could with the Gaussians.

You might think to just use $1/k$ for the other tail, but in that case the inevitable rounding error from the cutoff would grow exponentially out of control. A better approach, when it's feasible, is bidirectional filtering --- not in the filtfilt way, where the two unidirectional filters are *composed*, but where the results of the two unidirectional filters applied to the same input signal are *added*.

This bidirectional approach might give adequate results with a single exponential tail in each direction, with the first impulse in the oscillation being a quarter-cycle away from the origin. This would be two subtractions and two multiplications per sample, plus whatever low-pass nonsense you need to do to get rid of the third and higher harmonics.

Summing flat oscillation plateaus

The procedure mentioned earlier for generating a Gaussian-windowed oscillation consists of convolving three or more rectangular-windowed oscillations. But another possibility is to *add* scaled rectangular-windowed oscillations; for example, 64 oscillations scaled by 1/64, 32 oscillations scaled by 1/64, 16 oscillations scaled by 1/32, 8 oscillations scaled by 1/16, 4 oscillations scaled by 1/8, 2 oscillations scaled by 1/4, and one oscillation scaled by 1/2. This gives you a sort of stepped-pyramid approximation of the sinc shape, which you can then perhaps smooth a bit by convolving it with one or more windowed oscillations at the same frequency.

This stepped pyramid requires a *single* oscillator (one subtraction), seven subtractions to get the steps, then six additions (with binary scale factors) to get each side of the sinc from them, for a total of 20 operations per sample. Several more operations might be needed to add the central lobe and smooth the steps.

(Maybe triangular-windowed oscillations would be a better basis function, at least for the final tail; or you could tag on an exponential decay.)

Not worrying much about high harmonics

Any departure from the perfect sinc shape in the resulting filter's impulse response represents some kind of departure in the frequency response from the desired boxcar --- either in passband flatness or in some nonzero response in the stopband. But some kinds of departure are less harmful than others; for example, the comb filters we're using here have not one passband but an infinite number, spaced at odd harmonics of the normal passband. In some sense this is an extreme departure from ideal behavior, but it's not a particularly bad one; unless the desired passband is very wide, the extra passbands are located far enough away that it's easy to filter them out adequately with fairly simple low-pass filtering.

By contrast, if you want a filter that passes 140 Hz to 150 Hz, and you instead get a filter that passes 140 Hz to 151 Hz, that extra hertz will be an extremely difficult error to remove. These sparse filters might actually be able to do a better job at this than conventional FIR and IIR filters, because they can afford to use much wider support, which means they can get much sharper frequency cutoffs.

Undertone filtering

Because comb filtering passes (either all or odd) harmonics just as strongly as the fundamental, you can compose combs at different frequencies to get a filter that passes the common multiples of those frequencies; for example, one third, one fifth, and one seventh of the desired frequency (35/105, 21/105, and 15/105), maybe with a feedforward comb to notch out any unwanted frequencies. This is

useful when the frequency you want is not close to a factor of your Nyquist frequency (or half the Nyquist frequency, in the negative-feedback case).

(An alternative in such cases is often to use spectral inversion.)

Topics

Handling Landsat 8 images in limited RAM with netpbm

Kragen Javier Sitaker, 2014-04-24 (4 minutes)

Landsat 8 images are now freely available, including the 15-meter panchromatic band that was new in the Landsat 7 ETM+ sensor. The thermal bands have lower resolution than in the L7 sensor, but whatevs.

An immediate problem is how to deal with the images in the Level 1 Data Product. They're 16-bit TIFFs with dozens to hundreds of megapixels; it turns out that, at least on my netbook, things like ImageMagick (`display` and `convert -sample` anyway) and the GIMP just do not manage to open them in a reasonable amount of RAM. netpbm seems to be able to come through here, successfully generating a thumbnail of a 225-megapixel image in only three minutes:

```
anytopnm LC82250842013110LGN01_B8.TIF | pnmscale -height=600 | \
    pnmtopng > small-pan.png
```

The results in a rather dim, but still 16-bit, image, with a maximum pixel value of 9007; a contrast autostretch with `pgmnorm` helps, but leaves the image proper rather low in contrast, because the black border pixels are so far from the image values. `pnmhisteq` results in a striking and highly legible grayscale.

In the thumbnail, Buenos Aires is 40x34+365+278 out of the 624x600 image (found with `display small-pan.png`, then Image Edit → Region of Interest). The original image is 15201x14621, according to `anytopnm LC82250842013110LGN01_B8.TIF | head -2`. That means I should be able to extract a 974x829 image at (8892, 6774) to find the city, using `pamcut`:

```
time anytopnm LC82250842013110LGN01_B8.TIF | \
    pamcut -left 8892 -top 6774 -width 974 -height 829 | \
    pnmtopng > buenos-aires.png && \
    < buenos-aires.png anytopnm | \
    pnmhisteq | \
    pnmtopng > buenos-aires-stretched.png
```

It would be a lot more efficient to break these images up into compressed tiles of near the latency-bandwidth product of the disk drive, using `pamdice`, and mipmap them, rather than spending over a minute rereading the entire 400-megabyte GeoTIFF for every operation, but at least it's workable. The above took a little under 90 seconds, producing a striking image of most of the city (my RoI was a little too conservative) in `buenos-aires-stretched.png`. Every street and every plaza is clearly visible, but not every building. Using `pgmnorm` instead of `pnmhisteq` gives much better results, with large-scale patterns becoming visible. The resulting city map is only about 1.5MB in PNG form or 470kB in JPEG form.

It would probably be a big improvement to add chroma data from the other bands, but that's a little more work.

Now that it's so easy to get unlimited Landsat 8 scenes, we can quite reasonably make movies of construction and the like, albeit on a block-by-block basis rather than a building-by-building basis. That is, you'll be able to see which block construction is happening on, but not what shape the buildings are, unless they're humongous.

(If we figure the latency-bandwidth product is 500kB and that we need about 1.5 bytes per pixel, the tile size would be around 600×600; this particular scene would then be 25×26 tiles, and it would probably make sense to produce 3:1, 9:1, and 27:1 reductions, adding another 1+9+27=37 reduced-size tiles to the original 650; the total would be some 350MB. Divide by roughly two to account for the fact that the zero pixels added around the edges compress to almost nothing.)

Extracting bands 1, 2, and 3 for red, green, and blue, we have

```
for band in 1 2 3; do
    time anytopnm "LC82250842013110LGN01_B$band.TIF" |
    pamcut -left 4446 -top 3387 -width 487 -height 415 |
    pnmtopng > buenos-aires-$band.png
done
rgb3toppm <(anytopnm buenos-aires-3.png | pgmnorm) \
          <(anytopnm buenos-aires-2.png | pgmnorm) \
          <(anytopnm buenos-aires-1.png | pgmnorm) |
    pnmtopng > buenos-aires.rgb.png
```

This produces a somewhat legible color image of the same region as previously, but it's fairly unsaturated.

Hardware multiplication with square tables

Kragen Javier Sitaker, 2019-02-08 (updated 2019-07-09) (4 minutes)

If you can build a high-speed routing network in a small amount of silicon, you can build an extremely high-throughput multiplier for high-latency multiplies by using square tables.

$xy = ¼((x+y)^2 - (x-y)^2)$; for example, 579×414 is $¼((579+414)^2 - (579-414)^2) = ¼(993^2 - 165^2) = ¼(986049 - 27225) = ¼\ 958824 = 239706$. (See Multiplication with squares (p. 1983) for more on this.) This seems potentially interesting in the context of modern high-throughput computing, in which multipliers occupy a significant amount of silicon area and power consumption. Squaring a number can be done with a table lookup, which is relatively light on power consumption. The remaining addition and two subtractions can be done quite a bit more easily.

The difficulty, of course, is that a large table occupies a very great deal of silicon area. But perhaps all is not lost — we can share this large table among many concurrent multiplications, if they are latency-tolerant.

Consider, for example, a 32-stream 10-bit×10-bit multiplier built using this scheme. Each pair of 10-bit numbers entering the multiplier at one of 32 multiplier ports gets its sum and difference taken; these are sent into a mesh routing network to be squared, each tagged with an output port. The 1024-entry lookup table is split into 64 independently operating lookup tables of 16 entries each; on every cycle, each such lookup table receives a 10-bit input from the network along with the routing tag (or, occasionally, an idle notification), and in a single cycle places the 20-bit or 18-bit result and the routing tag onto a second mesh routing network. So, every cycle, we're doing 64 10-bit squarings. These squares make their way through the second routing network to output buffers, where they are paired up with their partner from the input and subtracted.

The queuing-theory bit is somewhat tricky in that it's totally plausible to do a bunch of multiplications by the same number or by similar numbers. Similar numbers can be broken up a bit by some kind of simple hash ($x \wedge x >> 5$, for example) so they don't all hit the same lookup-table shard, but some amount of replication is probably unavoidable to handle many multiplications by the same number. Alternatively, perhaps the original numbers themselves could serve as the routing tags, thus permitting the coalescence of multiple concurrent requests for the same number; this would require somehow duplicating the results on their way to the subtractors. Regardless, some amount of nondeterminism in performance is unavoidable with this scheme.

The routing network from the inputs to the multiplication table can probably consist of three layers of 16 4×4 17-bit crossbar switches with output buffers to wait on contention; similarly the routing network from the table to the output can probably consist of three layers of 16 27-bit crossbar switches.

Such a device could carry out 32 10×10-bit multiplication results

every cycle, with a typical latency of 8 to 11 clock cycles. The bulk of the silicon area is the 1024-entry 20-bit (or 18-bit) square table; the crossbars, adders, and subtractors should be relatively small by comparison. (Actually, is that bullshit? Is it possible that those crossbars are fucking huge, even though they don't contain many transistors, just because of the wires?) Scaling it up to, say, 16-bit × 16-bit multiplications would involve scaling the table up to a 65536-entry 32-bit table, which is 100 times larger; but, if split among a correspondingly larger number of independent table lookup units, this would perform 4096 16×16-bit multiplications every cycle, with a variable latency of 15 to 20 clock cycles. At 400MHz, it would provide 1.6 trillion low-precision multiplies per second.

If an electronic crossbar switch turns out to be infeasible, another possibility is optical free-space routing.

The Stretch book is truly alien

Kragen Javier Sitaker, 2018-11-27 (6 minutes)

Reading the 1962 book about Stretch. There are a lot of strange ideas and terminology in here.

"Edit" seems to be used in a sense I don't understand.

IBM, especially at that time, had a habit of plagiarizing other people's ideas, so it's hard to tell what's really new here; but Stretch was the first IBM computer, at least, to be pipelined, though this was called "virtual memory," predating the use of that term to mean swapping to disk.

The idea of a "program" solving a "problem" for a "sponsor" is pretty far from our current understanding. So, too, the justification of "multiprogramming" (also "time-sharing"): "it becomes economically practical for a person seated at a console to observe his program during execution and interrupt it while considering the next step", and also to "avoid delaying the calculator [!] for input-output".

The disk storage (intended for 250,000 words per second, though only half of that was achieved: 8 megabits per second, seek time 150 ms; the terms "DASD" and "fixed disk" do not appear) was considered to avoid the need for "very-high-speed magnetic tapes."

"On line" and "off line" also appear, in quotes, to describe different ways of entering input data: on directly connected devices, or using physically separate devices that produced magnetic tapes, "the fastest possible medium".

"To an increasing extent, bits in even a scientific computer represent things other than numerical quantities: elements of a program metalanguage, alphabetic material, representations of graphs..."

A rather striking feature is that Stretch's memory, in 1961, had a 2.1-µs cycle time, which they considered rather slow (thus its 64-bit word size). Nowadays the main memory of my laptop (whose CPU uses a 64-bit word size) can produce bursts substantially faster than this, at close to 1 ns, but random accesses still cost it nearly 100 ns, which is only 21× faster.

Stretch could address 2^{18} words, but the first 32 words were its registers; I imagine this wasn't useful to user programs because of the memory-protection scheme explained below. Register 0 was the zero register, "a bottomless pit."

Memory protection was provided as follows: "The interpretation and execution of instructions is monitored to make sure that the effective addresses are within boundaries defined by two [address-]boundary registers."

Only floating-point math was bit-parallel; logical operations and fixed-point arithmetic were done by "the serial section" of "the arithmetic unit", which was not yet called the ALU (though "Instructions that combine bits by logical and, or, and exclusive or functions have been available in earlier computers."). This had the advantage that the operands didn't have to be word-aligned, or even byte-aligned, but could instead be at arbitrary bit offsets. "Byte-aligned" wouldn't have made any sense anyway — "The

number of bits used to encode individual characters may be varied. Thus a decimal digit may be compactly represented by a binary code of 4 bits, or it may be expanded to 6 or more bits when intermixed with alphabetic information."

It still had only a single accumulator (and 15 index registers) but the accumulator was two words, which I think means 128 bits! This despite extensive handwringing about how hard they worked to wring the most out of their slow memory (this was the reason for the pipelining, which prefetched).

The index registers were 64 bits wide even though memory addresses were only 24 bits ("A complete word-and-bit address forms a 24-bit number."). So they used the extra bits to count loop iterations and specify a "refill address" for reloading the register, and there's a "progressive indexing" mode "in which the index quantities may be advanced each time they are used".

Its indirect addressing mode was wild: "The term *indirect address* refers to an address that gives the location of another address. An indirect address may select an immediate address, a direct address, or yet another indirect address. Indirect addresses are obtained in the 7030 by the instruction LOAD VALUE EFFECTIVE, which places the effective address found at the specified memory location into an index register for indexing a subsequent instruction. Multiple-level indirect addressing is obtained when LOAD VALUE EFFECTIVE finds at the selected location another instruction LOAD VALUE EFFECTIVE which causes the indirect addressing process to be repeated."

The interrupt vector table was called "a table of fix-up instructions".

When talking about data formats for address arithmetic, the data formats shown are actually instruction word formats, suggesting that despite the ample index registers on the machine, self-modifying code was common.

One of the strange uses of "edit": "For example, a floating-point datum may be developed as a unit in a computation, its components then used in radix-conversion arithmetic, and the characters of the result finally used as units in editing for printing." I think maybe "edit" means "format" (although the Fortran statement is FORMAT, not EDIT.)

Aha, there's a definition: "A final class, *editing operations*, includes all operations in which data are transformed from one format to another, checked for consistency with a source format, or tested for controlling the course of the program." So "editing" includes comparisons for control flow!

The paradoxical complexity of computing the top N

Kragen Javier Sitaker, 2017-01-04 (7 minutes)

Comparison sorting is O(N log N) in the best case, using one of the standard sorts (mergesort, quicksort, heapsort, binary search trees, library sort, or a variant of one of these). In large datasets, the log N factor can reach 20 or 30, which represents a significant slowdown. But often people are comparison-sorting because they want the top M items: top 1, 10, 20, 30, or 100, say. Surprisingly, getting the top 100 items can be done in linear time (O(N)) using quickselect!

Quickselect is a version of quicksort that recurses only on one partition. If you have a million items, the first pass will examine all million of them; the second pass will examine, typically, half a million; the third pass typically a quarter million; and so on, until the 30th pass examines just one item. (I think there's a little bit of a fudge factor, as with quicksort, which uses 1.39 N log N comparisons on average; but I will ignore that for the moment.) This adds up to just under two million compares and half that many swaps.

When quickselect is done, each of the pivot elements it chose, including its final result, partitions the array into items smaller and larger than itself. So to get the top 100 elements, it is sufficient to invoke quickselect to select the 100th element, and then take the first 100 elements of the reordered array.

The paradoxical complexity of sorting the top N

This has a sort of paradoxical result. Suppose you have 256 elements and you want the top 64 of them. Quickselect can give you this top-64 result in about 512 comparisons and 256 swaps. But now if you want to comparison-sort *just those 64 elements*, so that you get the top 64 in order, you need 1.39 N log N comparisons, which is 534 comparisons, more than it took to find that top-quartile in the first place!

This gets worse as the problem size gets bigger, if we hold the quantile fixed. If you have four billion elements and you want the top quartile, you can get them in 8 billion compares, but fully sorting that top quartile will take you 42 billion compares, five times longer. At that scale, even the top eighth is faster to find than to sort fully once you find it.

Improving quickselect average-case time for extreme order statistics

Median-of-median is a way to improve quickselect's worst-case time (from quadratic to linear), but we can also improve the constant factor of the linear average-case time with one weird trick. Using a variant of the median-of-3 pivot approach, you can improve quickselect's linear-time average case by up to a factor of 2 by better pivot selection, especially when you're looking for a fairly extreme order statistic.

The improvement is limited to a factor of 2 because vanilla quickselect does less than 2 comparisons per element to start with, and computing an order statistic exactly will require examining each element at least once.

You do this by picking a first-step pivot that has a high probability of reducing the next step by as much as possible. For example, if you're looking for the 0.1% quantile of a billion items, you can sample 2000 candidate pivots and take, say, the 0.2% quantile from them (using about 4000 comparisons if you just use regular quickselect), which is very likely to partition the billion-item list into a very large list that does not contain the candidate item and a very small one (only about two million items) that does contain it. This reduces the problem size from the first step to the second step by a factor of 500 instead of a factor of 2, and so you will need on average only 1.004004 comparisons per element out of the billion rather than almost 2 comparisons per element.

This approach can, of course, be applied recursively, both in the pivot-selection step and on the reduced-size problem.

Also, since this approach depends on the position of the desired element within the reduced window, it may work to improve quickselect's performance significantly even for non-extreme order statistics. For example, if you're seeking the median, and your first-step pivot turns out to be very close to the median, then what was originally the median becomes an extreme order statistic in the first recursive call. Perhaps you're seeking the median of a million items, and your initial pivot turns out to be element #499000. Now the value you are seeking is element 1000 out of the 501000 you're selecting from in the next recursive call. With this approach, you can sample 500 or so candidate pivots, and probably manage to reduce your problem size down to about 2000 elements in the next step, ending up needing only about 1 506 000 comparisons (I think) rather than the nearly 2 million you would need with vanilla quickselect.

The expected improvement factor on any step is limited to about the square root of the number of elements. That's because finding a pivot to reduce the interval by some factor F is going to require selecting it from somewhere around F candidate pivots. (I've used 2F in the examples above; I don't know if 2 is the optimal factor.) But once you're examining more candidate pivots than the number of elements you expect to have remaining after partitioning with the pivot, you're not winning any more; you're losing.

I'm not sure what the optimal number of candidate pivots to consider is, and I'm also not sure about the optimal size of the range to try to consider. It seems like you'd want to have great assurance, generally, that your small range is big enough to include your target element in it, because otherwise you've just squandered an entire pass over the input data. As the desired order statistic wanders toward the median, though, the loss from such a miss diminishes, and the potential gain becomes smaller.

Coinductive keyboard

Kragen Javier Sitaker, 2016-07-30 (4 minutes)

The traditional way to scan a keyboard is with row and column lines which are connected through mechanical keyswitches. This runs into some trouble with bouncing and contact oxidation, as well as number of moving parts; a solution is to use variable capacitors instead, where pressing a key brings two pieces of foil close together, but not into contact, maybe squishing some plastic foam in between them or something. This prevents contact oxidation, since there is no contact to make sparks, and bouncing, since a small deviation in distance will produce only a small deviation in capacitance.

It still requires about $2\sqrt{N}$ wires for N keys, though. As an alternative, consider using selective inductive coupling instead of selective capacitive coupling: pushing a key pushes a ferromagnetic core through some coils of wire, greatly increasing the inductive coupling between those wires.

You could imagine, for example, using five "exciter" wires, each of which runs through 25 air-core coils, arranged in a 5×5 matrix. Each of these coils is physically near a coil on a "row" wire, which runs through the 5 coils on a row for this exciter wire and also the corresponding 5 coils on the corresponding row for each of the other 4 exciter wires, and a "column" coil, which has a corresponding column-wise arrangement. Normally, you have limited inductive coupling between the wires, but pressing a button inserts a ferrite core through all three coils, strongly coupling any AC signal on an exciter wire to a corresponding row and column wire. The signal is only weakly coupled to the other row and column wires. (A factor of 20 difference between coupling with and without the core should be easily achievable.)

In this cubic arrangement, 15 wires are adequate to scan a 125-key keyboard, while the traditional matrix arrangement would have needed 23.

But it's possible to go further with more coils: instead of coupling just three coils, let the inserted core couple, for example, five coils. An exciter current on one of three exciter wires can produce a current on four other wires, each chosen from a set of three; in this case, we have 15 wires scanning 243 keys.

It's also possible to go further with coil polarity: each coil can be wound in either of two different directions, resulting in an induced voltage with a phase difference from the exciter voltage. You could maybe also use different numbers of turns on different keys, but that seems like it is going to start to be flaky when the core is incompletely inserted. (That's the same reason to prefer using, say, five wires to scan five columns, rather than four.)

There's no reason, then, to leave some of the sense wires inactive on each keystroke. You could run each sense wire through each key with a coil in one or the other direction; for example, you could have three exciter wires which each excite 32 keys, plus five sense wires which run through all 96 keys, with a coil in one or the other direction, producing a unique 5-bit binary code for each of the 32 keys for a given exciter wire. This gives you 96 keys with only 8

wires. Since the codes are balanced, the stray inductive couplings through keys that are not being pressed should mostly cancel out.

That logic brings us inexorably to preferring only a single exciter wire, which brings us finally to 128 keys using a single exciter wire and 7 sense wires: 8 wires for 128 keys, a great improvement over 23.

If the sliding core slides through a hole in a high-permeability member that curves around to behind the coils, then it can close a magnetic circuit, reducing the total circuit reluctance by orders of magnitude, thus increasing the inductive coupling dramatically.

This keyboard design has the great advantage for klutzes like me that it contains no uninsulated electrical conductors and no tight clearances, so it should work perfectly well even if it's, for example, immersed in salt water or filled with Coca-Cola.

More thoughts on powerful primitives for simplified computer systems architecture

Kragen Javier Sitaker, 2015-08-18 (updated 2015-11-02) (165 minutes)

XXX transactions are useful for reactive programming because they prevent ordering problems?

In 2012 I wrote about "choosing powerful primitives for a simplified computing system", including as examples gzip and other things, and speculating about automated cache management. Well, since then, automated cache management has kind of gone mainstream in the form of "reactive programming" frameworks. What other things could drastically simplify our software systems?

My focus here is on what kinds of mechanism could support a wide variety of applications, eliminating complexity from the application code, without having to write and maintain separate, specialized versions of that mechanism in different parts of your computing system; and by so doing, make the system less complex, more approachable, and more adaptable to new situations. I'm looking for candidate components with a high "strength-to-weight ratio", in the sense that their internal complexity is low compared to the functionality they provide, and also a low "surface-to-volume ratio", in the sense that they impose very little extra complexity on applications that use them, compared to their own internal complexity, so the application is simplified greatly by not containing its own reimplementation of their functionality.

In particular, such mechanisms need to be acceptably efficient across their wide range of uses, rather than performance-optimized for one particular use. If this isn't the case, experience has shown that people will write customized versions of them for their particular application, rather than investing effort in further optimizing the general-purpose mechanism. The result is that specialized mechanisms proliferate, overall system complexity explodes without a corresponding increase in power, composability suffers, and none of the specialized mechanisms receives enough attention to make it efficient. This should sound familiar, since this is the tarpit we're in today.

I believe this matters for a few different reasons.

One is that, as Dan Ingalls says, to be a medium for personal expression, a system needs to be comprehensible by a single person. And this is the vision that has motivated Smalltalk, the VPRI STEPS project, and Chuck Moore's FORTH work. It unfortunately suffers a bit from mostly appealing to very independent-minded people.

A second reason is that this poor architecture results in decreasing returns to software work, which matters economically at a societal level. People's day-to-day lives are largely driven by what we might call economic factors: do you have to spend your time washing clothes by hand and sewing them up, or can you use machinery to make that easy? Is your house warm? Do you have running hot water and safe drinking water? What do you have to do to make a

living — does it compromise your health or moral integrity? XXX

A third reason is that software freedom is fundamental to individual human rights, to collective economic justice, and to individual economic justice in the 21st century, but the freedom to study and modify software you can't understand is only theoretical, and the power of that freedom is multiplied by the modifications and enhancements you actually can manage to make in your limited time.

Software freedom is fundamental to individual human rights because whoever controls the software controlling your cellphone, your pacemaker, your hearing aid. They can see photos of your genitals, if you ever take them, and from Snowden's revelations we know that some of them pass them around the office for laughs. They can trick you into thinking your friends hate you, that your husband is cheating on you, that the Jews faked the Holocaust. They can judge you based on what you read or who you're friends with, and secretly tell other people about those judgements, and those other people may be the police. Once you have the pacemaker, they can kill you, and nobody will ever know it wasn't natural.

Software freedom is fundamental to collective economic justice because it allows every country or group of people to prosper independently of the rest. Over time, we can expect the strong standardizing tendency of software to standardize on a small number of operating systems, a small number of web browsers, and so on. Without software freedom, that will result in enormous economic returns accruing to the vendors of the dominant software, which can then extend their monopoly power into new areas of software: perhaps Apple, Microsoft, Google, Facebook, and Amazon, but just as likely, a few new companies that you haven't heard of yet, probably in China.

Software freedom allows everyone to participate in production, while proprietary software moves us toward a world where, if you don't live in Seattle, Shenzhen, or California, you can only consume, or at best source "user-generated content", not produce or participate as an equal.

Many governments have responded to this harsh reality by trying to pretend that software is just one industry among many, and they can import software just as they import oil, while focusing their domestic industry on shipbuilding or steel production or something. But the truth is that your shipyards, your ships, and your steel mills will get most of their value from software — if not in 2015, then surely by 2035.

Software freedom is fundamental to individual economic justice because unless you were born to wealth, your other choices are joining the startup lottery, where almost all the participants end up worse off than if they hadn't played, and being employed, where almost all of the value you produce will be skimmed off by your employer. By contrast, when you write free software, nobody can ever take it away from you. In fact, even when *other people* write free software, nobody can ever take it away from you. (By contrast, when other people write free-in-theory-but-not-in-practice software, it can totally be taken away from you. Like if the maintainer decides to stop supporting your platform, or bundle some kind of adware you hate.)

Any economically productive activity that you can do with

software becomes more productive when there is more free software out there for you to draw on.

The World-Wide Web, for apps

The Web actually provides us with some tremendously powerful primitives that simplify a lot of applications, even as they make others more complicated. Out of the box, a webapp gets:

• a gentle learning path;
• a typographic layout engine with a relatively powerful box model and excellent Unicode support;
• image and sound decoding and caching;
• alpha compositing;
• a hierarchical UI event system;
• some degree of incremental relayout;
• a high-level reflective prototype-oriented OO language with closures and reasonably efficient implementations: JS;
• sufficient robustness in the event-driven programming environment that your app will probably still mostly work even if some features are throwing exceptions;
• a vector drawing library that's even easier to write in than PostScript, which is saying a lot: SVG;
• a compound document system where you can OLEishly embed one document in another, including mutually untrusting documents;
• a mobile-code system that downloads your webapp once and updates it on the client only when it's changed, and potentially only the parts that have changed (if you configure your server headers correctly or if you use a cache manifest);
• by far the best debugging tools I've ever used anywhere: Firebug and the Firebug clone that comes with WebKit;
• serialization of simple data for free with JSON;
• simple persistence (e.g. using localStorage);
• a SQL engine (although that's been deprecated);
• sending some text over the network to a server in a single line of code;
• network protocols that provide you fault-tolerance by default as long as you obey the REST constraints;
• transparent network protocol compression;
• a global namespace for remote objects that encompasses the actual physical globe, not just your program's "global" namespace.

I'm not sure that these primitives have a great "strength-to-weight ratio", in the sense of providing a lot of power for low implementation complexity, or for that matter even low interface complexity, but the difference between a JS webapp and, say, a Tk program to do the same thing is pretty big.

Consider this "microblogging" program in ksh, like a non-networked version of Twitter:

```
while read line; do
    ENTRY="$(date +'%d-%m %H:%M:%S'): $line" echo "$ENTRY" >> microb.log
    clear; cat microb.log; echo -n "sup-> "
done
```

Here's an equivalent in DHTML, with has better text layout,

scrolling, search, navigation, and editing, and automatically live-upgrades itself to the latest version of the code after each post, although it's a bit more code and I think it runs slower:

```
<script>var ls = localStorage, d = document;
function add(name, html) { ls[name] = (ls[name] || '') + html }
function esc(text) {return text.replace(/&/g,'&amp;').replace(/</g,'&lt;');}
d.write(ls['microblog'] || '');</script>
<form onsubmit="add('microblog',new Date+': '+esc(this.line.value)+'<br>')">
<input name=line autofocus>
```

If you take out the HTML-escaping code, the DHTML version also has rich text.

Going back to how we would do things in 1995, a Tcl/Tk version of the same thing would have to take care of a lot of these things by hand. I started writing it, in the same ridiculously compressed style as above:

```
#!/usr/bin/wish -f
text .blog; label .sup -text sup; entry .e -textvariable e
pack .blog -side top -fill both -expand true
pack .sup -side left -fill x; pack .e -side left -fill x -expand true
bind .e <Return> blog; proc blog {} {
    global e; .blog insert end "$e\n"; set f [open microb.log w]
    puts $f [.blog get 1.0 end]; close $f; set e ""
}
```

XXX include full version

This is still lacking a bunch of things, even compared to the shell version, including reading the microblog file at startup, not losing data in machine crashes, making the textarea itself non-editable (?), adding the dates, focusing the text entry, not being an ugly gray, and so on. And this isn't even hitting any of the web's strong points, like compound documents, networking, garbage collection, or SVG.

If you wanted to replace the web as an application platform --- which is certainly what both Apple and Google are trying to do with their respective smartphone operating systems, but also the intent of platforms like VPRI's STEPS --- you need to understand the strengths of the platform as well as its excessive complexity. Some of those strengths are in fact powerful primitives, like those mentioned above. Others are more subtle and in fact work against the VPRI vision of an overall system that is as simple as possible, such as the Principle of Least Power, the gentle learning path, and View Source.

Other candidates

What other powerful primitives might have a high "strength-to-weight ratio" in a computing system, in the sense of enabling us to build much more powerful systems with very small amounts of code?

Content-addressable blob stores for persistent, self-certifying trees

Traditional Unix-like and MS-DOS-like filesystems provide expandable virtual disks: "files," which are mutable sequences of

bytes, supporting random-access read and write, plus appending data at the end. Instead, a variety of more recent filesystems and related systems either do not permit modification of existing "files" at all, or only allow appending to them, and identify stored blobs by using a one-way hash of their contents; name-to-blob-hash mappings are typically stored in another blob. Systems using one or another variant of this design include the Xanadu Ent, WAFL, Venti, GoogleFS, FreeNet, Wax, IPFS, Tahoe-LAFS, Bup, Jumprope, Nix/Guix, git-annex, and most importantly, Git and BitTorrent.

This permits very efficient comparison of filesystem trees and storage of slightly-modified versions of existing trees, since deep equality can be performed by an inexpensive shallow equality test, just as with hash-consed in-memory persistent data structures.

IPFS's author calls this the "Merkle DAG" model: parent nodes link to their child nodes with secure hashes, just as in a Merkle tree, without the linearity requirement of the tree.

The one-way-hash "names" are "self-certifying" in the sense that the mapping from the name to the blob contents can be checked by the reader, so they do not need to rely on the storage provider. Another kind of "self-certifying name" consists of a public key or a one-way hash of one, although there are tricky issues related to this.

Avery Pennarun (the author of Bup) wrote a very compelling advocacy of the position that content-hash-addressable blob stores are such a powerful technology that they invert much of our conventional wisdom about data storage. XXX link it!

Could you replace most or all of these blob stores with a single blob store? Could you provide a single blob-store interface to write your application software on top of, allowing you to run it against any of these blob stores? (Git-annex already kind of contains such a thing internally.)

Distributed hash tables

These are worldwide key-value stores with some degree of resiliency against malicious participants, and much of the yearly [what is that thing where Boon Thau Loo published so many papers called? IPTPS?] workshops focused on versions of these. In concert with self-certifying names, they allow distributed blob stores to have new blobs added to them, and they allow participants with a common interest to exchange rendezvous information without depending on a central server.

The earliest DHT work was "consistent hashing" at Akamai, but later systems include Chord and Kademlia. BitTorrent uses a DHT to bootstrap "trackerless" torrents.

DHTs are mostly only used for decentralized systems (that is, systems to which it is infeasible for any party to deny access to any other party), but their failure properties in the face of malicious participants are not well understood.

Is it possible to use a single DHT implementation for many different applications?

Persistent data structures

Unfortunately, "persistent" has acquired two confusingly similar and conflicting meanings, both of which have "ephemeral" as their antonym, because most people are illiterate troglodytes who never

venture outside their cave to see what's happening in the larger world, so they invent confusingly conflicting terminology. In this case, I'm not talking about your program's data surviving restarting it or restarting your computer (because the data is on disk or something), but rather data structures which might be in volatile RAM, but which you don't modify. Instead, you make new, modified versions of them. If you use efficient persistent data structures, most of the structure will be shared. This is the kind of "persistence" that pertains to most of the standard data structures in, say, Clojure.

This pretty much requires a garbage collector or its moral equivalent, like reference counting or a linear type system. RAII is not going to help you out here. This also means you have no idea why your program is using so much RAM.

There are a few different advantages to persistent data structures over their "ephemeral" cousins, the kind where you modify them in place. One is that they're less bug-prone: no more aliasing bugs where you passed a dict to some function and then to another function and then the first function modified it. Another is that you get "undo" without any extra complexity in your code. This is pretty important if you're, say, trying to do software transactional memory (see below) or backtracking. A third is that if you actually are using a bunch of different versions of a data structure (like in the backtracking case) they'll probably use *less* memory. A fourth is that you can access them without locking, and replicate them without fear (whether across the CPU caches of your different cores or halfway around the world) so they can give you better efficiency. (They're a crucial enabling technology for CRDTs; see below.) A fifth somewhat subtle performance point is that, if you *are* using a garbage collector, they prevent you from wasting CPU time on its write barrier, while mutable data structures have you beating on the write barrier all the time.

I mentioned above that an immutable blob store is in a sense a store for persistent data structures. Hopefully that is clearer now.

"Hash consing" is a technique applicable only to persistent data structures: when asked to create a given data structure, you hash it to see if it already exists, and if so, return a pointer to the existing instance rather than making a new copy. This allows you to perform deep-equality testing in constant (and small) time. Content-hash-addressed blob stores provide this feature, but only if you are careful not to include any extraneous data.

Clojure's standard library already includes a wide variety of persistent in-RAM data structures that are simple to use and useful to many applications. Could these be abstracted so that the same code also supports distributed and blob-store cases?

Pub-sub

Publish-and-subscribe systems, also known as event-based integration systems or event buses, allow you to connect together very-loosely-coupled subsystems with real-time notification. These are universal in financial institutions, but are also used in systems at a variety of scales to reduce coupling between modules.

Typically, when a publisher publishes an event on a topic, all the subscribers to that topic receive a copy of the event, shortly afterward or possibly not at all. The publisher is not informed of the success or

failure, and does not know how many subscribers exist.

The use of this technique in user interface programming goes back at least to MVC in the 1970s, where the model would notify all of its views that it had changed and they might need to redraw.

As a current and local example, when I save this text file in my editor, the kernel sends an inotify notification to any processes that have registered to receive notifications for this file; this can trigger reindexing it in a full-text-search engine, updating a filesystem browser window, or output of extra lines from tail -F. And of course group chat systems like IRC, Slack, and WhatsApp are a very direct application of pub-sub; and D-BUS is the center of a modern Linux desktop, for better or worse, mostly worse.

Usually, these systems are capable of losing messages, because the desirable decoupling they provide between subscriber and publisher prevents them from applying backpressure to slow down a publisher who is publishing messages faster than some subscriber can process them. (It would, after all, degrade service to all the other subscribers as well.) Lampson's Hint that a system must shed load to keep functioning in the case of overload constrains the overall system to lose messages in this case; typically this is done by discarding extra messages at an event-bus-providing server and possibly notifying the subscriber that messages have been lost. In cases where the messages are being used for cache invalidation, recovery typically involves an expensive re-replication of state.

(Content-addressable blob stores can make re-replication much less expensive! So can rolling hashes, mentioned next.)

One particularly simple way to solve that particular problem is to make each subscription one-shot: to receive another message, you must renew your subscription.

Windowing systems almost universally support some kind of pub-sub notification, though sometimes synchronous and even with a reply capability built in.

Could we replace the wide variety of pub-sub mechanisms in use, often intertwined with a horrific amount of application-specific policy, with one or a few pub-sub mechanisms?

Rolling hashes, or “the rsync algorithm”

Rsync efficiently discovers duplicate file chunks between two replicas of a file, even in the face of insertions and deletions, by hashing one replica of the file by aligned blocks, then computing a "sliding" or "rolling" hash over all possible blocksize-sized blocks in the other replica, whatever their alignment or overlap with one another. This allows it, like magic, to transmit only the missing data over a (presumably slow) connection, despite not being able to directly compare the two versions of the file.

This same approach is used by rdiff-backup to efficiently find a small delta to apply to a potentially large file, as well as by bup (for a similar purpose), zsync (a replacement for rsync that precomputes the block hashes on the server side and therefore requires no run-time computation on the server side, permitting efficient synchronization from a dumb blob store), Zbackup (an alternative to bup), ssdeep for computing and recognizing malware signatures, Jigdo, and Jumprope.

Could we support all of these rolling-hash-based applications with a single distributed data structure?

Backtracking or nondeterminism

From the depths of the 1970s, Prolog and SNOBOL come at thee! Nondeterministic programming is a lot like normal programming, except that parts of your program can "fail", and then if you've provided an alternative path, they will take it. The most everyday version of this is the regular expression:

```
decode_pattern = re.compile("(.{11}) (\\d+)<([^>]*)>(\\d+)\n")
```

This example, taken from a project I'm working on called Gab, matches lines like `m0oTzNujJpx 6<I=EInw>6\n`.

If you're not familiar with regular expressions, the "\d+" means "look for as many digits as possible without making the pattern fail". If the pattern fails afterwards, the "\d+" will try matching fewer and fewer digits, until it can't match any, at which point it will itself fail.

In one sense, this particular regexp is not a particularly great example because it's carefully written to be deterministic: it can never backtrack and then succeed. If we were to replace the "[^>]" *with* ".", so that it could match any string at all and not just a string that doesn't contain the ">" symbol, then it would start by matching to the end of the line, then fail since it didn't find a ">" there, and backtrack until it did find one. In another sense, this is a fantastic example of how, in practice, we work very hard to keep the poor performance of constant backtracking under control when we use nondeterministic constructs.

Nondeterminism implemented by backtracking is fantastic for parsing: you write down a program that could *generate* the language you're trying to parse, and use nondeterminism to "execute it backwards": try all the possible paths of execution until you find one, or the one, that generated the string you're parsing. PEGs, which are the most interesting advance in parsing algorithms in a decade or two, have a very simple semantics in terms of backtracking. The "packrat" PEG-parsing algorithm guarantees linear-time parsing by memoizing partial parsing results.

Database queries are easily conceptualized as nondeterministic programs. `SELECT FOO.A, BAR.B FROM FOO, BAR WHERE FOO.C = BAR.C AND BAR.D > 10` has a very simple interpretation as a nondeterministic program.

The everyday "diff" is also easily conceptualized as a nondeterministic program, but in this case it isn't sufficient to find *some possible* set of edits to get from the old version to the new version; we want *the smallest* or *nearly the smallest* set of edits. And the standard quadratic dynamic-programming LCS algorithm to solve it can be understood as a way to tame the exponential blowup of choices with memoization (see below).

There are a large number of different ways to rein in the exponential complexity blowup that seems inherent to nondeterministic programming, mostly specific to one or another domain. Packrat parsing uses memoization, limited context, and implicit limits on backtracking; practical Prolog programs use cut; Datalog uses stratified resolution, which is a lot like memoization; truth-maintenance systems note the proximate causes of failures; SQL systems use indices and hash and sort-merge joins; parsing systems in general use lookahead; regular-expression engines sometimes use DFA compilation, Boyer-Moore search for constant strings, and tables of the locations of improbable bytes in the string,

and can also use suffix-table indices (see below); and so on. It would be very useful to have a unified framework that avoids all this duplication of mechanism, and moreover can be applied to make nondeterministic execution in new domains reasonably efficient without needing to invent another special-case hack.

Might such a general efficient nondeterministic-computing algorithm exist?

Memoization

Several of the wild exponential nondeterministic domains are tamed by memoization; in the Packrat case, all the way down to linear time. (You could also view the lazily-constructed DFA approach to regexps as being memoization to get linear time.) Memoization is storing the arguments and return value to a function in a "memo table" so that they can be returned next time without recomputing the function. At the best of times, it magically makes your program go faster, sometimes astronomically faster in the presence of recursion. It is a kind of computation caching, and it's also central to the Self-Adjusting Computation paradigm of incremental computation that I'll mention later.

Memoization in practice can be tricky to win at, due to both false misses and false hits in the memo table, and also for efficiency reasons.

False misses occur because the function is being invoked with data that it does not care about, which is not always obvious; perhaps it depends not on the exact value of some numeric argument, for example, but only on the number of digits in it. This can be fixed by dividing the function into two functions, one of which reduces the input data to the necessary, but this modification seems artificial without the context of memoization.

False hits occur because some data not considered for the memo-table lookup affects the return value of the function, or because the function has some other effect. If the function has arguments that refer to some mutable data structure, mutating that data structure between calls to it may affect its results such that you wouldn't want to reuse the memoized result.

Efficiency is tricky for a variety of reasons. If the function is a thin wrapper around some other function, memoizing one or the other of them will probably give you the benefit of memoizing both of them, at half the cost. Looking up the arguments in the memo table can be expensive if the arguments are large data structures and you aren't using hash consing. If the arguments are mutable, you may have to copy them. The memo table can use up a lot of memory. If the function is rarely or never called twice with the same arguments, memoizing it will only make it slower.

Under some circumstances it may make sense to share a memo table across runs of a program or even across a whole distributed system. Indeed, this is a major function of build systems like `make` and `ccache`, but it could potentially be useful for smaller computations as well. I read a paper about using a precomputed distributed memo table of optimizations to enable absurdly aggressive compiler optimizations, for example.

Could we provide generally useful memoization with one or a few memoization mechanisms, orthogonal to rather than mixed into the

code being memoized?

Memoization is closely related to deterministic rebuilding (see below).

Monads

There are already too many tutorials on what monads are, so I would not try to explain, even if I knew. I just want to point out that sometimes you can write a function with one monad in mind (lists, say) and then run it in another one (for example, backtracking, although in a lazy language there may not be so much difference).

How often do we write code that is unnecessarily coupled to a single monad when it could instead be reusable across different monads?

Constraint solvers and logic programming (like SQL, but more so)

I think I mentioned this in my original post (XXX did I?): SAT and SMT solvers are now powerful enough to replace a fairly wide variety of custom code in things like compiler optimization. Maybe they could be the unifying approach to nondeterminism that I was saying was needed! I don't know enough about them, though.

They are also a crucial enabling technology for formal methods: you can use them to find test cases that will break your program, or prove that there are no such test cases.

Unfortunately, I have no experience with SAT or SMT solvers, so this is very speculative!

How widely can we apply SMT solvers to simplify our software? What's the simplest SMT solver that's efficient enough to be useful in common cases?

Truth maintenance systems, due to Stallman and Sussman as refined by Doyle, are a kind of nondeterministic constraint solver that notes what sets of assumptions have led to inevitable constraint violations (through a kind of relevancy logic), improving the performance of the search by large exponential factors by cutting off nonviable search branches early.

This is a key aspect of modern SAT and SMT solvers.

Prolog was the first logic programming language, introducing nondeterministic programming, and can be viewed as a kind of constraint solver. It led to a lot of excitement in the 1970s and early 1980s as a general declarative system, but practical Prolog programs have to intersperse evaluation-strategy information rather intimately with declarative information in order to achieve usable levels of efficiency. Consequently, Prolog and similar systems such as KL1 failed to fulfill the high hopes many had had for it, and in particular caused the failure of the Japanese Fifth Generation Computing Systems project, resulting in part in Japan's continued failure of development in the software field.

Will Byrd and his colleagues have been working on a new family of logic programming languages named Kanren, whose smallest member, μKanren, from 2013, is 39 lines of Scheme, but even miniKanren is only 265 lines. A version of miniKanren has been incorporated into Clojure's standard library under the name "core.logic". miniKanren's constraint solving is powerful enough to automatically enumerate, for example, quines or programs that

produce a particular output, and there is a theorem prover written in a variant called αKanren which can not only search for a proof for a given theorem, but also the theorems that can be proved from a given set of postulates, including theorems matching a particular pattern.

As the old miniKanren page explains:

> KANREN is a declarative logic programming system with first-class relations, embedded in a pure functional subset of Scheme. The system has a set-theoretical semantics, true unions, fair scheduling, first-class relations, lexically-scoped logical variables, depth-first and iterative deepening strategies. The system achieves high performance and expressivity without cuts.

PrecoSAT, Armin Biere's SAT solver, apparently was a competitive-performance SAT solver in 2010; it is only about 5300 lines of C++.

Array languages like APL

In APL, I can write the following:

```
D ← A + B × C
```

and it can correspond to any of the following in C:

```
D = A + B * C;
for (i = 0; i < n; i++) D[i] = A + B * C[i];
for (i = 0; i < n; i++) D[i] = A + B[i] * C[i];
for (i = 0; i < n; i++) D[i] = A + B[i] * C;
for (i = 0; i < n; i++) D[i] = A[i] + B[i] * C;
for (i = 0; i < n; i++) D[i] = A[i] + B[i] * C[i];
for (i = 0; i < n; i++) D[i] = A[i] + B * C[i];
for (i = 0; i < n; i++) D[i] = A[i] + B * C;
for (i = 0; i < n; i++) for (j = 0; j < m; j++) D[i][j] = A + B * C[i][j];
for (i = 0; i < n; i++) for (j = 0; j < m; j++) D[i][j] = A + B[i] * C[i][j];
```

and so on. That is, not only does the APL code avoid writing the loop out explicitly; it *abstracts over whether there's a loop at all*, as well as how many levels of loop there are, allowing you to use the same code in the loop case and in the loopless case.

In many cases in C, we would actually write something like this instead:

```
int D(int A, int C) {
    return A + B * C;
}
```

perhaps using a global constant B, in which case the APL has saved us the overhead of a function definition --- not only syntactic, but also mental. Note that if B stops being a constant, we need to modify the argument list.

Given how often we find that something we thought was a constant is in fact a variable, this seems like a potentially very useful decoupling.

Of course, vector languages like APL, Octave, and R are in some sense very much stuck in the 1960s: you have integer array indices all over the place, with no safeguard to keep you from accidentally indexing a nonsensical array with them; no useful garbage collection of indices is possible; and accidental performance bugs are ubiquitous.

Note also that APL is not capable of interpreting `D ← A + B × C` as the following:

```
for (i = 0; i < n; i++) for (j = 0; j < m; j++) D[i][j] = A + B[i] * C[j];
```

--- a limitation which is, to me, a direct consequence of the unprincipled and undisciplined hot integer-index action ubiquitous in array languages. If the earlier-mentioned varying interpretations are in fact valuable, this one seems certain to be valuable as well. But APL requires us to explicitly call it out as `D ← A + B ∘.× C`, since otherwise it has no way of knowing that the indices of B and C are semantically orthogonal, unless they happen to be of different cardinalities, in which case it barfs.

Despite this, it is common for a function written with Python scalars in mind to work correctly elementwise on parallel Numpy vectors, or one written for vectors to work correctly on matrices.

I feel that there is a very close connection between these vector-valued variables and the table-valued variables of SQL, or the variables in backtracking languages like Prolog which may have some arbitrary collection of values during a single repeatedly-backtracking invocation of a predicate (or function, if you're not in Prolog). Each of these unusual semantics allows a single statement to be polysemically interpreted as an operation over an arbitrary-sized manifold, or just a single point on that manifold, according to context.

Array languages explicitly expose parallelism that is implicit in other languages, and they directly provide operations such as reduction and scan which have nonobviously parallel algorithms available. This has driven efforts to distribute array-language expression evaluation across clusters and to vectorize it on GPUs and using SIMD instructions.

Despite all this, array languages have serious obstacles in their way: their effective lack of type-safety makes it difficult for them to provide useful error messages, or often any error message rather than a numerically incorrect answer; their unprincipled nature often converts programming in them into puzzle-solving, and limits the dimensional decoupling that is achieved in practice; and their potential for brevity is a seductive but fatal temptation. To use them effectively, you more or less have to represent your data with parallel arrays, and those are unfashionable nowadays in part because of the lack of type-safety mentioned above, but also due to ever-present consistency bugs under update and clumsy support for dynamic and local allocation.

(I have an unfinished essay coming up where I compare and contrast the dominant memory models of programming languages, which conveniently all can be identified with one or another programming language from the 1950s: FORTRAN's parallel arrays, COBOL's nested records, and Lisp's object graphs. Array languages are firmly in the FORTRAN camp, although Numpy has been adding record types.)

Is there a formulation of array languages that would be broadly useful to many different applications, including exposing hardware parallelism in an easy-to-use form, without compromising the

comprehensibility of the application code?

Probabilistic programming systems

We can treat parsing by nondeterministic backtracking as attempting to simulate the execution of a program that could have generated the string we are trying to parse, conditional on the actual contents of the string --- we backtrack when the output conflicts with an observation. Probabilistic programming systems are a generalization of this paradigm, or from the other side, a generalization of hidden Markov models: we begin with a prior probability distribution in the variables that we are trying to estimate, and we update it according to observations of the actual facts.

A recent paper in the area by Kulkarni improves the state of the art in certain difficult computer vision problems, and matches it in others, by estimating the probability distribution in a simple probabilistic image-generation program: https://mrkulk.github.io/www_cvpr15/1999.pdf

There are a number of probabilistic programming languages now available, but I've never tried any of them. Could you use some kind of probabilistic computing system to replace backtracking nondeterminism in general? Does it have a hope of being efficient? (This seems to be what Oleg Kiselyov and Yukiyoshi Kameyama did by implementing a logic-programming system using Oleg's probabilistic-programming system Hansei, in their paper "Rethinking Prolog".)

Could you avoid coding the Viterbi algorithm for HMMs?

miniKanren (see above, also written by Oleg, among others) has been extended to probabilistic logic programming as probKanren, using Markov Chain Monte Carlo evaluation.

Incremental or self-adjusting computation

Umut Acar's self-adjusting computation algorithm is a mechanical transformation you can apply to a batch algorithm to get an incremental algorithm (one which, given a set of changes in its inputs, propagates them to changes in its outputs) that is in many cases optimally asymptotically efficient. He uses ubiquitous memoization of a CPS-transformed version of the program, I think with hash consing, to do this, and uses a "virtual clock" to ensure that side effects do not invalidate the memoization when re-executing functions whose inputs have changed. (I think. I haven't managed to finish his dissertation yet.)

That is, the idea is that you run the transformed algorithm once to get its output, and then to update the output for a changed input, you re-execute only the parts of the program that are affected by the changed input. He's demonstrated speedups over the raw batch algorithm of several orders of magnitude, in exchange for a slowdown of a factor of 5 or so while running the trace of the initial execution.

Hammer has been extending this work, and Jane Street recently published their implementation of SAC for OCaml: https://blogs.janestreet.com/introducing-incremental/

This is a very interesting kind of decoupling: your code is decoupled from whether it is being used to compute the entire output or only a change to it. This is potentially very useful not only for efficiency but also for debugging ("What parts of the program would

change their results if this input changed?", leading to "What part of the input affected this part of the output?") and for dynamic program dataflow analysis in general. You could imagine using such an execution trace to replace a scalar input with a vector, as in the array-languages item above, and to rapidly provide feedback to optimization algorithms which want to know which input changes will improve their utility function.

Can we apply this kind of incrementalization to programs that were written without it in mind, as a compiler for nonstandard semantics? (I think that's been done!) Does it subsume backtracking, if the decisions taken at nondeterministic backtrack points are treated as input? Can we do all of this efficiently without using tens of gigabytes of RAM, perhaps by making more judicious choices of what to memoize?

Fully homomorphic encryption

A lot of effort has gone into developing very clever cryptographic protocols to protect parties from one another in ways that would not be needed if they were willing to rely on the integrity of a common "trusted entity", traditionally called "Trent", because any person or machine you nominate as Trent is in fact corruptible. As Szabo explains [XXX], FHE allows you to collectively create a "virtual Trent" that carries out any agreed-upon computation whose correctness and confidentiality all participating parties can verify.

That is, if you have a practical FHE protocol, that protocol would subsume essentially all cryptographic protocols, in theory.

The problem now is how to make FHE sufficiently efficient to be practical for anything.

Convergent replicated data types

Also known as "CRDTs".

Eventually-consistent databases have been a topic of some interest ever since some PARC work in the 1990s argued that ACID was wrong for many applications, although of course Lotus Notes was an eventually-consistent database since its inception in the early 1980s. Interest in them exploded after Eric Brewer's CAP conjecture (later theorem), which showed precisely how high the price of ACID was, and about half of the NoSQL fad, including the influential Amazon Dynamo paper, which I STILL haven't read, was an exploration of the eventually-consistent design space.

The problem is that with Notes, or Riak, or the git plumbing, the database doesn't reach consistency on its own. It just tells you that you have a conflict and you need to resolve it. It's up to your application code (in the case of git, the porcelain) to resolve the conflict, and probably in some cases to throw itself upon the user's mercy so they can resolve the conflict. Even if the application contains ad-hoc application-specific code to resolve the conflict, that code usually gets tested pretty rarely, and it's not at all unusual to have subtle bugs in it that will sometimes resolve a given conflict incorrectly.

CRDTs are a way of resolving update conflicts between different replicas that come with proofs of convergence: if your application (or database!) uses a CRDT algorithm to update a particular replicated data store, the merging process is guaranteed to always converge,

always to the same state regardless of the order of merge operations, and generally without losing any data (although that depends on which CRDT!) That is to say, "eventually consistent" becomes an automatic guarantee, not a statement of hope.

CRDTs offer an automatic way of replicating data to keep it available in the face of node or network failure while compromising consistency guarantees to a lesser degree.

A very simple CRDT which is foundational to most of the others is a set or bag to which things can only be added, not removed. Conflicting updates are simply resolved by taking the union.

AI optimization algorithms

SAT is, in a sense, the problem of inverting a Boolean function. You have a big propositional expression, which you know evaluates to true; you want to know what the values of the variables in it are, or at least whether there is any possible set of values for those variables. Similarly, nondeterministic and probabilistic computation can be viewed as other function-inverting problems.

Optimization algorithms solve a related problem: they are trying, more or less, to *approximately* invert a *black-box* function, a function whose behavior we hope is in some sense orderly. This is harder than SAT because we don't get to look at the code for the function, but also easier because the algorithm gets some indication of how close it is.

(Actually they're usually trying to maximize or minimize the function.)

There's a whole huge family of numerical optimization algorithms from AI: random sampling is the simplest, of course, but then you have hill-climbing (gradient descent), the simplex method for linear parts of the problem, simulated annealing, genetic algorithms, and so on. If you relax the black-box constraint and make your function differentiable (see automatic differentiation below), gradient descent becomes enormously easier, and the possibility of using something like Newton's Method to try to find zeroes opens up. And, since optimization typically involves re-executing the same code repeatedly with slightly different inputs, self-adjusting computation may be able to speed it up by orders of magnitude.

It is very common for it to be easy to evaluate the goodness of a solution to a problem, but algorithmically tricky to efficiently find a good solution. Consider the particle-system text layout algorithm Alan Kay was so excited about in VPRI STEPS --- wouldn't it be better to just specify what a good paragraph layout looks like, then search for one, as TeX does? Photogrammetry, structure-from-motion, point cloud coregistration, G-code planning for a 3-D printer, image dithering, lossy image or audio compression, lossless compression, edit-sequence computation (text diffing), place and route --- all of these are problems that can be easily cast into the numerical optimization mold.

Michał Zalewski's afl-fuzz combines genetic algorithms with compile-time instrumentation (see below) of object code programs to search through their execution paths, with the primary objective of finding bugs that lead to crashes, but has demonstrated the capability to generate valid SQL statements and JPEG files by probing SQLite and libjpeg.

How much can we abstract out these optimization algorithms to decouple them from the details of particular problems we are solving with them? How much code could we avoid writing if we can simply provide a computable utility function to optimize and apply a generic optimization algorithm to it? Can we make that more efficient by automatically incrementalizing or differentiating it? What's the relationship between SMT solvers and optimization algorithms?

Graph search algorithms

A* search is a provably-optimal graph-shortest-path algorithm, which takes an "admissible" heuristic to possibly improve its choices, usually allowing it to beat the heck out of Dijkstra's algorithm in performance. If the heuristic is admissible but not useful (for example, always returning 0), it decays to Dijkstra's algorithm in the worst case. It's commonly used for pathfinding in video games, and commonly with an inadmissible heuristic, which can cause it to find suboptimal paths. Amit Patel has a fantastic presentation of it.

Many search problems can be conceptualized as graph search (or tree search, since a tree is just a graph that is sparsely connected in a certain way). It's necessary that the choices be discrete, or discretizable.

What's the relationship between A *and the optimization algorithms discussed in the previous section? Can you use A* search efficiently for problems like dithering an image or superoptimizing a basic block?

Particle filters

Particle filters attempt to approximate an evolving continuous probability distribution by sampling it with hypotheses or "particles" that concentrate in the more probable parts of the space under the information you have so far, allowing multimodal probability distributions. Probably one of the various demos of this dynamical process on the web is better than some text at explaining it.

Particle filters are currently being successfully applied to a variety of hard perceptual or inference problems, including beat-tracking in music, motion-tracking in video, robot localization from noisy sensor data in confusing environments, 3-D object tracking, and automatic electrical fault diagnosis.

The same "importance sampling" mechanism used by particle filters also underlies some probabilistic programming systems (see above); for random variables drawn from a continuous distribution, even the random continuous drift that allows particle filters to explore points nearby in a continuous space might be useful.

XXX I should probably see if I can find people relating these two things to each other and make sure my understanding of the terms is right.

What else can we use particle filters for? Software-defined radio filtering, clearly: the frequency, phase, and direction both of the desired signal and of the loudest sources of nearby-frequency interference should be quite amenable to particle-filter estimation.

Transparent persistence, or single-level store

This is the other kind of persistence: storing your data on disk. If you've programmed an AS/400 or Squeak or run things inside VirtualBox (see virtual machines, below), you already know what this

is like: you need to explicitly separate your long-term persistent data from your ephemeral data in order to support code upgrade, but you don't need to make that separation just in order to not lose data when you turn the machine off.

Transparent persistence allows you to build a computing system without building a filesystem, and it supports fault recovery and process migration, and in particular it simplifies reasoning about capability systems, but it puts some extra demands on other parts of your system. Random number generators (like /dev/urandom) are not secure after restoring the system state from a snapshot (see below about snapshots). Your garbage collector needs to be comfortable with the idea that you have terabytes of data.

Without snapshots (see below), transparent persistence on spinning-rust disks poses certain problems of consistency: disk operations just before a power outage may have been reordered and some arbitrary subset of them may be lost. There's no guarantee that, when the machine reboots, the on-disk state will be consistent.

This particular powerful primitive is in no way new, forming as it does the bedrock of Lisp, Smalltalk, and AS/400 systems since the 1970s. In those systems, it does simplify some aspects of software, but it may be that it is a feature that doesn't pay its own complexity cost, except when used to implement features you can get no other way. Part of the problem is that most of the difficulty of persistence is not, in fact, the need to write serialization and deserialization code, but rather the need to distinguish irreplaceable data from dispensable data and to carry forward the irreplaceable data to new versions of the software. Rails migrations and Spark RDDs (see "deterministic rebuilding", below) may turn out to be bigger advances in persistence than single-level stores were.

Ropes

Lots of programs manipulate lots of strings, some spend most of their time manipulating strings, and network packets and the current states of disk files, memory regions, entire disks, and all of memory are also strings. With the usual terminated or counted array string representations, every string operation implicitly takes a potentially unbounded amount of CPU time, and many common operations, like replacing characters in the middle of a large string and appending large strings, do in practice take significant amounts of CPU time. And the standard string representation is not persistent (in the functional-programming sense; see above).

There's a heavier-weight representation of strings called "ropes" which *is* persistent, and in which most common operations are logarithmic-time or constant-time; in particular, concatenation is usually constant-time, although this varies a bit. A rope is either an immutable array of bytes (or characters), a concatenation of two or more ropes, implemented with pointers to them, or sometimes a pure function that can be invoked to retrieve characters within that range. You need to memoize (see above) subtree lengths to ensure that indexing is logarithmic-time. With hash consing, ropes enable string comparison to be done in constant time, too, which is particularly beneficial for memoization (see above). (I think rolling hashes are necessary and sufficient to make hash consing of ropes efficient.)

This is useful for two reasons: first, because string manipulation is

so expensive that we add a lot of complexity to our program designs in order to avoid it, and ropes may offer the opportunity to avoid that; and, second, because memoization is a very-broadly-applicable optimization.

Jumprope and bup are two rope-based storage systems that store their nodes in content-addressable block stores (see above) using rolling hashes (see above). Rope-based disk storage is particularly helpful for machine state snapshots (see below) which are often large, with a great deal in common with previous versions of the snapshot.

Erlang uses a very minimal kind of rope for I/O, called "IO lists": the various byte output routines accept "IO lists", defined as either a "binary" (Erlang blob), a byte, a Unicode binary, a Unicode character, or a cons of IO lists. This gives it constant-time concatenation among strings destined for output, which is enough to make it very fast at generating network packets.

I've started working on a non-persistent (in the functional sense: not immutable) variant of rope I call "cuerda", which I think has the potential to replace not just native string types but also filesystems, editor buffers, and most parse trees, including things like the accursed DOM. (I would prefer it to be persistent, but I haven't found a reasonably efficient way to provide certain other functionality I deem essential on persistent ropes.)

In a sense, WAFL and other modern filesystems like it are ropes-for-storage, although they usually embody tree structures, not simple linear strings.

XXX mention stratified B-trees?

What if some kind of rope were the normal kind of string, and also your filesystem? Could that simplify the whole system? (With a single-level store (see above), they could be the very same tree structure, although that might be undesirable for performance reasons on spinning rust, due to how it demands much more locality.)

Snapshots of state, ephemeral and durable

Unix creates new processes with the `fork()` system call, which results in two processes that are identical in nearly every way, each with its own private virtual memory space. This used to be a fairly slow operation, especially before 3BSD, when it involved physically copying the process's entire memory space. However, modern Linux machines can carry it out thousands or even tens of thousands of times per second, because the virtual memory mappings are merely marked copy-on-write.

afl-fuzz takes advantage of this efficiency to test thousands of random test inputs per second. OCaml's debugger uses the same facility in its debugger to "freeze" process execution at various points in the past, allowing you to step time *backwards* as well as forwards.

Similarly, QEMU, VirtualBox, and Xen support freezing the entire state of a virtual machine (see below), including its display, memory, and virtual devices, allowing you to back up to that checkpoint and resume execution from it later. Emacs does the same thing to speed up startup; Squeak and other image-based Smalltalk systems do the same, as mentioned above under "transparent persistence". Xen's "Remus" feature maintains a continuously-updated snapshot of the entire virtual-machine state on a remote machine, so that in the case of a hardware failure, you can

continue executing on the remote machine without rebooting.

WAFL avoided (avoids?) filesystem corruption on power loss by only committing internally-consistent snapshots of the filesystem to spinning rust, once per second; as a bonus, the snapshots share storage, and so old snapshots are accessible. This permits safely backing up a consistent snapshot of an active RDBMS transactional store. The same functionality is provided by ZFS, ext3fs jbd, and various LVM systems, which can be used as layers underneath other filesystems and transactional stores to ensure that recovery to a consistent state is possible, both after a power failure and after a failed system upgrade.

Git, of course, snapshots the source files it controls in your repository as a commit, storing them in its Merkle DAG in its content-addressed blob store (see above), which in turn is a CRDT (see above). Nix is a package manager and Linux distribution (with a GNU/Linux variant called Guix) that uses the same approach for configurations of installed software.

Some caution is needed: although snapshotting automatically converts ephemeral data structures (in the functional-programming sense) to persistent ones, they may not be *efficient* persistent ones, either in time or in space. If you're appending to an amortized-constant- time growable buffer, for example, and you snapshot its state just before it reallocates to twice the size and then repeatedly replay forward from that snapshot, it will rapidly become inefficient. And if you're snapshotting an object that references mutable objects, you need some way to convert them to immutable objects (and back to mutable objects when you revivify them), which generally involves copying, spending both space and time.

What if you could efficiently snapshot any part of your running system, ephemeral or persistent, at any time, and freeze it and possibly duplicate it for later? Could you implement this efficiently for mutable object graphs with help from the garbage collector's write barrier? How broadly could you apply this principle? (Maybe you could use this feature to implement the clone() operation for a prototype-based object system.) If you apply it to real-time mutable data structures, do you get guaranteed-efficient persistent data structures? What if you had Git for in-memory objects? What if all your software and data could be frozen and easily migrated between low-power handheld devices and more powerful laptops, or incrementally between data centers?

Virtual machines

Unix processes are virtual machines, although their I/O architecture is not borrowed from any physical machines. Unfortunately, they have access to so much system-wide state that it is often inconvenient to do what you want to do inside the confines of a single process; and there are programs you may want to run that are written using some other I/O architecture.

Whole-machine or near-whole-machine emulation, as with QEMU, VirtualBox, or Xen, is now a common system administration technique again, as it was in the 1960s; it allows you to snapshot the machine state (see above), to pause the machine's execution, to migrate it to a different host, to restart it from a snapshot, and to indirect its I/O through some virtual device. It's still very computationally expensive. In the other direction, chroot and

similar process- isolation mechanisms in Linux and FreeBSD are being beefed up, with things like Docker and the Nix/Guix isolated build environment (see below about deterministic rebuilding) to allow them to do more of what whole-machine emulation does.

Perhaps more interestingly, MirageOS is a set of libraries for building "operating systems" that are really just application processes, running bare on top of a Xen or similar hypervisor, thus reducing the security attack surface of your system by eliminating the operating system's TCP/IP stack, and allowing a transition to an overall simpler operating environment to proceed incrementally rather than all at once. You could imagine running a self-contained simple system like Squeak or Oberon under a hypervisor like Xen, communicating with a Linux guest to run legacy applications such as Chrome. Qubes is an OS project using an approach like this one to improve Linux security. (Unfortunately, Xen still relies on Linux drivers to handle the hardware.)

Virtual-machine emulation also provides crucial debugging capabilities that dramatically accelerate the first steps in the development of new operating system kernels, and potentially the debugging or analysis of existing ones. Back in the 1990s, the "spa" SPARC Performance Analyzer was a very slow virtual-machine emulator that was used to deeply examine the execution of processes on a simulated SPARC, in some cases using techniques similar to compile-time instrumentation.

(Virtual machines also have potential uses in information archival: a well-defined virtual-machine specification with emulators written in it capable of running other software could enable the recovery of lost software and the file formats implemented by that software. Such a fictional scenario, centered around the "UM-32 Universal Machine", was the premise for the ICFP 2006 Programming Contest.)

Historically, we have often introduced virtual machine instruction sets not modeled on any physical CPU for a variety of reasons, including improving debuggability, allowing compilers to run their code on new machines without retargeting (the original excuse for the JVM, ridiculous now that HotSpot is much larger than javac), efficiently supporting operations not supported by the underlying machine (in the case of the WAM, for example), and stuffing more program code into limited memory (the reason for the Excel bytecode interpreter, the BASIC Stamp bytecode, the Microsoft BASIC-80, and to a significant extent, Smalltalk-80). You could imagine in particular that a snapshot of a system could be more useful if it were portable between CPU architectures, allowing you to migrate running applications between your cellphone and your server, but I'm not aware of anyone having done this.

Probably introducing new virtual CPU architectures will not simplify a computing system. At this point, instead of emitting bytecode, you should probably emit machine code for a common CPU, like i386, x86-64, ARM, MIPS, PowerPC, or maybe MMIX or RISC-V, and run it under an emulator for that CPU if necessary. You can emit really dumb machine code, and it will still run faster and be simpler than emitting and interpreting bytecode. This also has the advantage that someone else has probably already written an efficient implementation of your "bytecode machine" for most

popular architectures out there, and you can use object-code instrumentation and analysis to add new features either to code built with your own system or existing code.

But maybe I'm wrong and there is some possible system simplification, even today, from designing an abstract virtual machine.

Automatic dependency tracking and deterministic rebuilding

`make` is the standard Unix utility for avoiding unnecessary recompilation by memoization (see above), but it requires you to explicitly and statically specify the dependencies of each build target, and it almost invariably omits dependencies like the compiler executable itself and the Makefile rule.

Meteor is a JavaScript framework in which you run your presumably deterministic "computations" in a sort of transaction (see below about transactions) that tracks what they read and write, intermediating their access to a remote database. Then, if there is a change in any of the things they read (probably because some other computation wrote to it), they can re-execute your computation. This automatically detects the things that could have changed the result of your computation, using exactly the same mechanism as Composable Memory Transactions. In this way, you can construct a reactive dataflow computation with dynamic topology without ever explicitly specifying dependencies, and as long as your computation accesses no data that Meteor cannot audit access to.

Debian, Nix, Guix, and the Tor Project are using a similar approach to get reproducible compilation products from possibly unreliable compilation machines: by knowing all of the inputs to the compilation process, including the compiler executable, they can detect and recover from a compilation process on one machine producing incorrect executables, either due to bugs or due to attackers attempting to inject malicious code. Generally these reproducible-build systems identify the compilation inputs with a secure hash and store them in a content-addressed blob store.

This reproducibility also makes it possible to memoize the compilation process (see above about memoization), avoiding actual runs of the compiler that are not motivated either to verify reproducibility or because the inputs have changed. Vesta and ccache are two systems that work this way.

(Acar's Self-Adjusting Computation also, in some sense, works the same way, at a much finer granularity.)

ccache even automatically tracks compiler inputs the way Meteor does, as does Bill McCloskey's memoize (now on GitHub), which uses strace and is therefore slow. redo, implemented by Avery Pennarun, tracks inputs comprehensively and dynamically (like Meteor) but not automatically.

Apache Spark is a system for scalable cluster computation which deterministically computes "RDDs" either from stored input files or other RDDs, and which records the "lineage" of each RDD, which is to say, all the inputs that went into creating it; this enables RDDs, or parts of RDDs, to be recomputed in the case of machine failure.

RDBMSes do automatic dependency tracking to automatically update indexes and, if supported, materialized views. However, I

think RDBMSes typically use a different technique, which I'm calling algebraic incremental updates (see below), rather than rebuilding parts of an index or view from scratch when they have been invalidated. If simple rebuilding could be made adequately efficient, which is kind of what Acar's self-adjusting computation claims, maybe RDBMSes wouldn't need to support algebraic incremental updates.

This kind of automatic dependency tracking could dramatically improve the efficiency of snapshots (see above): anything that could be automatically rebuilt does not need to be included in the snapshot, and indeed that is how we manage our source code repositories.

If previous build outputs are stored in a distributed cache, they typically are stored in their entirety, perhaps compressed. However, they are often very similar to one another. Using a rolling-hash-based system like bup or Jumprope could conceivably allow the storage of orders of magnitude more cached build outputs, which could be a useful alternative to finer-grained dependency tracking like SAC.

A common performance problem in C and especially C++ compilation is header-file parsing; due to recursive `#include` lines, it is common for a single source file to include tens or hundreds of megabytes of header files, which must all be tokenized. A common approach to this problem in the past has been to add "precompiled header" support to the compiler, which serializes the state of the compiler to the filesystem at some predetermined point, and then attempts to use the serialized state only when it is safe to do so. This tends to be bug-prone. A possible alternative would be to snapshot the compiler's runtime state several times per second during the compilation, annotating the snapshot with the set of inputs so far consumed; then, when a rebuild is called for, the old inputs can be compared to the new inputs, and the previous compiler run can be resumed from the last snapshot which had not yet read any changed data. This will not speed up the compilation of one C source file using data from the compilation of another (except perhaps in the sense that the snapshots could share space due to after-the-fact substring deduplication in storage), since the compiler receives the differing command lines immediately on startup, but it will speed up the recompilation of modified files, potentially by a much larger factor than mere precompiled headers.

A totally different alternative way to avoid precompiled headers would be to parallelize the tokenization process using a parallel prefix-sum algorithm; a third approach would be to make the token stream itself memoizable, so that you only need to retokenize any given header file when the header file itself or something it `#includes` changes.

Prefix sum, cumsum, or scan

The prefix-sum problem is to compute, say, 1 3 6 10 15 21 from 1 2 3 4 5 6, or 32 5 1 32 1 from 32 -27 -4 31 -31, or using max instead of addition, 1 2 2 4 4 4 4 8 from 1 2 1 4 1 2 1 8; each output item depends on all the input items at its position or earlier, but the associativity of the operation used to combine them allows the use of a variety of efficient parallel algorithms to compute it in logarithmic time. This means that if you can cast your problem into the format of a prefix-sum with some associative operation, you can more than likely get reasonable parallelism out of it.

Now, note that function composition is associative! It might seem that this would allow you to simulate any sequential process in logarithmic time on a parallel machine, but in fact that is only the case if you have a bounded-space representation of the transition function over an arbitrarily long period. For example, if you're concatenating millions of 3x3 matrices or simulating a 20-state Levenshtein automaton (or a lexer) over a gigabyte of text, this approach does indeed work! But for, say, parallelizing the execution of a virtual machine, it probably won't.

Prefix sums are included in APL and some other array languages as a fundamental operation, called "scan", "\", or "cumsum", but in some of these languages, it is not applicable to arbitrary associative binary operations.

One of the standard parallel prefix-sum algorithms recursively builds a segment tree over the input array; if memoized, this provides an efficient logarithmic-time lazy incremental algorithm, even when the operation in question does not admit inverses (the common examples being max, min, or associative bitwise operations.) The same segment tree can then be used for the range-minimum-query problem and its variants, even though RMQ is more general than the problem of returning an item from min-scan problem (since the range being queried need not start at the beginning of the vector).

(If the operation does admit inverses, you can instead incrementalize it using algebraic incremental updates; see below.)

This is a generally applicable strategy for incrementalizing algorithms expressible as prefix sums. For example, if you use a finite state machine to syntax-highlight an editor buffer or conservatively approximate a CFG parse, you can build a segment tree of state mappings over substrings of the input, which allows you to update the entire output in logarithmic time after localized changes to the input, such as edits to an editor buffer.

One of the standard applications for the plain-vanilla addition version of prefix sum is to rapidly compute box filters, also known as simple moving averages, sometimes as an alternative to mipmapping of images and in other DSP applications. They can also be used to calculate arbitrary linear IIR filters.

PID control

PID control is a fairly general linear control algorithm to push a system in the direction of the state you want. You exert a push that is a weighted sum of three components: the difference between the desired and actual state (the Proportional component), one that is the Integral of the difference in order to correct offset errors, and one that is the Derivative (or differential) of the current state in order to damp oscillations which would otherwise result from the other two components in the presence of hysteresis or phase delay in the system.

PID control is very widely used in the control of physical machinery in industry by microcontrollers or PLCs and even pneumatic controllers and analog circuits.

(Hmm. Maybe this is not actually that powerful?)

String similarity

useful for compression, virus scanning

Suffix arrays

A suffix array of a string is a permutation of the indices into that string, sorted so that the suffixes of the string starting at those indices are lexicographically sorted. Any particular chunk of a suffix array lists the places in the string that a given substring occurs, lexicograhically sorted by what's after it. (Well, maybe a range of substrings.) It's a lot like a KWIC index, except that it is fully comprehensive.

Suffix arrays are a simplification of suffix tries, such as Patricia trees (I've never been entirely clear on whether Patricia trees are a particular kind of suffix trie, or just another name for suffix tries). Once you have computed a suffix array for a corpus of text, there are a variety of queries you can execute efficiently on it: all occurrences of a given substring, the probability distribution of characters that *follow* a given substring, all matches of a particular regular expression, all approximate matches of a given string (using a Levenshtein automaton), and so on. As you can imagine, this is useful for data compression, and, indeed, the Burrows-Wheeler Transform used in bzip2 is suffix-array-based. Suffix arrays themselves are large compared to the text they describe (N log N bits for an N-character text, so commonly 5 or 6 bytes per byte of text) but there are suffix-array-based things I don't understand called "compressed indexes", such as the FM-index, which represent a text in a compressed form and support both decompression and efficient search operations on it efficiently.

Historically, suffix-array construction was very computationally expensive, which is one of he main reasons bzip2 is slow. But now there are new suffix-array construction algorithms (SA-IS, the skew algorithm, and a third one which I think is called SA-IR) that are linear in time and use a reasonably small amount of memory, like, less than twice the space of the final result.

This linear-time ("O(N)") bound is particularly intriguing since comparison-based sorts have a proven (?) complexity bound of O(N log N) time. It turns out that there is no contradiction: to have N distinct keys, each key needs to occupy at least $\log_2 N$ bits, so O(N log N) comparison sorting can actually be O(N) in the total size of the database.

Often, though, it isn't! So suffix-array construction could conceivably be an absolute performance win as well as a simplifying tool.

Most database sorting, indexing, and search problems are in some sense a subset of the substring-search problem.

Field search with suffix arrays: If a record has the string "CA2777697A1" in the field "patentnumber", most representations of it will also contain "CA2777697A1" as a substring, and probably not very many other records will. Indeed, with appropriate choices of encoding, you can ensure that, for example, the string "&patentnumber=CA2777697A1&" will occur exactly and only in the representation of records with that string as the value of that field. This extends in an obvious way to prefix (`patentnumber like 'CA27%'`) queries and range (`year between '1972' and '1977'`) queries, although multi-column indices can only be emulated in this way if the column sequence is a substring of a column sequence strictly observed in the representation of every record. On the other hand, this gives you N(N-1)/2 multi-column indices on N columns out of the box for

free, if your table is in 1NF and you observe this ordering constraint, as well as suffix searches: `patentnumber like '%7A1'`.

It's also possible to do full-text fielded search in this way by using regular expression search (`/&body=[^&]*Argentina/`) but I don't expect that to be very efficient. It's probably better to do full-text fielded search in some other way, such as by doing a full-text unfielded search and then examining each result to see if it's in the right field, or if that's inefficient, by concatenating the desired field into a separate corpus.

(This approach, without the suffix arrays, was the basis of the cult PC database program askSam in the 1980s, 1990s, and into the 2000s: its "records" were free-form text; a "field" was just a field name followed by square brackets with text within, like `patentnumber[CA2777697A1 ]`; and it used a full-text index to support fielded search. askSam is still around, though somewhat less popular than before.)

askSam was more like what we call a "document database" nowadays, like MongoDB; its records were not in 1NF.

Record sorting with suffix arrays: clearly if you want to sort the "patentnumber"-containing records in the above table by patentnumber, you can simply look at the chunk of the suffix array for strings beginning with "&patentnumber=", and find the beginning of the record each such substring falls within. If you insist on ordering strings like "X", "X%", and "Xa" in that order, you can change the delimiter from "&" to ASCII NUL. I suspect that using magical "out-of-band" "bytes" as delimiters is the easiest way to get this kind of thing to work correctly, although it's no doubt possible to devise an escaping scheme that preserves collating order and allows this sort of reliable substring testing to find field boundaries. (All three of the practical linear-time suffix-array algorithms cope well with odd-sized alphabets, and in fact use them internally. Probably the best way to represent the out-of-band values in memory is by storing a list of their indices.)

In the Canon Cat, Jef Raskin suggested that perhaps instead of seeing our data as a plurality of different files addressed by name, we should see it as one document, perhaps a very long one, divided into sections, which can be addressed by content, simply by doing substring searches. (I'm not sure if his later work on The Humane Environment continued to attempt this.) Suffix arrays make it possible to scale instant substring search up to at least hundreds of gigabytes of text, if not more.

Aside from full-text indexing, sorting, and compression using suffix-array-based schemes like the BWT, suffix arrays have also been used for LZ77 and LZSS data compression, and compact infinite-order Markov-chain models of text.

What else could you simplify in a computing system by using suffix arrays?

Levenshtein automata

Levenshtein automata are finite-state machines that recognize strings with up to a given Levenshtein distance from a desired search string; in particular, you can simulate a Levenshtein automaton in parallel on a sorted or trie index (including suffix-array indices) to find all the fuzzy matches to a desired search string in a body of text. The automata grow in complexity as the maximum Levenshtein

distance grows, but for distances of 1, 2, and even 3, the nondeterministic Levenshtein automaton has relatively reasonable size.

This is useful not only for words that someone might have misspelled, but also ssdeep forensic hashes of malicious code, nucleotide or peptide sequences,

XXX

Formal methods

"Formal methods" here means theorem-proving, specifically machine-checked proofs of the correctness of programs. Although this line of research goes back to the 1960s, it has started producing major results in the last few years, as people have finally started getting it to scale to real-world programs, including the seL4 secure kernel, the CompCert C compiler, a security kernel for an experimental browser called Quark, and forthcoming work that reports having verified the crash recovery of a filesystem. Essentially all of this has been done in a system called Coq so far, although other systems like Isabelle/HOL are intended as possible alternatives.

Of course, proving your source code correct doesn't help you much if the compiler introduces bugs in the process of compiling, which is why CompCert has been so central to this work. But much of the machinery of languages like C, and especially C++, is intended to do the same kind of thing that things like Coq are good at — statically find bugs, and automatically select possibly-correct behavior (such as applying a floating-point multiplication operation to two floating-point numbers) instead of clearly-incorrect behavior (such as applying an integer multiplication operation to them).

A recent paper from Kennedy, Benton, Jensen, and Dagand, "Coq: The World's Best Macro Assembler?", investigates the consequence — obvious in retrospect — that maybe we should just use write Coq code to generate the assembly or machine code, along with a proof of correctness.

This approach also offers the possible promise of being able to verify properties that aren't verifiable at C level, like a worst-case bound on the number of bytes needed for the stack, or execution timing for a timing loop; and it avoids the whole issue of proving the correctness of an inherently complex program like a C compiler.

Myreen and Curello have also formally verified a bignum implementation in AMD64 machine code using the HOL4 theorem prover.

Coq proof tactics are not Turing-complete — they are guaranteed to terminate — but they are capable of proving substantially more interesting safety properties of programs than the type systems of languages like C, Java, and even OCaml. (I suspect that C++'s template system is Turing-complete, just very clumsy, in the same league as languages like BF.)

This suggests a possible way to rehabilitate Forth, which is little more than an assembly language with expressions, compile-time metaprogramming, and reflection. The problem with Forth, in my limited experience and in hearsay, is that it's too bug-prone, and so you development starts to get slow pretty soon due to the bugs. But it invariably takes less total code to do anything in Forth than in any other language, if you count the code implementing the primitives.

Perhaps a Forth could constitute a useful penultimate level of intermediate representation, or even a better target language than assembly, for such a program of formal verification at the machine-code level.

Could you extend this macro-assembler approach into a full convenient programming language embeded in Coq or a similar proof assistant? What else could you simplify with a good proof assistant?

Hash tables, expandable arrays, and sorting

This, more than anything else, is the basis of languages like Python, Perl, Lua, Tcl, JavaScript, and arguably the Unix shell: two generic container types (or, in Lua's case, just one) allow you to represent things conveniently, and make the language easy to learn. Typically these use the Lisp object-graph memory model, in which all values and storage location are a single machine word in size, usually populated by a pointer.

Original Lisp in itself can be seen as the first such language: even McCarthy's 1959 paper had association lists in it, implemented FORTRANishly using parallel lists of keys and values, rather than in the now-standard alist representation of a list of pairs. But Lisp lists are optimized for structure-sharing ("persistence") and recursion at the expense of rapid indexing, mutability, and memory-efficiency, and Lisp's traditional representation of finite maps makes similar tradeoffs. This disfavored imperative code.

So Perl's 1987 minimal combination of arrays, associative arrays, and a convenient imperative scripting language turned out to be an extremely useful combination, particularly combined with regexps for input processing and string interpolation for output. Perl didn't have pointers before Perl 5, more or less obligating you to use parallel arrays or parallel associative arrays, but it was still eminently practical for a huge collection of tasks.

(REXX has "compound variables" which were associative arrays, which, like Perl4 associative arrays, couldn't be passed as arguments. REXX dates from 1979. But it doesn't have lists, and unlike Lua, there's no way to find out how many items are in a numerically-indexed compound variable.)

This kind of decomposition works best if the underlying implementations of the data structures are acceptably efficient across a broad range of uses; Lisp lists' O(N) append-item

Add sorting to arrays and associative arrays, as Perl did, and a whole host of traditional algorithms become simple. Parnas's famous 1972 paper is about how a group of programmers could coordinate through formal specifications to implement a KWIC index, essentially the following Perl program, which he says "could be produced by a good programmer within a week or two". It took me about 20 minutes, although it wasn't my first time. It needs about ten or twenty times as much RAM as the size of its input.

```
while (<>) {
    @w = split;
    push @lines, "@w[$_+1..$#w] | @w[0..$_] $.\n" for (0..$#w-1);
}
print sort @lines;
```

(I think this program works in Perl 4, but I don't have a copy handy to test.)

I took another hour or so to write a much more efficient, if nearly as obfuscated, version in Python, which can produce a KWIC index of the Bible in a few minutes on my netbook:

```
import sys

pos, aw, a = {}, [], []         # Each word is represented by index in aw
for r in sys.stdin:             # Build list of lists of word ids in a
    b = r.split()
    for w in b:
        if w not in pos:        # Assign an id to the new word
            pos[w] = len(aw)
            aw.append(w)
    a.append([pos[w] for w in b]) # Encode the line with word ids

g = sorted(range(len(aw)), key=aw.__getitem__) # Compute word sort permutation
v = [None] * len(aw)                           # Invert the permutation...
for i, j in enumerate(g): v[j] = i             # Now v[g[i]] == i.
a = [[v[w] for w in b] for b in a]             # Rewrite lines with permuted ids
cs = [(ln, wn) for ln, b in enumerate(a) for wn, _ in enumerate(b)]
cs.sort(lambda (lnx, wnx), (lny, wny): cmp(a[lnx][wnx:] + a[lnx][:wnx],
                                           a[lny][wny:] + a[lny][:wny]))
p = lambda ws: ' '.join(aw[g[w]] for w in ws) # map back to original words
sys.stdout.writelines("%5d: %s | %s\n" % (ln, p(a[ln][wn:]), p(a[ln][:wn]))
                      for ln, wn in cs)
```

(This task, of course, is trivial and perhaps even unnecessary if you have a suffix array already computed (see above). But it's an excellent example of how powerful primitives reduce the complexity of previously complex tasks.)

Smalltalk, perhaps the original exponent of "powerful primitives for a simplified computing system", has OrderedCollection and Mapping (XXX?) types, but culturally it doesn't emphasize them; instead, it has a wide variety of specialized collection types available, and it emphasizes defining new application-specific means of aggregating and finding things, perhaps wrapping an OrderedCollection or something.

Python has in some sense decayed a bit from this ideal: added to its basic tuple, list, and dict generic containers, we now have sets, generators, an entire `collections` module with containers like defaultdict and deque, some of which are dangerously bug-prone. While it's very useful to be able to define application-specific collection types and use them via ad-hoc polymorphism, and often these specialized collections are significantly faster in particular uses, I worry this makes Python harder to learn than it used to be, and perhaps also reduces the power available by combining components — although at least these new collection types all support common sequence and iterable protocols.

And of course bencode and JSON, and the systems based on them like BitTorrent and MongoDB, are entirely based on these two container types, plus primitive numbers, strings, and null. Bencode goes an additional step and ensures that the mapping between data

structures and serializations is one-to-one, like ASN.1 DER, allowing cryptographic signatures and the use of content-hash-addressable storage.

Could we simplify our systems and improve their composability by designing them to handle more data in JSON-restricted forms?

Finite binary relations

One alternative that has occurred to me to the hash/array/sort combination described in the previous item — or Lua/JS/REXX's version where you use a hash of int keys instead of an array, or PHP's version where the key-value pairs are ordered — is finite binary *relations*, as opposed to the finite binary *maps* provided by hashes. Relations allow potentially more than one value for the same key; you can implement them as, for example, hashes of sets.

I've written about a database query language based on binary relations at http://canonical.org/~kragen/binary-relations, but I'm still not sure if it's a good idea. But this is not about writing databases with query optimizers and queries and whatnot; this is about using binary relations as the standard container type in a very-high-level programming language.

At the level of objects in a programming language, relations have some possible advantages over maps. Relations are closed under inverse, composition, and transitive closure, as well as the set-theoretic operations union, intersection, difference, and symmetric difference, which operate on the set of their key-value pairs; furthermore, the inverse of the inverse of a relation is the original relation, relational composition is associative, the set-theoretic operations are commutative and associative, and there are various distributive theorems you can prove. You can try to define analogous operations on maps, but I can't think of definitions that support these properties.

If your relations are implemented with some kind of search tree over the keys, rather than a hash table, then the keys can be efficiently traversed in sorted order at any time, even when keys are being added and deleted dynamically. This obviates not only explicit sorting by keys but also explicit heaps; a search tree has the same asymptotic complexity for the usual heap operations.

Considering the KWIC program again, let's see what it would look like if Python had implicitly-ordered relations instead of dicts and "lists".

```
import sys
```

Now we don't need two separate collections for the words, but we still do need to be able to rapidly map from a word to its id as we are building up the word-id-sequence representation of the input text. So let's store the words as the keys of a relation, their ids as the values, and use a counter. (Actually, maybe I should have done this before.)

```
n, aw, a = 0, {}, {}

for r in sys.stdin:
```

Do we want iteration in this Relational Python to be, in some sense, iteration over a relation? That is, do we want sys.stdin to

somehow present its lines as a relation, or do we keep the same iteration protocol, which iterates over a sequence of things? I think we should keep the same protocol, because the nature of iteration isn't changing, just the containers. Iteration is still the execution of a block of code a sequence of times.

```
b = r.split()
```

Now what does split() return? Presumably a relation, but where do the words go — keys, values, or both? And, if not both, what's the other side? I think the answer is that, since the field sequence in `split` is usually important, and we usually want to be able to do field lookups by number, it should be a relation from field numbers to words. Here, we do care about the sequence of words eventually, since we need to do cyclic shifts of them eventually.

But now we need to iterate over the words that don't have ids, and we don't really care what order that happens in. This sounds like set subtraction, which we've already said is a fundamental operation on relations, but the set we're subtracting isn't exactly `aw`, the relation from words to their ids; it's just `aw`'s keys. But that's potentially a very large set, and we wouldn't want to do anything proportional to its size after every word.

So we're declaring that getting the set of keys of a relation is a constant-time operation, which seems plausible, since it doesn't require building a new key tree; it just requires interpreting the traversal results slightly differently. We're also declaring that a set is represented as a relation that stores the single value `True` for each key.

```
for w in b.valueset - aw.keyset:
```

(Since the keyset and valueset operations are so fundamental, it might be a good idea to provide syntactic sugar for them, like @b or aw@ or something.)

We probably don't want to have an `x[y] = z` operation for relations, since `x[y]` is an unordered set of things, and the fundamental operation is not replacing that set with a single item, but rather adding an item to that set. (Although, in this case, we've just verified that that set is empty.) So for now I'm going to use a method, although some kind of syntactic sugar might be better.

```
    aw.add(w, n)
    n += 1
```

Now we are faced with the need to translate the line (a mapping from field indexes to strings) through the id table `aw` (a mapping from strings to ids) before adding it to `a` (a mapping from line numbers to sequences of word ids). This is just relational composition, which I will represent with the infix operator @:

```
a.append(aw @ b)
```

The order of the arguments to `@` is the traditional one for relational or functional composition: the range values of `b` are the domain values (keys) of `aw`, the range values of `aw` are the range values of the result, and the domain values (keys) of `b` are the keys of the result.

You could read this as "Values from `aw` at the keys from `b`. It's kind of like `aw[b]` except that `b` has a whole sequence of indices for `aw` (in its values), not just one.

One potential problem here is that relational composition is well-defined when the value on either side of the composition is missing: `{4: 5, 6: 7} @ {1: 2, 3: 4}` is just `{3: 5}`, silently ignoring the absence of any key 2 in the left relation and any value 6 in the rightmost relation, while the Python expression `[pos[w] for w in b]` will instead raise an exception if `w` is not in fact found in `pos`, which is probably a programming bug and the kind of thing you would want it to catch. We could define `@` to do that, but I'm not sure we should.

This .append operation generates a new index by adding 1 to the previous greatest index in the relation, which is a thing that can be fetched in either constant time or logarithmic time.

Next, we need to permute the word ids according to the words, in order to derive new word ids that will induce the correct lexicographical ordering of cyclically-shifted lines. But, since relations are implicitly traversed in the order of their keys, this sorting is achieved by simple relational inversion, after which we get the new word ids by counting — using the `list()` function borrowed from Python, which in Relational Python turns an iterable into a relation with counting numbers as its keys:

```
g = list(aw.inverse())
```

Then, we need to calculate the inverse mapping, from our original word ids to our new word ids, and use it to rewrite our representation of the text.

```
v = g.inverse()
a = list(v @ b for b in a)
```

So far the program is slightly simpler than before. Now, though, it gets slightly more complicated, because the original code used a comparator function instead of a key generation function to specify the sort order of the cyclic shifts, specifically in order to avoid the materialization of the entire universe of cyclic shifts in memory at once. Using a key function instead of the comparator makes it run about three times faster on small datasets, but also use about 70% more memory on my example dataset. (My Python code uses about 12 bytes of RAM per input byte with the comparator optimization, and about 30 bytes of RAM per input byte using the key function.)

However, it's fairly simple to create a key class that lazily generates the key it wants to be sorted by, if we declare that relations use this **key** method to compare and sort their keys, but don't store their return values or leave an arbitrarily large number of them out there hanging in space unfinished.

```
class K(namedtuple('K', ['ln', 'wn'])): # line number, word number
    def __key__(self):
        return list(a[self.ln][self.wn:]) ++ a[self.ln][:self.wn]

cs = {K(ln, wn) for ln, b in a.items for wn in b.keys}
```

Here I'm declaring that ++ is the list concatenation operator,

which returns a new relation that is a superset of the first relation, with the values from the second relation assigned to new indices as per `.append`. The list() call is needed because slicing a relation returns you the key-value pairs from that slice unchanged.

The {} comprehension there is a set-comprehension, implicitly mapping each key to `True`; if it had a `:` after `K(ln, wn)`, it would be a relation comprehension.

There's a problem here, though, which is that `a[self.ln]` is actually an entire set of lines that happens to be, presumably, just one line. I need to figure out how to handle that. XXX

The remainder of the code is simplified slightly from the Python version, although it omits the `|`. It's assuming a `key()` top-level function that invokes the `__key__` magic method.

```
sys.stdout.writelines("%5d: %s\n" % (k.ln, ' '.join(aw @ g @ key(k)))
                      for k in cs.keys)
```

I'm not sure exactly what kind of thing the tuple there in the string-formatting operation should be; is it a relation? Should it not exist? Should I be writing it with {} or []? XXX

Transactions and transactional stores for concurrency

Transactions are an architectural style for building systems, whether distributed or otherwise, that contains the effects of each computation inside a "transaction", whose reads and writes are monitored, and whose writes are not visible to other transactions until it "commits". If it fails (according to arbitrary logic inside the transaction), it doesn't commit, and therefore has no effect. The system prevents transactions that had read data that was been written before they committed, either by preventing it from being written (perhaps by delaying or aborting the transactions that try to write it) or by automatically aborting and retrying the transaction that depended on the outdated data. In this way, the transaction system achieves an illusion of pure serial execution, while in fact permitting great concurrency and even parallelism.

Ideally, in fact, the transaction should never be able to read any data that were written after it started, in order to ensure that no implicit consistency constraints among different data that it might read are violated. For example, a transaction calculating the average packet size on a network interface might read the number of packets transmitted and the number of bytes transmitted, then divide them. If this result is to be correct, the number of bytes it is dividing must correspond to the number of packets it is dividing by.

(This is obviously easier to achieve if you have persistent data structures, in the functional-programming sense.)

This kind of transaction is known as ACID: it's "atomic", in that either it has all of its effects or none of them; "consistent", in that only transactions whose internal failure logic does not abort them will be committed; "isolated", in the sense that concurrently executing transactions can have no effect other than perhaps aborting them; and, kind of unrelated to all of the above, "durable", in the sense that none of these properties are lost if your computer loses power in the middle of the operation, and in particular no committed transaction will be lost.

Practical transactional systems often relax some of these properties to some extent. For example, it's very common for database systems that can provide fully-ACID transactions to support lower "isolation levels", perhaps permitting a transaction to see an inconsistent state of the database as it reads a sequence of different things.

The "Composable Memory Transactions" paper from 2005 or so proposes using transactional *memory*, implemented in software, as a general concurrency control mechanism for threads. The CMT transactions support nesting, and an outer transaction can react to the failure of an inner transaction by trying an alternate code path; this permits a more modular equivalent of the Unix select() call or the Win32 WaitForMultipleEvents, simply by trying such an alternation of nested transactions that each fail when the event they await has not yet happened. If any one of them succeeds, then the overall transaction continues; otherwise, it fails, and is later automatically retried when any of the data it read before failing have been modified. This permits the automatic interconversion of blocking and non-blocking APIs, something not possible by any traditional means other than first-class continuations.

There's an interesting correspondence between this kind of transaction failure and failure in nondeterminism implemented by backtracking. When you hit a failure in a backtracking system, you undo all the effects that led to that failure, back to the latest backtracking point, and then try the next alternative from that point. This is exactly the same thing that happens in CMT when an inner transaction fails: all of its effects are undone, and the outer transaction can either fail in response, or try a different alternative. In both systems, only when the outermost transaction succeeds do you get to see the set of assignments that it made. One interesting difference is that, in backtracking systems, the outer transaction can fail the inner transaction after it has already "committed", possibly causing it to succeed with a different set of effects.

This kind of transactional-memory discipline probably isn't reasonably efficient and effective without either hardware transactional memory support, or a sufficiently smart compiler or prover, to ensure that no effects escape a transaction before it is committed.

Obviously you can implement this kind of transactional-memory interface with a networked server instead of stuff in the same process as the transactions; although you can't prove that the stuff on the other end of the socket is respecting the requirement to have no effect if it gets aborted, having it in a separate process makes other kinds of isolation more plausible to implement, and the possible high concurrency may be more valuable when you can spread it across a whole network.

Also, there's a clear connection to automatic dependency tracking and deterministic rebuilding, as well as to reactive programming: the read and write tracking the transactional memory does is the same read and write tracking a reactive programming system like Meteor does, and indeed the re-execute-when-an-input-changes logic used by the CTM paper for transactions that haven't committed is the same thing Meteor does for "computations" that are still live. You could even imagine a nondeterministic search algorithm like a truth maintenance system implemented in these terms: if transaction A makes a write that results in a failure in a later transaction B, then transaction A is rolled back retroactively, along with all the things resulting from it, and re-executed with that write rigged to blow

up — at which point A can either fail, or handle the error by trying a different write.

All of this could be implemented at a number of different levels. One interesting level, for interacting with current systems, would be running a shell script inside an isolated environment monitored by a transaction system; it can read files and directories, write files, and spawn subtransactions, and if it completes successfully, then its writes are committed and become visible to other scripts. By itself, this would suffice to simplify certain kinds of system management tasks: you could abort long-running scripts halfway through without fear that they would leave things in an inconsistent state, and the transactional discipline would ensure that concurrent execution didn't cause subtle bugs. (And no more tempfile race holes!) But the prospect that you could, later on, automatically re-execute the script if any of its inputs changed, perhaps with a frequency limit or extra wait time, and perhaps automatically deleting its previous outputs in the interim — that seems like it could simplify a lot of things.

All of this shell-script stuff seems like it would work best with a blob store, in order to make it practical to distribute this work across machines, and also so that the operation of "committing" and making visible the output files can be done quickly.

We normally think of ACID transactions as being incompatible with eventually-consistent and partition-tolerant databases, because of Brewer's CAP conjecture (later somebody's XXX theorem), which is that you can't be consistent (in the sense of serialization), available (in the sense of always handling all requests), and partition-tolerant (maintaining these in the face of network partitions). But the above suggests a way to achieve at least ACI transactions in an eventually-consistent partition-tolerant system: if you remember the entire transition history and dependency graph, then you can commit a transaction and, when you find that it was in conflict, later roll it back, along with everything that transitively depended on it, then re-execute them in a proper order. This sounds pretty wild, but it is more or less the way that the US credit card and banking system work: any transaction can be disputed and rolled back for a month or three, which may result in rolling back other dependent transactions. It kind of means that your system can never make any promises to the outside world, though, which is becoming a friction point for interactions between US financial institutions and things like Bitcoin and physical goods delivery, which do not support rollback.

Re-executing the whole dependent sub-DAG of transactions at the timestamp when you discovered the conflict should be safe, at least if only one node is doing it. Re-executing them at their original timestamps with the new data could result not only in them writing different contents to the same locations, which is harmless since that only affects other transactions in the dependent sub-DAG that you were going to re-execute anyway, but also writing things to locations they didn't write to before. This could result in the need to re-execute other transactions that weren't originally part of the dependent sub-DAG. I don't know what the best choice is here. (However, I'm deeply struck by the correspondence with Umut Acar's self-adjusting computation algorithms, in which function calls are required to pass values around only by reading and writing memory, to read values from memory only at the beginning of a

function, and you re-execute function calls if their inputs changed — and each function invocation is timestamped with a virtual clock in order, if I understand correctly, to allow safely memoizing functions that access memory.)

This whole re-executing thing requires that the code that was executed in the transaction be preserved so that it can be re-executed later if the transaction needs to be rolled back and redone due to a conflict. In a distributed database context, you probably want to reference that code with a hash stored in a content-hash-addressable storage system rather than by saving a copy of your entire source base in every replicated transaction record.

(Also note that if you're saving and replicating the entire past history of transaction inputs, timestamps, and code, plus an initial database state, you have in effect turned your database into a CRDT; you replicate this history, perhaps using gossip (see below), and can then deterministically replay all the transactions to deterministically rebuild the current state of the database, and any node doing this will get the same results. This may be simpler to do if you in fact execute the transactions serially, eliminating the need to track inputs and outputs at fine granularity, though the more usual transaction approaches may give you better performance.)

This may be a foundation that simplifies operational-transform-based collaborative editing systems like Etherpad and Gobby.

Automatic differentiation

> Automatic differentiation … computes … any derivative or gradient, of any function you can program, or of any program that computes a function, with machine accuracy and ideal asymptotic efficiency.

It's an abstract-execution technique that executes programs on data that is annotated with its partial derivatives with regard to input data values, which is to say, the numerical Jacobian matrix of the program (and the Hessian, ad infinitum), evaluated at a point. Alexey Radul wrote a comprehensive introduction. It's easy to implement; Conal Elliott wrote a 2009 paper on this, where the first example shows how to do it for first derivatives of scalar functions only in 30 lines of Haskell.

The idea is that when you call a function and it produces some data structure full of values, you get not only the values, but also a lazy list of which inputs each of those values (locally) depends on, and what the coefficient of variation is between them at that point, and similarly for what that variation depends on, with minimal overhead.

This could be particularly useful with AI optimization algorithms that are trying to find input values for a piece of code that will produce a given output value, such as zero, or a given image. Gradient descent needs to know the gradient, after all. The alternative is hill-climbing by groping around in various directions looking for a local improvement, like a caterpillar at the end of a twig, which can be very slow in a high-dimensional space.

A lot of these are only feasible with what's called "reverse-mode" automatic differentiation.

There's clearly also a relationship here with incremental computation, which exactly computes the new value of a function after an incremental change to the input by tracking which parts of

the computation depend on that input; truth-maintenance-system constraint solvers, which trace back constraint violations they find to the minimal combination of nondeterministic guesses they made that will cause that constraint violation, in order to avoid wasting time with that in the future; probabilistic programming, which in some sense traces back observations of outputs to probability distributions over nondeterministic variables that would be needed to produce those outputs; neural networks (see below), whose "training" works by adjusting edge weights to reduce the difference between the output and the desired output, and indeed AD applied to neural-network evaluator does produce the backpropagation outputs; and interval arithmetic, which can produce conservative approximations that are much less conservative if it knows which uncertain input variables or intermediate computations an uncertainty bound depends on (consider $b \cdot b \cdot b \cdot b$ vs. b^4).

In particular, both incremental computation and automatic differentiation have to deal with the problem of preserving overwritten state when applied to imperative programs that use mutation internally; the body of knowledge that has developed around automatic differentiation is likely to be useful for implementing incremental computation.

Automatic differentiation only determines the derivatives in the local neighborhood of the computation that was actually carried out, and so in particular conditionals are not reflected; automatic differentiation will compute that `x ? -y-z : w/2` has a nonzero derivative relative to either `y` and `z` or to `w`, but not relative to all three, and not relative to `x`. For this reason, I expect it to be complementary to logical/symbolic search and deduction systems like miniKanren or SAT solvers or other constraint solvers, thus saving those systems from having to consider individual bits of a numeric result. (An SMT solver, if I understand correctly, is just a SAT solver extended with such an external "theory checker".)

(Similarly, the original truth maintenance system in Stallman and Sussman 1977 was a nonlinear circuit simulation package, kind of like an early SPICE; it was used to search among combinations of cases for piecewise-linear circuit component models, each case considered then being solved by a linear constraint solver.)

In the mathematically-oriented programming language Julia, there are several automatic differentiation libraries, and one named ReverseDiffSource is used by the Markov Chain Monte Carlo engine Lora to compute gradients of statistical models for, as far as I can tell, probabilistic programming systems (see above).

Interestingly, it turns out that the Tapenade automatic differentiation system uses program-state snapshotting (see above) and deterministic rebuilding (see above) to allow its reverse-mode automatic differentiation to work on imperative programs that overwrite part of their state during execution.

"The largest application to date [to have been automatically differentiated] is a 1.6 million line FEM code written in Fortran 77."

How widely can automatic differentiation be applied? Does it indeed synergize with efficient constraint solvers like miniKanren or CVC4, as I speculate above?

(I don't really understand automatic differentiation, so I hope none of the above contains any grievous errors.)

Bitcoin

Some years ago, after a conversation with Aaron Swartz, Zooko wrote a paper with an unmemorable title, now generally known as the "Zooko's Triangle paper". He proposed that although we would like globally-unique names in computer systems to be human-readable, securely dereference to the correct referent, and not be vulnerable to a centralized authority, in practice we can only achieve any two of these three properties.

Specifically, secure hashes, as used in content-hash-addressable blob stores, are not human-readable (the best we've been able to do is reduce them to about 80 bits and use representations like "able merit floor gower jerry jews sd", "ADD RAKE BABY LUCK MADE GOLD FEET SEEN", or "企珓鑣毒昕传"), and other kinds of global names are not "self-certifying", in Mazières's sense, so it would seems that we have to trust some external authority to certify them. Of course, fully homomorphic encryption (see above) could in theory enable this problem to be solved, but it's still not feasible, and when Zooko wrote his paper, it wasn't even on the radar.

Bitcoin, a variation on Nick Szabo's property title clubs, came out some years later. As Aaron pointed out, it demonstrated an alternative: a replicated global data store subject to nearly arbitrary consistency constraints that was not vulnerable to any particular participant, without having to figure out how to do FHE.

Bitcoin and pseudonymous cryptocurrency systems like it may be the most powerful primitive in this list, to the point that I suspect they may be a bad idea — the reason I haven't participated so far. Frictionless cross-border capital flows like those enabled by Bitcoin were expected to result from Chaum's centralized anonymous "digital cash" systems, which instead failed in the market. As Intel physicist Timothy C. May famously observed at the Hackers conference (perhaps Hackers 1989?), such flows seem likely to make taxation essentially voluntary, resulting in the collapse of governments. As pointed out later on the cypherpunks list, they could also enable pseudonymous betting to be used to crowdfund political assassinations, something that John Poindexter tried in 2003 in the Total Information Awareness program, resulting in a Congressional inquiry; this also seems likely to result in the collapse of governments.

I expect this to be a traumatic event, possibly resulting in the destruction of civilization.

However, Bitcoin also can be applied to solve a variety of difficult distributed-systems problems, and civilization might survive it and therefore be able to apply it to them. Naming is one; remitting money to your family overseas is another; email postage to stop spam is another; secure P2P rendezvous advertisement is another;

XXX

Deep neural networks

Conservative approximation

of what? parsing, say, or interval arithmetic.

Closures and Continuations

This is the Scheme 1975 vision of powerful primitives: closures give you one single way to do ad-hoc polymorphism, by giving you

in a sense first-class templated functions which you can press into service both as objects, as lazily evaluated values, and as basic blocks for control-flow constructs; and call-with-current-continuation gives you one single control-flow construct that subsumes threads, exceptions, Common-Lisp-style resumable errors, and backtracking, and allows you to invert control flow and turn blocking functions into nonblocking ones, and vice versa, which is kind of like the transactional memory concurrency constructs I mentioned above. Raph Levien's Io language provides a clean syntax that uses closure invocation even for statement sequencing.

Unfortunately, in a sense these constructs are *too* powerful.

If a continuation can be saved from anywhere, it's unsafe to irreversibly clean up resources on exit from the block where they are used; a continuation invocation could transfer control back inside, for example to implement thread context switching. At last I think `dynamic-wind` has been added to the Scheme standard, but it is substantially harder to use than `unwind-protect` or `try/finally`. Unrestricted multi-use first-class continuations can be implemented simply by allocating all your activation records on the heap, but implementing them *efficiently* more or less requires implementing segmented stacks, which makes every function call more expensive, although stack segmentation also makes threads a heck of a lot cheaper.

And even very clever compilers are unlikely to match the zero-cost exception handling that's standard in modern C++.

In a sense, using one single construct for all of these things requires both the human reader and either the compiler or the runtime to reconstruct a conservative approximation of some knowledge that was in the head of the original author (is this a thrown exception, a backtrack, or a thread context switch?), but who didn't write it down.

The same problem attends the use of closures and tail-calls for all control flow. The set of variables captured by a closure is purely implicit, so both the human reader and the compiler must reconstruct them; consequently, the lifetime of variables in a language with closures is purely implicit. But the compiler needs this lifetime information to produce efficient code, the author needs it to write code that works, and a human reader needs it to understand the code.

So I feel that, while continuations and closures are extremely powerful *semantic* primitives, and they have brilliantly elucidated many crucial aspects of compilation, their strength-to-weight ratio as *system-building* primitives is in doubt. They do result in shorter source code, but they often don't succeed in decoupling the code built on top of them from the aspects of the implementation they elide.

You could make many of the same accusations about dynamic typing, of course. I think the major difference is that while dynamic typing makes debugging easier (because the program mostly runs, and then when it crashes with a type error, you see an example of why), closures and first-class continuations make debugging harder.

You could make a similar accusation about implicit imperative control-flow sequencing: your program implicitly specifies a total ordering of computational steps to perform, and then the compiler works hard to recover the partial order you actually had in mind, in order to be able to execute your code efficiently. Nowadays, so does

your out-of-order-executing CPU.

Collaboration facilities

Succinct data structures

"Succinct data structures" are an extension of the compressed indexing work I mentioned under "suffix arrays". Unfortunately, I don't understand them. XXX

Interval arithmetic

Interval arithmetic is a particular form of conservative approximation (through abstract interpretation), with two principal uses: preventing numerical errors and avoiding computation.

Numerical errors are ubiquitous where we use floating-point math, because floating-point has finite precision, so its results are commonly approximate. The IEEE-754 floating-point standard offers control of the rounding mode — you can request that calculation results be rounded, for example, up or down. This allows you to, for example, calculate the sum of a list of numbers twice, once rounding up and once rounding down, and be sure that the true result was bounded by the two calculated results.

In interval arithmetic, instead of calculating with individual numbers, we calculate with (min, max) pairs of numbers known to bound the true quantity. Calculating (a, b) + (c, d) is quite simple: it's just (a + c (rounded down), b + d (rounded up)). Some other operations, like multiplication, are more complicated: (a, b) × (c, d) might be (a × c, b × d), but, for example, if a and b are positive and c and d are negative, it will be (b × c, a × d), with the appropriate rounding. Division is a bit more complicated still: (a, b) ÷ (c, d) might be a neighborhood of infinity, if c and d have opposite signs.

Interval-arithmetic libraries are available for bulletproofing your numerical computations by, as above, doing each operation two or more times, using different rounding modes. This can save you a lot of numerical analysis. These libraries are powerful and well-developed, but they are not really what interests me at the moment.

The more interesting case, to me, is avoiding computation.

SICP gives the example of approximating the zero of an arbitrary continuous, not necessarily differentiable, function, by recursively subdividing an interval in which it is seen to cross zero. You can extend this to find the zero locus of an arbitrary continuous multidimensional function by using interval arithmetic to rule out intervals where the function cannot be zero. But the technique has fairly broad applicability.

Consider backface removal. In rendering a solid bounded by polygons viewed from the outside, you can avoid half the occlusion computation if you eliminate the polygons that face away from the camera, since they will always be occluded by polygons on the near side of the object. So you can compute the normal for each polygon and consider whether it's facing toward or away from the camera.

This still involves computing something for each polygon on each frame, though. Interval arithmetic can save us. Suppose that the surface mesh is recursively divided into regions, and we store intervals for the x, y, and z components of the normals of the polygons in each region. Now, we can traverse this tree recursively and not even

descend into parts of the surface all of whose polygons face away from the camera, or for that matter all of whose polygons face toward the camera. It's only the mixed regions that require examination.

This saves us nearly all the computation for the backfaces, but we are still traversing the tree on each frame. We can do better still. Suppose we are rotating the object at a fixed, slow speed. Then, the rotation matrix for a given span of time can *also* be represented with interval coefficients, and we can multiply the normal intervals for mesh regions through this rotation matrix, discovering which parts of the surface don't face the camera at all during entire time intervals.

Somewhat similarly, when you're rendering, if you can compute the color at a point on the screen, and then bounds on the *gradient* of the color in pixel coordinates for a region around that point, you can determine whether that area contains any detail that needs to be rendered. If it's just a smooth gradient (the d[color]/dx and d[color]/dy are tightly bounded), you can render just a smooth gradient. And if you're computing an animation, you can also compute bounds over time.

(This is in some sense related to memoization and incremental computation: it allows you to change an input to a function slightly and retain its previous value, as long as you don't move outside an interval for which you've computed the result.)

I'm trying to remember the name of the guy who did his dissertation on precise interval-arithmetic rendering of implicit surfaces.

This is a kind of wild generalization of the widely-known bounding-box culling technique in computer graphics, and it allows us to achieve enormous economies of computation by computing that entire regions of a space of possibilities are of no interest. It's common to get three, four, or five orders of magnitude speedup with this approach, which you can then apply to focusing in more detail on the areas where more detail is called for.

It seems clear that this kind of possibility-bounding can work hand-in-hand with AI search algorithms (or simple nondeterministic search) and optimization algorithms, although I've never seen it applied in that way. If your SMT solver is looking for a contradiction in a region, you may be able to rule out the entire region at once. If you can place bounds on the "goodness" of points in an entire region of the parameter space, you may be able to quickly focus in on parts of the parameter space that are possibly of interest.

This only works usefully for operations that are in some useful sense mostly continuous, where reducing the size of the domain you're considering for an input will provoke a usefully reduced size of the range over which the operation's outputs are to be found. The bit-reversal function, for example, will tend to wreak havoc on interval-arithmetic approaches; you can only put useful (min, max) bounds on its output once its input is inside a very small range indeed. An interesting question is whether you can extend the kind of tractability that interval arithmetic provides to other kinds of functions, perhaps by using different representations than simply (min, max) pairs.

For example, earlier today I was optimizing a proportional-font word-wrap algorithm, which is one of the more expensive parts of a text-rendering system, simply because it has to examine every

character of the text it's wrapping to discover its glyph width. You could imagine a precomputed general-purpose interval tree covering the text, consisting of statements like "characters from 1032 to 1040 are all in the alphabetical interval 'a' to 'l'". From such an interval and a similar tree built over the font metrics, you could calculate a glyph-width interval: all the characters in that range then have a glyph width between 2 and 4, perhaps. And that would allow you to bound the sum of those glyph widths to be in the range (8×2, 8×4), which means that it's much less than the line width.

You could imagine a word-wrap algorithm expressed in a higher-level form, seeking the last candidate linebreak character before the prefix sum of the glyph widths of the characters exceeded the column width, being executed efficiently by progressively approximating the width-exceeding crossover and the last candidate linebreak, avoiding examining most of the characters.

But it seems obvious that such an algorithm, if it were useful (most likely it would only be faster than visiting every character once the lines became unreasonably long) would work *much better* if the interval tree over the text bounded the text's *glyph widths*, not its *codepoint values*, because the mapping from codepoint to glyph width is so irregular. As soon as your interval includes both 'l' and 'm', it spans the full range of possible glyph widths — even if the text itself is "the"!

Lempel-Ziv compression: an update

Gossip

IPv4 provides you with a universal address space and a low-latency unreliable datagram sending facility. Put the seven bytes of a destination IP address, protocol number, and port number into the head of an IP datagram, calculate the checksum, and hand it to your nearest router, and it'll likely get delivered to its destination. This is a seriously powerful primitive, enabling you to knit together all kinds of disparate unreliable transport networks into a single giant network: the inter-net.

Unfortunately, the only application that this directly provides is voice-over-IP, or maybe unreliable instant messaging. TCP is a little higher-level in some sense: it gives you a virtual serial-port connection or bidirectional pipe. This is still very low-level for many applications.

A gossip protocol is a way to share data among a group of participants despite unreliable and intermittent connectivity among them; whenever two succeed in rendezvousing, they interchange information. Typically gossip is used to converge on a gradually-growing set, but you can substitute any CRDT (see above) for the graduallly-growing set.

Gossip is no higher-level than TCP, and indeed many routing protocols are gossip-based. You can run it on top of other protocols, of course, and Bitcoin (see above) distributes both transactions and mined blocks using gossip.

Generally gossip protocols are resilient against information loss, but not against information flooding, and flooding can be the effective equivalent of loss. This typically means that either you must be able to identify and disconnect flooders, for example in a gossip-net

including only your laptop, your phone, and your server; or you must be able to drop messages when a flood is in progress, resulting in information loss. Bitcoin ameliorates this problem using hashcash (the proof of work being the hash of the newly mined block) but this approach doesn't ensure that legitimate messages will be propagated; it can raise the price of propagating them too high.

Algebraic incremental updates

Several of the earlier items in this document talk about incrementally updating the result of a computation by means of memoizing small pieces of it and only re-executing the parts affected by an input change. However, in some cases, a more efficient approach is available; Manuel Simoni wrote about it a few years back in the case of incremental MapReduce.

Doing a MapReduce incrementally with the memoizing approach is possible, of course.

The map function runs on an input chunk and produces a sorted mapped-input chunk in the filesystem; this file is in a sense a memoized result of the map function, or rather a whole pile of memoized results, and a small change to the input file generally should produce a small change to this output file, and it can do so efficiently if you can figure out what part of the output file corresponds to unchanged input.

The reduce function is a bit trickier, since it's running on an arbitrarily large set of mapped-input chunks with the same key. We can take some advantage of the fact that those chunks are in an arbitrary order, so the reduction is more or less required to be associative and commutative, so we can apply the reduction operator in a tree topology, which is an optimal configuration for memoization to be able to minimize the work for an input change, to O(log N).

However, in many cases, the reduce function is not merely commutative and associative; it also admits an inverse. (Min, max, and other quantile functions are the usual exceptions.) In these cases, a much more efficient approach is available, which processes input changes in O(1): when a mapped-input record goes away, you update the reduction function's output with its inverse; when a new mapped-input record is added ("inserted" into reduce's input), you simply update the reduction function's output with it; and mutations can be handled as a removal composed with an insertion.

This is also the way that relational databases normally handle index updates. They do not recompute the index for a table when a value in an indexed column changes, not even reusing memoized mergeable index blocks built from unchanged blocks of records; they delete the old value from the index and insert the new one. In this case, the "reduction" operation could be considered the updating of a sorted master file with a sorted update file containing insertions and deletions, and sometimes it is actually implemented this way, accumulating updates in a "side file" until they are large enough to be efficiently applied.

I'm calling this approach to incremental updates "algebraic" because it depends on algebraic properties of the reduction function: that it is commutative, associative, and admits an inverse, making it an Abelian group operation, I think. XXX

The old trick of compositing on-screen objects using XOR is

another example of this: to move a sprite, you would first quickly XOR it with the pixels at its old position, and then at its new position, rather than calculating a bounding box for the update that needed to be slowly redrawn from some kind of scenegraph. METAFONT's representation of filledness (each pixel contains a count of how many times it's been painted; 0 is white, anything else is black) would also be amenable to such an approach to animation, perhaps without the overlap artifacts that attended the XOR approach.

Are there other cases where such an algebraic property of a reduction or combination function could be exploited to get rapid incremental updates of cached computation results? Is there an automatic way to discover them, perhaps through abstract interpretation, thus avoiding the need to explicitly program the algebraic incremental update in each case?

Compile-time instrumentation and object-code instrumentation

A lot of the techniques discussed here involve augmenting some kind of program with extra new functionality: maybe running it forwards and backwards, or changing its regular number arithmetic into arithmetic on intervals or Jacobians. In an interpreted object-oriented language, that's fairly easy: instead of passing in a Number object, you pass in an Interval object or whatever. But what if you're dealing with code that isn't interpreted, maybe because you want it to run fast?

You can abstractly interpret machine code, of course, amounting to a sort of augmented emulator. Valgrind and AFL show two approaches to this problem: AFL inserts extra tracking code into the program at compile-time, and Valgrind inserts it into the program's machine code. A framework for this kind of instrumentation allows you to perform such analyses on arbitrary programs, without having to build the programs around the particular kind of abstract execution that you want.

I am not yet sure how useful this is, but I suspect that the answer is "very useful indeed". With this kind of technique, you can in theory build programs or subroutines with any existing toolchain that produces machine code, then treat them as any of a variety of abstract models.

This might seem like a very difficult thing to do, and indeed Valgrind is a monument to great software engineering, but I think you can probably get a significant fraction of the way there with relatively little effort. The /bin/ls installed on this netbook is about nineteen thousand instructions; half of those are mov, movl, or jmp, and getting to 18000 involves also call, lea, je, cmp, test, add, nop, jne, pop, sub, push, xor, ret, cmpb, movzbl, movb, sete, and or. If you handled common instructions like those and the other control-flow instructions, and you were running on a 386-family CPU, you could probably have a slow general-purpose path for the instructions you didn't write special handling for, simply by snapshotting the registers, jumping to a piece of code that has the instruction, and then snapshotting the registers again to see what changed.

This is a fair bit of code, but a lot less than a decent C compiler.

Partial evaluation

A lot of software optimization techniques have to do with specializing a generic algorithm for a particular set of circumstances. A polymorphic multiplication is slow; a 32-bit by 32-bit integer multiply is faster; a 32-bit integer multiply by the number 10 is potentially faster still. Automatically deriving these simpler versions, given the general case and an argument to hold constant, is "partial evaluation" or sometimes "specialization". A lot of the C++ STL could be thought of as partial evaluation of ad-hoc polymorphic operations: you take, say, a generic sorting algorithm and you specialize it for a particular container type, which itself is a generic container type specialized for a particular element type. In a language like Smalltalk, all of these algorithms and containers might be equally polymorphic, but with the type decisions made at run-time rather than compile-time.

An interesting aspect of this class of optimizations is that they are often applicable at the source-language level, rather than requiring a separate lower-level language to express them in, as register allocation often does.

The three Futamura projections are a particularly recursive application of this concept.

In the first Futamura projection, an interpreter specialized for a particular input program becomes an executable version of that program, an approach which may be useful even in its crudest form if your objective is merely simplifying installation; but given the mythical Sufficiently Intelligent Optimizer, is a rigorous way to automatically derive an executable from a source program and an interpreter.

Of course, automatically deriving an executable from a source program is compiling it. So if you partially evaluate the partial evaluator (!) with respect to the interpreter argument, you have generated a compiler from the interpreter, again automatically. This is the second Futamura projection.

Thus, if you partially evaluate the partial evaluator, whose two arguments are a program and an input to hold constant, with respect to its program argument, you have generated a compiler-compiler, which will convert an interpreter for any language into a compiler for that same language.

In a sense, this is cheating a little bit: your "compiler" can only run on the same platform the interpreter ran on (and which the partial evaluator was equipped to understand and optimize code for), so this doesn't work for cross-compilers, and somebody had to write the executable code to perform each of the operations in the interpreted language — either using another compiler, or in machine code, or the code for whatever platform the interpreter was written for. Typically people write partial evaluators for "nice" platforms like Scheme or C instead of hairy platforms like AMD64 or Forth, so this doesn't really help you with compiler bootstrapping, by itself.

It could help enormously with compiler optimizations, though, and compiler optimizations expand the scope of high-level constructs that you can write without an unacceptable loss of performance.

Implementing partial evaluation in a useful way involves program slicing — tracing the flow of values through the program from the fixed argument — and also abstract interpretation, since often the

useful statements that we can deduce about intermediate results in the program are not their exact values but merely particular predicates that are true of them at particular points in the program.

From another point of view, mechanical partial evaluation allows us to move computation freely between compile-time and run-time, letting us metaprogram in exactly the same language our run-time program is written in, and indeed mixing code at the two times freely. (Under some circumstances such an intimate commingling might be undesirable — for example, if you want to be able to predict the run time or memory usage of the output program. But perhaps you could make queries or assertions about the compiler output to fill this gap.)

A very similar kind of partial-evaluation-at-run-time is what's behind Acar's algorithms for self-adjusting computation: you have a hoard of precomputed results flowing from the input arguments that didn't change, and you need only compute the results that flow from the arguments that did. This suggests that cross-fertilization between the approaches may be fruitful: any techniques that can accelerate or simplify one of them are likely to be applicable to the other. Self-adjusting computation is in some sense more powerful, in that its hoard of memoized results allows an efficient response to a change in *any subset* of the inputs, rather than just *one particular subset*; but partial-evaluation systems can use specialized machine operations for the interactions between the fixed and variable subsets of values.

In particular, you may be able to generate a partially evaluated program by taking an execution trace of a self-adjusting program with respect to a particular set of changed input values. You may have to use either abstract execution (changing the input values to "unknown 1", "unknown 2", etc.) or systematically explore the space of possible sequences of taken branches (like American Fuzzy Lop, perhaps, or perhaps using a more systematic approach of backtracking to before each branch and taking it the other direction, with some kind of conservative trace merging in order to keep trace proliferation finite. You can either reason backwards from a branch condition to find inputs that will lead to it, or you can conservatively assume that if conditional X was computed transitively from input Y, then it's possible for input Y to make it go either way, and force it to go the wrong way, thus generating a conservative approximation of the possible Y-driven control flows.)

How wide a spectrum of optimizations can partial evaluation take over? What kind of language would be best suited for use with it?

Linear algebra

Matrix multiplication, that kind of thing. Maybe this is too obvious to mention, since it's fundamental to 3-D rendering, to statistical computing, to scientific computing in general, and so on. Still, it's not applied to as many things as it could be, in part because it's often considered purely numerical in nature.

As one example, the table of defined symbols in an executable or library could be thought of as a vector along a dimension of symbols, with the signal's definition (usually a memory address) at each point. The table of *undefined* symbols (unresolved relocations) in an object file (including an executable or library) is a (sparse) matrix whose rows are symbols and whose columns are memory addresses that refer to those symbols. Multiplying the symbol table through the

relocations matrix gives you a (sparse) vector of values to be added to the object file. In this way, a general-purpose parallel, distributed, or incremental sparse-matrix-multiplication algorithm provides you with a parallel, distributed, or incremental linker.

(In practice, you might have different relocation types, and on the 386, the addresses might not be aligned, but you nevertheless need to compute carries, so it's not quite as simple as regarding the object file as a large dense vector of words some of which contain memory addresses.)

Convolution

Convolution is a well-established powerful primitive for digital signal processing and the mathematics of linear time-invariant systems, in particular because of two very useful properties for improving computational efficiency:

• **Closure under composition.** Any linear time-invariant transform of a signal can be represented by convolution with some kernel, and convolution with any kernel is a linear time-invariant transform. This means that convolutions are *closed under composition*. In particular, linear time-invariant transforms of *discrete* signals can be represented by convolution with *discrete* kernels, and the kernel representing the composition of some discrete kernels has a length that is the *sum* of their lengths. This means you can compose together an arbitrary sequence of convolutions into a single convolution, then apply that convolution in a single operation. This is analogous to the closure properties of matrix multiplication, which is so useful to 3-D rendering; of arithmetic operations on the generator representation of continued fractions, as explained in HAKMEM, which is useful for exact arithmetic on all computable real numbers; and of interval arithmetic.

• **Pointwise product implementation.** Convolution is homomorphic to pointwise product under the Fourier transform, which is to say that the convolution of two functions is the inverse Fourier transform of the pointwise products of their Fourier transforms, which means that convolution can perform frequency-selective filtering. (This is the "convolution theorem".). Also, the Fourier transform of the pointwise product of two functions is the convolution of their Fourier transforms, which you can intuitively derive from the angle-sum trigonometric identities, and which gives rise to useful properties like superheterodyning and the limited bandwidth of the sidebands of amplitude modulation.

• **Commutativity.** When the underlying pointwise multiplication operation is commutative, convolution is commutative.

Because of the product-multiplication property, the convolution `f*g` of kernels `f` and `g` will not contain any frequencies that are not present in both `f` and `g`. (This may be useful for optimizing the implementation of the convolution operation by computing with downsampled versions of the kernel.)

Entirely in the domain of time-domain signal processing, you could imagine an evaluator for a complex expression DAG of convolution operations, discrete samples, repetition operations, weighted sums, delay operations, and domain restriction that used strategies similar to those of a SQL query optimizer to find an efficient evaluation

strategy for the expression within specified precision and performance constraints, using any number of the AI search techniques mentioned above. I don't think anyone has done this yet; typically the evaluation strategy is programmed manually by some dude in Matlab.

Convolution is used in particular for signal filtering (including image blurring and sharpening) and for simulating the effect of some physical system, whether optical, electrical, or audio, in particular including audio reverberation.

But there are domains a bit outside of what we usually think of as signal processing that could also benefit from convolution.

You can synthesize a xylophone tune by convolving the score, a time and frequency representation composed of impulses whose dependent variable is note volume, with a instrument patch, and extracting the frequency=0 slice. If frequency is represented using equal-temperament semitones, other parallel slices are transpositions.

The scores for some simple kinds of canons are the convolution of the score for the dux with a repetition and transposition function.

If, instead of using impulses, you use white noise all along the duration of a note, you can synthesize some kinds of sustained instruments, like violin and pipe organ, from windowed samples.

Instead of compositing the "glyphs" of a "sound font" into a temporal representation, you can composite the glyphs of a font into a window by convolving the font with a signal whose (x, y, glyph-id) impulses place and color individual glyphs. If you composite them into a 3-D opacity field instead, then you can get font resizing, drop shadows, pen width and shape, crude bolding, and glyph composition from features such as serifs, stems, and stroke thicknesses into the bargain, if you add an additional dimension of feature type or stroke thickness.

Similarly, an animation could convolve cels with (x, y, z, t) paths, perhaps followed by the same kind of 3-D or 2½D projection to provide opacity. It might be desirable to do the convolution in a space with five to seven dimensions, perhaps including rotation or even stretching, in order to express more of the desirable operations of animation.

A potential great advantage of this kind of unified convolutional architecture is that it is relatively practical to allow the user to ask "Why?" about a thing they see and get a reasonably comprehensible answer, without incorporating a lot of special-purpose mechanisms for answering "Why?" in each case.

Much of the above might not be practical with existing convolution code optimized for discrete samples, high density, and low dimensionality, but techniques based on interval arithmetic, query optimizers, and/or automatic differentiation (see above) could make them practical.

Discrete convolution is an operation built from two fundamental operations, multiplication of corresponding elements and summing the products. The associativity property that give rise to its closure under composition would seem to require some kind of algebraic ring to operate over, although I don't know that it depends on *all* of the ring postulates. Schönhage–Strassen multiplication is one application of convolution over a finite ring $\mathbb{Z}/n\mathbb{Z}$ (i.e. the Galois field $GF(p^n)$), but we could also imagine, for example, computing a convolution

over quaternions or 4×4 matrices representing three-dimensional transformations. (Such a convolution is not commutative. Can you compute it with the Fourier-transform trick anyway?)

But what about other data structures commonly used in programming? Can convolution be applied productively to things like polynomials, bits, strings, lists, binary relations, and finite maps (dicts), with some other operations standing in for multiplication and addition?

The most common example is Elias and Viterbi's convolutional coding for error correction, which XORs together certain plaintext bits from a sliding window to produce coded bits. A 1:1 convolutional code is exactly a convolution of a bitvector kernel with the plaintext, using AND and XOR (which are multiplication and addition in $\mathbb{Z}/2\mathbb{Z}$), but by itself is useless; the normal procedure is to interleave several such 1:1 codes, so that one bit from each code forms a "codeword". (And then, typically, you throw away some of the bits.)

You could, again, consider the different kernels to be displaced along an axis perpendicular to the text, and then two-dimensional convolution in the bit ring produces the bits of the convolutional code spread out on a two-dimensional plane.

http://www.math.nthu.edu.tw/~amen/2011/101219-4.pdf is about "polynomial division by convolution" XXX

http://stackoverflow.com/questions/22683195/boolean-convolution-algorithm XXX points out that you can convolve bitvectors in O(N log N) time by using the number-theoretical transform (FFT in $\mathbb{Z}/n\mathbb{Z}$) for a ring size larger than the shorter vector, and then saturate the results a the end.

http://mathoverflow.net/questions/10237/does-the-convolution-theorem-apply-to-weaker-algebraic-structures says, "it is a major open question in discrete algorithms as to which algebraic structures admit fast convolution algorithms and which do not." … "A substantially subquadratic algorithm for (min,+) convolution would (to my knowledge) imply a subcubic algorithm all-pairs shortest paths in general graphs, a longstanding open problem." Also mentions infimal convolution.

Optimizing compilers to machine code

Optimizing compilers are of course a standard tool in the programmer's toolkit since FORTRAN I, but usually we use them, but our programs don't. But there are a lot of cases where our programs *could* use them.

This is all mostly about constant-factor performance improvements, so you might want to skip it if you don't believe in those.

Suppose you've parsed a SQL query and derived the best query plan you can for it, but you estimate that it's still going to have to examine 5 million rows. What should you do?

Well, one possibility is to compile your query plan into C, then compile it into machine code with a C compiler, then run it. TCC can compile hundreds of lines of code per millisecond, and even GCC can compile a few lines of code per millisecond. The result typically

is only faster than interpreted code executed by an optimized interpreter by constant factors, but the constant factors can be substantial, like 5 to 30. It can make the difference between executing the SQL query in 15 seconds and executing it in 500 milliseconds.

There are a couple of obstacles to using this technique ubiquitously. One is that the result is potentially harder to debug, because of the extra level of indirection. Another is that if you have to write the compiler yourself, it's considerably harder than writing the interpreter, especially when you have to port to a new architecture. A third is that typically there are some fiddly bits relating to mprotect() and runtime dependency on the compiler and getting memory that's both writable and executable.

The main one, though, is the compilation speed. If an ad-hoc SQL query takes 100ms to run interpreted, you can't justify spending 200ms in a C compiler to get it to run in some shorter time.

A simple technique that improves compilation speed substantially, especially at low optimization levels, is to emit an abstract syntax tree rather than a sequence of bytes. This is the approach taken by Lisp environments that provide `eval`; its argument is an S-expression, which is essentially an AST. Unfortunately, compiled Lisps are usually kind of slow. Racket and Clojure may be shaping up to be exceptions.

There are several different practical ways to do this today in different programming environments:

- ObjectWeb2 ASM is a very widely used system for rapidly emitting JVM bytecode, which is then "interpreted" by compiling it to machine code and then, if it becomes a bottleneck, by running the bytecode through an optimizing compiler.
- LLVM, although its compilation is fairly slow, was originally intended for this purpose, and it can still be used for it, even though it's been mostly retargeted for ahead-of-time compilation.
- LuaJit compiles arbitrary code in a superset of Lua with many low-level constructs added to machine code, for amd64, i386, or ARM.
- TCC is very fast and supports most GCC extensions to C; it has a compile-into-memory mode, or you can generate a .so dynamic library and use `ldopen` to read it in. The emitted code is on the order of 5 times slower than code emitted by GCC with optimization, and only marginally worth than GCC without optimization. Even GCC is capable of compiling a few hundred lines of code in well under a second, as long as you don't `#include` big header files.
- Even compiling machine code into memory yourself isn't that hard, though it's nonportable; you can implement a simple system in C in a few hours and a few hundred lines of code. It's handy to use `gcc -fverbose-asm -Wa,-adhln=foo.lst foo.c` in order to see what constructs GCC generates.
- `eval` in PyPy also compiles Python code into optimized machine code, and MyHDL uses this to get enormous speedups for simulating digital hardware.

Of course, compilers are related to nearly everything else I've been talking about.

Memoization is such a helpful technique for compilers that we've been caching compiler output for decades (using automatic

dependency tracking and deterministic rebuilding), and `ccache` is a content-addressable blob store for memoizing C compiler output. A lot of the tradeoffs with compilation speed become less of a problem if you can memoize the compilation result, like a cached SQL query plan.

There has been experimental work on building distributed compilers that save the optimizations they've discovered in a common optimization store so that they can be reused later without having to search for them. (I forget who wrote that paper.) Users sometimes switch browsers because of the performance of their JS compilers. Compilers tend to be heavy users of pointers, and they tend to not have to run under strict deadlines or tight resource constraints, so FP-persistent data structures are a good fit for them. Incremental compilers, which would only recompile the part of your code that you'd edited, used to be popular; of course, it can be difficult to efficiently identify which part that was, and perhaps rolling hashes can help. (Incremental linkers are still popular, and the boundary between compilers and linkers is somewhat fluid.) Compilers frequently use backtracking search and constraint solving to find applicable optimizations, and memoized backtracking gives us PEG parsing. Nondeterministic search over compiler executions (or, rather, interpreter optimizations) is what miniKanren uses to automatically generate programs with certain properties. Not only can you use partial evaluation to implement a compiler; you can also use a compiler to implement partial evaluation. Indeed, there is a very fine line between compilers from a language into itself and partial evaluators. Some virtual machines, like QEMU (by the author of TCC), are implemented largely as compilers from the machine code of the guest machine into the machine code of the host machine.

A cute algorithm for card-image templates

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

There's a trick I think I saw originally in REXX, and which I think originally comes from the IBM mainframe world.

Suppose you have a record with some fixed format and you want to reformat it. For example, you have this:

```
199712100036325SITTLER   KRAGEN
```

And you want to reformat it to this:

```
KRAGEN    SITTLER    $00363.25  10/12/1997
```

The thing that would make this easy would be if you could write a couple of "picture" lines showing the desired input and output, and have software apply the transformation automatically:

```
199712100036325SITTLER   KRAGEN
19YyMmDd23456780PQRSTUVWXopqrstuvwx
opqrstuvwxOPQRSTUVWX $23456.78  Dd/Mm/19Yy
KRAGEN    SITTLER    $00363.25  10/12/1997
```

So far that's nothing terribly special. You use the correspondence of the characters in the before-and-after picture to show where to move the input characters around to in the output.

The special part is that it turns out you can implement this with a simple character substitution, the same kind of thing you would use to transform uppercase to lowercase or vice versa, or remove accents from ISO-8859-1 text for accent-insensitive comparison, or translate between EBCDIC and ASCII. Here's what it looks like in Python.

```
>>> import string
>>> the_input = '199712100036325SITTLER   KRAGEN    '
>>> beforepic = '19YyMmDd23456780PQRSTUVWXopqrstuvwx'
>>> afterpic  = 'opqrstuvwxOPQRSTUVWX $23456.78  Dd/Mm/19Yy'
>>> cipher = string.maketrans(beforepic, the_input)
>>> string.translate(afterpic, cipher)
'KRAGEN    SITTLER    $00363.25  10/12/1997'
```

So first we compute a character substitution that would convert `beforepic` into `the_input`. Then we apply that substitution to `afterpic`, and we get the desired output.

It's not a very versatile trick --- all the characters in `beforepic` have to be distinct, so it can't work in this form for anything over 256 bytes, it only handles fixed-width fields, and you can see I had a hard time coming up with reasonable-looking characters to use in the templates even in this small example. But the clever thing about it is that, given the existing ability to translate a string of characters according to such a table of correspondences, and the ability to construct such a table from a before and after string, it only takes a

couple of lines of code.

Recursive curves

Kragen Javier Sitaker, 2019-06-10 (5 minutes)

Thinking about the issues in Dercuano drawings (p. 64), I came up with some ideas that I think will be pretty interesting for interactive drawing. As usual, they are (sort of) algebraic and recursive.

The fundamental *spatial* element of the system is a curve, what you might call a path or a polyline. A curve is a continuous function from some interval of t points in time to (x, y) points in space, so it has direction and potentially variable velocity and duration as well as positions. (Maybe it also has a continuously varying pressure.) All curves start at time $t=0$, but they may have different end points.

The easiest way to create a new curve is to draw one with the mouse (which, in Some musings on applying Fitts's Law to user interface design and data compression (p. 1164), I found had a bandwidth of about 6 bits per second) or a multitouch touchscreen (which I haven't really tested yet but am hoping to find will have better bandwidth; it does have pressure). But you can also create curves that are straight lines or circles.

Each curve also has some kind of visual attributes, like width, color, transparency, blurriness, and some kind of noise texture, for each of stroke and fill. For right now, though, I'm less interested in those than about the purely positional ones.

Given a curve C, there are several unary operations that give new curves: C.reversed, which is the same positions in reverse order; C.normalized, which is the same positions with their time interval compressed or stretched to $t \in [0, 1]$; C.closed, which adds an instant straight-line jump back to the start; and C.constant, which makes the velocity along the curve constant, but doesn't change its duration. If curves also carry pressure information, there's also C.monoline, which sets the pressure to unity; C.brush, which sets the pressure to the reciprocal of the velocity; and C.invbrush, which sets the velocity to the reciprocal of the pressure. I want on-screen buttons of some kind to select these operations.

There are also operations to combine a curve, or set of curves, with a point: C + P translates the curve by the (x, y) coordinates in P, while P·C rotates and scales the curve (around its start point?) by the parameters in the point. I want interactive operations for invoking these with a point I specify interactively using the mouse or using pinch-zoom with two fingers. These two operations $P_0 \cdot C + P_1$ form a "frame of reference".

Each point along a curve can be associated with a frame of reference in different ways, and another curve can be transformed by that frame of reference. First, there's a translated frame of reference, where the rotate-and-scale part of the transformation is the identity. Second, there's a translated-and-rotated frame of reference, where the rotate-and-scale part of the transformation scales by unity but rotates so that the tangent forward along the curve is always in the same direction, or in some arbitrary direction when the tangent doesn't exist. Third, there are translated-and-rotated frames of reference where the scale is taken from the velocity or pressure of the curve.

The operation C_0.interpolate(C_1, C_2, N) produces a set of N

curves. The first curve is C_1 translated and rotated to the beginning of C_0, and the last curve is C_2 translated and rotated to the end of C_0. The curves in between interpolate smoothly between them. Another similar operation does the same thing without the rotation. These operations are invocable in a direct-manipulation kind of way; initially C_1 and C_2 are the same, and N can be interactively adjusted up and down.

(Hmm, maybe this is the wrong formulation? Maybe I actually want to add C_1 and C_2 to the definition of C_0? In that case the objects become drawings rather than curves? Maybe I want to be able to interactively see the interpolated curves as I'm drawing C_0? Maybe drawing C_0 is, at least normally, a context-menu operation on C_1? What about adding noise to the interpolated curves?)

The idea is that a variety of visual repetition with variability, including things like grids, hatching on one side of a line, wood textures, starbursts, and tree branches, becomes straightforward and easy to express and to adapt, while capturing the real Kolmogorov complexity of the drawing in the data structure that is built up.

Transmitting low-power TV signals around your house via RF modulation with an SDR

Kragen Javier Sitaker, 2019-12-01 (6 minutes)

Suppose you want a multi-monitor setup. As Elda King points out your monitors are more convenient to use if they're wireless, and perhaps more trustworthy (and certainly lower latency) if they have no RAM. Fortunately, there's a device that already exists with these attributes: the analog TV. They are currently being discarded in enormous numbers.

What would it take to use many analog TVs as prosthetic wireless monitors for your computer system? Merely an RF modulator, ideally on unused TV channels, and an antenna that's just strong enough to reach across the room. If it uses near-field transmission it might be able to be even more local and more efficient than the inverse-square law would suggest. RF modulators for VHF channels 3 and 4 were common home-computer accessories around 1980, but using cables rather than antennas to connect to the TV.

You don't get a whole lot of resolution with the analog TV standards: NTSC is 525 lines, while PAL and SECAM are 625 lines, with 4:3 aspect ratios --- 700x525 or 833x625 in theory if you use square pels, but some of that is lost to overscan, the HBI and VBI. The 625-line resolution has a 49-line VBI, so you only get 576 lines on the screen, or 768x576 if you use square pels; NTSC has only 486 visible lines out of its 525, or 648x486 with square pels. And because this is *interlaced*, one-pixel-thick letters can be hard to read as they flicker at 25 or 30 Hz. Analog HDTV never hit the mass market anywhere but Japan, so if you want higher resolution, you need to transmit DVB.

Still, if you're transmitting many frequencies at once, you can run many TVs at once.

NTSC is amplitude-modulated, which is why snow is such a problem, and the whole signal is 6 MHz wide. The VHF channels are in the 30 to 300 MHz "VHF" band, while the UHF channels are in the 300 MHz to 3 GHz "UHF" band. In North America, channels 2 to 6 occupy 54 to 88 MHz, 6 MHz each, while channels 7 to 13 occupy 174 to 216 MHz, again 6 MHz each, while UHF channels 52 to 69 occupied 698 MHz to 806 MHz until 2009, channels 14 to 20 occupied 470 to 512 MHz, channels 21 to 36 occupied 512 to 608 MHz, channel 37 was reserved for mostly radio astronomy, and channels 38 to 51 occupy 614 to 698 MHz until 2020; unlicensed devices are officially permitted in the 652-663 MHz range, including part of channels 44 and 46, and all of channel 45. Until 1983, 806 MHz to 890 MHz was UHF channels 70 to 83, so older TVs might be able to receive those, too.

Aside from channel 45, probably any transmission on these frequencies is illegal in the US unless you do it inside a Faraday cage.

The bandplan here in Argentina is presumably different, but harder to get information on.

A quarter-wave monopole antenna at 806 MHz would be 93 mm, so efficient antennas are compact and easy to build, and the "far field" might be the other side of the room. UHF frequencies transmit almost entirely by line of sight and are even substantially attenuated by building walls. The VHF frequencies, below 300 MHz, have much better wall penetration and can take advantage of ground bounce; at the lower extreme of 54 MHz, a quarter-wave monopole is 1.39 m long, which is inconveniently large, but by the same token, near-field communication can extend out several meters --- the Fraunhofer distance $2D^2/\lambda$ for a 2-m antenna would be 1.44 m, and a 4-meter loop antenna might be practical, as discussed in Can you bitbang wireless communication between AVRs? How about AM-radio energy harvesting? (p. 2509), which would give you a near-field range of almost 6 meters.

You only get about a third of a megapixel per TV channel, so you need at least three channels, 18 MHz of bandwidth, to get a megapixel, and thus at least 36 Msps, better 50 Msps. The USRP N200 and N210, like the USRP2 before them, have dual DACs running at 400 Msps. So they should easily be able to handle that DAC demand if you can compute the waveform; indeed, at the DAC level at least, they should be able to transmit on 66 contiguous NTSC TV channels at once, covering the entire UHF TV band!

Of course it would be foolish to attempt to transmit a signal in this way that you wanted to maintain confidential, since your neighbors can probably tune in to it.

Vladislav Fomitchev KM4VTH demonstrated this more or less working in 2018 using GNU Radio, a HackRF One (US$600 in Argentina), and a signal flow graph he constructed, and marble has demonstrated doing something similar with GNU Radio, a HackRF One and PAL. Argilo has published a flow graph for transmitting ATSC on 438 MHz with GNU Radio and a BladeRF; the BladeRF has 61.44 MHz sampling and 2x2 MIMO and costs US$420 from SparkFun but isn't available in Argentina.

Harvesting energy with a clamp-on transformer

Kragen Javier Sitaker, 2013-05-17 (7 minutes)

Clamp-on ammeters have a ferromagnetic "clamp" that encloses a wire in a closed magnetic circuit; the magnetic field induced in the ferromagnetic material is proportional to the total net current flux enclosed by the clamp, and you can measure this field precisely with a Hall-effect sensor, thus distinguishing wires carrying a load from wires that don't.

You could use the same approach to build a low-power electronic device that powers itself by leeching energy from the magnetic field around a current-carrying wire, without needing a direct electrical connection. This could enhance safety and reliability and ease installation, since you can "plug in" such a device without making a direct electrical connection, and if the device shorts out, it won't cause an electrical fire. Not only could it harvest power without ever coming in contact with the wire, it could harvest power without even coming near the wire; it need only enclose the wire with a loop of ferrite without also enclosing its return path.

Effectively this is a clamp-on transformer, with the "primary winding" of the transformer having only one turn of wire. If that wire is normally carrying, say, 100 amps, then the secondary winding of the transformer with, say, 1000 turns, could draw up to 100 milliamps; but if the total available voltage to be dropped through that one turn is 240 volts, the secondary winding would need to handle 240kV, which is difficult. If we limit the secondary winding voltage to 10V, then the voltage drop on the primary will be an insignificantly small 10mV, and the total power being transmitted can be up to 10mV * 100 A = 1 watt; the secondary winding then can draw up to 1 watt / 10 volts = 100 mA still. That's enough power to allow the use of a very simple power supply (say, a diode, a small capacitor, and a 7805) and a relatively inefficient electronic device.

If you don't enclose the wire in ferrite, but simply put a ferrite rod near the wire and perpendicular to it, you'll be able to harvest orders of magnitude less energy, but installation would be even easier.

Inductive coupling is only one possible way to harvest energy from power-line fields. Capacitive coupling is also feasible. However, the 60Hz of typical line power presents an extremely difficult problem for capacitive-coupling energy harvesting. If you manage 10pF of capacitive coupling to a power line field, which is probably about all you can hope for, your $1/\omega C$ capacitive reactance is 270 megohms at 60Hz. The other side of your power-supply input is then going to be your capacitive coupling to ground at around 100pF, I think. (Would it be better or worse if you had a wire to ground? Better, I assume.) You're going to need a power supply with an input impedance in the hundreds of megohms in order to be able to take advantage of that. Megohms or tens of megohms is probably feasible with CMOS; hundreds of megohms is probably not.

However, all is not lost! Fluorescent lights and high-intensity discharge lights powered by AC produce much-higher-frequency

harmonics, some one to two orders of magnitude higher in frequency. This brings the capacitive reactance down to the megohms to tens of megohms range you need.

So you could parasitically capture a significant fraction of the line voltage, but only in the high-frequency harmonics produced by the discharge.

Another approach, which would be more practical in areas without electrical lines, is to harvest atmospheric electricity, either from actual lightning strikes or directly from the atmospheric voltage gradient. During a lightning storm, atmospheric voltage gradients can reach 100kV/m, only an order of magnitude below air's ionization strength. In clear weather (the "fair weather condition"), it falls three orders of magnitude to some 100V/m.

A lightning rod struck by lightning has some 30kA available, but only for tens to hundreds of microseconds. If you erect a ten-meter lightning rod, you could in theory harvest up to a megavolt of the lightning's voltage --- a few megajoules per lightning strike. If you put your lightning rod on a mountain top, you could perhaps get several lightning strikes per month, for a total average power on the order of a watt.

Harvesting the energy of a lightning strike, however, seems like a really difficult problem. A 1000:1 step-up transformer as discussed above could reduce your 30kA to some 30A, at the cost of boosting your megavolt to a gigavolt. If you put a series of these transformers along the lightning rod's path to ground, you could drop only a tiny fraction of the voltage through each one, making the situation more manageable. If you can dump this massive amount of power through a low-resistance path into some kind of resonating circuit, you could then store it for milliseconds up to seconds in order to harvest it at a more reasonable pace.

Harvesting the atmospheric voltage gradient directly seems much more feasible, and I've heard you can do it as simply as holding up a spent fluorescent light tube in one hand in a thunderstorm. In the absence of a separate source of ions, you need a corona discharge to couple your wire to the atmospheric charge, which means that you need points sharp enough that the electric field intensity at the point is above air's ionization strength. If you're working with, say, only 1000 volts, then you need micron-scale conductive sharp points to generate ionization, and preferably enough of them to support a substantial ionic current. By contrast, if you have 400kV --- say, a two-meter fluorescent tube plus a two-meter-tall person, in a thunderstorm with 100kV/m --- then any conductive point radius below around 40cm will produce a sufficient field, if I remember my electrodynamics correctly. The points of the prongs on the end of the fluorescent tube are on the order of 0.4 mm in radius, so they should work down to about 400 volts.

The question, then, is how much current and thus power you can expect to draw at these voltages. It's observed that the fluorescent lamp in the thunderstorm experiment will simply flash periodically as the lamp's parasitic capacitance to ground charges sufficiently to ionize its contents and discharge the capacitance. If I SWAG this, we have a 1ms flash per 5 seconds at 40 watts with a 200V breakdown voltage, giving 40 microamps average charging current; or maybe charging a 1pF parasitic tube capacitance to 200V in 5 seconds, giving

about 40 picoamps. This difference of six orders of magnitude suggests that I don't know enough about the problem even to guess.

Analemma sundial

Kragen Javier Sitaker, 2019-07-05 (11 minutes)

There are a variety of sundial designs that incorporate the solar analemma in one or another form, so that they can provide the precise time according to current civil time standards — which hold that each day and each second should have the same length despite the eccentricity and consequent inconstant speed of the Earth's orbit and, thus, the solar day.

A spot on the wall

I was thinking in particular of using the sunbeam reflected from a small round mirror to illuminate a spot on a wall; the point illuminated on the wall will vary according to both the time of day and the angle of elevation of the sun.

```
    |       |
    | light |w
    \-------|a
mirror      |l
            |l
```

Each day the sunbeam will sweep a (noncircular) arc across this wall, but from day to day the arc will vary as the elevation angle of the sun does. The total variation in elevation from solstice to solstice is about 47°; it is fastest near the equinoxes and slowest near the solstices. I roughly guess that that means that, at its fastest, it moves about half a degree per day, which is rather pleasantly the size of the sun as seen from Earth.

This means that, if the mirror is small enough, the spot on the wall will also take up about half a degree (32 arcminutes) as seen from the mirror. So, in theory, you could mark the arcs on the wall for each day of the year; they will gradually be displaced by a quarter of a day each year until being reset by the leap year.

This means that, in theory, you could mark two times of day on the wall at each point, one for when the sun crosses that point moving north and one for when it is moving south. Or you could switch out the wall twice a year, on the solstices, and mark one time of day on the wall at each point.

Since an hour is 15° (360÷24), half a degree is about two minutes, so each point along the centerline of the spot's track will be illuminated for about two minutes. This would seem to pose some difficulties for telling time with a sundial with less error than two minutes, but if the mirror is small, the spot is a well-defined circle with the size of the sun's disc, and you can see the location of its center to a precision of something like a tenth of its width; this should permit a timekeeping precision of something like ten seconds.

For those ten seconds to constitute about a millimeter of motion, the distance from the small mirror to the wall needs to be about 1.4 meters, although perhaps this can be productively folded up using additional mirrors. At this distance, the 32-arcminute sun disk will project as a 13-mm-diameter circle convolved with the shape of the

mirror. (If you want a sharp boundary on it without sacrificing as much brightness, you might consider using a mirror in the shape of an annulus; an annulus convolved with a solid circle has the same diameter, but a much sharper boundary, than two solid circles convolved.)

Caustics

Suppose that the wall is itself a mirror, but not a flat one. Then it will reflect the spot elsewhere, for example onto a screen, but distorted and possibly changed in direction. It can form caustics in the reflection, and these caustics can have stronger contrasts than mere solar caustics, because the light falling on the wall comes from a smaller point source than the sun's disc. (It might be worthwhile to make the mirror subtend, for example, 8 arcminutes; at the 1.4-meter distance suggested above, this is about 3.3 millimeters. (Assuming we're using a circular mirror, not an annulus.)

To focus the spot back to a 3.3-mm point at the same distance would merely require a radius of curvature of that same 1.4 meters. The versine of half of 32 arcminutes is about 1.1×10^{-5}, so if you made the 13-mm spot a spherical reflector, its center would need to be cut deeper than its edges by about 15 microns, a number which varies only a little as the focal length and direction vary. See Caustics (p. 1619) for some notes on how to shape nearly-flat surfaces to arbitrary shapes with this kind of precision.

In particular, it wouldn't be that hard for a series of facets to reflect the beam to the same place on the screen as the sun's image passed over them, so that instead of scanning across the screen, the projected image stayed in the same place; but it could vary from one facet to the next. And if the facet is convex rather than concave, it could be larger than the 13-mm illuminated area on the wall, rather than smaller, though at the cost of brightness.

(And there don't need to be actual facets; you can use a smooth curve only occasionally interrupted with the kind of discontinuity you see in Fresnel lenses. Facets are just a crude discrete approximation of the problem.)

Unavoidably, though, since each point along the center of the track is illuminated for two minutes, there will be a certain amount of fading from one image to the next over the course of those two minutes.

One particularly attention-getting image to project might be the current time, written in Arabic numerals, with a colon, like the various "digital sundial" projects that exist.

This poses the problem of how to avoid a vague superposition of numerals during the two-minute transition from one facet to the next. A possible solution is to use a larger number of smaller facets, so that the facets close to the transition zone are projecting not just the current time but the *negative* of the adjacent time; on one side of the boundary of the 12:46 to 12:48 transition, for example, you would project a mostly gray image with "12:4" in white, "6" in white, and "8" in black, while on the other side, you would project the "8" in white and the "6" in black. Thus, as the preponderance of light shifted from one side of the boundary to the other, the "6" would fade to gray and be replaced by the "8".

(To keep the black image from being obtrusive a bit further over,

you'd want to counterbalance it with a dimmer and perhaps blurrier white image, etc.; I think the brightness curve ends up looking something like the derivative of sinc. Essentially you're trying to Wiener-filter out the low-pass temporal filter imposed by the sun's nonzero width in order to get a sharper transition.)

This approach to getting faster transitions by counterbalancing with inverse images probably precludes the use of *caustics* in the sense of places where the Jacobian determinant (of the position of the beam on the screen as a function of its position on the mirrored wall) vanishes, since that could easily create more brightness than you could counterbalance, but you can still vary the magnitude of that determinant substantially to vary the brightness. But your contrast ratio might be limited to 2:1, which sucks.

This poses the additional question of whether the facets would need to be so small that diffraction would pose a problem. If the individual facets were 1 mm across and were effectively planar at the level of 100-μm-diameter "microfacets", which seems feasible, the Airy limit ($1.220\lambda/D$ for a circular aperture, as explained in Caustic business card (p. 255)) would be, say, 1.22·555 nm / 100 μm, about 23 arcminutes of diffraction-limited divergence. So, yes, diffraction would start to pose a problem; the wall might need to be larger and further away, and you might need to use larger microfacets. But it's not so overwhelming that I think it makes the problem infeasible, just challenging.

Scratch holograms

Suppose that instead of using caustics, you use Bill Beaty's scratch holograms. You stick a bronze plaque on a wall, paint it with clear polyurethane, and put a peephole nearby. The reflection off the scratches on the plaque from the sun when you're looking through the peephole displays the current time.

A simple approximation, which is easy to improve on, is to divide the plaque into pixels, and add scratches to each pixel to reflect the sun at every angle where it should be lit up. As long as the scratches aren't too dense, the scratches at different angles will only interfere a little bit with each other, but it still might be a good idea to display different times on different parts of the display to reduce the "burn-in" effect of too many scratches in the same place. If the plaque is facing north (or south, if you're in the northern hemisphere *like a sucker*) and the peephole is in front of and below it, the sun will move through nearly a whole 180° arc each day, but faster close to noon.

Correcting for the Equation of Time can't be done by displaying different images at different times of year depending on the elevation, but it could be done to some extent by moving the peephole; the angle at which a point P on a scratch reflects is when it is perpendicular to the plane including your eye, the sun, and P. So moving the sun a little to the left is equivalent to moving your eye a little to the right, and vice versa. So it might be adequate to mark dates along the bottom of a viewing slit to show you where to position your eye. (Maybe a part of the plate you view from the side instead of from below could tell you what the sun's elevation is and thus what the date is.)

As with the analemma, I'm not going to do the math for the angles

right now.

The scratches, though, I will. The scratch depth needs to be at least on the order of a wavelength of light (say, half a wavelength) in order to scatter incoming light properly — the ray entering at a point should leave as a plane. It is unreasonably challenging to make the scratch walls much steeper than 45°, and indeed with the usual kind of abrasive scratches, you'll get

An IDE modeled on video games

Kragen Javier Sitaker, 2019-04-08 (5 minutes)

I was thinking about the famous Martin Shkreli screencast with Excel where he spends a few minutes working up a basic analysis of a company's balance sheet. Although in a sense what he's doing is mostly very simple, the demo is very flashy, and I certainly wouldn't be able to do it as quickly. He ends up spending an unreasonable amount of time cutting and pasting individual numbers from his browser into Excel.

Then I thought about the kids at my high school who played half an hour of Tetris per day (between classes) during a school year, which worked out to about 90 hours of Tetris practice spaced over most of a year. They reached fairly impressive speeds at Tetris, though one day I was wandering around Kobe and wandered into a video arcade where I saw some random Japanese dude doing Tetris things I had never imagined a human could do. He probably had thousands of hours of Tetris practice spaced over several years.

Typing games can rapidly improve typing speed once you've learned the basic touch-typing technique, while day-to-day typing, lacking the same time pressure, usually won't.

Programming often involves a lot of fiddling with user interfaces that don't offer a very direct way to get the result you're looking for, or determine whether you've gotten it, even for things that conceptually aren't very complicated. Some aspects of programming naturally involve deep thought, but others just involve rapid trial and error, and the higher the frequency at which this can be done, the better.

I wonder if you could hack together some kind of IDE that would enable interaction at a video-game pace, with video-game-like smoothness, and a series of exercises that would provide you with incentives to learn to use it smoothly, the way video games first guide you through a tutorial to learn their user interfaces and then use the gameplay to bring you gradually to a near-superhuman level of performance with them. Perhaps it could provide you with responsive interaction options you could use to incrementally approximate the program you wanted, getting rich, instant, and varied feedback on the program you had gotten so far and what the next possible steps would look like.

Some example mechanics:

- Extrinsically-organized prizes to guide you.
- Programming by example, as in Excel, gives you the opportunity to see an example output from your algorithm as you are developing it step by step. In some cases, it would be useful to see several outputs from different runs in parallel.
- Whether or not you're programming by example, it's useful to visualize the inputs, outputs, and intermediate values of any algorithm, whether these be test inputs or real inputs. But different kinds of data might have different kinds of visualizations. As in Excel, scalar numbers can be visualized as numbers; univariate functions could be visualized as plots or perhaps played as sounds;

bivariate functions could be visualized as images, 3-D plots, scatterplots, face plots, series of slices, and so on; tabular data can be displayed in tables; strings can be rendered as sequences of glyphs; and so on. Bret Victor's work visualizing Nile offers inspiration here.

• When programming by example, in general, you have some values and some operations on them that can yield further values. If you're focusing on one or two values in particular, there's some set of operations you're likely to apply to them to get more values. For example, if your value is a set of angles, likely operations might include elementwise sine, cosine, and tangent, as well as minimum, maximum, and cardinality. The menu of these operations can include a visualization of the operation results next to each operation, like Instagram filters.
• Tests can go red and green as your implementation changes; implementation code exercised by no green tests can be colored red, while implementation code with no test coverage can be colored grey. Generative tests can run continuously to produce new test cases, and individual test cases can be visualized.
• Quantitative visualizations of input data can be interactively edited, changing the data in real time. This suggests either using constraint-solving systems to specify the visualization or using iterative optimization algorithms to seek an input to an imperative visualization algorithm that will most closely approximate a given output.
• Algorithms learned from test data can be applied to further random data and the results visualized, or input data collated from other sources.
• Tutorials can focus on particular available algebras — integers, GF(2^{32}), strings, and so on — or particular families of algorithms.

Notes on a possible household air filter

Kragen Javier Sitaker, 2018-05-05 (updated 2018-05-15) (10 minutes)

I was thinking about filtering the air in my house, which is on a major thoroughfare with lots of diesel buses, burning that dirty high-sulfur diesel fuel which produces a lot of soot.

The standard approach, of course, is HEPA filters, which are made of disposable paper. I was thinking that a possible improvement would be to bubble the air through liquids, which could catch not only particulates but also a number of gases. Also, if you color the liquids, illuminate them with LEDs, and keep them in transparent tanks, it would look a lot cooler than a HEPA filter. You could use a series of such tanks to eliminate a lot of different particulates.

After the bubbles finish the tanks, they would need to pass through a fine screen to filter out any remaining droplets.

My apartment is 101 m³; filtering all of the air in it every six hours would thus require 4.7 ℓ/s of airflow, which is 10 cfm; as described in House scrubber (p. 248), you can get that out of a 75mm-diameter 4-watt 3000 RPM fan designed for a CPU cooler. However, that fan won't generate the head needed to bubble the air through a liquid; if we have a series of four tanks, each with liquid 100mm deep and of more or less the density of water, then we need 18 watts just to counteract the hydrostatic pressure, let alone producing the necessary flow rate through the bubble orifices. This suggests that perhaps using a few axial fans in series, each designed for a substantially higher flow rate, would likely do the trick.

XXX how do you calculate the head to produce a given flow through an orifice?

If the tanks are 10% bubble by volume, which seems like achievable and difficult to exceed by much, and the bubbles take 500ms to rise to the surface, then you need 23½ liters in each tank. If the tanks are 2 meters long, then they need to be 117½ mm wide in order to contain this much liquid.

You would need some system for replacing dirty filter liquids at some point, either manually or automatically. This is ideally done in batches to minimize the mixing of old dirty liquid in the new clean filter liquid.

Possibly useful liquids include:

- Plain water, which increases humidity, absorbs droplets of water-soluble liquids airborne from previous tanks, and absorbs particulate pollutants that aren't hydrophobic. It will also dissolve small amounts of gaseous contaminants, but probably not enough to be useful.
- Vegetable oil, which absorbs hydrophobic particulate pollutants. Any oil would work for this, but vegetable oil has the advantages that it's nontoxic, has very low vapor pressure at room temperature, and has somewhat higher surface tension than many alternative oils, reducing droplet formation. Used frying oil would likely work.
- Propylene glycol, which is nontoxic, has very low vapor pressure,

won't rot, and will absorb both hydrophilic and hydrophobic particulates, as well as vapors of many volatile organic compounds. It has relatively high surface tension (36 mN/m), reducing droplet formation. A lot of VOCs that won't dissolve significantly in vegetable oil are completely miscible with propylene glycol. It's also quite hygroscopic, so it serves to reduce humidity, but this could be a problem if it results in substantial dilution in normal use. At room temperature, propylene glycol reaches equilibrium with 60%-humidity air only once it's absorbed about 20% of its own weight in water!

• An aqueous solution of $CaCl_2$ or a similar salt will reduce humidity, potentially down to a very low level. Aside from directly controlling the humidity of the output air, this could be used to reduce the dilution by humidity of a later propylene-glycol or similar stage. Calcium chloride is also nontoxic. (An anhydrous calcium-chloride desiccator is actually what Dow's *A Guide to Glycols* recommends for drying air that will be in contact with propylene glycol if a nitrogen pad is not feasible.)

• An aqueous solution of a weak acid or weak base, such as sodium bicarbonate, could remove reactive gases such as SO_2 from the air. If you use calcium hydroxide (not weak!) or calcium carbonate for this, you produce gypsum as a bonus.

• Calcium hydroxide would also remove CO_2 from the air. If this is desirable, ethanolamine, diethanolamine or triethanolamine (in aqueous solution) may be a better choice, because it's substantially easier to "regenerate" by heating (to 120° in the case of ethanolamine) to drive out the carbon dioxide (somewhere outside). These unfortunately require at least 5 but ideally 200 atmospheres to absorb the carbon dioxide.

Regeneration

I mentioned above that the ethanolamines absorb a lot of carbon dioxide, which can be driven back out by heating, "regenerating" them. The topic of regeneration is interesting in general: rather than discarding the dirty filter liquid, you go through some kind of process to clean it, thus extending its life.

Particulates can be removed by filtration, but in some sense this is not a solution — you could have just filtered the air. More interesting is if you can remove them by centrifugation or flocculation.

Hygroscopic solutions such as propylene glycol and aqueous calcium chloride can also be regenerated by heating to drive off some of the water.

Pebble-bed alternatives

As mentioned earlier, Dow's recommendation for drying air that will be used to pad propylene glycol is to use an *anhydrous* calcium chloride desiccator. As I understand it, this is a pebble-bed kind of affair, with solid crystals of calcium chloride with air space between them.

Other kinds of pebble-bed-like things include the following:

• Platinum or palladium catalytic converters to remove organic compounds from the atmosphere, including even methane, as well as nitrogen oxides and ozone. Since a substantial part of the pollution

from both Otto and diesel engines consists of unburnt hydrocarbons, nitrogen oxides, and ozone, this could be very helpful in the city. These need to be hot to work, typically requiring a refractory substrate such as alumina, and they produce carbon dioxide, which may need to be managed.

• Activated carbon to adsorb many kinds of contaminant gases.

• Oxide or hydroxide of calcium, lithium, sodium, magnesium, or even potassium, to combine with carbon dioxide or (I assume) nitrogen oxides.

• Sodium bicarbonate is famous for adsorbing unpleasant odors, and would also eat acid gases like SO_2 or nitrogen oxides, though not carbon dioxide.

In general, pebble beds have the advantage over bubble tanks that they have no minimum pressure to operate. Also, as desiccators, they can reach lower humidities than aqueous solutions of salts can. They have the distinct disadvantage in this case of looking substantially less bitchin.

Also, pebble beds are less suited to continuous-flow processes. You can regenerate pebble beds in place by taking them out of service and passing a regenerant over them — typically hot air, but activated carbon needs a hot non-oxidizing gas instead, such as hot carbon dioxide. Steam is not suitable, as it degrades the carbon to produce highly toxic water gas. (It would be nice to have a non-oxidizing gas that isn't flammable or absurdly reactive, and is liquid or solid at room temperature, so that your activated-carbon regeneration gas doesn't pose a suffocation hazard. But nothing occurs to me at the moment.)

Plasma alternatives

If you want an air purifier that looks *really* cool, nothing can beat plasma, especially a reduced-pressure plasma with different alkali metals evaporating into it (from oxide or carbonate feedstocks applied to your electrodes, presumably). This will look especially cool if it uses high-frequency AC and it's inside a thin glass envelope so you can guide the plasma arcs with your fingers! But probably corona discharge in approximately atmospheric pressure is more practical.

Like a catalytic converter, this will also burn unburnt volatile hydrocarbons, and maybe also particulates, but the resulting gas is very far from breathable — it contains a substantial fraction of brown nitrogen oxide (NO_2), plus ozone and nitrous oxide (NO_2). The N_2O is reactive enough that you can combine it with just about anything (maybe bubbling it through sodium bicarbonate would be the easiest choice) but I'm not sure what to do about the ozone and nitrous other than using a catalytic converter from a car.

Oxidizing sodium, lithium, potassium, or even calcium or magnesium into the plasma, in addition to producing super awesome colors, might help to cut down on the nitrogen oxide production, too. But then you need to make sure you filter the generated metal oxides out of the air before you breathe it. Maybe some kind of hot acid refractory would work. Silica, for example, famously combines with sodium hydroxide to produce sodium silicate.

(Sodium and potassium nitrates are "saltpeter", a stable mineral that acts as the oxidant in gunpowder. Calcium nitrate, "norwegian saltpeter", also works for this. Magnesium nitrate is also stable. These are mostly used as fertilizer these days.

??? What are sodium, lithium, potassium, calcium, and magnesium nitrates like?

??? What are the other acid refractories?

Maybe the ozone could be made safe by passing the resulting gas over a "pebble bed" of something like used yerba mate or coffee grounds, thus converting it into relatively harmless carbon dioxide, and maybe a bit of water.

Argentine oscilloscope pricing 2016

Kragen Javier Sitaker, 2016-08-16 (4 minutes)

http://articulo.mercadolibre.com.ar/MLA-602979566-protec-osciloscopio-20-mhz-modelo-p-3502-c-_JM is a more or less typical cheap used analog oscilloscope: the 20MHz Protek P-3502C. The price is AR$3500 = US$232.

http://www.tek.com/oscilloscope/tbs1000b-digital-storage-oscilloscope Tektronix's cheapest current scope is this TBS1000B line; the lowest-end scope in the line is the TBS1032B, with 500Msps and 30MHz analog bandwidth, for US$450, with a recording length of 2500 points.

http://articulo.mercadolibre.com.ar/MLA-620039875-osciloscopio-hantek-6022-be-20-mhz-_JM is a typical USB oscilloscope: the Hantek HT6022BE20MHz: 20MHz, AR$5000 (=US$331), 1MΩ 25pF input impedance, 48Msps, 8-bit resolution, 20mV to 5V gain range.

https://www.seeedstudio.com/item_detail.html?p_id=736 is the Seeed Studio DSO Quad 4-channel Digital Storage Oscilloscope, which costs US$169. It claims 72 Msps but doesn't make any claims about analog input bandwidth on its two analog input channels. IIRC Seeed is an open-hardware shop; they do publish DSO Quad schematics and the Wiki lists user apps and it seems like they're using an AD9288BSTZ-40 for their ADC.

It seems like you ought to be able to meet or exceed the capabilities of the Hantek unit for a much lower price, especially using recycled chips. I mean basically this is two high-speed ADCs (or one with a demultiplexed input) hooked up to a USB interface in a metal box, right?

Three candidate ADCs are the US$3.69 TI ADS830E/2K5, the US$4.50 Maxim MAX19505ETM+T, and the US$3.28 Analog Devices AD9283BRSZ-50, which last is available in quantity 1 from Digi-Key at US$6.01.

The AD9283 family is 90mW, has 475 MHz analog bandwidth, a 46.5 SNR, a 1V p-p analog input range, and runs off 3 volts. "Low-cost digital oscilloscopes" are explicitly called out as a use for the thing in its datasheet; Matthew Lai designed such a scope based on a slightly higher-speed member of the family. It claims ENOB of 7.5 bits at 27 MHz input, which is better than the Hantek unit.

Its input capacitance is only 2 pF. It says its input resistance is only 7 to 13 kΩ, which seem to be pullup and pulldown resistors to the power rails. So you probably need some kind of preamp, like maybe an opamp or something, to get high input impedance.

Lai's design uses an FPGA to buffer the digitized signal. The Seeedstudio design uses both an FPGA and also an ARM Cortex microcontroller.

Lai's design's analog front end was as follows:

Input goes into a 1MΩ metal film resistor in parallel with 20pF ceramic cap (not sure about this). Buffered by a Texas Instruments OPA656 wideband op amp with JFET input (very high impedance, which we need, because the probe has high input impedance. Downside? bloody expensive).

There are a variety of OPA656 parts; Digi-Key has the OPA656U at US$10.69, but I think he may have used a slightly more expensive one, but maybe the price has come down since 2010. The OPA656 family seems like it might be somewhat overkill for this, with a 230MHz bandwidth and gain-bandwidth product, 70 mA output current (!!), and 65dB open-loop voltage gain.

Lai's total BOM cost is US$107.58; a quarter of this is these op-amps, and another quarter is the THS7002 preamp.

The Gelfand Principle, or how to choose educational examples

Kragen Javier Sitaker, 2007 to 2009 (8 minutes)

I was reading Doron Zeilberger's Opinion 65 about the Gelfand Principle, which he ascribes to Israel Gelfand. I'll restate what he says here.

He says it is better to begin by explaining that 1+2 = 2+1, and then go on to explain that this is true for all pairs a+b = b+a and that this is called the commutative property of addition, than to begin by giving the name, explaining that it means that always a+b = b+a, and then by giving an example. And he points out that 1+2 = 2+1 is the best example to use, because there's nothing particularly special about it. 0+1 = 1+0 is true, but in general 0+x = x+0 = x, and so someone might think that this commutative property is a special feature of 0. (In linear algebra, the identity matrix works this way: for all conformable M and identity matrices I, IM = MI, even though matrix multiplication is not commutative in general.) And 1+1 = 1+1, but that's because of the reflexive property of equality, not the commutative property of addition. So 1+2 = 2+1 is the simplest nontrivial example. It's a better example than, say, 424 + 501 = 501 + 424, because it's easier to prove: 1+2 is 1+(1+1), and 2+1 is (1+1)+1, and addition is associative, so those are the same.

In general, he argues, "Whenever you state a new concept, definition, or theorem, (and better still, right before you do) [you should] give the *simplest* possible non-trivial example." He also says:

> The Gelfand Principle should also be used in research articles. It is much easier to follow a new definition or theorem after a simple example is first given. Even proofs would be easier to follow if they are first spelled out concretely for a special case.

I agree. In fact, I've often groused to myself about mathematical papers being written in the opposite style. (I've spent some time lately reading John Backus's "Can Programming Be Liberated from the von Neumann Style?", which is not technically a math paper but contains theorems anyway, and it would be considerably improved by an application of this principle.) I've wondered whether other people --- certain mathematicians maybe --- actually find it easier to understand things in what seems to me like a backwards order: theorem first, then example.

(Amusingly, Zeilberger states the principle before he gives the above example of it, thus violating the principle he is trying to promote; however, he follows it in part, in that the commutative principle is probably the simplest possible nontrivial example of stating a theorem.)

Apparently, however, other people also feel that the Gelfand approach is the correct one. In response to Zeilberger's article, Tim Gowers wrote:

> I've just looked at your opinions page for the first time for a while, and read your article on two pedagogical principles. I was particularly interested in the first [the Gelfand Principle], because as a result of editing the Princeton Companion I have become incredibly conscious of it myself -- I'm tempted to say that I discovered it independently. Of course, it doesn't bother me that Gelfand got there first -- it is

SO clearly correct that it would be a miracle if I had not been anticipated. Instead, we have the depressing miracle that something so obvious should be practised by such a small percentage of mathematicians. I feel quite evangelistic about this, and have already started a one-man (except that now I see that you are an ally) campaign to publicize the principle. For example, a few weeks ago I was asked to give a talk about the Princeton Companion, and EXAMPLES FIRST was one of the main themes (which I illustrated by an example first: I gave a ridiculous and unmemorable definition of a "C-space" which was in fact a mathematical model of a car, and as soon as the word "car" was uttered, the definition was magically easier to remember).

I had always been aware, of course, of the value of giving the simplest non-trivial example. The thing that has really struck me is the value of giving it FIRST. I think it is very important to stress that this is an independently important part of the Gelfand principle (or else, if you were not including it, a separate and equally important principle).

Here is my "proof" that it is better to start with concrete examples and proceed to abstract definitions than it is to begin with the abstract definitions. If you give the example first, then it is easy for the reader to understand, so not much effort is needed to remember anything. Then, when you are presented with the abstract definition, you have a mental picture of an example, so the various components of the abstract definition become labels that you attach to this picture. If, on the other hand, you give the abstract definition first, then the components are meaningless, so you have no choice but to memorize them as if you were learning Chinese vocabulary or something. Then when you see the example, you have to go back and see how this meaningless stuff does in fact mean something. But that effort of memorization should have been unnecessary!

Dijkstra, unsurprisingly, disagrees (in EWD757-3):

There exists a school (I wouldn't call it a "school of thought") that believes in "teaching by example" and in "discovery by example". I don't. I concluded EWD376, which describes in detail the actual steps in which I had solved a problem from graph theory, with:

"Finally we draw attention to the fact that we did not draw a single example to explain what we were talking about or (even worse!) to discover what the program should do. And this, of course, is as it should be."

So what's the analogue in computer programming? You could argue that it's test-first programming, where you write the unit test before you write the code, and hopefully people will read it in the same sequence. The unit test is usually a better unit test if it's exactly this simplest non-trivial case. (Maybe it's better if there's an additional test that doesn't try to be simple, just in case you were mistaken about how trivial the case was.)

But in the mathematical case, you don't just write down the premises of the example, write down the conclusion, baldly assert that some theorem exists to connect the two, and then proceed to explaining what that theorem is and proving it in the general case. Instead, you demonstrate that the conclusion is true of that particular example, and then state the theorem and proof for the general case. This is much more similar to walking through the program as it executes the test case in a debugger and looking at all the intermediate values.

There was a thread on LtU about "Ivory Towers and Gelfand's Principle", on motivating language features with examples:

If an example has a solution that is nearly as good without a given language feature, then that example is not a good motivation for that feature. Perhaps not following this principle is partly what earned FP it's ivory tower reputation.

There was also a thread about this on LiveJournal.

Some notes on reverse-engineering The Wizard's Castle

Kragen Javier Sitaker, 2018-04-26 (9 minutes)

I remember when I was a kid I used to love playing Joe Power's "Wizard's Castle" game, which is about 900 lines and, as I learned today, originally ran on the 16-kilobyte model of the Exidy Sorcerer home computer at the New Directions in Computing computer store, after which the Kingdom of N'Dic is named.

When I was a kid I tried to understand the source code of the game, since after all it is only 900 lines, written in a programming language I was pretty familiar with, and performed a function I was pretty familiar with, having spent hundreds, if not thousands, of hours playing the game. Unfortunately, I didn't know what I was looking for.

I just downloaded the IPCO version of the the game from myabandonware.com and find that it's still somewhat hard to understand the source. Unfortunately this version is broken, or rather cheated — the map is revealed starting from the beginning of the game. So I needed to fix the bug, which turned out to be that line 4150 said:

```
4150 IF Q > 99 THEN Q=Q-100 ' LET Q=34 TO HIDE ROOMS
```

when it should say:

```
4150 IF Q > 99 THEN Q=34 ' LET Q=34 TO HIDE ROOMS
```

It also has a bug on line 3590, which says:

```
3590 PRINT CHR$(27);"E"
```

This is the clear-screen sequence for the Heath H89 and H19, but this version of the program is for GW-BASIC or BASICA; this line should just say

```
3590 CLS
```

Here is a sort of dictionary of the subroutines, goto targets, and variables in the program.

A$: a temporary input variable.

Q: a temporary variable used in many places for many things.

R$: an array of the 4 player race names. RC: the index of the player's race.

SAMP$: a parameter indicating whether the program was invoked from IPCO's SAMPLES.BAS program; if "YES" (due to being invoked as CHAIN "WIZARD", 1010) then, upon exit, it reinvokes SAMPLES.BAS rather than exiting to the BASIC prompt.

1000: program entry point

RF: a boolean indicating whether you have the Runestaff OF: a boolean indicating whether you have the Orb of Zot

L: an array of 512 ints, representing the castle contents. For

whatever reason (perhaps resulting from the conversion from the Sorceror version which stored this array in character RAM), this is a one-dimensional array with indices calculated by FND(Z) rather than a three-dimensional array. L entries have 100 added to them to mark them as "unknown". Valid numbers range from 1–33 and 101–133, with 34 as a sort of special case representation of the whole 101–133 range for the map.

The valid values are:

- . AN EMPTY ROOM
- E THE ENTRANCE
- U STAIRS GOING UP
- D STAIRS GOING DOWN
- P A POOL
- C A CHEST
- G GOLD PIECES
- F FLARES
- W A WARP
- S A SINKHOLE
- O A CRYSTAL ORB
- B A BOOK
- M A KOBOLD
- M AN ORC
- M A WOLF
- M A GOBLIN
- M AN OGRE
- M A TROLL
- M A BEAR
- M A MINOTAUR
- M A GARGOYLE
- M A CHIMERA
- M A BALROG
- M A DRAGON
- V A VENDOR
- T THE RUBY RED
- T THE NORN STONE
- T THE PALE PEARL
- T THE OPAL EYE
- T THE GREEN GEM
- T THE BLUE FLAME
- T THE PALANTIR
- T THE SILMARIL

These are used to index into C$() and I$() mentioned below.

The two other special unique items (the Runestaff and the Orb of Zot) do not have their own codes; the Runestaff is in the possession of a monster (and is thus in the same room with it) while the Orb of Zot is "disguised as" a warp, and in fact behaves as one.

C$(): an array of the 34 strings describing different room contents; the 34th is the dummy entry "X".

I$(): an array of the 34 characters to display different room contents on the map.

9590–9620: a subroutine to pick a randomly chosen empty room and set its contents to Q, returning its results in X, Y, and Z.

C: a 3×4 array of ints. C(1,4), C(2,4), and C(3,4) are used to

represent whether the player is afflicted with particular curses, I think — a leech that drains your gold, lethargy that makes you move more slowly, and forgetfulness, which slowly erases your map. These curses are found in particular empty rooms. This logic is in lines 2940–3050.

Lethargy apparently just makes you eat more often, but not eating doesn't harm you. This has the feeling of an unfinished feature. However, lethargy also gives monsters the initiative in combat.

H: the last time you ate. T: The current time.

W$(): an array of weapon and armor names; NO WEAPON is index 1, while NO ARMOR is index 5.

E$(): an array of 8 dishes one can cook from monsters.

WV: one less than the index of your current weapon in W$(), or 0 if you are empty-handed.

AV: 5 less than the index of our current armor in W$(), or 0 if you are empty-handed. AH: your armor's health or armor's hit points; when this reaches 0, the armor is destroyed.

LF: 1 if the player has a lamp, 0 otherwise. FL: the number of flares the player has. BL: 1 if the player is blind, 0 otherwise. BF: 1 if the player has a book stuck to their hands, 0 otherwise.

T(): an array of 8 ints which are 1 if the player possesses the corresponding treasure or 0 otherwise. These are in the same order as the numbers for the room contents; for valid indices, T(Q) represents the possession of C$(Q+25).

O(): an array of 3 ints containing the coordinates of the Orb of Zot
R(): an array of 3 ints containing the coordinates of the Runestaff

O$: the returned user input from the subroutine at 9830 or other input subroutines

FNA(Q): returns a random number in [1, Q]

FNB(Q): returns Q wrapped to the range [1, 8] (i.e. (Q-1) % 8 + 1), which is what you want for wrapping coordinates to the 3×3×3 hypertorus structure of Zot's castle

FNC(Q): returns Q if Q<19, otherwise 18; used for saturating arithmetic on character attribute values (strength ST, dexterity DX, intelligence IQ), which cannot increase past 18.

FND(Z): returns the index into L at which to find the contents of castle room (X, Y, Z).

FNE(Q): returns, roughly, Q % 100 — used to compute the true contents of a possibly unmapped room.

X: an X-coordinate in the castle, normally that of the player (but also an implicit argument to FND); saved in A when a temporary value is needed

Y: a Y-coordinate in the castle, normally that of the player (but also an implicit argument to FND); saved in B when a temporary value is needed

Z: a Z-coordinate in the castle, normally that of the player; saved in C when a temporary value is needed

A, B, C: used to save the player's X, Y, and Z at times; also used in one place temporarily for the coordinates of the Orb of Zot. Also, during combat, A is used to store the index of the monster type (12 less than its index into C$().)

VF: 1 if vendors are angry with you, 0 otherwise

Y$: a prompt string

NG: the number of games played so far, used to avoid

reintroducing the game

1–1200: initialization code for the whole program

1240–1390: initialization code for a new game ("restocking the castle")

9770–9820: subroutine to print a line of asterisks

9830–9870: subroutine to request a generic one-letter choice from the user in O$, with two entry points — the entry point at 9830 prints a blank line and a prompt, while the entry point at 9850 does not.

2920–8410: the main game turn loop.

My attempt to learn about jellybean electronic components

Kragen Javier Sitaker, 2017-02-08 (updated 2019-09-29) (22 minutes)

What parts are "jellybeans", and what are they like?

FETs

Normal FETs are N-channel enhancement-mode MOSFETs; JFETs, depletion-mode MOSFETs, and to some extent P-channel FETs are weirder.

G.M. Electronica's power MOSFET list

Here's a table of 16 popular FETs I found, with prices in quantity 1 from Digi-Key.

PN	Vds	A	ohms	Qg (nC)	¢	W	type
2N7000	60	.2	1.9	2	36	.4	
2N7002	60	.115	7	2	38		
IRF630	200	9	.4	45	86	75	
IRF9630	200	6.5	.7	29	151	74	P-chan
IRLI630G	200	6.2	.400	40	229	35	
IRLML6344	30	5	.029	6.8	36	1.3	
IRLML6402	20	3.7	.065	12	40	1.3	P-chan
EPC2036	100	1	.065	.910	97		GaN
SI3483CDV	30	8	.034	11.5	89	4.2	P-chan
FQP27P06	60	27	.070	43	134	120	P-chan
NTD4906N	30	54	.0055	24		2.6	obsolete
IRF7307	20	4.3	.140		83		dual (P&N)
BSS138	50	.200	3.5		24		
CPC3703CTR					70		depletion
2N5457	25	.01			230		JFET
2N5458	25	.01			230		JFET
SiS410DN	20	35	.0048	41	94	52	
PSMN4R0-40YS	40	100	.0056	38	88	106	holy shit
IRF540N	100	33	.044	71	145	130	fuck
IRF9540N	100	23	.117	110	189	110	P-chan
IRF9530	100	12	.300	38	138	88	P-chan SyC

The IRF630 N-channel FET https://www.digikey.com/product-detail/en/stmicroelectronics/IRF630/497-2757-5-ND/603782 is a monster. It's Digi-Key's most popular IRF* part (twenty thousand in stock at 86¢ quantity 1, 39¢ in quantity 1000) and can switch 9 amps (with pulses up to 36 amps) at up to 200 volts in 20 nanoseconds. Even G.M. Electronica, which generally only carries obsolete parts, lists an IRF630 in their catalog. And the TO-220 package can dissipate 75 watts. It includes an antiparallel zener capable of about ten amps for overvoltage and flyback protection. Its main drawbacks for Arduinoish use seem to be that it doesn't turn fully on until about 6 to 10 volts on the gate, its on-resistance is a high-for-a-power-FET 0.4Ω, and its max gate-source voltage is only 20 volts; but even at 4 volts, it's ohmic

with a reasonably low resistance up past two amps, maxing out at about three. Five volts gets you up to 11 amps. SyC Electrónica has it for US$0.75. It has a P-channel counterpart, the IRF9630, of which Digi-Key only has 2000 in stock; it's slightly worse at 6.5A and 0.8Ω.

The logic-level counterparts to International Rectifier's IRF *parts are the IRL* parts. One popular one is the IRLML6344 http://www.digikey.com/product-detail/en/infineon-technologies/IRLML6344TRPBF/IRLML6344TRPBFDKR-ND/2538162 (36¢ for one, down to 11.3¢ each) which switches 5A, 30V, at only 29mΩ, and turns on at 2.5V on the gate. Digi-Key has 650,000 of them in stock. A similar, slightly crappier, P-channel device is the IRLML6402 http://www.digikey.com/product-detail/en/infineon-technologies/IRLML6402TRPBF/IRLML6402PBFCT-ND/812500. The IRF630 itself has an IRL version, the IRLI630G, with the same 200V but a slightly lower current of 6.2 amps and like 70 ns of delay, but this is apparently a rare bird — Digi-Key charges US$2.29 for one.

The 2N7002 is Digi-Key's absolute most popular FET, with 1.6 million in stock; it's another N-channel FET that even G.M. Electronica carries; Digi-Key has 184 models, the most popular being

https://www.digikey.com/product-detail/en/diodes-incorporated/2N7002T-7-F/2N7002T-FDIDKR-ND/1837287, which is 38¢ for one and 8¢ each for 1000. This is a smaller-signal part — although it can handle 60V, it can only do up to 115mA and 300mW, and its on-resistance is multiple ohms (like 7Ω). But it switches at 2.5V, also in the same 20ns as the IRF630. At 5V gate voltage it reaches 500 mA, which (because of the high resistance) will burn it up if you let it continue. The ON Semiconductor version http://www.digikey.com/product-detail/en/on-semiconductor/2N7002LT1G/2N7002LT1GOSCT-ND/917791 is cheaper, as low as 2.958¢ in quantity 1000.

SyC Electrónica doesn't have the 2N7002 (though G. M. Electrónica does), but they do have the similar 2N7000 for US$0.12 http://www.sycelectronica.com.ar/articulo.php?codigo=2N7000. 60V, 200mA, 1.9Ω, switches on at 3V Vgs. eLemon carries it too at almost the same price http://www.elemon.net/BuscarSubRubros.aspx?Action=2&GrupoId=TR&RubroId=1710&SubRubroId=4. Even Tom Jennings recommends it!

The 2N7000/2N7002 datasheet from Fairchild doesn't give its Qg directly, but it seems to be designed for a 10V Vgs and has typically 20pF and up to 50pF of input capacitance, which I guess would mean 500pC? But ST's datasheet for their obsolete 2N7000 gives that for Qgd, plus another 800pC of Qgs, for a total of 1.4 to 2 nC.

The most popular non-2N7002 FET at Digi-Key is the EPC2036, which is a bumped gallium-nitride die (900µm square) with no packaging (to avoid bond-wire inductance!) https://www.digikey.com/product-detail/en/epc/EPC2036/917-1100-6-ND/5224979 for 97¢, down to 39¢. Needless to say, G.M. Electronica has never heard of it. It switches 1.7A at up to 100V with a resistance of only 65mΩ, which is supposedly about a 30 times higher breakdown voltage than can be achieved at that resistance with silicon, with a gate charge of only 910 pC, about an order of magnitude lower than MOSFETs, on a gate capacitance of about 80

pF. As a result, they can switch at over 10MHz. Apparently GaN power transistors like this debuted in 2010, which is why I hadn't heard of them until now.

Digi-Key's most popular P-channel MOSFET is Vishay's SI3483CDV, with six hundred thousand in stock at 89¢, down to 41¢. It switches up to 8 amps at up to 30 volts, and can handle gate-source voltages of up to 20 volts. Being a P-channel device, the drain and source are backward from the more common N-channel type: the source is positive, drain negative, and the gate voltage is measured below the source.

Other candidate P-channel MOSFETs people on #electronics recommend for default use include the IRF4905 (94¢, -55V Vds, 0.02Ω, 74A, 200W, 2-4 V threshold voltage, fully on at 10 volts, 180 nC gate charge, 18 ns turn-on delay time, 99 ns rise time, 61 ns turn-off delay time, 96 ns fall time).

In P-channel MOSFETs, SparkFun recommends the FQP27P06 https://www.sparkfun.com/products/10349 for 95¢; Digi-Key has them https://www.digikey.com/products/en?keywords=fqp27p06 for $1.34 down to 61¢. They switch up to 27 amps at up to 60 volts.

Tom Jennings recommends the NTD4906N. G. M. Electronica doesn't carry it, and Digi-Key marks it as obsolete. I don't understand its datasheet, which has wildly different current and power numbers. I suspect I didn't understand any of them.

For building an H-bridge, it's often useful to use N-channel and a P-channel MOSFETs together, and sometimes they come in a package for this purpose; the IRF7307 is a popular such device at Digi-Key https://www.digikey.com/product-detail/en/infineon-technologies/oo IRF7307TRPBF/IRF7307PBFDKR-ND/1648232 for 83¢ down to 37½¢, with twenty-two thousand in stock. G. M. Electronica also carries it. It can switch 4.3 amps at 20 volts in 100ns; its resistance is 50 mΩ on the N-channel side and 90 mΩ on the P-channel side. This is convenient, but in the standard design, you kind of have to use the same supply for the gate as for the load.

For a MOSFET with lower switching voltage, people seem to suggest the BSS138. http://www.digikey.com/product-detail/en/on-semiconductor/BSSoo 138LT1G/BSS138LT1GOSDKR-ND/1831753 lists it at 24¢ down to 4.6¢, switching 50V 200mA, with a high on-resistance of 3.5Ω. Sure enough, though, it passes almost 400mA at a 2.5-volt gate voltage.

Depletion-mode MOSFETs are apparently very exotic; Digi-Key's most popular one is the high-voltage 70¢ CPC3703CTR, of which it has almost forty-eight thousand in stock.

Of all of these, the only ones I've seen mentioned in Horowitz & Hill are the 2N7000, the 2N7002, and the BSS138. Neither GM nor SyC has the BSS138. Horowitz & Hill also tout LND150, DN3435, BS170, MMBF170, 2N5457, 2N5458, 2N5459, and BS250 parts as popular.

The 2N5457 and 2N5458 are available at SyC, though not GM. Digi-Key has them for US$2.30 (!!) down to US$1.01 but they sound inferior to others mentioned above (25V, 10mA). They're JFETs, though, so not directly comparable to the MOSFETs above.

All of the above are good only up to less than ten amps. The SiS410DN, by contrast, handles up to 35A; it's a 20V N-channel

MOSFET in a somewhat unusual package with almost 215,000 available at Digi-Key for 94¢ down to 43¢. Even more impressive, Philips/NXP/Nexperia's PSMN4R0-40YS, which came out in 2010, does 100A at 40V, up to 106W, costs 88¢ down to 51¢, and has 77,000 available at Digi-Key. Here in Argentina, apparently the only power MOSFETs people sell are higher-voltage International Rectifier (Infineon) HexFET parts like the IRF540N — at Digi-Key, 10,000 in stock, 145¢ down to 66¢, 33A at 100V, nice low 4V threshold voltage, and available from both G.M. and SyC. SyC sells it for 60¢. The P-channel counterpart is the IRF9540N. All SyC has in stock is the IRF9530, which is rated for only 12A.

Other drivers

Amusingly, the TIP120 bipolar NPN Darlington Jennings recommends replacing with an unavailable MOSFET is still "Active" https://www.digikey.com/product-detail/en/fairchild-on-semiconductor/TIP120/TIP120-ND/1052441. It switches 60V at 5A and costs 61¢ down to 26¢, but as Jennings points out, its 1000:1 or 2500:1 current gain is vastly inferior to power MOSFETs'; its voltage drop is many times higher, especially at low current; and its switching time is vastly longer at around 1000 ns.

The ULN2003 costs US$0.40 at SyC: http://www.sycelectronica.com.ar/articulo.php?codigo=ULN2003 It's an array of seven 500mA 50V 250ns current-sink Darlingtons with built-in flyback diodes. It's like a seven-pack of somewhat lower-powered TIP120s.

There's an 8-transistor version, the ULN2803, and (as I found in Microlens vibrating lightfield (p. 1219)) there used to be a high-side switching version UDN2891, but it's obsolete now. One alternative is the TI TLC59123 (US$1.81), which is an 8-output latching high-side driver, which has the advantage that it ignores its inputs except at clock edges. It's only 13.2V, unlike the 60V ULN2003, but it's also 500mA per channel, and it can supposedly be clocked at "up to 1 MHz" with clock pulses of 100ns and 100–200 ns propagation delays.

Bipolar transistors

Aside from the TIP120 and ULN2003 mentioned above, we have transistors. For example, https://www.digikey.com/product-detail/en/diodes-incorporated/MMBT3904-7-F/MMBT3904-FDICT-ND/815727, the MMBT3904, for 12¢ down to 2½¢, a SOT-23 NPN small-signal transistor. That's the SOT-23 version of the 2N3904, thus the weird prefix.

Thyristors

SCRs, triacs, and occasionally diacs are the workhorses of powerline switching. They typically turn on in 100 ns. Unlike MOSFETs, they fail open rather than closed (I think), but they have the disadvantage that you can't turn them off until the next zero-crossing of the waveform. Also, unlike MOSFETs and unlike relays (the other alternative for powerline switching), they have substantial voltage drops and so dissipate substantial power from the load current.

You might think that this would entirely prevent you from using them for switching DC, but the standard trick to solve this problem is to put an LC resonator either in series or in parallel with the thing so that the current drops to zero at some point, turning the thyristor off. This is called a "self-commutation circuit".

Triacs are the usual thing to use for powerline switching, since they have a gate electrode like a regular transistor, but can handle power in either direction like a diac. A typical triac might be the 95¢ STMicroelectronics T405Q-600B-TR ("Applications: Mahjong machines, lighting dimmers"), which can block up to 600 volts; once you trigger it with 1.3V and 5 mA on the gate electrode, it can carry up to 4 amps (dropping 1.5 V or less), and will continue to do so until the load current drops below 10 mA.

Diacs have no trigger electrode; they're triggered just by reaching the breakover voltage, like the no-longer-produced Shockley diode. A diac is like two Shockley diodes in antiparallel. A typical diac is the 49¢ Micro Commercial LLDB3-TP "silicon bidirectional diac", which breaks over at 28–36 volts in 2 µs and can handle two amps. While it's turned on, it drops 5 volts. There are higher-voltage diacs, as you would expect, but they're all fairly low power.

SCRs, the classic thyristors, are unidirectional, like Shockley diodes, but have a gate electrode, like a regular transistor or a triac. A typical SCR is the Littelfuse SK055NRP, which costs US$4.81 and can handle 55 amps RMS when you turn it on (or surges of 650 amps), dropping 1.8 volts, and can block up to a kilovolt when off, leaking 30 µA. You turn it on by feeding 40 mA into its gate at 1.5 volts, and it turns off when the current drops to 60 mA. I'm not sure how much reverse bias it can handle.

Op-amps

The LM324, from 1975. Available (LM324D, LM324N) at G.M. and (LM324, LM324-SMD) at SyC, mentioned in Horowitz & Hill, etc., 35000 available at Digi-Key for 48¢ down to 12¢. A quad bipolar op-amp that runs on 3V to 32V good to gain-bandwidth of 1.2MHz, open-loop amplification of 100k×, not quite rail-to-rail, 10 mA output.

Horowitz & Hill recommends the TLC272 as a popular MOSFET-input alternative to the LM324 and the LF411 and LF412 as JFET-input alternatives. The LF411 (available from GM) touts being "pin-compatible with the standard LM741", has 3 MHz of gain-bandwidth, sucks only 50pA from its input, costs US$1.19 down to 54¢ (but only has one op-amp on the chip), runs on up to 18 volts, 200k× open-loop amplification, ±12V output, like 20 mA output current. Digi-Key has 3000 available. The TLC272 (available from GM) spews out 30mA at up to 16 V and 2.2MHz of gain-bandwidth, sips an incredible 0.7pA of input current, and has two op-amps on a US$1.34 (down to 60.9¢) chip.

The LM741 itself (from 1968!) has stock of 68000, costs 66¢ down to 28¢, does 1.5MHz GBP at 80nA of input, 25mA of output, and up to 36V. I wasn't quite sure what its major advantages over the LM324 are, but it seems to cost about five times as much. Fortunately, both chips are popular enough that people have discussed this very question previously; they claim the LM324 is noisy and has crosstalk, but runs off a single supply instead of needing positive and

negative supply voltages.

Digi-Key's most popular item in the op-amp category is the tiny 70¢–53¢ MCP6031T-E/OT, which is rail-to-rail and can spew out 23mA while taking in 1pA, but only up to 10kHz and 5.5V. It's touted as having super low consumption. They suggest using it for battery current monitoring and "sensor conditioning", whatever that is. They have almost 165000 in stock.

In non-super-low-frequency opamps, Digi-Key's most popular item is the TSV321IDT, with 142000 in stock, but only available in quantity. The similar TSV324IPT, by contrast, is available in quantity 1 for 58¢, down to 24.9¢, with 162000 in stock. It's a quad rail-to-rail 1.4MHz GBP op-amp chip with a 70nA bipolar-class input current, 80mA output current, and up to 6 V.

If we demand another order of magnitude in gain-bandwidth product, we exclude 85% of the op-amps on Digi-Key and the price goes up a little; the LM7321MF/NOPB from 2008 is US$1.83 down to 54¢, has 45000 in stock, and is a rail-to-rail 20MHz op-amp with 1100 nA input bias and 100mA output at up to 32V.

An additional order of magnitude excludes half of the remainder, and we end up with things like the OPA356AIDBVR, for US$1.91 down to 94¢, a 200MHz GBW (450MHz unity-gain!) voltage feedback amplifier (?) with rail-to-rail output, 3pA input bias current, 100mA output at 5V, and 80 dB (!) open-loop gain, 11500 in stock. This seems to be where modern op-amps are normally.

None of the popular Digi-Key opamps seem to be available locally.

Power management

The LM317 is a 100mA 71¢ linear regulator adjustable over 1.2 to 32 volts output and accepting 3.7 to 38 volts input. It's 30¢ at SyC.

The 7805 is a 1A 62¢ linear regulator fixed at 5 volts output. There are other versions with other voltages, like the 7812, and the 79xx series is the negative-voltage counterpart. SyC has the 7805 for 35¢, and hasthe whole family, both negative and positive.

Viper-7 recommends instead the HT7333 and similar for low-current applications: "massively lower dropout voltage (around 1/10th) than 78xx regs, very low quiescent current (4uA), decent tempco (about 1mV per 2°C) and 0.2% line regulation."

Zeners

Digi-Key's most popular zener is the obsolete 50¢ MAZ30430ML, with 429000 in stock: 4.3V±7%, 200mW. Its cheapest available non-obsolete zener is the 5.1V 500mW 1N5231B-ND, with 16000 in stock, 11¢ down to 2.3¢; this is the 5.1V member of the 1N5221 series Horowitz & Hill use as their canonical low-voltage zeners.

Horowitz & Hill also suggest using the LM385 (1.23V, 63¢, 57000 in stock at Digi-Key, 10µA–20mA) instead of a low-voltage zener. Shirriff says the TL431 from 1978, an adjustable substitute for the LM385, is more common (42¢, 29000 in stock at Digi-Key, 2.5–20V, 600µA–100mA).

Viper-7's "Beginner's Shopping List"

Viper-7 from Freenode ##electronics wrote a page about which

3500 electronic components he thinks a beginner should buy for US$110, with links to AliExpress vendors. It doesn't go into a lot of detail in some cases, and I don't want to just copy the list here, but I'll point out a few notable things.

1500 of the 3500 parts are 1% resistors; historically 1% resistors were expensive, but they no longer are, so you might as well use them. However, he only recommends getting 30 different values to cover six orders of magnitude, which is five values per order of magnitude — presumably the standard 1.0, 2.2, 3.3, 4.7, and 6.8. This means you can hit any value to within ±10% with a single resistor, but if you need a more precise value you need to build a network.

In terms of capacitors (420 of them) he only recommends electrolytic and ceramic capacitors, and no large-value MLCCs — the ceramics only go up to 100 nF.

(He also recommends some inductors, of course, and 250 LEDs.)

He recommends relatively few discrete semiconductors, and unfortunately in some cases doesn't say which, but does specifically mention the IRLZ44N and IRF4905 (10 each).

In power supplies, he recommends getting 200 (unspecified) fixed linear regulators, plus ten LM317s; the only voltage reference he recommends is a bag of 140 zeners.

The only connectors he recommends are breadboards, jumper wires, breadboardable through-hole screw terminals, and a MicroSD adapter.

There's a section of recommended boards, including level shifters, Arduinos, serial adaptors, a NodeMCU, and an assortment of Arduino-targeted sensor boards.

The most interesting part is the "other ICs" section: ten 555s, five MCP23017 "16-bit I/O expanders", two TLC5940 16-bit 120mA PWM drivers, five LM348A clones of the 741 quad op-amp, ten LM324 quad op-amps, ten TL084 JFET-input op-amps, and ten LM339 comparators. (This is not counting the microcontroller boards he also recommends.)

Viper-7's a smart person with a fair bit of experience, so it's really interesting to see what they chose to include — lots of op-amps and comparators, a few GPIO kinds of chips, and some 555s — and what he didn't — switching regulators, voltage references, ADCs and DACs, class-D amplifiers, supervisory power chips, transistor arrays like the ULN2003, MOSFET gate driver chips, H-bridges, microcontrollers that aren't already on a board, adjustable LDO regulators, memory, CMOS 555s, SSI or programmable logic.

More generally, he also doesn't recommend a wide variety of discrete parts: no power resistors, resistors below 10 Ω, crystals, LED drivers (even WS2812s), film capacitors, tantalum capacitors, supercaps, relays, batteries, transformers (!), motors, or JFETs; no IGBTs, solid-state relays, or thyristors; no lasers, switches, speakers, microphones, or displays; no protoboards, solder, or solder braid; and not even any 2N7000s, though he says they're often included in BJT assortments, even though they aren't BJTs. (I want to be clear that I'm not disagreeing with their choices — on the contrary, I'm saying that if you disagree with them you should have a reason.)

All in all, a really interesting set of recommendations, one which I think will probably help a lot to make electronics as a hobby more accessible.

How can we take advantage of 16:9 screens for programming?

Kragen Javier Sitaker, 2012-12-17 (2 minutes)

Modern laptop screens are 16:9 rather than the traditional 4:3. They're also much higher resolution. Could you take advantage of this for programming? It's helpful to see a lot of text on your screen at once for programming, but we're somewhat inflexible about the shape of the text, since it's not easy to reformat program source code for wider and narrower windows.

The traditional terminal format was 80x24 or 80x25, the former of which is also the default size for xterm and gnome-terminal; each glyph contained roughly 5x8 pixels which were almost square. There's a "5x8" font that ships with X11 that shows what this looked like; try `xterm -fn 5x8`. There's also a 5x7 font, which is just about as readable, and there are somewhat less readable 4x6 fonts floating around. The appearance on an LCD is a little blockier than it was on the hardware terminals, because their pixels were not neat little squares like LCD pixels, but rather fuzzy dots or horizontal segments of scan lines.

However, modern LCD displays actually have not only grayscale but also three times the horizontal resolution of a CRT with the same nominal number of pixels. This extra horizontal resolution can be, and is, used to dramatically the readability of text, which correspondingly allows the use of smaller fonts.

So let's suppose, conservatively, that we can use 3x6 fonts, which are really 9x6 --- 54 subpixels per glyph rather than the traditional 32, which ought to be eminently readable. How much text can you fit on the screen?

Suppose you break up the screen horizontally into 80-column columns. Each of these will be 240 pixels wide; if you have a modest 1024x600 screen (very slightly narrower than 16:9) then you can divide 960 of the 1024 pixels into four 80-column columns, with another 64 pixels left over for margins, scrollbars, or other UI chrome. Each of these columns then holds 100 6-pixel-high lines of text, for a total of 400 lines, or six printed standard 80x66 pages.

Multiplication with squares

Kragen Javier Sitaker, 2017-07-19 (updated 2019-07-09) (5 minutes)

This is a table-lookup-based multiplication algorithm I wrote about some years ago which is not in much current use, even though it's much less computationally expensive than the standard algorithms.

$(a + b)^2 = a^2 + 2ab + b^2$
$(a - b)^2 = a^2 - 2ab + b^2$
$(a + b)^2 - (a - b)^2 = 4ab$
$ab = ((a + b)^2 - (a - b)^2)/4$

```
def mul(a, b):
    c, d = a + b, a - b
    csq, dsq = c**2, d**2   # Imagine these are table lookups.
    e = csq - dsq
    prod = e/4

    print 'c=%s, d=%s, c²=%s, d²=%s, c²-d²=%s, so %s·%s = %s' % (c, d, csq, dsq, e, a, b, prod)
```

For example, to multiply 7984839 by 11859552, first find their sum and (unsigned) difference: 19844391 and 3874713. Find the square of each: 393799854160881 and 15013400832369. Now find the difference of these squares: 378786453328512. Now divide this by 4 (an easy operation on a binary computer; somewhat trickier in decimal): 94696613332128. And that is indeed the product of these numbers.

If you have a table of squares to do lookups in, this involves a sum, two differences, two table lookups, and a division by 4 (a shift right by two bits, in binary). These all involve a number of bit operations that grows linearly with the number of bits in the input numbers, but require a square table whose size is exponential in the size of the input numbers.

(This algorithm was known to the ancient Babylonians, who tabulated squares divided by 4 to facilitate it; flooring the squares is harmless in this case.)

One disadvantage of this algorithm is that, to multiply numbers up to N, your table of squares must include numbers up to 2N. If the numbers you are multiplying are both even or both odd, a slightly different identity allows you to use a table of squares of only N numbers:

$((a + b)/2)^2 = ¼(a^2 + 2ab + b^2)$
$((a + b)/2)^2 - ¼a^2 - ¼b^2 = ½ab$
$2((a + b)/2)^2 - ½a^2 - ½b^2 = ab$

This requires three table lookups instead of two, and the same three additions and subtractions, plus a couple of halvings and a doubling rather than two halvings. If the table contains the halves of the squares, you save the halvings but need a final multiplication by 4.

So, consider 61·65. (a+b)/2 = 63, and $63^2 = 3969$; twice that is 7938. $½61^2 = 1860½$, and $½65^2 = 2112½$. So our final result is 7938 - 1860½ - 2112½ = 3965, and this is correct. This didn't require us to find the squares of any numbers bigger than our multiplicands.

However, rounding the numbers in the table of half-squares would be unsafe for this algorithm.

All known bounded-space multiplication algorithms take a number of bit operations that grows superlinearly in the number of bits in the input numbers: multiplying by partial products takes $O(n^2)$ operations (which was conjectured to be optimal from 1952 until 1960), Karatsuba multiplication (see Karatsuba (p. 2090)) takes $O(n^{1.59})$ operations, Toom-Cook multiplication takes $O(n^{1.47})$ operations, Schönhage-Strassen multiplication takes O(n log n log log n) operations, and Fürer's algorithm and the De-Saha-Kurur-Saptharishi multiplication algorithm take time that is still superlinear, but only barely.

However, for numbers of under about 100 decimal digits, multiplying by partial products is the fastest of the above-listed algorithms in practice. But this square-table algorithm is faster than multiplying by partial products even for numbers of moderate size.

For example, the above calculation involved calculating 44 decimal digits of results; doing the calculation by summing seven eight-digit partial sums into the 14-digit result would have involved calculating 60 decimal digits of results. So this is an efficiency improvement. However, it presupposes a table of over eleven million squares, which would be several volumes if printed on paper.

The crossover point where this algorithm uses fewer bit operations is probably around 16 bits. The square table becomes impractical in size somewhere between 8 bits and 50 bits, depending in part on how long you can wait to get the results. If you're multiplying a lot of pairs of numbers, it might actually make sense to pipeline a millisecond's worth of products while you're waiting for the square table lookup results to come back from a highly parallel, distributed square table. (See Hardware multiplication with square tables (p. 1886).)

What is the type of lerp?

Kragen Javier Sitaker, 2017-01-08 (5 minutes)

The linear interpolation operation, lerp, is fundamental to a number of algorithms; you can derive Bézier curves and B-splines from it, it provides a differentiable version of the conditional operation, and of course it is directly applied in computer graphics and numerical computation of all kinds.

There are some interesting questions related to its type.

Definition

It's sometimes defined as a function of five parameters:

$\mathrm{lerp5}(x_0, x_1, y_0, y_1, x) = y_0 + (x - x_0)\cdot(y_1 - y_0)/(x_1 - x_0)$

This gives you the interpolated value of y at x, given that it should be y_0 at x_0 and y_1 at x_1.

However, this can be productively decomposed into two functions of three arguments:

$\mathrm{howfar}(x_0, x_1, x) = (x - x_0)/(x_1 - x_0)$
$\mathrm{lerp}(y_0, y_1, t) = y_0 + t\cdot(y_1 - y_0)$
$\mathrm{lerp5}(x_0, x_1, y_0, y_1, x) = \mathrm{lerp}(y_0, y_1, \mathrm{howfar}(x_0, x_1, x))$

And it is the lerp function defined in the middle there that we are concerned with.

Given the usual algebraic identities, we can transform its formula into a different form that is sometimes easier to use. Writing out the algebraic transformation in great detail, we have

$y_0 + t\cdot(y_1 - y_0) =$
{distributivity}
$y_0 + t\cdot y_1 - t\cdot y_0 =$
{unity}
$1y_0 + t\cdot y_1 - t\cdot y_0 =$
{definition of subtraction in terms of adding negative}
$1y_0 + t\cdot y_1 + -t\cdot y_0 =$
{commutativity}
$1y_0 + -t\cdot y_0 + t\cdot y_1 =$
{distributivity}
$(1 + -t)\cdot y_0 + t\cdot y_1$
{definition of subtraction in terms of adding negative}
$(1 - t)\cdot y_0 + t\cdot y_1.$

I'm going to consider lerping in domains where some of these identities don't apply, and (I assert) it will be interesting to consider which ones.

This leads to the definition

$\mathrm{lerp2}(y_0, y_1, t) = (1 - t)\cdot y_0 + t\cdot y_1$

I believe this was the computation Turing originally proposed to compute the definition of a conditional branch instruction in his proposal to build a computer.

Type signature of lerp

What are the types of the parameters and result of the lerp function given above? They need not all be the same; in the fully general case, there are six of them:

$\mathrm{lerp}(y_0\colon T_0, y_1\colon T_1, t\colon T_2) = y_0 + (t \cdot ((y_1 - y_0)\colon T_3)\colon T_4)\colon T_5$

which gives us the type signatures for the component operations:

$(x\colon T_1) - (y\colon T_0)\colon T_3$
$(x\colon T_2) \cdot (y\colon T_3)\colon T_4$

$(x: T_0) + (y: T_4): T_5$

So far, this is sort of vacuous. But we only have to add a couple more constraints and it gets interesting! The usual case in lerping is that you want the result to be y_0 sometimes, y_1 other times, and somewhere in between at still other times. For that to be a coherent wish, those three values need to have the same type:

$T_0 = T_1 = T_5$

This reduces our component operation signatures to the following:

$(x: T_0) - (y: T_0): T_3$
$(x: T_2) \cdot (y: T_3): T_4$
$(x: T_0) + (y: T_4): T_0$

If we arbitrarily add the additional constraint that $T_3 = T_4$, we have a simple algebraic structure that looks like an affine space:

$(x: T_0) - (y: T_0): T_3$
$(x: T_2) \cdot (y: T_3): T_3$
$(x: T_0) + (y: T_3): T_0$

Here T_0 is the affine space, T_3 is its associated vector space, and T_2 is the underlying scalar field of the vector space. Computing lerp doesn't depend on the validity of any of the eight vector axioms or the axioms of the affine space, but to the extent that those axioms hold, more interesting properties will hold of lerp's results. For example, when $t=1$, normally you want the result to be y_1, but in many practical cases with floating-point numbers, it won't be!

To take a concrete example where the three types are different, T_0 might be (the type of) a mapping from a set of (lat, long) pairs to a temperature reading represented as a floating-point number interpreted in degrees Celsius; T_3 might be a mapping from a set of (lat, long) pairs to a temperature difference represented as a floating-point number interpreted in kelvins; T_2 might be simply a single unitless floating-point number; and the three arithmetic operations might operate pointwise on their values.

This is practically useful in finding errors in programs because it is physically meaningless to multiply a number interpreted in degrees Celsius by some number. It is 22°C here right now; if I multiply 22 by 2, getting 44, and then interpret that 44 as 44°C, I have computed a temperature with no meaningful relationship to the original temperature. In Fahrenheit, these temperatures are 71.6°F and 111.2°F. If a program is doing such a computation, it is very likely erroneous, although not in every case.

This definition of lerp does not do such a computation.

Phosphorescent laser display

Kragen Javier Sitaker, 2016-08-16 (8 minutes)

Scanning an ultraviolet diode laser over a cheap phosphorescent screen should give you a very inexpensive, high-resolution, very-low-refresh-rate display screen.

Projecting an image with a laser suffers from a few problems. One is that, if the part of the laser beam that would fit through someone's pupil is bright enough, it can be an eye safety hazard. Another is that the beam must be scanned very rapidly over the screen in order to provide the illusion of a stable image, and equipment for scanning the beam very rapidly is energy-hungry and expensive.

We can solve both of these problems with multiple ultraviolet lasers.

Eye safety

Ultraviolet light below about 400nm is blocked by the lens of the eye, so it will not be focused onto the retina and cause the instant retinal burns that are the principal danger of visible and especially infrared lasers. However, it can cause lens damage if continued over a period of time, including cataracts. Below 315nm, it cannot even penetrate the cornea, so it instead will cause only acute photokeratitis, which will heal unless it is very severe indeed.

However, in discussing the *kinds* of damage that can be caused, we risk losing sight of the *quantitative* safety factor. The IEC 60825 maximum permissible exposure for a 355nm ultraviolet laser over the course of a millisecond is 100 watts/cm², falling to under 1 watt/cm² if the exposure extends to an entire second, and down to 1 mW/cm² if the exposure continues for a kilosecond. By contrast, the MPE for a visible-light laser is 10 milliwatts if for a millisecond, or 3 milliwatts if for an entire second, converging with the ultraviolet MPE levels at 1000 seconds.

That means that the safe power levels for brief exposure to ultraviolet lasers are around 100 times higher than for visible-light lasers. This means you can send a great deal more energy to your screen at a safe power level. It might be a good idea to wear UV-blocking goggles and to couple your UV laser with a lower power, but painfully bright, but not dangerous, red laser, in order to trigger people's blink reflex. 1mW should be plenty.

An alternative way to provide eye safety under normal circumstances is to project the laser onto one side of a screen while you look at the other side, enclosing the laser, scanning apparatus, and back of the screen inside a sealed, opaque box.

One unfortunate aspect of this approach, though, is that there aren't any laser diodes of shorter wavelengths than 370nm commercially available yet. https://www.thorlabs.com/NewGroupPage9.cfm?ObjectGroup_ID=5400 offers Thor Labs's new 375nm 70mW ultraviolet laser diode L375P70MLD for US$4300.

Refresh rate

A phosphorescent screen will not only convert a certain fraction of

the laser illumination into light, but also continue to glow over a long period of time, exponentially decaying. This acts as a single-pole low-pass filter on the image signal, attenuating frequencies faster than the time constant of the phosphor by 3dB per octave.

Zinc sulfide's phosphorescence decay time constant is a few seconds to a few minutes. (I found some paper claiming 9', but that seems implausibly long to me from experience with glow-in-the-dark toys). This means that once a glowing image has been drawn on the zinc sulfide with the laser beam, it will stay there, gradually fading, for a few minutes.

This means that you can draw an image on the screen with a laser over a period of seconds or minutes, and it will continue to be visible. This means that you can draw a fairly complex image even with a fairly slow apparatus for scanning the laser beam across the screen. It also means that you can't erase anything: you have to wait for it to fade.

It also means that it takes seconds to minutes for the image to reach full brightness, but because of the logarithmic brightness perception of human vision, this is not as much of a problem as you would expect. (I'm guessing this from my experience with analogue oscilloscopes with zinc sulfide screens.)

Copper-doped zinc sulfide is by far the most common glow-in-the-dark material.

It might be worthwhile using a secondary, say, red laser to draw a smaller amount of graphical information that can be instantly erased. This will work better if the screen is not sensitive to the wavelength of the secondary laser.

Erasing

https://physics.stackexchange.com/questions/79860/why-is-a-laserpointer-able-to-erase-a-glow-in-the-dark-sticker reports that a red laser pointer was able to *erase* the glow from a glow-in-the-dark sticker (presumably ZnS:Cu). There is a video of this phenomenon at https://www.youtube.com/watch?v=kUteUH7mz0A, but the erasure seems temporary.

Multiple lasers

Laser diodes themselves are relatively inexpensive; Digi-Key has 1.5mW infrared lasers at US$5.76 and red 5mW lasers at US$12.52. But as the power goes up, cost increases sharply. Their cheapest 20mW laser is US$46.07 (green), their cheapest laser over 40mW is a 120mW 405nm near-ultraviolet unit for US$78.44 (this is the wavelength used by Blu-Ray players), and the only more powerful laser diode for which they list a price is an 175mW near-ultraviolet unit for US$452.

Given this price curve, you can probably get not only more visible light output but also more information on the screen by using several different laser diodes, each pulsed rather than CW, so that sequential points on the screen are often drawn by different lasers. Using two to six separate lasers will increase the energy throughput of the laser bottleneck significantly, without affecting the rest of the system.

Also, laser diodes can be controllably pulsed much more rapidly than mirrors can scan the beam — MHz in the common case or GHz

in exceptional cases — and you can draw minimally readable letterforms by interrupting three or four vertical lines:

```
 #  ##  # #  ##  ###  #  # #  #
# # # # ### #  # #  # #### ## #
### ##  ### #### ###  #### # ##
# # # # # # #  # #  # #  # #  #
# # ##  # # #  # ###  #  # #  #
```

Given three or four laser beams with a slight angle offset between them horizontally, you could sweep them vertically with a single movement of the mirror while pulsing different dash patterns on them to draw the letters.

Resolution calculations

You should be able to do a few megapixels this way, but probably not much more.

Suppose you're using a 2m² screen, with the laser 1.5m away, and you have a 1mRad-divergence beam, which is a pretty normal divergence for a laser pointer. Then your spot will be 1.5mm across, so your screen is only about 1300×1300 "pixels", for a total of 1.8 megapixels. If you can get a better-quality laser spot of 0.5mRad, you can get four times that, or 7 megapixels.

(The diffraction-limited divergence angle is $2\lambda/(\pi w)$, where λ is the wavelength and w is the beam-waist radius. So for a 650nm red laser to have 1mRad divergence, you need $w > 2 \cdot 650\text{nm}/(\pi \cdot .001) \approx 0.4$ mm. Larger collimating optics can produce smaller divergence, but you aren't going to get that beam waist below 0.4mm even if the beam waist is on the screen.)

However, you may only be able to illuminate a small fraction of these pixels at a time; even expensive laser-show galvos are rated at under 50kpps, and even in two minutes, 50kpps is only 6 million points. Simpler scanning apparatus, perhaps driven by scavenged hard disc voice coils or by paper cone speakers, might only hit 1kpps, and thus only 120k pixels illuminated per laser. With multiple lasers and dash patterns, you could actually paint all of those pixels, a few thousand per second.

Can you bitbang USB with an ATMega's RC oscillator?

Kragen Javier Sitaker, 2017-04-04 (1 minute)

An overview of USB says low-speed data is "clocked at 1.50Mb/s with a data signalling tolerance of ±1.5% or 15,000ppm" so you can clock it with a [ceramic] resonator instead of needing a crystal.

AVRs' internal RC resonators are mostly not quite this precise; even at a fixed temperature and voltage and after user calibration, they're rated to vary by 2%, at least on the ATtiny2313. But on the ATMega series (at least the 48/88/168/328 series used in the Arduino), they're rated to ±1% under these circumstances. So a resonator is needed to bitbang low-speed USB on the ATtinies, but maybe not the ATMegas.

Granite texture

Kragen Javier Sitaker, 2019-05-08 (updated 2019-05-09) (5 minutes)

(Probably far from an original idea.)

I was thinking about texture generation today, and in particular what you can do in a fragment shader, where deciding which pixels to affect is not a thing you can do. This seems like it could be a real problem, since many real-world textures are the result of a lot of different objects moving around; for example, the exposed stones in a sawn concrete surface are in some sense scattered randomly, as are the leaves on a forest floor. But in a fragment shader you can't just generate some random points and place leaves at them, at least not in a way that scales when you zoom out.

Random points don't look random

I was reminded that when people look at independent identically distributed random points, they generally think they don't look very random, because clusters of points randomly occur, and so the density of the points varies even at fairly large scales. Many natural textures — the stones in the concrete I mentioned before, for example, but also hairs on the skin, cones on the retina, bubbles in a foam — break up such clusters by a sort of "relaxation" in which points move away from one another, evening out the medium-scale density variations, and eventually the large-scale ones too.

Maybe random-looking points can be a perturbed periodic lattice

But maybe another approach would be to start with a very even dot distribution and perturb it enough that it looks random. You could have some perfectly regular lattice of cells, with a dot at the center of each — a square or hexagonal lattice — and generate a two-dimensional value of Perlin noise by which to perturb the dot at that center. As long as the dot doesn't overlap the next cell, the algorithm to determine the color of a pixel is very simple; if z is the pixel coordinate:

```
c = round(z)
fragColor = hypot(c + r1 * noise2d(c) - z) > r2 ? bg : fg
```

If we expand r2 or especially r1 to the point that the dots start to wander into adjacent cells, that simple seven-instruction algorithm starts to fail; if we run it for all the adjacent cells, though — 5, 7, or 9 of them, depending on how many candidates there are — we can determine which of the neighboring cells' dots are overlapping us, at the cost of a work multiplier of 5, 7, or 9.

Maybe you can build a fake Voronoi diagram this way

In the same way, you can draw an almost-Voronoi diagram by having no dot-radius threshold, just coloring the pixel according to which dot's center it's closest to. This will occasionally depart from

the real Voronoi diagram because long, sharp projections will occasionally be truncated early by cell boundaries; perturbing the cell boundaries slightly with more noise may be a good way to keep that subtle.

How to draw granite

Well, what's granite? Granite consists of a lot of crystals of minerals of different colors which grew as the magma cooled, each one nucleating with some random position and orientation and growing around that center, faster along some planes of their crystal structure than along others. At first only zircon and calcium-rich plagioclases can crystallize (or forsterite, but it doesn't occur much in granite), but as the temperature drops, other minerals like pyroxenes, more sodic plagioclases, micas, and eventually even quartz can crystallize. As the crystals grow, they deplete the local magma of their own mineral, which means that when the leftover magma eventually does crystallize, it will be of a different color.

This is precisely the kind of prolonged multivariate field dynamical process that's hard to simulate in a fragment shader†, but perhaps we can generate a similar-looking result by perturbing the Voronoi distances according to a random skew matrix. That is, before computing the magnitude of the displacement from the pixel to a dot center, multiply that displacement vector through a skew matrix particular to that dot (generated from yet another call to noise). This should make the "crystal" tend to be longer in some apparently-random directions, and shorter in others. If the skew matrix also has a random determinant, some "crystals" will be larger and others smaller.

This is a terribly goofy way to generate this image, though, as you can solve precisely where the grain boundaries are going to be. You don't really need to do all this computering for every pixel.

† Could be harder — at least crystallizing magma isn't turbulent.

Marking metal surfaces with arcs

Kragen Javier Sitaker, 2016-10-06 (4 minutes)

Engrave a metal surface with a controlled low-energy arc because, like a laser, it can deliver very high power levels, but it's a lot easier to build than a laser is. You can vaporize a little bit of metal, or you can melt it and then blow it away with air.

There are a couple of things that make it difficult to melt metals. One is that most metals don't melt until they're pretty hot, so you can't melt them at all with things that only get moderately hot, like most flames. (Jet fuel, as they say, can soften steel beams until they can support almost nothing, but not melt them.) The other is that it's a good heat conductor, so if you deliver the heat slowly, it gets conducted away and the metal never gets very hot. Aluminum especially is a good heat conductor.

The easiest approach is to bring an electrode, charged with a capacitor, toward the surface of the oppositely-charged metal until the air breaks down and the energy discharges in a spark.

Striking an arc in air needs on the order of 300 volts at a minimum at a distance of about 13 microns. If you have a 1-microfarad low-ESR capacitor supporting that arc, it has an energy of about 45 millijoules. Vaporizing aluminum takes about 14 kilojoules per gram `(((2470 - 20) K 24.20 J/mol/K + 10.71 kJ/mol + 284 kJ/mol) * 27.0 g/mol)`, the majority of which is from its heat of vaporization. That means that this spark can vaporize about three micrograms of aluminum, which sounds insignificant, but if it's hemispherical, it's actually a crater about 160 microns across, which you will note is more than ten times the distance from the electrode to the workpiece. A 160-micron crater is clearly visible and palpable; it's comparable to the kerf you get from a laser cutter.

That's kind of a best case, though, because some of the heat will go into heating the electrode and the air, some of it will be conducted away, and some of it will go into heating the already boiled metal in its gaseous form. If the workpiece is connected to the negative side of the circuit (the cathode), most of the heat of the arc will be deposited at the surface of the workpiece, as it is bombarded by ionized air, rather than on the marking electrode, which is receiving only electrons.

Thermal runaway concentrates the electrical current on the hottest part of the cathode, as that's the part that can emit the largest number of electrons, so the spot that the arc heats can be very small indeed.

That still leaves the question of how fast the whole discharge happens, which depends crucially on the E/I curve of the arc, where most of the resistance in the circuit is found. The RC time constant of just the electrode and wires can easily be around a microsecond, which would imply a power of around a kilowatt and a power density of 50 gigawatts per square meter or 50 kilowatts per square millimeter, which is in the neighborhood of what metal-cutting lasers put out, so it should probably work okay. (WP says 1500 watts in a 25-micron laser spot is common, and you can cut 1-mm aluminum at 14.82 cm/s at 1000 W; if we figure the kerf is 200 μm, that works out to 12.5 mJ/μg, very close to the value of 14 I calculated above; and at

that rate the laser is vaporizing a volume of material comparable to our crater every 36 microseconds, which should be an easily achievable speed for the spark.)

Topics

A principled rethinking of array languages like APL

Kragen Javier Sitaker, 2015-05-16 (updated 2019-09-30) (31 minutes)

What accounts for the power and convenience of array-processing languages like Matlab, R, and APL? Can we get it without having to pay the high readability and bugginess costs associated with these languages?

I feel that I may finally have an account of what's going on here, and not only can we get better error-checking out of it, we can get a language that is more expressive (in the sense of more power in less tokens), more readable, and more efficient than traditional array-processing languages.

Though I think the present note is self-contained, the initial development of the idea was in Index set inference or domain inference for programming with indexed families (p. 1434) in probably 2007 or 2008.

The basic idea

A variable in a computer program has a value that varies. Sometimes when a piece of code runs, the variable will have one value; other times, it will have another value. (In many languages it can change even during the same run, but that is not relevant to what I am considering here.)

These values are functions of some arbitrary set of inputs, often implicit in their context. In image processing, a brightness value might vary by X, Y, color channel, and frame number; in statistical processing, an elapsed-time measurement might vary by trial number; in rendering, a pixel color might vary by shading algorithm, camera position, and the states of all the objects in the input scene. It can be hard to tell what they depend on, and indeed assuming that a variable is constant relative to a given input, when in fact it ought to vary, is a common source of bugs. (You could argue that this is the source of the difficulty of caching.)

We could think of these inputs as being dimensions in a many-dimensional space, and each point in this space as being a possible universe — perhaps a very small possible universe with only a few variables in it, but a universe nonetheless.

Array languages allow us to reify this space in runtime variables, and thus to write programs that act across entire subspaces of it, rather than the pointwise and one-dimensional approach taken by ALGOL-family languages like C or Java.

Some examples from ray-tracing

Consider this C code, from My Very First Raytracer:

```
static color
pixel_color(world here, int ww, int hh, int xx, int yy)
{
  vec pv = { (double)xx/ww - 0.5, (double)yy/hh - 0.5, 1 };
  ray rr = { {0}, normalize(pv) };
```

```
  return trace(here, rr, 1.0);
}
```

This code is invoked a number of times with the same `world`, `ww`, and `hh` variables, but with varying values for `xx` and `yy`; but you can't tell that from looking at it. Similarly, when it invokes `trace`, it invokes it many times with the same `here` value, different `rr` values, and the same `importance` value of 1.0. But it needs to be written as a function, or at least a loop, to allow this flexibility in `xx` and `yy`.

In a sense, in this code, `xx` represents not a single integer, but an entire plethora of possible values, maybe even an infinite series of values; it's not a scalar, but rather a function of which pixel we're looking at. When we write the division of `xx` by `ww`, we are not writing the division of a single floating-point number by a single integer, but rather all the floating-point numbers `xx` will ever convert to in the lifetime of humanity, by all the possible image widths `ww` will ever contain in the lifetime of humanity. Or, if we limit our perspective to a single execution, that division instruction will eventually be used to divide all of the horizontal image pixel coordinates by the image width — redundantly, many times, in fact, once for each line; so it's a machine instruction that implicitly represents a vector operation.

But this is a rather unusual hermeneutics of the C and machine code.

The C code enforces a particular order of evaluation: it is not capable of beginning to evaluate a second call to `trace()` until the first one is done, and no way to evaluate a second call to `pixel_color` until the first one is done. But this may not be the most efficient way to find out what color the pixels should be.

The C code, you'll notice, also has a fair bit of syntactic overhead associated with allowing these variables to vary; they have to be declared as parameters. What if, instead, we were programming in a language where these variables explicitly, in the source text and in memory at run time, represented an entire vector of possibilities — a sort of more principled APL? Maybe we could write it something more like this:

```
pixel_color = trace(here,
                    ray(vec(0,0,0), normalize(vec(xx/ww-.5, yy/hh-.5, 1))),
                    1.0);
```

(We're also getting some brevity here by not having to name the temporary structs.)

A language with an APL-like evaluation strategy could figure out that `xx` and `yy` vary independently, while `ww` and `hh` don't vary at all, and so generate a ρ`xx`×ρ`yy` space of possibilities for the `vec`s that we're normalizing, where ρ is the APL operator that gives the shape of a matrix. (More detail on how to do this is in the next section.)

I think that's the ultimate philosophical justification for APL's conformability and broadcasting rules; if you're ray-tracing 640 columns and 480 rows of pixels, for example, then a value that is constant for all those pixels is merely a scalar; a value that varies by column but not by row will be a 640-element vector; a value that varies by row but not by column will be a 480-element vector; and a

value that varies by pixel will necessarily be a 640×480 matrix. So it makes sense to divide `xx` by `ww`, or `yy` by `hh`, but doing anything with the two of them together requires an outer-product operation (which in APL is explicit) or reducing one or the other of those axes of variation into being some kind of dummy variable, like an index of summation or whatnot.

But APL of course can't tell that your 3-element vector representing the X-coordinates of the three spheres in your scene isn't really compatibly dimensioned to a three-element vector that represents the X, Y, and Z coordinates of the camera, say. Array-dimensions typing is weak typing, much like the currently fashionable approach of typing everything as a string. And this is why outer products are necessarily explicit in APL, while I think a more principled array-processing language could infer most of them.

Here's another example, from the same program:

```
static vec
scale(vec vv, sc c) { vec rv = { vv.x*c, vv.y*c, vv.z*c }; return rv; }

static ray
reflect(ray rr, vec start, vec normal)
{
  // Project ray direction onto normal
  vec proj = scale(normal, dot(rr.dir, normal));
  // Subtract that off twice to move the ray to the other side of surface
  vec reflected_dir = sub(rr.dir, scale(proj, 2));
  ray rv = { add(start, scale(reflected_dir, 0.001)), reflected_dir };
  return rv;
}
```

(The .001 fudge factor there is to keep the reflected ray from hitting the same surface again from the inside due to rounding errors.)

The `scale` function here obviously only exists because C is not an array-processing language. Or does it? If we were trying to write a `reflect` that handled many normals at once in arrays, it wouldn't be totally insane to use three separate arrays of X, Y, and Z components of the normals. Taking just the first line of `reflect` and translating it into C written as if it were Fortran:

```
static void
scale(sc vx[], sc vy[], sc vz[], sc c[],
      sc vox[], sc voy[], sc voz[], int n)
{
  for (int ii = 0; ii < n; ii++) {
    vox[ii] = vx[ii] * c;
    voy[ii] = vy[ii] * c;
    voz[ii] = vz[ii] * c;
  }
}

static void
proj(sc vx[], sc vy[], sc vz[], sc dx, sc dy, sc dz,
     sc vox[], sc voy[], sc voz[], int n)
{
```

```
  sc dots[n];
  for (int ii = 0; ii < n; ii++) {
    dots[ii] = vx[ii] * dx + vy[ii] * dy + vz[ii] * dz;
  }
  scale(vx, vy, vz, dots, vox, voy, voz, n);
}
```

You may not agree yourself that this would not be totally insane, but hopefully you can agree that this is a way to do this that Fortran programmers would think was not totally insane. Also you can see that an enormous benefit of APL over Fortran for this kind of thing is that you have at least some hope of changing your mind about whether it was the rays or the normals or both that you wanted to have more than one of, because making the loops and indexing implicit there means that you don't have to change the code to index into a `dx` array and maybe not index into a `vx` array.

(Also there are probably some combinations of dimensions and CPU models for which the more predictable memory access of this version would actually make it faster despite its smaller ratio of computation to memory locations accessed. And obviously if your loops are implicit and your non-implicit operations are subject to interpretation overhead, as in Numpy or normal APL implementations, the array approach is going to be hugely faster.)

Coordinates in three-space, though, are definitely the kind of thing that it's reasonable to think of as numbering from 0 to 2 or from 1 to 3, rather than being unrelated attributes of the same thing. Then you might want your array of normals here to be represented as an n×3 array rather than three arrays of n or an array of n structs with three fields. And then things like the `scale` function fall away entirely, but you need some way to specify which dimension you're summing over when you compute that dot product. APL +/ has a default of operating over the *last* dimension, and the option of specifying a different dimension by its numerical index, as in `+/[1]`.

This seems ad-hoc and unreadable to me, like much of APL. But if you have named your axes of variation, and one of them is the XYZ distinction, then you could very reasonably say `XYZ.sum()` or `+/[XYZ]`, and it would be clear, turning the XYZ variation into a dummy variable; if you applied it to some kind of aggregate with more than one XYZ distinction (introduced with an explicit outer-product operator) or no XYZ distinction, you would get an error.

And then you could write

```
proj = normal * XYZ.sum(raydir * normal)
```

instead of the 20 lines of crap above, and furthermore keep that abstract over whether you have a single normal and many ray directions, a single ray direction and many normals, many normals of which each corresponds to a different ray direction, or even (what APL could never do implicitly) many ray directions and many normals, of which we implicitly want the Cartesian product.

And then maybe you could write the whole function like this:

```
proj = normal * XYZ.sum(raydir * normal)
reflected_dir = raydir - 2 * proj
```

```
reflect = ray(start + reflected_dir * 0.001, reflected_dir)
```

When it comes to implicitly broadcasting operations over different dimensions, C is equivalently succinct to an array language — modulo the data typing and abstraction overhead that it requires in order to give you variables at all. But because C values are only implicitly, in an esoteric hermeneutics, vectors or universes of possibilities, it is difficult to write something like the `XYZ.sum` function above; instead we are reduced to writing explicit loops, or as in this case, explicitly textually repetitive code.

Getting more rigorous: a functional semantics with implicit arguments

Okay, "rigorous" and "semantics" may be an exaggeration. But I'll try to at least outline a rigorous semantics here.

Suppose that, instead of considering variables such as `normal` to hold scalars, vectors, or matrices of some finite size, we instead consider them to hold computable functions, but functions whose domain is not necessarily known or finite. This is not a big leap: we can consider the vector [6 832 4] as a function f over a domain of three integers: it returns 6 when invoked as f(0), 832 when invoked as f(1), or 4 when invoked as f(2).

In this interpretation, we lift the usual arithmetic operators to operate over functions of one argument in the usual way: `*`, for example, is the function we would usually write in the λ-calculus as `λf.λg.λp.(f p)*(g p)`, or in Python as `lambda f, g: lambda p: f(p)*g(p)`; and we consider constants such as `2` to denote constant functions like `K 2` or `lambda p: 2`.

But what is this mysterious `p` argument? It's a context or point in this multidimensional possibility space mentioned eralier, the one that's usually left implicit, so it needs to include all the axes of variation we were talking about earlier; to get traditional APL semantics, you would want it to be something like a stack of numbers, but dicts are more fashionable these days than stacks, arrays, or lists, so let's consider it to be something like a Lisp alist indexed by symbols, each symbol denoting some axis of variation.

So now we can interpret this line:

```
proj = normal * XYZ.sum(raydir * normal)
```

as meaning (in Python):

```
def proj(p):
    return normal(p) * sum(raydir(q) * normal(q)
                           for q in XYZ.possibilities_augmenting(p))
```

Here `possibilities_augmenting` is a method of the `XYZ` dimension that gives you versions of the point `p` with all possible values of `XYZ` substituted into it. Thus the first call to `normal` might return either the `x`, the `y`, or the `z` component of some particular normal; but all three of those will be multiplied by the same dot product.

Of course, this is not intended to suggest that it must be calculated in this fashion, which would be immensely wasteful; it's intended as a specification of the relationship between inputs and outputs.

This suggests an implementation of the `vec` function mentioned earlier, which in the C program was a `struct` type:

```
def vec(x, y, z):
    values = {XYZ.x: x, XYZ.y: y, XYZ.z: z}
    return lambda p: values[p[XYZ]](p.without(XYZ))
```

That is, the functions produced by `vec` consume the `XYZ` dimension of their input and dispatch to any of the three functions that were passed in as their X, Y, and Z components. So this expression from the `pixel_color` function:

```
vec(xx/ww-.5, yy/hh-.5, 1)
```

when invoked with `z` will dispatch to the constant function denoted by `1`; when invoked with `y`, will dispatch to the function denoted by `yy/hh-.5`, which itself will dispatch to `yy`, which in this program varies by pixel, and to `hh`, which doesn't vary at all during a run of the program, and to another constant function that returns 0.5.

Another useful higher-order function is a "renaming" or "aliasing" or "axis rotation" or "reshaping" function which turns one axis into another:

```
def rename(a, b, f):
    return lambda p: f(p.without(a).with(b, p[a]))
```

Considered spatially, this prevents `f` from varying over axis `a`, rotating the motion of `p` along `a` into motion along the new axis `b`. Considered relationally, this renames column `b` of the inputs to relation `f` to `a`. This is the operator you need for carrying out explicit outer products; if `f` and `g` are both vectors on axis `b`, then `rename(a,b,f)+g` gives you their outer product sums, with the values of `f` varying along the new axis `a` and the values of `g` varying along axis `b` as before. (This `rename` function also gives you general axis transposition, in a sense.)

This "context" or "point" object may carry a whole collection of context attributes with it that most of these functions don't bother to access, and can pass along to their callees without mentioning them explicitly.

(If we think in terms of N-ary relations rather than in terms of functions, you could think of this "point" as a query-by-example partial record. But that's not very consistent with the functional semantics described above.)

In theory, if all of your component functions being combined by means such as lifted operators, `rename`, axis-construction functions like `vec`, and dummy-axis-introduction functions like `XYZ.sum`, have finite discrete domains along some axis, you ought to be able to compare those domains and detect mismatches, and then you ought to be able to describe the multidimensional domain of the combined function. This is a lot like type-checking. You might even be able to do it at compile time, and if you have compile-time axis variables analogous to type variables in parametric polymorphism, you might be able to do the type-checking polymorphically at compile time.

(Also note that this eliminates run-time bounds-checking, just as structs do.)

APL has some axis-transformation functions: compress, expand, take, drop, and the sort of hidden operation of indexing a vector by another vector, which is like binary relation composition or like a different form of compress. You could consider these either as generating new axes or as subsetting the domain along an existing axis. In APL, it's the former, and so you have to be careful to compress all the attributes you care about by the same boolean vector, or index all of them through the same index vector.

It seems like it might be more useful here to implicitly intersect domains along the same axis, which is after all what we are doing when we implicitly take the outer product of a scalar and a vector. However, the operation of *obtaining the valid indices* along some axis or all axes (i.e. ρ) then must introduce a new axis to arrange its results along.

Inter-loop dependencies

So far, all of the above, however nicely it motivates and elaborates APL's default rules for conformability and broadcasting, only covers scalar operations and nearly trivially parallelizable vector operations with no interloop dependencies. Operations like reverse, rotate, grade-up (indirect sort), scan (prefix sum), and even take and drop don't treat the points along the axis as floating in space independently, but rather having a total order, with even predecessor and successor operations, and correspond in languages like C to loops with interloop dependencies.

I can imagine a bunch of different possible ways to handle these: all axes could be ordinal; grade-up could create an ordinal axis from a non-ordinal axis or axis subset, and scan, reverse, rotate, take, and drop could simply fail to compile when applied to non-ordinal axes; instead of rotation you might have a "next index" or "previous index" function which, since it knows which axis it's acting along, knows when to wrap; and so on.

This is an important area to do a good job in, and there will be nonobvious interactions among factors. These are, of course, the areas in which ALGOL-family programs have to declare data structures and SQL optimizers start having to plan out join plans, so we shouldn't expect easy wins in this area.

My raytracer example is in some sense carefully chosen to minimize this; it constructs almost no intermediate data structures, unless you count 3-vectors as "data structures".

Efficiency

GPUs, but also multithreading and SIMD instructions and cache prefetch and improved locality by avoiding memory access to unused columns. "Blocking" or "tiling" for efficiency; also "deforestation".

Parallel prefix sum and parallel sorting are well-studied problems. To the extent that these operations are sufficient to efficiently solve computational problems, we should expect programs written in this fashion to benefit from fine-grained parallelism more easily than regular programs.

Rethinking this again, the basic idea is that some variables have values that depend on the circumstances, and there are a variety of circumstances (or dimensions or scales) that may or may not be relevant to the value of any given variable. The latitude and

longitude of each house on a block are different, but perhaps we consider the temperature of the entire block to be identical — but it varies by time of day, which the latitude and longitude do not.

There are different kinds of dimensions; Stanley Smith Stevens described them as "levels of measurement". Some are categorical/nominal rather than quantitative; quantitative dimensions can be ordinal (sortable), interval dimensions (subtractable; affine?), or ratio dimensions (with a zero element and thus divisible). Also, quantitative dimensions may be discrete or continuous.

Pointwise operations on variables are straightforward.

Rethinking yet again, the idea is sort of that each variable is sort of a function of other variables:

```
f = a * b + c
```

Or we could say it invokes those other variables as subroutines, and eventually it bottoms out in inputs (the dimensions). So the above statement is isomorphic to something similar to this:

```
def f(x, y, t):
    return a(x, y) * b(y) + c(x, t)
```

But when we quantify over a dimension (or, perhaps, even a dependent variable?) we are generating an argument locally rather than merely passing it along; similarly when we index, which is a form of composition!

```
f = c + +/[x] a * b
```

If `+/[x]` is summing along x, this decodes to something like the following:

```
def f(x, y, t):
    return sum(a(xi, y) * b(y) for xi in xs) + c(x, t)
```

The difference, of course, is that all this default parameterization is purely implicit.

This is closely analogous to dynamic scoping in Lisp.

Comparison to GNU MathProg and ZIMPL

GNU MathProg, also known as GMPL, and ZIMPL are two languages for defining models ("linear programs") for a linear optimizer to optimize. (This is called "linear programming". See Some notes on the landscape of linear optimization software and applications (p. 1285) for details.) They have essentially the same data model; in what follows I will use the MathProg terminology and syntax.

I wish I had read about these systems earlier, because much of what I describe above is already present in them. Unfortunately, I didn't learn anything about them until 2019.

Here is a slightly tweaked example of a MathProg model from the GLPK distribution, licensed under the GNU GPL version 2. It describes some kind of industrial metallurgy planning problem,

perhaps finding the cheapest way to mix two tonnes of an alloy within desired concentration limits from a combination of recycled scrap and fresh metal.

```
/* plan.mod */
var bin1, >= 0, <= 200;     var bin2, >= 0, <= 2500;
var bin3, >= 400, <= 800;   var alum, >= 0;
var silicon, >= 0;
param sival := .38;

minimize
value: .03 * bin1 + .08 * bin2 + .17 * bin3 + .21 * alum + sival * silicon;

subject to
yield: bin1 + bin2 + bin3 + alum + silicon = 2000;
fe: .15 * bin1 + .04 * bin2 + .02 * bin3 + .01 * alum + .03 * silicon <= 60;
cu: .03 * bin1 + .05 * bin2 + .08 * bin3 + .01 * alum <= 100;
mn: .02 * bin1 + .04 * bin2 + .01 * bin3 <= 40;
mg: .02 * bin1 + .03 * bin2 <= 30;
al: .70 * bin1 + .75 * bin2 + .80 * bin3 + .97 * alum >= 1500;
si: 250 <= .02 * bin1 + .06 * bin2 + .08 * bin3 +
    .01 * alum + .97 * silicon <= 300;
```

(`glpsol -m plan.mod -o plan.out` reports that the optimal values for the design variables are `bin1` ≈ 44.3, `bin2` ≈ 844, `bin3` ≈ 534, `alum` ≈ 421, and `silicon` ≈ 156, resulting in a `value` of $307.46.)

In the above example, all the variables and parameters are scalars, but MathProg also supports models incorporating aggregates. Here's another tweaked example from the GLPK distribution:

```
/* Chvatal V. (1980), Hard knapsack problems, Op. Res. 28, 1402-1411. */

param n > 0 integer;
param log2_n := log(n) / log(2);
param k := floor(log2_n);
param a{j in 1..n} := 2 ** (k + n + 1) + 2 ** (k + n + 1 - j) + 1;
param b := 0.5 * floor(sum{j in 1..n} a[j]);
var x{1..n} binary;
maximize obj: sum{j in 1..n} a[j] * x[j];
s.t. cap: sum{j in 1..n} a[j] * x[j] <= b;
data;
param n := 15;
```

In these languages, the expressed values — the values that expressions can evaluate to — are called "elemental values", and they can be strings (which are mostly treated as opaque atoms and are sometimes called "symbolic values"), integers, real numbers, logical or binary values, or sets of these, called "elemental sets". Their denoted values — the values that can be identified by names — include the expressed values, and also "model objects", which consist of "sets", "parameters", "variables", "constraints", and "objectives". All of the model objects other than objectives are "indexed" by n-tuples drawn from some "subscript domain" which is the Cartesian product of a possibly-empty sequence of sets.

The logical or binary values are *true* and *false*. The other kinds of

elemental values have their usual programming nature and support the usual operations, including string concatenation, substrings, transcendental functions, exponentiation, and set arithmetic.

Parameters and variables are essentially identical in structure; they are partial functions from their subscript domains to elemental values. The only difference is that when you run the optimizer, you choose the parameters, while the optimizer chooses the variables. There are rules limiting the structure of numerical expressions to ensure that they are linear in the variables; I will not be concerned with that here, but that is the reason for thus drawing the distinction at the language level rather than, for example, specifying it with the objective.

Confusingly, there are two related entities called "sets": the expressed value, called an "elemental set", and the model object, which is a denoted value. The difference is that the denoted value is indexed, like parameters and variables; it is a partial function from its subscript domain to elemental sets.

Constraints are partial functions from their subscript domains to Boolean values. The optimizer looks for a "feasible solution" which makes them everywhere true, and which maximizes or minimizes the objective among all feasible solutions.

The only iterative operations are `sum`, `prod`, `min`, and `max`, `forall` and `exists` for sets, the implicit `forall` on each constraint, and a set-comprehension operator on (elemental) sets that amounts to a Cartesian product filtered by a logical expression. All of these implicitly include an elementwise transformation function.

There is, I think, no way to compute an elemental set whose contents depend on the value of a variable, and the other kind of sets (the model objects) are specified as part of the model, so they can't depend on the value of a variable either. This serves the purpose of ensuring that MathProg and ZIMPL models can be "translated" into the formats MPS and CPLEX LP, which do not support any aggregate values at all, only affine equations and inequalities in real, integer, and logical variables.

Since (elemental) sets are the only aggregate values that expressions can evaluate to, expressions as such can only describe pointwise computations. Consider this line from the above example:

```
maximize obj: sum{j in 1..n} a[j] * x[j];
```

This defines an objective called `obj` which is to be maximized, defined as $\Sigma_j a_j x_j$. `1..n` is a range expression which produces a set of 15 integers from the integer parameter `n` = 15; `{j in 1..n}` declares the "dummy variable" `j` (confusingly, not related to the meaning of "dummy variable" in statistics) which is scoped to the "integrand" of `sum`, `a[j] * x[j]`, which indexes the real-valued parameter `a` and the binary-valued parameter `x` with the 1-tuple `j`, producing respectively a real and a binary value for a given value of `j`, which are then multiplied together; and finally `sum` produces a real number by summing 15 values computed from its "integrand".

This approach to aggregate operations is very different from the APL approach, in which you would write `+/a×x`, which is at least considerably fewer user interface operations. In the principled APL I'm thinking about, `+/` would need to somehow indicate which axis

(or dimension or index) it wants to sum along: `+/j a×x`, for example, if the axis were in fact called `j`, or `(sum (j) (* a x))` in Lisp S-expression syntax. However, for reasons described in A formal language for defining implicitly parameterized functions (p. 144), I think this approach will probably lead to variable-capture problems of the same kind encountered in Lisp macros, and so it's probably best to scope the variables bound by such iterative operations lexically; this leads to the formulation `+/j a[j=j]×x[j=j]`, which abbreviated to `+/j a[j]×x[j]` looks very similar to the MathProg approach. The biggest difference is that the limits of the sum come from the domain of the "integrand" rather than being explicitly specified.

(The indexing or reshaping operation `v[k=e]` is a special case: it binds variables dynamically rather than lexically, since otherwise it would not work.)

MathProg variables and parameters correspond roughly to the array variables described above, and indexes and sets are conflated above as "axes of variation" or "inputs". A big difference from APL is that in MathProg elementary sets are first-class values, while in APL axes are not any kind of value at all, except in the implicit sense that they are functions from your program's inputs to some dimension of some array. Also, sets in MathProg are unordered, while many operations in APL only make sense if some axes are ordered sequences of index values, notably prefix sum or scan \, encode ⊤ and decode ⊥ (the names come from their use for number base conversion), grade-up ⍋ and grade-down ⍒, reversal and rotation ⌽, take ↑, drop ↓, and catenate ,.

Can you make a vocoder simpler using CIC filters?

Kragen Javier Sitaker, 2017-06-28 (updated 2018-06-17) (2 minutes)

I was thinking about how to make a vocoder on the way to the office today, and it occurred to me that a fairly simple approach might be to use CIC filters.

Essentially the idea is that, for a single band, you use a moving-average filter (or more than one) over past samples to get a decimated (and thus low-pass-filtered) version of the signal; then you use a recurrent comb filter fed with, say, a subtraction between adjacent decimated samples, to estimate how much it's oscillating at harmonics of the comb filter's fundamental. Because the signal is decimated, you have very little frequency precision, which is what you want for vocoder band detection.

In particular, most human voice energy is between 64 Hz and 2048 Hz, which is a range of only five octaves; Wikipedia says, "There are usually between eight and 20 bands," so something like half-octave resolution is called for. Dudley's original 1939 Voder used 10 filter bands. I think it might be necessary to subtract amplitude signals from overlapping bands to get such high frequency precision with simple decimated signals.

Then you can use a similar process in reverse to apply the band coefficients to the carrier signal you want to vocode.

I'm thinking that it might be possible to get a working vocoder in about ten or twenty lines of C with this approach.

...having tried it in Numpy, I'm no longer as optimistic, although maybe there's a way. The issue is that you need really good attenuation in the stopband, and to be able to invert by subtracting, you need really, really precise zero-phase response — one milliradian of phase error is already a limit of -60dB on your stopband attenuation, and 10 milliradians is -40dB. I think it might still be possible.

Reduced affine arithmetic raytracer

Kragen Javier Sitaker, 2017-05-10 (1 minute)

I want to do a reduced-affine-arithmetic raytracer.

The idea is that an "image" is a function from pixel coordinates x and y to color component intensities r, g, and b, and we merely want to compute an adequate approximation to that function. We recursively subdivide the image into rectangular regions, and restrict ourselves to a linear approximation within each region, so that the overall approximation is piecewise linear (though not necessarily continuous between the pieces).

In this way, we can avoid spending much computation time on smooth gradient regions, concentrating on the regions where aliasing is possible.

Extending this, a "video" is a similar function, but has three independent variables: x, y, and t. This allows us to avoid spending computation time on parts of the scene that don't change much from frame to frame.

You can derive such an approximation by applying a self-validated arithmetic model from a mathematical description of the ray-traced scene. Most self-validated arithmetic models only give you zeroth-order approximations in any given region; interval arithmetic and the use of Lipschitz constants are examples. Affine arithmetic gives you a first-order approximation, but it is crushingly computationally expensive; reduced affine arithmetic, though it doesn't provide such tight bounds, is more efficient, and has been successfully used for raytracing.

Improving Lua #L with incremental prefix sum in the ∧ monoid

Kragen Javier Sitaker, 2018-12-18 (7 minutes)

Lua's #L operator, to find the length of a list, is implemented by a binary search through indices to find an index j such that L[j+1] is nil but L[j] is not. This is not constant-time and produces erratic results, but it allows the indexed assignment operation L[j] = nil to be, I think, amortized constant time.

The solution

A more predictable approach (or less euphemistically, an approach that always gives the right answer) would add a binary tree onto the side of tables and make L[j] = nil logarithmic-time like #L. The idea is simply that you maintain a set of user-invisible keys full(n, m) such that

$$\texttt{L[full(n, m)] == true} \iff \exists i \in \mathbb{Z} : i > 0 \wedge b^i = m \wedge m \mid n \wedge \forall j \in [n, n+m): \texttt{L[j] != nil}.$$

(We ignore the abomination of L[0] here.)

The base or branching factor b is a tradeoff between storage cost and efficiency; 2, 3, 4, 8, or 16 might be reasonable choices. The node size m is a power b^i of b, and its start index n is a multiple of m.

Algorithms in more detail, with asymptotic costs

When you set an index L[j] to nil, you need to look for full($\lfloor j/b^i \rfloor$, b^i) nodes that contained that index, deleting them and increasing i until you don't find one; at worst this takes $\lceil \log(|L|)/\log(b) \rceil$ iterations, where $|L|$ is the number of items stored (at integer indices) in L; so, for example, deleting an item from a list of up to 16 777 215 items and b = 4 might require up to 6 iterations.

Conversely, when you set an index L[j] that was previously nil to a non-nil value, you may need to create up to a logarithmic number of full($\lfloor j/b^i \rfloor$, b^i) nodes; each node that is created requires verifying the existence of b-1 existing child nodes that are siblings of the node just created, treating indices L[k] as if they were full(k, 0) nodes. In our example, this potentially involves creating or examining 4 nodes at each of 6 levels, a total of 24 iterations.

These are worst-case numbers; in most cases, deleting a numeric-index table entry would not require the deletion of any full(n, m) nodes, and adding one would not require the creation of any full(n, m) nodes, and for typical usage patterns they would be amortized constant time, just like the current implementation. But it would be easy for a program to provoke the worst-case logarithmic

slowdown: create a large list and repeatedly delete and recreate its first element.

Computing #L would follow a logarithmic-time process similar to the present process, first walking up through the full(0, b^i) items until it found the largest one, then walking back down looking for successor nodes to last children. In the worst case, this requires examining b full(n, m) nodes at each of ⌈log(|L|)/log(b)⌉ levels; our example list of 16 777 215 items would require examining 24 full(n, m) nodes, just like insertion. The difference from the current implementation is that the answer it gives is precisely the index of the first non-nil item whose successor is nil.

The storage overhead is up to |L|/(b–1) invisible table items that do not exist in the current implementation.

This is precisely the parallel prefix-sum algorithm used for incremental rather than parallel computation in the ∧ monoid. Using the ∨ monoid gives an alternative definition which could be computed in a similarly efficient way, also complies with the current definition, and is more similar to the definitions in sister languages like JS and Perl, would return the index of the *last* non-nil item (whose successor is therefore nil). I think this is wrong for Lua, because it's unnecessarily incompatible with the behavior of `ipairs`.

Improving constant factors

As a locality and space optimization, it might be desirable to store the full(n, m) items in a way that somehow tacks them on to L[n+m-1] rather than as separate table items, sort of like a skip list. For example, you could store them in a bitmask indexed by log(m)/log(b). (This allows the initial examination of the full(0, b^i) items in #L to be done with a single instruction on some CPUs.) Alternatively, you could store them separately as ⌈log(|L|)/log(b)⌉ bitvectors of logarithmically decreasing numbers of bits, but that seems like it could be complicated if you start storing things at high indices.

As a complicated optimization, you could lump these bits into lumps big enough to amortize storage overhead; taking again b = 4, in a 128-bit lump of level j, you could have 64 nodes of full(n, b^{5j+1}), 16 nodes of full(n, b^{5j+2}), 8 nodes of full(n, b^{5j+3}), 4 nodes of full(n, b^{5j+4}), and 1 node of full(n, b^{5j+5}), using 93 of the 128 bits. You need one such level-0 lump for each run of 1024 list items, a level-1 lump for each run of 1 048 576, a level-2 lump for each run of 1 073 741 824, and so on; and you need zero such lumps until you have a run of 4 items that's properly aligned to generate a lump. This limits the worst-case space overhead to 25%, if the lumps are the same size as normal table entries.

In the case of b > 2, this storage optimization would also allow the use of simple bit masking operations to simultaneously test for the existence of all children. But, for insertion and deletion, this mostly helps with the worst case, because in the average case, you're overwhelmingly testing membership in the table itself.

The b tradeoff

Choosing b to be larger makes assertion of new values and computation of length almost proportionally slower (O(N/log(N))), but also reduces storage overhead by b–1 and makes deletion

logarithmically faster (O(1/log(N))).

Since deletion is much less common than insertion, it would be nice if there was a way to shift that factor of N over to the deletion algorithm. I haven't found one. You might try the simple approach of making nodes at a given level conditional on the existence of not just all of their children but all of their previous siblings. Thus insertion creating a new node at a given level need only check for the existence of its previous sibling to decide whether to create its "parent", but deletion potentially needs to delete all of its following siblings. But insertion at the beginning retains the same worst case, and the usual case is amortized constant time, just as before. So I think this doesn't really help.

Trellis-coded buttons to run a whole keyboard off two microcontroller pins

Kragen Javier Sitaker, 2013-05-17 (updated 2019-06-13) (30 minutes)

(I think this was published previously on kragen-tol, but this version has been improved somewhat.)

Based on some discussions with Nick Johnson, I was thinking about a "downloadable tinkerer's tricorder", software that would turn a commodity microcontroller into a powerful LCR meter, and an additional application occurred to me: a keyboard with up to several dozen keys, supporting N-key rollover ("NKRO"), using only two microcontroller pins, one with ADC and the other with digital output, or even a single pin, and a couple of dirt-cheap passive components per key, with latency of a few milliseconds or even down into the submillisecond range.

This represents an order-of-magnitude reduction in cost for NKRO keyboards, which are essential for some kinds of video games and for advanced chording input methods.

Background: relative cost of different parts

Pins on chips are among the most expensive resource in modern circuitry. A small diode, resistor, or capacitor, with no special requirements, will cost between a sixth of a cent and a whole cent (diodes are the expensive items here), but going from an 8-pin chip to a 14-pin chip will cost you at least a dollar; each pin, in effect, costs as much as 20 to 100 resistors! And adding another 8-pin chip will cost you about 50 cents, but at least three of those pins will be tied up with power and communication, costing you ten cents per pin, or more.

Pushbutton switches cost nearly 10 cents if you buy them as separate components, but they're cheaper if you make an assembly with many of them built into a single component. As a result, if you dedicate a microcontroller pin to each pushbutton, you nearly double the cost of the pushbutton, and maybe much more if your keyswitches are really cheap.

More than one key per pin

So, in addition to the standard matrix multiplexing approach, designers occasionally hang several pushbutton switches off one I/O pin on a microcontroller, each controlling a different resistance. Then you can use a voltage divider so that each pushbutton creates a separate voltage, which you can measure with an analog-to-digital converter.

It sounds crazy to use an ADC and some resistors to save an I/O pin or two, but the fact is, lots of microcontrollers have one or more ADCs built in already, and you can time-share it between different uses on different pins. So it doesn't cost you anything extra.

The most famous design that does this is probably Limor Fried's Monochron. A variant that avoids the need for an analog-to-digital converter is the PaperTecladoRC, which charges up a capacitor

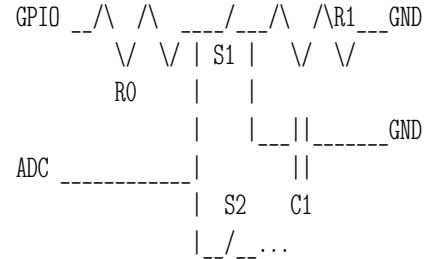
("condensador") and then measures its time to discharge to logic zero through the resistor network, rather than making an analog voltage measurement.

(In the standard matrix multiplexing approach, which is how basically all but the most expensive keyboards work on everything from pocket calculators to Macbook Airs, you make an N×M matrix where each keyswitch connects one of the N rows to one of the M columns, and you alternately energize each row to see which columns get energized. You can get two-key rollover with this approach, but not NKRO, and you still need a substantial number of I/O pins, typically around 20.)

Trellis-coding your keys to get N-key rollover on a huge number of keys

It occurred to me that you can do much better than this. Rather than merely discriminating between different *resistances* attached to each button, you could discriminate between different *complex impedances*: connect each button through not only a resistor but also a capacitor. Now we can subject the pin to a time-varying signal, such as a transient pulse, and watch its response.

To consider one possible concrete realization of this approach, consider this layout:



Your GPIO pin, a switchable voltage source, connects through a resistor R0 to a common bus to which all the pushbuttons connect. Your ADC is also connected to this common bus. Each pushbutton Si connects the bus to a resistor Ri and a capacitor Ci, each of which is grounded on the other side; that is to say, they're in parallel.

This is more or less the configuration of a *single* AVR I/O pin in input mode: you can either connect the pullup resistor R0, which is an imprecise and nonlinear resistance in the 20kΩ–50kΩ to VCC, or leave it in a high-impedance mode where it won't source or sink more than a few microamps. However, it's convenient to us to use *two* pins, both because it lets us use a higher-resistance pullup resistor and correspondingly lower-capacitance capacitors, and because it makes our pullup resistor much more precise.

Suppose one of the pushbutton switches S1..SN is pressed; let's say S1. Now, if we bring the pullup high, the voltage measured by the ADC will rise eventually to VCC R1/(R0+R1). If the various Ri are sufficiently different, we can use the ADC to distinguish which of them it was. Indeed, if they're sufficiently different that the sum of each subset of their conductances is sufficiently different to be distinguished by the ADC, we can distinguish *any subset* of them, which is to say that our keyboard has "N-Key Rollover", or NKRO, an advanced gaming keyboard selling point. (According to the

documentation for Plover, a Stenotype input method that can get 250 words per minute on a regular NKRO keyboard, you can't find a full-size NKRO keyboard for less than US$50.)

If you have a 10-bit ADC, you could conceivably distinguish 1023 different keys merely by their resistances by this method, but you can't distinguish more than 10 of them if you want to be able to distinguish all of the possible chords (that is, get NKRO). Also, your resistances need to really be distinct, which is difficult: we're talking about 1023 different resistances, with better than 0.1% tolerances here for the highest resistances, which is hard to find. (From browsing Digi-key, it seems like regular sixth-of-a-cent resistors these days are ±1%; regular antediluvian resistors are ±20%; ±0.5% resistors cost half a cent; the resistance of the same resistor normally varies by more than 0.1% with temperature.)

Worse, the resistances need to be precisely aligned with the bit transitions of the ADC, and the top one needs to have 1022 times higher resistance than the pullup. So in practice I think you'd be lucky to distinguish 8 different keys on resistance alone with NKRO unless you trim each resistor after assembly.

But that's what the capacitances are for! If you have two different keys with the same resistance to ground, but different capacitances, they'll both eventually arrive at the same steady-state voltage — but they'll take different amounts of time to get there. Better yet, you can measure the charging speed with greater precision than you can the final voltage, and taking multiple measurements as the capacitor charges can give you better than 10 bits of precision by averaging over time.

(In effect, you're using trellis-coding: the complex impedances of each key at a given arbitrary frequency are a sort of exponentially distributed lattice in one quadrant of the complex plane. Although we're actually adding the *reciprocals* of the impedances (we're adding the complex analogues of conductance; maybe there's a word for this), those are also exponentially distributed such that every subset of them has a unique complex sum, and all of these complex sums are far enough apart that we can distinguish them despite measurement error.)

Suppose tracing the curve over time gives us 12 bits of precision on the resistance (by averaging 16 samples) and 12 bits of precision on the RC time constant. Intuitively I think it should be easy, then, to distinguish 6 different resistances and 9 different capacitances, for a total of 54 keys with NKRO, on a single ADC pin!

To be slightly more precise, we probably want the largest resistance value to be somewhat larger than the pullup resistor value. Suppose we choose 220kΩ for our pullup. We want the smallest resistance value to be less than the error in the largest; and we want all the sums of resistance values to differ by more than the sums of their errors. This suggests using resistances of 500kΩ, 220kΩ, 100kΩ, 50kΩ, 22kΩ, and 10kΩ; if they, improbably, all had an error of 1%, that would be 5kΩ+2.2kΩ+1kΩ+500Ω+220Ω+100Ω = 9020Ω, which is less than 1kΩ. A seven-bit ADC measurement would probably be enough to distinguish between them, and 10 bits definitely will. IIRC, experiments have shown that the nominally 10-bit successive-approximation ADC on the ATMega328 and friends can still give you an effective number of bits ("ENOB") of 7 at about

1Msps, which is to say a microsecond per measurement. In the "worst case", you'd need about 11 bits' worth, which I think is about 600 microseconds (four successive measurements) on the ATMegas.

(I'm a little fuzzy on the exact ADC numbers, unfortunately, but I think they may actually be significantly better than the above.)

Then we need to do the same trick for the capacitors. The smallest capacitance we can reasonably measure will be one that charges fully through the pullup in a single 600-µs measurement, so the RC time constant should be around, I don't know, 50µs. If the pullup is 220kΩ, that puts it at 227pF (say 220pF for practicality). Then you could use nine capacitances of 220pF, 470pF, 1000pF; 2200pF, 4700pF, 10000pF; and .022µF, .047µF, and 0.1µF.

The slowest RC constant, then, should be 0.1µF × 220kΩ, or 22 milliseconds. But since you're using an ADC, you don't need to wait for the capacitor to charge fully, just enough that you can accurately measure its rate of charging — say, ten samples or ten out of 1024 ADC counts, whichever is faster. In the worst case, the 0.1µF capacitor will be in parallel with a 10kΩ resistor, which means its final charged voltage would be 10/(220+10) of the 1023-count max: 45 counts. Charging 10/45 of the way will then take 1.25 time constants, or 28 milliseconds.

That's only marginally acceptable, so it's probably worthwhile to blacklist the one, three, or six slowest combinations. The two next-worst are 0.1µF in parallel with a 22kΩ resistor, which will have the same RC constant, but the final voltage is almost twice as high, so you'll rise by 10 counts in only 14 milliseconds; and 0.047µF in parallel with 10kΩ, which will have less than half the RC time constant and the same asymptotic voltage, so will also need only 13 milliseconds. The next three worst are 0.1µF with 47kΩ, .047µF with 22kΩ, and .022µF with 10kΩ, all of which need about 7ms. So if you eliminate these six keys, you can measure any keychord in under 4ms.

(Another way to improve this: on the AVRs, there's the possibility of using an internal 1.1V bandgap voltage reference instead of VCC. At a typical 5 volts, this will increase the precision of the measurement of this initial voltage rise by a factor of almost five, and thus decrease that 28ms to some 6ms.)

So that gives you a 48-key NKRO keyboard with worst-case 4ms latency for the cost of two microcontroller pins (20¢), 49 1% resistors of six values (10¢), 48 1% ceramic capacitors of nine values (25¢†), and 48 keyswitches (480¢ if discrete, much less if made as one piece, much more if you use Cherry high-end mechanical keyswitches) for a total of some US$5.35, or US$0.55 as the cost of the keyswitches themselves approaches zero.

This is an order of magnitude cheaper than the US$50 cost of existing NKRO keyboards, or two orders of magnitude cheaper if the keyswitches are free.

† I'm actually having a hard time finding cheap capacitors with reasonably precise capacitances. This could limit the effectiveness of the idea — but see the section at the end for how to fix this.

Information theory shows it won't work quite that well

There's some kind of problem with my calculations, though. You need 48 bits of entropy to get NKRO on a 48-key keyboard. If you have an estimate of the RC time constant with a precision of 50µs with an upper limit of 3ms, as I've postulated above, that's almost 6 bits of entropy. That, combined with a 12-bit measurement of voltage at some known point in the charging curve (the result of averaging some 16 samples) gives you 18 bits. That's less than half of what you need. In the absence of nonlinear components such as diodes, those two parameters will be able to predict any further measurements down to the limit of measurement noise. So at best you can get 18-key rollover — and that's ignoring that many of the combinations of final voltage and RC time constant are outside of the feasible region!

In practice, I think that given 18 bits of data like that, you can probably identify a unique RC time constant and asymptotic voltage for each key, even if the nominal values of the resistors and capacitors were equal. (Precision of ±1% steals the top 6 bits of each parameter, leaving 6; using lower-quality, more-variable components would help by adding more randomness.) If you train the microcontroller for a given keyboard, storing calibration constants for each key and then adjusting them with a linear correction for an estimated temperature (assumed to be constant across the keyboard), you could probably reliably distinguish several thousand keys — but without NKRO.

Ways to improve performance

If the problem is that we only get 18 bits of entropy and we need 48, here are some approaches.

The most glaring problem is that we need at least 9 bits of precision on the capacitance measurement, but our hypothesis above is that we're only getting about 6 bits of RC time constant, which represents the contribution of C. Maybe my calculation is off: maybe from a series of 10-bit voltage measurements, even over only a maximum of some 60 sample times, we can extract some 9, 10, or even 11 bits of precision for RC. Maybe use a least-squares fit in some kind of transformed space.

But that only gets us to, like, 23 bits, when we need 48! We need more entropy! (Even an ADM-3A had 59 keys.) Unless we just want a Stenotype, which has exactly 23 keys.

A second approach, as mentioned earlier, is to incorporate nonlinearity. For example, if you add a diode somewhere in the network for each switch, your RC time constant changes with voltage, according to the diode's characteristics. This might provide another 12 bits of entropy, if you have diodes with enough variability whose voltage drop is comparable to that of the resistor at comparable currents. By itself, that could get us to maybe 30 bits, at a cost of another 24¢ at half a cent per each of 48 keys.

A third approach is to use another ADC pin and pullup resistor from the same GPIO pin, giving you, in essence, a second separate keyboard, at a cost of some 10¢. This approach scales linearly to as many ADC pins as you have available on your microcontroller, at some cost to sampling rate per pin and therefore necessitating somewhat larger capacitors. If this is the only approach you take to improve performance over the basic approach, so that you can only handle about 18 keys per ADC pin, then one GPIO pin and three

ADC pins (40¢ of pins) should get you to 54 keys, or maybe a bit more if you push it. That's enough for a full compact keyboard, at a cost of 75¢ (55¢ - 20¢ + 40¢) of electronics, plus the keyswitches.

If we combined all three of the above approaches, you'd be getting 35 bits on each of three input pins, for 105 bits in all: enough for a full keyboard with keypad, at a cost of, I don't know, a dollar or two of electronics, plus the keyswitches.

However, there's also a solution that works with *no extra hardware*! Since we're able to scan the entire keyboard at 250Hz, it's really completely unnecessary to consider all possible new keyboard states as equally likely. An actual human being won't be able to press and release more than one or two keys in any 4ms interval. So of all the candidate new keyboard states, we can take the one with the smallest hamming distance from the current keyboard state, and we'll essentially always be correct.

(That insight is from reading posts by Talkingjazz about their rotary switch decoding problem: http://www.arduino.cc/forum/index.php/topic,20125.0.html.)

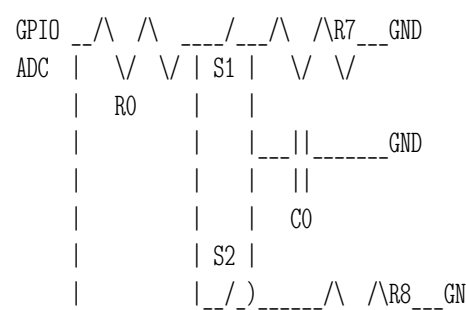
Yeah, or use a shift register like a normal person

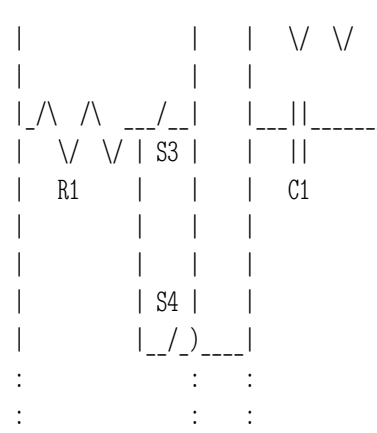
You could use a ten-cent 74HC165 shift registers and eight pullup resistors for each set of eight keyswitches, and chain them all together in a long line feeding into one pin on your microcontroller. You need two more microcontroller pins to clock the shift registers and to enable them. Cost for 48 keys: 30¢ for the microcontroller pins, 60¢ for the shift registers, 24¢ for the pullup resistors, total of US$1.14, plus the keyswitches themselves. This is maybe more expensive than the trellis-coding approach, but it sure is a lot simpler.

The improved single-pin trellis-coding approach

Here's a better version. In the simplified form I analyze here, it doesn't support NKRO, but although I haven't analyzed the more-complex NKRO variant, I anticipate that hacking NKRO in will be feasible.

The entire keyboard has two connections: the probe/power/sense connection and ground. Each (logical) row is connected to the sense connection through a different-value resistor; each column is connected to ground through a different-value resistor in parallel with a same-value capacitor. The microcontroller charges the sense connection for different periods of time and then switches its pin to analog input mode to measure the decay curve, then repeats the process.





(Here in this diagram we have two rows and two columns; the first row charges through R0 and contains S1 and S2, while the second row charges through R1 and contains S3 and S4. The first column charges C0 through S1 or S3 and discharges it through C7, while the second column charges C1 through S2 or S4 and discharges it through R8.)

Let's be concrete. Consider a US$1.30 48MHz STM32F031C4 with its 1Msps 12-bit ADC, running at 3.3 volts. (See Notes on the STM32 microcontroller family (p. 3176) for more details.) It's driving a 7×7 keyboard, which is missing 12 of its potentially 49 keys in the corners, leaving 37 keys; row 0 has 4 keys (missing columns 4, 5, and 6), row 1 has 5 keys (missing columns 5 and 6), row 2 has 6 keys (missing column 6), row 4 has 6 keys (missing column 0), row 5 has 5 keys (missing columns 0 and 1), and row 6 has 4 keys (missing columns 0, 1, and 2.) All the capacitors are 0.001-μF MLCCs. The resistors for row and column 0 are 1 kΩ; for row and column 1, 2.2 kΩ; for row and column 2, 4.7 kΩ; for row and column 3, 10 kΩ; and thus 22 kΩ, 47 kΩ, and 100 kΩ for the remaining three rows and columns.

Column 0 discharges with a time constant of 1 μs; column 2 discharges with a time constant of 2.2 μs; and so on, until column 6 discharges with a time constant of 100 μs. This is true regardless of which row it was charged by. During the discharge cycle, the only voltage across the row resistor comes from the I/O pin's input leakage current, specified in the datasheet as ±0.2 μA, thus producing an error of ±20 mV across row 6's 100 kΩ resistor, and proportionally less on the other rows, so the microcontroller can sense the column voltage with quite adequate precision. That is, the discharge time constants vary like this across the keys:

```
[  1.    2.2   4.7   10.                      ]
[  1.    2.2   4.7   10.    22.               ]
[  1.    2.2   4.7   10.    22.    47.        ]
[  1.    2.2   4.7   10.    22.    47.   100. ]  μs
[        2.2   4.7   10.    22.    47.   100. ]
[              4.7   10.    22.    47.   100. ]
[                    10.    22.    47.   100. ]
```

The timing precision needed to distinguish these columns is thus only about a factor of 2.

The voltage from which the discharge curve is falling depends on the charging time, asymptotically approaching the voltage in the

middle of the voltage divider formed by the row and column resistors. So it ranges from 3.00 volts for r0c3, r1c4, r2c5, and r3c6 to 0.30 volts for r3c0, r4c1, r5c2, and r6c3. The other voltages, though they vary slightly, are around 0.60 volts, 1.06 volts, 1.65 volts, 2.27 volts, and 2.72 volts. Note that errors in the capacitance do not affect these asymptotic voltages at all. Here's the full table of asymptotic voltages for each key:

```
[ 1.65  2.27  2.72  3.                    ]
[ 1.03  1.65  2.25  2.7   3.              ]
[ 0.58  1.05  1.65  2.24  2.72  3.        ]
[ 0.3   0.6   1.06  1.65  2.27  2.72  3. ] V
[       0.3   0.58  1.03  1.65  2.25  2.7 ]
[             0.3   0.58  1.05  1.65  2.24]
[                   0.3   0.6   1.06  1.65]
```

However, a third parameter also distinguishes the rows: the charging time constant. If the charging time is short enough, the voltage will not quite reach the asymptotic voltage described above, which can be ascertained by doing multiple measurement cycles with different charging times. The charging time constant is the RC product of the 1-nF column capacitor and the parallel combination of the column discharge capacitor and the row charge capacitor. The microcontroller cannot directly observe the charging curve, since during the charge cycle it sees 3.3 volts on its I/O pin (an unknown fraction of which is dropped across the row charging resistor), although perhaps it could pause the charging periodically to take a sample.

The charging time constant ranges from 0.5 µs (r0c0, each with a 1-kΩ resistor) to 50 µs (r6c6, each with a 100-kΩ resistor). The whole array of charging time constants is as follows:

```
[  0.5    0.69   0.82   0.91                        ]
[  0.69   1.1    1.5    1.8    2.                   ]
[  0.82   1.5    2.35   3.2    3.87                 ]
[  0.91   1.8    3.2    5.     6.88   8.25          ] µs
[         2.     3.87   6.88   11.    14.99  18.03]
[                4.27   8.25   14.99  23.5   31.97]
[                       9.09   18.03  31.97  50.  ]
```

Note that the contours of this time-constant table run nearly at right angles to the contours of the asymptotically-approached voltage; that is, where the asymptotic voltage provides the least information, the charging time constant provides the most information. Avoiding zones where this charging-time-constant information is weakest is the reason for omitting the corners where the resistance values are too far apart.

Since these charging time constants are using the same capacitance as the discharge time constants, over the same range of voltages even, errors in the capacitance will affect them both by the same factor. However, if we treat the capacitance as entirely unknown, we entirely lose the information about the magnitude of the resistances — the ratios of the charge and discharge times follow the same diagonal pattern as the asymptotic voltages.

You *could* recover some of that resistor-magnitude information by

doing a charge cycle through on-chip pullup resistors, as suggested for the earlier-outlined design, or the pulldown resistors the STM32 also has (making it a sort of discharge cycle instead — you'd want things to be charged first). The pullup and pulldown resistors are not very precise, and their values probably vary widely with the chip temperature, since they're presumably polysilicon and not, you know, metal film or carbon or something. But they might be good enough to help you compensate for capacitor errors.

So this design gives you 37 keys for the cost of one microcontroller pin (which I said earlier was 10¢), 14 resistors of 7 values (2.3¢), 7 ceramic capacitors (3¢), and 37 keyswitches (370¢ if discrete, much less if made as one piece, much more if you use Cherry high-end mechanical keyswitches) for a total of some US$3.85, or US$0.15 as the cost of the keyswitches themselves approaches zero — two thirds of which is the imputed cost of the microcontroller pin! None of the components need to have a precision of better than 10%, but it's particularly insensitive to the values of the capacitors, which could easily have capacitance errors of a factor of 2 or 3 without doing much harm. And that's good, because (as I mentioned earlier but didn't fully appreciate at the time) ceramic capacitors, which are the cheap ones, have pretty imprecise capacitances which vary a lot by voltage.

Earlier I priced the pin at 10¢, but perhaps on an STM32 I should lower that cost; the STM32F031x4 has 39 GPIOs and only costs US$1.30, so maybe its GPIO pins only cost 3¢. On the other hand, it wouldn't be surprising if you had to dedicate the entire STM32 computer to the keyboard-processing task.

How much measurement error are we going to have on these charge and discharge curves? Let's suppose the ADC is using the µC's internal bandgap reference, which is specified as 1.2–1.25 V. This gives us plenty of sensitivity for even the 0.3-volt signals: those start out as a third of full scale, 983 LSBs. The ADC's total unadjusted error is specified as ±4 LSBs, or ±1.22 mV.

The hardest measurement to take might be a 3.0-volt signal with a 100-µs discharge time constant — if we let it charge fully, it'll be out of range for the first 92 samples. (I'm assuming that'll just give us a full-scale reading, not a blown chip. Also I'm ignoring the issue of charging the 8-pF sample-and-hold capacitor in the ADC's frontend, which could add a significant error to quickly-changing signals when the input impedance is high.)

So we have about ±2% error from the bandgap reference, ±0.1% error from the ADC, ±1% from the resistors, and probably ×/÷ 2 from the capacitors — an error I'm optimistic we can calibrate out.

Every millisecond of measuring the charge/discharge waveforms gives us close to 1000 samples of data. In theory, two samples are enough to fit an exponential decay toward a known zero voltage, and three samples are enough to fit an exponential increase towards an unknown asymptotic voltage, so these 1000 samples should give us about 23 dB of noise immunity — an ENOB increase of 4, giving us effectively 16-bit precision on the measurements of the three components we're trying to measure.

This suggests to me that 37 keys is really aiming low, and we could potentially do orders of magnitude more.

What about NKRO? As described, the circuit topology has a

really serious key-ghosting problem: there's no way to distinguish the sets of keys {r2c2, r4c2, r4c4} from {r2c2, r2c4, r4c4} because they both connect exactly the same sets of wires together. The simplest solution to that aspect of the problem is to put a different precision resistor in series with each keyswitch. Additional measures that might help include adding capacitors to ground from the row lines, providing a pair of capacitances to come into equilibrium through the keyswitch resistor during the discharge cycle, and giving every component a slightly perturbed value, rather than having many resistors and many capacitors of the same value, which produces ambiguity.

Memoize the stack

Kragen Javier Sitaker, 2015-09-03 (5 minutes)

Memoization is a fairly general technique for making pure functions faster to compute, particularly in the presence of incremental changes to input data, but it usually has to be applied judiciously. The memoization runtime overhead on a function call is fairly large compared to a primitive function call (a bit larger than an order of magnitude), the space overhead of the memoized arguments and return values is potentially many orders of magnitude larger than that of the original program. To make things more complicated, some functions are worth memoizing because, although they run for less than a microsecond, they are called many thousands of times per second, while others are worth memoizing because, although they are only called a few times per second, they run for tens of milliseconds; and, furthermore, if a function A does most of its work in a function B, and function B is mostly called by function A, it may be the case that either A or B is worth memoizing, but not both A and B, since memoizing either of them will dramatically reduce the cost of the other. Finally, two functions C and D, which would seem to be equally worth memoizing given their respective runtime costs, might have vastly different memory costs to memoize, and so we might vastly prefer to memoize the one that will use less space.

In the face of all of this uncertainty, I propose that perhaps a simple and reasonably effective way to figure out what to memoize may be to scan the stack at every minor garbage collection (a task which cannot be omitted from garbage collection in any case) and note the particular activation records currently present upon it. If our activation records are in fact allocated on the heap in the nursery, then GCs almost cannot fail to occur regularly during ordinary computation, so the probability for an activation record to be present at garbage-collection time is a good approximation of how much computation time it represents. If we then evacuate these activation records to the next generation, they will then be safe from minor garbage collection, and furthermore if we mutate them by writing a pointer to their eventual return value into them, the write barrier will shanghai the return value from the nursery into their generation upon the next minor collection.

This, then, should provide us with a reasonably good facsimile of a memoization policy that retains in memory the activation records of calls whose past results we are likely to wish to consult once more. Still, it cannot yet inform us of which *functions* we ought to instrument with a memo-table probe, nor does it of itself organize them into a queryable memo table. After all, even if dozens of activation records for a given function are copied out of the nursery, that function might be called dozens of times with different arguments, or dozens of millions; in the second case it may not be worth patching memoization overhead into the function's preamble!

But let's suppose that we come up with some kind of approach to solving these problems, like the invocation counter HotSpot uses to decide which methods to optimize harder, sweeping the second generation to collect saved activation records into a table when it's

time to collect it, and estimating the amount of otherwise-garbage that each activation record hauls out of the nursery, or something.

A really strange benefit of this memoization mechanism is that it can possibly memoize functions whose return value turned out to be very expensive to compute even from the very first time they are invoked, with no ahead-of-time indication that they will be expensive. As long as they lived long enough and survived enough nursery collections, their return value will be properly saved, and future invocations will be able to use it.

With a sufficiently powerful and clever memoization mechanism, you could replace most or all intermediate data structures in a program with function calls that purported to compute a value from the original (externally provided) inputs, and trust that if those functions take a long enough time to run, then their return values will be stored in a hash table without any explicit intervention on your part. The best thing about that is that you wouldn't have to worry about when to update those intermediate data structures or how much of them to update. This is probably kind of a fantasy, though.

Rasterizing polies

Kragen Javier Sitaker, 2017-07-19 (3 minutes)

I was thinking about the problem of rasterizing a set of polylines filled with colors; for example, for rendering text from an outline font after some arbitrary geometric transformation. It occurred to me that it's probably reasonable to approximate each smooth segment of the polyline with a quadratic or cubic spline providing a fractional X-coordinate given the Y-coordinate; this explicit spline may need to have more knots than the parametric spline defining the original polyline in order to achieve adequate precision.

Note that computing the X-coordinate as a function of the Y-coordinate is transposed from the usual convention for graphing functions, established I suppose by Descartes from, probably, the Greeks' convention of writing their letters from left to right.

It should be possible to use interval arithmetic to conservatively approximate how precisely you need to approximate the parametric spline with the explicit spline.

Anyway, once you have a bunch of explicit splines, the inner loop of updating all of the X-coordinates for a new raster is just this:

```
x += Δx;
Δx += ΔΔx;
// and if they're cubic splines:
ΔΔx += ΔΔΔx;
```

These vector-addition operations can be carried out in SIMD or SPMD fashion, which can be up to 512 bits per instruction on modern computing hardware.

When we encounter a knot in the spline, we just need to update an element of the ΔΔx or ΔΔΔx vector with the new value. If we instead encounter a corner in the polyline, we also update Δx. A top edge, corner, or curve involves adding two new items; a bottom one involves removing them.

This gives us a vector of x-coordinates; if we sort that vector, we get partitions dividing the scan line into regions alternating inside and outside. (It may be worthwhile to keep all of the vectors sorted, since most of the time the order won't change from one scan line to the next.)

To keep the knots at least 16 scanlines apart without the errors getting over some size, I think we need an extra 4 fraction bits per order of polynomial; that is, for quadratic splines, we need 8 more fraction bits for ΔΔx than we would need for our desired precision of x, and for cubic splines, we need 12 more fraction bits for ΔΔΔx. This probably means that 32-bit fixed point with 16 fraction bits is adequate for most purposes, providing 16 levels of antialiasing with cubic splines, while 16-bit fixed or floating point is not, which means that a 512-bit vector is only 16 elements. But that's still enough to give a dramatic speedup.

Forth looping

Kragen Javier Sitaker, 2007 to 2009 (16 minutes)

Warning! None of the code I wrote for this post is tested, so it probably has bugs.

Warning! This message is almost entirely concerned with micro-optimizations for obsolete languages, obsolete CPUs, and CPUs that never shipped, and I don't even know very much about them.

Forth Definite Looping Constructs

I remember reading some years ago about how Chuck Moore tries to avoid use of the "DO...LOOP" construct these days. In http://www.ultratechnology.com/moore4th.htm he says:

```
Some of the people who don't like Forth might take to this. In 20
blocks of code I have no conditional statements or loops.  Good
Forth minimizes the number of conditional statements. The minimum
is zero.  I can say

: 5X X X X X X ;  : 20X 5X 5X 5X 5X ;

This is just as good as a loop. When running through memory the
code should compare an address to terminate rather than use a loop
count.
```

(Attributed to Chuck Moore's 1997 Silicon Valley FIG presentation: http://www.ultratechnology.com/color4th.html)

This struck me as crazy, since it makes the program considerably more opaque.

(In http://www.ultratechnology.com/1xforth.htm from 1999 he says he prefers tail-recursion to other looping constructs, and much of that is actually on display in the 1997 presentation as well.)

Moore has been working on top of his stack-based MuP21 and F21 CPUs since the early 90s, or at least pretending to by emulating them with assembler macros on Pentiums, which run a lot faster. These chips implement something like Forth operations as their native instruction set. But the run-time semantics of LOOP are not among their primitive operations; instead there are JZ (T0), which jumps if the top-of-stack is zero (excluding its carry bit), and JCZ (C0), which jumps if the carry bit on the top-of-stack is zero. (On these chips, each register on the stack drags along its own carry bit.)

I've been implementing a toy Forth system myself this week, and I got to LOOP, and you know, it's a little bit complicated. My implementation was something like 19 words in length. In view of Moore's overriding desire to get stuff done with a minimal amount of resources, his avoidance of LOOP no longer seems quite so incomprehensible.

So first I'll explain what I wrote, and then I'll show the much better solution from F-83.

What I Wrote

```
    defbytes _loop          # twiddles return address
    # ( -- ) ( R: X limit-1 limit -- X+1 ) in end-of-loop case
    # ( -- ) ( R: X counter limit -- X-N counter+1 limit ) in normal case
    # N is stored at X (in the instruction stream after
    # the call to _loop)
    # XXX we need a way to sign-extend characters; it's
    # confusing to write a positive number for a backward
    # jump.
    ## Also, this is way too long.
    .byte b_rpop, b_rpop, b_add1, b_rpop, b_twodup, b_xor
    .byte b_branch_on_0,7, b_rpush, b_rpush # not done yet, so jump back
    .byte                  b_dup, b_c_at, b_sub, b_rpush, b_exit
    .byte b_twodrop, b_add1, b_rpush, b_exit # done
```

That's hopefully equivalent to this Forth:

```
: _loop r> r> 1+ r> 2dup xor
    if >r >r dup c@ - >r exit then
    2drop 1+ >r ;
```

So it pulls its own return address off the return stack, pulls off the loop counter and increments it, pulls off the limit, compares the incremented loop counter to the limit, and if they're still not equal, it pushes them both back onto the stack, then fetches a jump offset from where its return address points and subtracts that from the return address before sticking it back onto the stack, then returns. But if they are equal, it throws them away, increments its return address by one to skip over the jump offset, and sticks it back on the return stack before returning.

That's a lot of work for something that has to be done inside every tiniest little definite-iteration inner loop!

I tried coding an assembly version, but it was complicated too, at 14 instructions.

F-83's LOOP implementation

The definition of LOOP from my copy of F-83 is in screen #75 of KERNEL86.BLK:

```
: LOOP
     COMPILE (LOOP)  2DUP 2+ ?<RESOLVE ?>RESOLVE    ; IMMEDIATE
```

So when you say LOOP in F-83, it compiles a call to (LOOP) into the word you're compiling, then does some compile-time jump-resolution stuff.

(LOOP) is in screen #11:

```
CODE (LOOP)   (S -- )   1 # AX MOV
LABEL PLOOP   AX 0 [RP] ADD   BRAN1 JNO
  6 # RP ADD   IP INC   IP INC   NEXT END-CODE
```

(I found these by running F83.COM in DOSBOX and saying "view loop" and "view (loop)". There's a built-in screen editor vocabulary that I don't really know how to use, but it brings up a screen editor on the definitions if you say "fix loop", at which point the word "a" switches between viewing the source code and the

"shadow" block containing the comments.)

I think this means the following in gas syntax:

_loop: mov $1, %ax # RP is the return stack pointer, defined in CPU8086.BLK screen 5 ploop: add %ax, (%bp) jno bran1 # jump if no overflow to "bran1" add $6, %bp # pop three items from return stack # IP is the interpreter pointer inc %si inc %si next # a macro defined as >NEXT #) JMP, which I assume means # "jump to the address >next"

"bran1" was previously defined in screen 9:

```
CODE BRANCH   (S -- )
LABEL BRAN1   0 [IP] IP MOV   NEXT END-CODE
```

which I'm pretty sure means branch: bran1: mov (%si), %si next

That just fetches a new address to jump to from the place the interpreter pointer currently points.

Notice how clever this is --- the common-case path length inside (LOOP) is only three instructions: MOV, ADD, JNO; and then there's one more MOV instruction inside BRANCH before we get to NEXT. But it's a little bit opaque.

In "Inside F-83" (insidf83.ZIP, 312170 bytes; see Chap4, 39424 bytes) C. H. Ting explains:

> F83 provides a solution by using three numbers on the return stack to handle the indexing and looping. The number at the bottom of the three is the address of the word right after LOOP, providing LEAVE with the return address to terminate the looping. The second number is the loop limit, offset by 8000H so that the index range from 0 to FFFFH becomes contiguous. The top number is the difference between the index and the limit, also offset by 8000H. At the end of the loop, LOOP increments the top number on the return stack by either one or the amount specified in the case of +LOOP, and tests for overflow from bit 14 to bit 15. The overflow condition occurs when the 8000H boundary is crossed from either direction. Therefore, both the positive and negative increments are handled correctly with a single run-time loop routine.

So the loop counter is one of the largest positive integers representable, and we increment it until it overflows. This does imply a bit more work on behalf of (do) though:

```
CODE (DO)   (S l i -- )   AX POP   BX POP
LABEL PDO   RP DEC   RP DEC   0 [IP] DX MOV   DX 0 [RP] MOV
  IP INC   IP INC   8000 # BX ADD   RP DEC   RP DEC
  BX 0 [RP] MOV   BX AX SUB   RP DEC   RP DEC   AX 0 [RP] MOV
  NEXT END-CODE
```

If I understand this, it means

```
_do:    pop %ax         # initial loop counter
        pop %bx         # loop limit
pdo:    dec %bp
        dec %bp
```

```
        mov (%si), %dx  # loop end address
        mov %dx, (%bp)
        inc %si
        inc %si
        add $0x8000, %bx # loop limit + 0x8000
        dec %bp
        dec %bp
        mov %bx, (%bp)
        sub %bx, %ax    # ax := initial loop counter - (loop limit + 0x8000)
        dec %bp
        dec %bp
        mov %ax, (%bp)
        next
```

If you're like me, when you read that code, you will shout, "What the fuck kind of sense does that make?" and haul out your Intel instruction set manual to see if maybe you've gotten the operands to SUB backwards or something. But of course the code is correct. (Skip the rest of this paragraph if that's already obvious to you.) The quantity -(loop limit + 0x8000) is the same as -0x8000 - loop limit, and -0x8000 is 0x8000, one more than the largest representable integer. So if the loop limit is 1, then this quantity will be 0x7fff, which will overflow after one iteration if the initial loop counter is 0. If it's 2, then it will be 0x7ffe. And so on. So then the "initial loop counter" is added to possibly reduce the number of iterations of the loop.

I think you could write this more briefly as follows, but hey, it's harder to build than to criticize, right? The one difference is that "pdo" now takes its parameters in %dx and %bx instead of %ax and %bx.

```
_do:    pop %dx
        pop %bx
pdo:    xchg %sp, %bp
        lodsw
        push %ax
        add $0x8000, %bx
        push %bx
        sub %bx, %dx
        push %dx
        xchg %sp, %bp
        next
```

Needless to say, this representation of loop state requires a little bit of computation to recover the loop counter in the word "I", in KERNEL86.BLK screen 15:

```
CODE I   (S -- n )
  0 [RP] AX MOV   2 [RP] AX ADD   1PUSH END-CODE
```

That is:

```
i:      mov (%bp), %ax
        add 2(%bp), %ax
        jmp push1
```

"1push" is one byte earlier than "next" --- presumably it pushes %ax, saving one byte on each of those primitives ("CODE words") that finish up by pushing a result. There's also "2push".

The Carry Variant

It seems like it would work just as well, and be somewhat clearer, to use the carry flag rather than the overflow flag --- so the loop is over when the loop counter increments up to 0. Here's my untested attempt at that variant:

```
_loop:  mov $1, %ax
ploop:  add %ax, (%bp)
        jnc bran1
        add $6, %bp
        inc %si         # couldn't we just lodsw?
        inc %si
        next

_do:    pop %dx         # initial loop counter
        pop %bx         # loop limit
pdo:    xchg %sp, %bp
        lodsw
        push %ax
        push %bx        # loop limit
        sub %bx, %dx    # dx := initial loop counter - loop limit
        push %dx
        xchg %sp, %bp
        next

i:      mov (%bp), %ax
        add 2(%bp), %ax
        jmp push1
```

The only changes are that we JNC instead of JNOing, and we don't need the add $0x8000. So in the 1 0 DO LOOP case, the thing pushed on top of the return stack will be -1, which will set the carry flag after one iteration.

The Carry Approach In High-Level Forth

Suppose we wanted to implement that same approach in high-level Forth (although without the third address on the stack for LEAVE). Instead of my ugly version:

```
: _loop r> r> 1+ r> 2dup xor
    if >r >r dup c@ - >r exit then
    2drop 1+ >r ;
```

we could have the nicer

```
: (loop) r> r> 1 um+
    if drop rdrop 1+ >r exit then    \ loop is done, or
    >r dup c@ - >r ;                 \ jump back and continue loop
```

in which the four normal-case instructions (mov add jno mov) of

the assembly version have become nine Forth addresses: r> r> 1 um+ if >r dup c@ - >r. (UM+ adds two numbers and leaves the carry on top of the sum on the stack.) This is slightly shorter than the 10 we had before, and probably considerably more efficient, because (at least at the moment, in my toy Forth) many of the words in the old version are interpreted, while in this version, all but "1" are machine-code primitives. The overall length of the thing also shortens from 19 cells (or bytes, in my case) to 17.

(do), however, gets very slightly hairier. My current version is as follows:

```
defbytes _do            # 10 0 DO ... LOOP loops 0, 1...9.
## This works by ( limit initial -- ) ( R: X -- X initial limit )
.byte b_swap, b_rpop, b_swap, b_rpush, b_swap, b_rpush
.byte b_rpush, b_exit
```

(I'm writing the return stack effect with the top-of-stack on the left, which is unorthodox.)

Which is like this:

```
: (do)  swap  r>  swap >r  swap >r  >r ;
```

Now we want (limit initial --) (R: X -- X initial-limit limit), so we have

```
: (do)  over -  swap  r>  swap >r  swap >r  >r ;
```

So this approach doesn't change the total program size, but it might be faster.

The Carry Approach Translated Into F21 Opcodes

These "real" Forth definitions:

```
: (loop) r> r> 1 um+
   if rdrop 1+ >r exit then
   >r dup c@ - >r ;
: (do)  over -  swap  r>  swap >r  swap >r  >r ;
```

would become something like this, in the four-instruction 20-bit words the F21 uses:

```
label (loop)  pop pop # nop
              1
              nop + c0 nop     \ jump if no carry; IIRC need NOPs before +
              cont
              pop drop drop #  \ carry, so exit loop
              1
              nop + push ret   \
label cont    push dup A! @A   \ fetch jump offset
              + push ret nop   \ and return to it
label (do)    pop A! over com  \ save return address in A
                               \ no swap, must use over
                               \ com is bitwise not; no subtract
              # nop + nop      \ no increment either; must use literal?
```

```
1
\ now we have on data stack: limit initial-limit
+ over push push \
drop A push ret  \ discard extra copy of limit, return
```

Now, I've never written an actual F21 or even MuP21 program, so I may have inflated that by a factor of two or three. (I'm not sure where jump targets are stored, for example, or in what format --- I assume as the next word --- or whether # and co and ret abort the instruction word, or whether there's a delay associated with memory references.) It's 14 20-bit words as I've written it, or 35 bytes, which is a reasonable code density --- my token-threaded Forth above makes it 27 bytes, and it's probably a bit over 35 bytes of x86 machine code.

But considering it from a speed point of view, it looks awful. The common-case path through (loop) is 15 instructions, if I counted it correctly --- that's 30ns on a 500MHz F21. While that compares reasonably with the time to do an empty delay loop on a 500MHz Pentium-II-class machine (my PIII Coppermine 700 runs x: loop x at 8.6ns per iteration) it's a heck of a lot slower than straight-line execution.

As it happens, looping is also a heck of a lot slower on my PIII. When I added four more instructions to that empty delay loop, it only slowed down by 3ns per iteration.

So Chuck Moore isn't crazy after all. He just prizes efficiency very highly.

Vanagon mail

Kragen Javier Sitaker, 2007 to 2009 (3 minutes)

Thanks to the wonderful people of the Vanagon list, I was able to find the parts I needed to rebuild our 1982 air-cooled engine last year, and our beloved Magic Bus has served my mother-in-law faithfully for about 2000 miles in the intervening year.

My wife and I have been visiting the San Francisco Bay Area during the last few months, and sometimes using the van. Unfortunately, this last week, the transmission died --- it feels pretty dead, really. The van is now at Valley Wagonworks in San Rafael, where Larry's Towing carried it this morning on a flatbed.

So now I'm faced with the choice of what to do with it. We need to sell it, because we're about to go back to Argentina in another month, and it won't do us any good there, and I think it may be telling us it's too tired to go on.

Paul at Valley Wagonworks suggests that he could put an overhauled GoWesty tranny in it for $1400, plus the $700 core charge (minus whatever is left of the old tranny --- synchro wheels and the casing, I imagine), plus I think some other incidentals. So that would cost around $1400. GoWesty would warrant the new tranny for four years. So then I'd have a fairly-good-condition 1982 Vanagon to sell.

Or he could put in a used transmission in exchange for the canopy and those 15-inch alloy rims that some previous owner put on it. This would also result in a fairly-good-condition 1982 Vanagon --- if the tranny is any good.

Or we could try parting it out. I just rebuilt the engine last year with a new Chinese head and set of pistons and two cylinders, and the engine sounds good, so that might be worth something; the battery is new; there's also the starter, the alternator, the 15" rims, a Dometic dual-power fridge, the propane stove, the aftermarket pop-top (this was an aftermarket camper conversion by some shop in Oakland), three good (but orange) doors, and I don't know what else.

But I don't know what's the best thing to do. Maybe I should try selling it for $5000 with the used tranny (and normal 14" rims, and no canopy), or $6400 with the GoWesty one? Are these realistic prices? What are the parts worth?

These are sad questions to be pondering, but perhaps their resolution can bring some joy to the new owner.

Notes on the Intel N3700 i915 GPU in this ASUS E403S laptop

Kragen Javier Sitaker, 2018-10-28 (updated 2019-05-05) (3 minutes)

So the "i915" Intel graphics are actually part of the N3700 SoC https://en.wikichip.org/wiki/intel/pentium_(2009)/n3700, launched in 2015, which is a 1.6GHz quad-core amd64 CPU with 16 Braswell "HD graphics" execution units, running at 400MHz.

https://ark.intel.com/products/87261/Intel-Pentium-Processor-N3700-2M-Cache-up-to-2-40-GHz-

https://en.wikipedia.org/wiki/List_of_Intel_graphics_processing_units#Eighth_generation says this is of Intel's "eighth generation", and its core config is "128:16:2" with 25.6 GB/s memory bandwidth, which means 128 FP32 ALUs, 16 EUs ("execution units", each containing 2 SIMD-4 FPUs), and 2 subslices, each containing 8 EUs and a 4 texels-per-clock sampler. It also says that each EU is capable of 8 multiply-accumulates per clock cycle (one per ALU, I guess) in single-precision floating-point, but 16-bit floating-point is capable of "2× floating-point performance". Also they can do integer operations at the 32-bit floating-point speed, or 64-bit floating-point at ¼ the 32-bit speed.

Doing the math, that suggests that it can do 400 * 128 million single-precision multiply-accumulates per second, or 51.2 billion. Intel likes to double-count these multiply-accumulates, as if the addition and the multiplication were two separate operations, which dishonestly inflates their published flops counts by a factor of 2.

By contrast, https://en.wikipedia.org/wiki/Nvidia_Tesla says the NVIDIA Tesla V100 GPU Accelerator, released in 2017, reaches 14900 single-precision Gflops, about 300 times faster. And https://en.wikichip.org/wiki/intel/hd_graphics_630 says the later Kaby Lake GPUs reach 134 single-precision GFlops with 24 EUs at 350 GHz, so maybe it's plausible. https://news.ycombinator.com/item?id=18146625 says the V100 also costs US$10k, which is about 30× what my laptop costs, so the laptop has 10× worse price-performance.

It supports OpenCL and GLSL.

https://github.com/Themaister/GLFFT is an FFT implementation that has been tested on another GPU in the family. https://software.intel.com/en-us/intel-opencl is OpenCL which I think supports it. https://en.wikichip.org/w/images/f/f4/Compute_Architecture_of_Intel_Processor_Graphics_Gen8.pdf is a detailed description of the compute architecture.

https://01.org/linuxgraphics/downloads/2018q1-intel-graphics-stack-recipe calls Gen8 "Coffee Lake".

https://software.intel.com/en-us/articles/introduction-to-gen-assembly is an introduction to its assembly language.

So an interesting thing here is that the GPU can do 51.2 billion single-precision multiply-accumulates per second, or 51.2 billion 32-bit integer ops. But the CPU is 1.6 GHz with four cores, each of which supports the SSE4.2 instruction set extensions, which supports SIMD operations on 128-bit vectors of, among other things, four 32-bit floating-point or integer values. Supposing that each core is capable of running one such instruction each cycle, that's $1.6 \cdot 4 \cdot 4 = 25.6$ gigaflops of single-precision floating-point. This is only half the power of the GPU, but still, I think, substantially more than the CPU's non-SIMD capabilities. There are even SIMD instructions that allow you to use these 128-bit registers as 8 16-bit integers or 16 8-bit integers, though nothing for half-precision floats.

The problem with the SIMD i386/amd64 instructions — other than being only having half the total computrons — is that there are a shitload of them, and the instruction set is quite irregular, in large part due to backward-combatibility concerns.

How to generate unique IDs for IMGUI object persistence?

Kragen Javier Sitaker, 2014-09-02 (3 minutes)

So, um, immediate-mode GUIs are pretty cool. They allow you to avoid using data memory for objects on the display, which not only reduces your memory usage, but also prevents desynchronization and avoids heap allocation.

One problem with IMGUIs is that they generally need an ID for each widget, which you can generate somewhat clumsily using `__LINE__` in C, as explained by Jari Komppa. This clutters up your code a bit. Adrien Herubel's IMGUI library avoids this problem by maintaining a hidden `widgetId`; in imgui.cpp, for example:

```
bool imguiCheck(const char* text, bool checked, bool enabled)
{
        g_state.widgetId++;
        unsigned int id = (g_state.areaId<<16) | g_state.widgetId;
    ...
```

This means that instead of writing code like this:

```
 toggle = imguiCheck(GEN_ID, "Checkbox", checked1);
```

you can write code like this:

```
 toggle = imguiCheck("Checkbox", checked1);
```

But it has the problem that if you insert more widgets inside the same scroll area, for example because you have a variable-length subsequence of widgets, then your IDs will shift, and your widgets will get confused about which of them is active or hot.

It's possible to avoid this problem by using a sort of DOM-tree-ish approach and expanding each widget identifier from a single ID number out to an entire path from the root of a widget hierarchy — perhaps you limit each level of the hierarchy to 256 elements, and then you can identify a widget up to 6 levels deep with 6 bytes.

(Additionally if client code can increment the current widget ID up to some number after passing through a region of variable widget count, that could help.)

The hierarchy need not correspond to any nesting of rectangles on the screen. It can be entirely conceptual; in the environment where I came up with it, it was a menu tree, where only the innermost menu of your navigation was ever displayed. It enables you to tell not only on which widget the current keyboard focus is, but also all of the things it's nested within.

Many times, though, you'll have more possible widgets to display than you want to display at a given moment. In these cases it would be nice to leap past all these widgets without, for speed, actually having to execute the code for each one — and if the number is arbitrary, executing the code for each one would take infinite time. So this containment hierarchy can serve as a way to efficiently disable

different parts of the world.

Sigh. I'm not sure if this approach really generalizes well...

I wonder what reactive programming has to offer here. Meteor-style reactivity has a similar feel to IMGUIs; is there a unity between the approaches I'm not seeing?

Inductor thermocouple sensing

Kragen Javier Sitaker, 2019-06-01 (21 minutes)

I was wondering if a simple way to measure the temperature of a thermocouple is to use an inductor, and it looks like a viable approach, perhaps even providing precision comparable to or better than the standard op-amp approach, though it requires much thicker sensor leads.

Thermocouples can generate substantial power — those used for safety cutoffs in gas appliances typically power solenoids directly — but very low voltages — typically 20–40 μV/°, with 41 μV/° for the common type-K thermocouple (which is the one commonly used in gas appliances). Being made of solid metal, they have very low output impedances, but the low voltages are not particularly friendly to precise sensing with essentially capacitive CMOS.

So what if we use an inductor and a switch to generate a higher-voltage waveform from the low-voltage thermocouple signal, then measure the waveform with a cheap microcontroller?

An LR circuit would amplify the voltage, but requires fast measurement

The conventional approach to solving this problem is to use an op-amp (maybe a chopper to mask out flicker noise) to amplify the output voltage to a level where you can conveniently digitize it, but it occurred to me that perhaps you could put a thermocouple in series with an inductor, then open the circuit so that the inductor is obliged to discharge through a higher, known resistance.

To be more specific, consider the problem of trying to measure a temperature between 600° and 1200° (against a reference temperature we will assume is 0°) using a type-K thermocouple in series with a 100-μH, 1-Ω inductor in parallel with a 100-Ω resistor. At ΔT = 1200°, the thermocouple generates 49.2 mV, thus pushing 49.2 mA through the inductor (and 0.492 mA through the resistor). When the thermocouple is disconnected, the 49.2 mA starts to flow through the resistor instead, raising the voltage across it to 4.92 V, which is easily measured without further amplification. The current is then declining at 49.2 A per microsecond, so we only have a few microseconds (L/R = 1 μs) to measure it in, which is challenging but not infeasible with an off-the-shelf STM32.

A larger inductor would give us more time, but to avoid annoyingly high voltages, would require a correspondingly smaller resistor, and so parasitic resistances would start to play a larger role.

An LC circuit should make the measurement task easier

A different approach is to use a capacitor instead of the resistor for the inductor to discharge through, so that the current can oscillate back and forth several times. With the same 100-μH, 1-Ω inductor, our inductor energy $\frac{1}{2}LI^2$ is ½·100μH·(49.2 mA)² = 121 nJ; if we want our capacitor to charge up to ±2.5 V or less (so we can bias the

whole oscillation into the +0–+5 VDC range), then $C \geq 2 \cdot 121\ \text{nJ}/(2.5\ \text{V})^2 = 39\ \text{nF}$. Using a conventional 0.047 μF capacitor, then, we get up to ±2.27 V, and the oscillation frequency is $1/(2\pi\sqrt{(LC)}) \approx 73$ kHz, so we need to digitize the result at at least 150 ksps to avoid aliasing, which is straightforward.

Q = sqrt(L/C)/R, which works out to about 46 — about 200 μs per factor of e decay (τ), so the signal should remain detectable for up to a millisecond or two. I think this is probably a higher Q than we'll actually get in practice, but maybe not much higher.

So the procedure is to open the switch (which needs to operate in less than about 10 μs) and measure the ringing-down signal in order to get a reasonably precise indication of its amplitude over time, and in particular to extrapolate what its initial amplitude was when the circuit opened.

The sources of error I can see here are:

• Error estimating the time-domain start of oscillation; an error of 1τ results in an error of e ≈ 2.7, so to get 10°C of error at 1200° we need about τ/120 = 1.7 μs. Measuring this *directly* would mean we'd need to sample at hundreds of kHz, but that isn't necessary — we know the precise phase of the oscillation start — the current was at near-max and the capacitor was charged only according to the resistance of the inductor (49.2 mV in the above example). So we only need the accurate phase of the signal (to within 0.78 radians in this case) and to successfully detect its first oscillation. (In theory we don't need to estimate this because we're controlling it, but there might be delay in the switch.) Roughly half of our samples give us phase information whose precision is comparable to the precision of the amplitude information in (roughly) the other half; if we have 1000 useful samples (1 ms) then we have a few hundred samples each telling us the phase with something like 12 bits of precision, so we have maybe 16 bits of precision on the phase: something like an error of 15 microradians, which gives us a time-domain error for the cycle start on the order of 30 ps, translating to an amplitude error of 0.15 ppm, and thus totally overkill precision of 180 μK.
• Error estimating the amplitude of the signal, which is potentially a sort of weighted average of contributions from all the samples, maybe with some nonlinear filtering to reject out-of-band noise. Our 2.27 V initial amplitude will decrease proportionally by some 2 mV/°, so even 10 bits of precision (in the weighted sum, not each individual measurement) should be adequate. Offsets are inconsequential. If we figure we have about a millisecond of useful 12-bit samples at a megasample per second, that's 1000 samples, which gives us a precision of about 17 bits, a precision of about 17 microvolts on the 2.27 V initial measurement, or 375 nV on the original low-impedance thermocouple voltage, working out to a totally overkill precision of 9 mK. (Of course, the precision of your analog voltage reference is going to be a limiting factor here, too; if it's not accurate to 17 μV, you're not going to hit that.)
• Error in estimating the voltage amplification factor of the circuit — the 49.2 mV to 2.27 V factor described above, which comes from $\frac{1}{2}L(V_0/R)^2 = \frac{1}{2}CV_1^2$, and thus $V_1^2 = (L/(CR^2))V_0^2$, so $V_1 = (1/R)\sqrt{(L/C)}\ V_0 = Q\ V_0$, precisely the Q factor of the resonator. This is most sensitive to the precise value of the inductor's resistance,

which will vary with the inductor's temperature, since the inductor is not a precision resistor. However, the fact that this is precisely the Q factor of the resonator is wonderful — it means that we can measure the rate of ringdown and get a very precise measurement of this very amplification factor, accurate as of that moment. If we let the 2.27 V ring down to 0.5 mV (the limit of a 12-bit ADC) that's about $8.4\tau \approx$ 1.6 ms, and getting a $10°/1200° \approx 0.8\%$ error in the time domain would require an error of about 13 µs — not plausible, since we're talking about a systematic timing error over many measurements. In the voltage domain, an error in estimating the Q factor of 0.8% would amount to a (differential!) voltage error of $1 - (1.008)^{8.4} \approx 7\%$, which is even less plausible.

The only remaining source of error in this voltage amplification factor, then, will be parasitic resistance in the thermocouple, its leads, and the switch, which are outside the resonating loop, and the capacitor, which is in the resonating loop but not part of the series resistance that sets the initial inductor current. As an example, a 2N7002's on-resistance is 7Ω (see My attempt to learn about jellybean electronic components (p. 1974)). This could be improved by adding resistance *inside* the resonating loop, in series with the inductor, thus reducing the Q factor and thus increasing the earlier-mentioned errors; this would probably be a good tradeoff.

• Switch slowness error: we're indirectly measuring a discontinuous step function in current through the thermocouple by way of measuring its 73-kHz component. But discontinuous step functions of current cannot exist in the real world of nonzero parasitic inductances; any real switch, whether solid-state, thermionic, or electromechanical, will take some finite time to open and close, and electromechanical switches have the even more alarming behavior of bouncing when they close. If these errors attenuate or strengthen the 73-kHz component of the step function, you could get potentially totally incorrect measurements or even a blown input circuit.

This is somewhat exacerbated by the fact that MOSFETs with low on-resistance are big power MOSFETs like the IRF540N (44 mΩ), and so they have much larger Qg (71 nC in that case, compared to 2 for the 2N7000 — see My attempt to learn about jellybean electronic components (p. 1974).) Driving 71 nC into the gate in under 100 ns, which I guess would keep the switch-slowness error under about 1% and thus the temperature error under 12° at 1200°, requires a large transient current of 710 mA; the IRF540N datasheet does claim its turn-off delay time is 39 ns and its fall time is 35 ns.

This problem, too, can be ameliorated with a Q-spoiling resistor in series with the inductor, reducing the error due to the switch's on-resistance and thus allowing the use of smaller transistors. ON Semiconductor's 2N7000 datasheet claims a 10-ns turnoff time and 1.2–5Ω on-resistance at room temperature.

It could also be ameliorated by using an exotic GaN power transistor like the 39¢ EPC2036 with its 65 mΩ and Qg = 0.91 nC, or possibly an electromechanical relay.

• Thermocouple error: the metals in the thermocouple may not be pure, and their purity may change over time, especially at higher temperatures. Eventually it will probably burn out. It should be easy to make this the dominant form of error, but presumably it's a form of error we can calibrate out, since at any given time it depends only

on the temperature we're measuring.

• Cold-junction compensation error: thermocouples really measure a *difference* in temperature between two points, one of which is typically inside the measuring instrument. This is probably not a major problem for the ±10° precision I'm looking for, since a calibration at 18° is good from 8° to 28° even without any temperature compensation.

Here I've talked about the possibility of using an extra resistor in series with the inductor — which could take the form of just winding your inductor with thinner wire, and therefore perhaps just buying a cheaper inductor — but another possibility is using a precision resistor of 10–100 Ω *outside* the resonant loop. This would avoid reducing the Q (though it's probably excessive anyway) and reduce the error introduced by resistance in the thermocouple's leads, but by dropping most of the thermocouple's voltage, it would also attenuate the signal being measured and make the results sensitive to the unknown drifting parasitic resistance of the inductor.

Since the dominant sources of error here are parasitic resistances (which can be measured), the unknown thermocouple characteristics (which can be calibrated), and switch slowness, you can probably get better measurements by using an electromechanical relay.

A thing to consider is that this approach can quite reasonably measure 100 samples per second, but the thermocouple's temperature can't vary under non-disastrous circumstances by more than a hundred degrees per second or so, and in many circumstances, not more than a degree per second. So errors that pertain to only a single measurement, like phase error, can be averaged out over hundreds of measurements to obtain another 4–5 bits of precision.

(XXX I am not sure my calculations of how many bits of precision you get from averaging over some number of samples are right; I think I may have dropped a squaring or a square-root somewhere. The above calculations are based on the idea that quadrupling your number of samples gets you an extra bit of precision, which is 6 dB.)

(This design might also be adaptable for use as an energy-harvesting frontend.)

Comparison with a variant of the usual design, which may perform worse

Horowitz & Hill (2015 edition) talks a bit about the problem of amplifying thermocouples. On p. 936 it explains that you can use a US$16 Cirrus CS5532 24-bit delta-sigma converter to digitize the signal "directly" — by way of its integrated chopper-stabilized programmable-gain amplifier, which you can set to 64× gain to get a ±40 mV input range, or 32× for twice that. They mention that they balanced their thermocouple lines around ground to reduce EMI pickup.

On p. 1033, they also mention the Maxim MAX6675, which is a "thermocouple-to-digital-converter chip" with SPI output, and on p. 1083 they mention the MAX31855 SPI thermocouple ADC with 0.25° resolution from -270° to +1372° and built-in cold-junction compensation. The 1989 edition has a good deal more information on the subject of thermocouples on pp. 989–992, in fact recommending 10kΩ or more of input impedance to avoid errors from lead resistance.

But basically you just rig up an op-amp to amplify the small low input voltage to a larger output voltage, in, for example, the simplest non-inverting configuration: connect the thermocouple to the + input and run a voltage divider across the - input between the op-amp output and ground, with, say, a precision 47kΩ resistor and a precision 1kΩ resistor. This circuit makes no difficult demands of bias current, input range, bandwidth, slew rate, output power, power consumption, stability, gain, or broadband (as opposed to flicker) noise, but it does require a low input offset voltage (and precision resistors). Horowitz & Hill suggest using a chopper-stabilized op-amp, which typically requires a couple of external capacitors, like the US$1.60 MAX9617 — typical offset voltage 0.8 μV + 5 nV/°, with a 10–140 pA bias current. 0.8 μV in this context is a temperature error of 0.02°. This is fine for my intended application of controlling a pottery kiln, but it seems large compared to the much smaller errors I was talking about above. Worse, its worst-case offset voltage is specified as 10 μV, which is a temperature error of 0.2°. Other choppers are comparable — some a little better, others a lot worse.

Horowitz & Hill (1989) recommend rigging up the op-amp as a differencing amplifier in order to get good common-mode rejection of EMI, which I think is in large part a function of the high input impedance they've chosen due to their fine wires; but they emphasize that low offset voltage, a microvolt or better, is essential.

In the land of garden-variety op-amps, things are much worse. The US$0.24 Microchip MCP6001T-I/OT I declared in Jellybean ICs 2016 (p. 817) to be "the world's cheapest op amp" is specified as ±4.5 mV input offset voltage, ±2μV/°. ±4.5 mV would be an error of ±110°. The LM324 is ±2–7 mV, the LM741 is ±1–5 mV, and the CMOS TLC272 is ±1.1–10 mV, though its precision-trimmed TLC277 variant is ±500μV. And that's before we even get into flicker noise and drift! So if you were in the unfortunate position of having to improvise the thermocouple amplifier with whatever op-amps you could scrounge (see Ghettobotics: making robots out of trash (p. 2747)) the straightforward circuit wouldn't work; the resonant tank circuit this note is about would be a lot better. You might be able to get the straightforward circuit, or an instrumentation-amplifier variant of it, to work with a trimming resistor, since you only need about an order of magnitude improvement to get to the 10° (400μV) precision I wanted.

But can the inductor hack compete with the precision of a chopper-stabilized op-amp for thermocouple sensing? The chopper here is giving us 10 μV of error on a 49.2-mV signal, an error of about one part in 5000, 200 ppm. The inductor hack above is estimated to get an error of about 0.15 ppm from the time-domain start error, 7 ppm from the amplitude estimation error, some small error I didn't actually estimate from estimating the Q factor (probably dominated by the same voltage-measurement error as the amplitude estimation, and so probably of similar magnitude), and some potentially large errors from parasitic resistances (≈4000 ppm if we assume that we're using the IRF540N and its on-resistance varies unpredictably by 4 mΩ) and switching softness (say, the IRF540N's 35-ns fall time reducing the measured voltage at 73 kHz by 0.25%, 2500 ppm — although I may be estimating that wrong). So it might be

possible to get the inductor hack below 100 ppm of error, especially by using exotic components like electromechanical relays or GaN FETs.

(But then Horowitz & Hill get serious about precision design and explain the design of HP multimeters with 0.1 ppm error.)

Measuring parasitic lead resistance with multiple measurements

The problem with the switch on-resistance and the resistance of the thermistor and leads in the above design is that it drops some unknown amount of voltage before getting into our resonating tank circuit. Parasitic resistances in the tank itself introduce no error, as long as they're on the inductor side, because they show up in our Q measurement of the ringdown.

The problem is that we're faced with a Thevenin voltage-resistance pair, the voltage coming from the thermocouple and the resistance coming mostly from its leads, and we're trying to estimate the voltage from a single measurement from outside of it. This is clearly going to introduce significant error, and is the reason Horowitz & Hill suggest using a high input impedance, even though the thermocouple itself is very low impedance.

A different approach is to add some more switches with different known, precision, low-drift series resistances. Then we can measure how much the voltage across our tank changes with these various resistances, and thus the internal resistance of our voltage source. In the absence of measurement error, two switches would be enough.

However, if we're talking about MOSFET switches, we have the problem that the resistance of each switch is significant, significantly different from other switches, and variable over time and with temperature. So it might be worthwhile to instead seek a way of taking multiple measurements to calibrate out the source resistance that lets us keep using the same switch.

Specifically, we can leave the switch closed for less time than is needed for the current through the inductor to reach its steady state, which we've calculated above is about 1.6 ms. If we leave the switch open for only 100 µs or 200 µs, for example, the current through the inductor won't have ramped up to its max, and so we'll get a smaller pulse when we open the switch again. These shorter pulses will depend less on the parasitic lead resistances, because until the current gets going, those resistances aren't dropping any voltage, so the initial ramp-up of current in the inductor is independent of lead resistance and indeed of any resistance at all. By taking several different such measurements, it should be possible to calculate the outside-the-loop parasitic resistances with good precision — not just the resistance of the leads but also of the switching MOSFET.

Energy storage in a personal water tower: pretty impractical

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

Reading http://physics.ucsd.edu/do-the-math/2011/09/got-storage-how-hard-can-it-be/ I was inspired to think about gravitational potential energy storage, which at 3 m of head is only about 29 J / kg, about 500× worse than lead-acid batteries' energy density.

But what if you had a personal water tower? You could totally make it 30 m tall. Better still, if you live in a very dry area, you could drill 100 meters down and put a water turbine down the pipe. `100meters * gravity` is 981 J/kg.

He suggests that maybe for a house you want to have like 30 or 100 kWh of storage capacity to ride out cloudy days when your solar panels don't produce energy. 50 kWh is 180 MJ, so at 100 meters of head, you need 180 tonnes of water. That's a spherical tank some 7 meters across.

This is far from an impossible construction project, but it's considerably harder than building the rest of the house.

If you have 180 tonnes of clean, potable water stored, that could in itself be a useful form of preparedness; water and oxygen are the only life-essential resources that it's not usually considered practical to store a year's supply of.

Alternatively, you could drill a 1km-deep well and lower a weight into it on a rope, perhaps slowly enough that the water resistance wouldn't cause too much inefficiency. If you have a 200mm-diameter borehole and a 150mm-diameter weight that is 500m long, it has a volume of 8.8m³; if it's mostly made of quartz, as inexpensive things of that size probably would, it will have a specific gravity of about 2.6, or 1.6 if we subtract buoyancy. So it will weigh about 14 tonnes, net of buoyancy, and thus have an energy capacity of almost 70 MJ (19 kWh).

You might think that a rope capable of lifting 14 tonnes safely would be too large, but Dyneema can handle that load at about a 6mm diameter (although at retail that rope might cost you a couple thousand bucks). A 20mm-diameter rope would be a more than adequate safety factor; it will occupy 160 liters of space above ground when lifted all the way.

Broadcast ECC with graceful degradation, or avoiding the cliff effect

Kragen Javier Sitaker, 2018-12-18 (5 minutes)

Digital TV has a severe "cliff effect": due to the excellent error-correction codes employed, you have no warning that the signal-to-noise ratio is worsening until suddenly you can't decode the signal. We can see this as an engineering deficiency — the channel capacity has not fallen to zero, but probably to just below the bit rate of the signal. And in other situations, when the signal-to-noise ratio was better, there was excess channel capacity that the system is just wasting.

Analog TV, though worse in many ways, was better at this. When the signal levels were severely degraded, you'd see more noise on the screen, which effectively amounts to a lower resolution.

Could you do something similar with digital TV?

Since the failure of the MBONE, the standard approach with internet TV (CUSeeMe, YouTube, Skype, Netflix, etc.) is to downrez the stream until the receiver is able to receive all of it. Could you do something similar without bidirectional transmission, e.g. for recording media or broadcast TV?

Consider transmitting a 1920×1080 signal — first in 16-bit RGB without compression, to simplify the discussion. You can mipmap a 1920×1080 frame into a 240×135 frame, a 480×270 frame, a 960×540 frame, and a 1920×1080 frame. If you do it by summing the 4 pixels in each higher-resolution frame to get the corresponding pixel in the lower-resolution frame, then someone in possession of any 4 of those pixels can produce the fifth pixel. This means that if you have successfully received the lower-resolution frame, you would be satisfied with ¾ of the pixels in the next-higher-resolution frame.

Since the higher-resolution has ¼ of the pixels, that would seem to suggest that encoding the image in this way is "free", in that it doesn't cost any extra bits, but that's wrong; the lower-resolution frames need more bits of precision to make this work. But the cost is moderate: if you have 5 bits of precision per color component in the 1920×1080 signal, you need 7 at 960×540, 9 at 480×270, and 11 at 240×135. This totals to 35 186 400 bits, 4 398 300 bytes, while the raw signal is 31 104 000 bits, so the cost is about 13%. But the smallest frame size is only 1 069 200 bits, about 3% of the total.

If you encode the smaller frame sizes with higher levels of redundancy, then a receiver who's experiencing more noise might be able to receive the smaller frames even if the larger frames are lost. If you double the redundancy at each mipmapping level, then in effect you are using 5, 14, 36, and 88 bits per color component per pixel at the different mipmapping levels, which gives you 58 708 800 total bits per frame, almost twice the original bit rate.

Perhaps you can decrease this overhead by doing similar subsampling along the time axis — update the smaller frames less frequently, without the ¾ reduction on the larger frames when they

aren't accompanied by a smaller frame — but the tradeoff is there. Any bits you dedicate to redundancy for the sake of noisier receivers are in some sense not available for increasing the resolution for quieter receivers.

This may not be a fatal flaw, though, because the usual system doesn't serve those quieter receivers that well either — the wide SNR margin they enjoy is being completely wasted. This system could provide them with an even higher-resolution and possibly higher-frame-rate signal encoded with even less redundancy, with the consequence that those receivers get better service, too.

So it's only a narrow range of SNRs, those just above the threshold of the usual system, where the usual system is superior. From perhaps 0 to 6 dB or 9 dB above completely failing to work, the usual system is an improvement. But anywhere below that, this multirate system provides degraded service instead of no service, and anywhere above that, this multirate system provides enhanced service instead of baseline service.

Apparently one scheme for degradable modulation like this is called "hierarchical modulation", and "scalable video coding" is the name for the H.264 feature that implements another aspect of the above.

Spark particulate sieve

Kragen Javier Sitaker, 2016-10-06 (updated 2016-10-11) (7 minutes)

Particulate matter in air is generally bad for your lungs, and it can be a problem under some other circumstances, like in hospital operating rooms, biology labs, or semiconductor or hard disk clean rooms.

One way to remove particulates from air is to filter it by passing the air through a thin sheet with a lot of small holes in it. Particulates that are bigger than the holes won't pass at all; some fraction of smaller particulates will stick to the filter. Ideally, all the holes would be the same size, because if there are a fair number of really big holes, most of the air will go through them.

The particulates that are of most concern for health are in the categories PM10, which is 2.5–10 μm in diameter, and PM2.5, which is 1–2.5 μm in diameter. So it would be useful to have a sheet of material that was full of holes under 1 μm in diameter.

Make the sieve from a thin sheet of metal with sparks

A spark of a well-controlled energy applied to a thin sheet of metal, such as gold leaf or the metallization layer on a sheet of Mylar, should vaporize a well-controlled amount of metal in a pretty round hole, requiring about 14 kJ/g to vaporize aluminum `(((2470 - 20) K 24.20 J/mol/K + 10.71 kJ/mol + 284 kJ/mol) * 27.0 g/mol)`. A cylindrical hole of 1 μm radius through an 0.5 μm layer of aluminum metallization would amount to about 400 attoliters or about a picogram of aluminum, requiring about 15 nJ of spark energy.

Gold leaf is probably more practical, since it can be free-standing at as little as 0.1 microns thick. I'm going to assume that the energy needed to vaporize an area of gold leaf is close to the energy to vaporize the same area of aluminum metallization, because gold is thinner, but denser, and with higher specific heat and heat of fusion.

Electrical circuit considerations

Getting a spark that's only 15 nJ in air may be actually kind of tricky, because Paschen's Law has a minimal voltage of about 300 volts to start an arc in air. It's tough to get parasitic capacitances below about 10 pF, and at 300 V, that holds about 450 nanojoules. So the hole you're going to blow in the metal with just the parasitic capacitance, if you go around charging things up to 300 volts and then touching an electrode to the sheet, that hole will be about six microns across.

As an alternative, you could maybe use an inductor and strike a spark like you were using a stick welder: first bring the electrode into contact with the workpiece, allowing current to flow through an inductive load, then move it away, striking an arc which continues until the inductor's energy is dissipated.

How much current can you have flowing without heating things up? A 34-gauge wire is 160 microns across (thus a cross-sectional area of 20 000 square microns) and can handle 300 mA. If your area of

contact is, say, 100 square microns, then the same current density would be 0.5% of that, or 1.5 mA. Let's say 1 mA to be sure it'll work. ½LI² = 15 nJ at I = 1 mA if L = 2·15 nJ/(1 mA)², which comes out to a very conveniently large 30 millihenries. It's easy to build a circuit with less than that amount of parasitic inductance.

The most popular off-the-shelf inductor in this range at Digi-Key is the Murata 13R336C inductor: "33mH Unshielded Wirewound Inductor 60mA 68 Ohm Max Radial". It costs 59¢. It's ferrite-cored, and craps out at a couple hundred kilohertz; I'm not sure what would happen if you try to break the contact faster than ten microseconds, but I suspect that you lose most of the energy to core losses. If that happens, that's a problem.

An air-core coil with 10 mm diameter and 20 mm length has 25 mH once it gets to 2500 turns, which is totally feasible to wind with magnet wire. But I suspect you'll have enough parasitic capacitance to prevent it from responding within less than a few microseconds.

So you can build a power supply circuit that provides up to 1 mA at some low voltage (say 1–10 V), run it through a 30 mH air-core inductor, hook that up to your graphite electrode, and you're in business. Then you just have to move the electrode away from the metal sheet fast enough that the inductor's energy is mostly dissipated in the arc and not in the resistances of the rest of the circuit.

(Will 1–10 V be enough to drive a milliamp through such a small point contact? I think so.)

Hole concentration

By peppering a sheet of metal with sparks of well-controlled energy, you should be able to get the sheet up to 1% hole even without controlling the hole position without a significant number of "hole collisions" producing oversized holes. Even up to about 10% hole, almost all the "hole collisions" will produce holes that are only oversized in one dimension. If you can control the hole position closely, then with hexagonal close-packing you can get arbitrarily close to $3\sqrt{3}/2\pi \approx 82.7\%$ hole; if you reach that limit, the sheet falls apart into tiny triangles.

Non-air-filter applications

You can use the same spark approach to blow holes up to nearly a millimeter in diameter in the metal sheet, with fairly precise control of hole size (under 1% error, say). This provides a way to produce very fine-grained "mesh" sieves with precisely controlled hole sizes, which in theory could separate particles up to a particular size with very high precision, at least if they don't stick to the filter.

Separating particles into precisely graded size groups is the first step to being able to separate them by density and morphology with an air updraft.

Finite function circuits

Kragen Javier Sitaker, 2017-02-16 (updated 2019-05-17) (29 minutes)

I was considering how to specify finite state machines, and some interesting ideas occurred to me.

This is related to the notation for directed graphs in Graph construction (p. 3226) and the algebra of textures in An algebra of textures for interactive composition (p. 1283). (Circuit notation (p. 1161) is more concerned with describing the topology of circuit netlists, as you might use for designing analog circuits, while this note is concerned with designing digital circuits, and in particular sequential digital circuits, in terms of finite functions on alphabets; when considering a circuit, this is a higher level of abstraction, though it may well be a lower one when considering some dynamical system you want to simulate with the circuit.)

Introduction and outlook

A synchronous sequential digital circuit is a finite state machine, FSM. At each clock cycle i, it has exactly one state $S_i \in \Sigma$, and on each transition of the clock, it enters a new state $S_{i+1} \in \Sigma = F(S_i, I_{i+1})$, where $I_{i+1} \in \Upsilon$ is its input at the end of clock cycle i, and $F \in \Sigma \times \Upsilon \to \Sigma$ is its "state transition function". In this way, it generates a word in Σ^* of letters from Σ from an initial state S_0 and a word in Υ^* of letters from Υ.

(This is "circuit" in the sense of an electronic device, not in the theory-of-computation sense of a DAG of combinational logic.)

For example, here's an execution trace of a finite state machine that transliterates from lowercase Greek into titlecase Roman letters:

```
Ii:  π λ α τ ο ν ␣ κ α i
     ↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓
Si: א→P→l→a→t→o→n→␣→K→a→i
```

It should be noted that, since Σ and Υ are finite, so too is $\Sigma \times \Upsilon$ to which the domain of the state transition function F belongs, so it is possible to list F explicitly as an exhaustive case analysis. The state transition function for the above example would include cases like these:

```
(א, π) → P
(P, π) → p
(P, λ) → λ
(Q, λ) → λ
(א, λ) → Λ
(n, ␣) → ␣
(␣, λ) → Λ
(␣, κ) → K
```

In this case the input alphabet Υ and the state alphabet Σ are not the same; although they each include a symbol represented as ␣ here, that is just a notational pun — it doesn't make sense to say that those symbols are the same symbol or that they are different symbols, since

they belong to different alphabets.

A full exhaustive case analysis here, supposing that Υ contains the 24 lowercase Greek letters plus $\_$, and Σ contains the 26 uppercase modern Latin letters, the corresponding 26 lowercase, $\_$, and the initial state $S_0 = \aleph$, would require $25 \cdot 54 = 1350$ cases. This table is awkward to write out by hand, but it is small enough to be easily manipulated by computer. However, nearly all circuits of interest have far too many possible transitions to fit such a table in the memory of a conventional computer.

In the registers of the circuit we store a S_i, represented as some arrangement of bits; we interpret the set of inputs as I_{i+1}; and we represent the state transition function F as the RTL of our circuit, which can be realized with LUTs, combinational logic made of DAGs of gates (the theory-of-computation meaning of "circuit"), an EPROM, or whatever.

To design the circuit, it is not necessary to list the registers or even Σ — they can be inferred from F and S_0. The representation of Υ can be specified or free for the optimizer to optimize.

Thus we can design a sequential digital synchronous circuit simply by specifying its state transition function. Since that function's domain is finite, it is possible to do so by enumerating all its cases. However, usually it is preferable to use a more powerful language to be able to compose the desired function from sub-functions that are separately understandable, verifiable, and reusable.

It bears repeating that these are not the "functions" of JS or C, that is, subroutines. Subroutines are executed over some period of time, possibly terminating and possibly crashing. I'm talking about the mathematical object called a function: a mapping from each domain value to exactly one range value.

I will outline here a design for a language for specifying such finite functions that, I think, combines a number of advantages in a way no previous design I've seen does.

Design goals

Concision, flexibility, tractability, simulability, synthesizability

A relational algebra

Above, a sequential circuit was described according to its state transition function — its domain being the cartesian product of some finite alphabet of states Σ and some finite alphabet of inputs Υ and its range being Σ — and some assignment of Σ and Υ to concrete bitstrings. To each item in the domain it associates precisely one item in the range. We can generalize this to a state transition *relation*, in which each item in the domain is associated with any number of items in the range; this describes a potentially nondeterministic circuit, or a design specification with some liberty. A common way for this to occur in real life is for the circuit to have "don't care" combinations which we expect not to arise in practice. For example, a specification for adding BCD numbers need not specify what happens when the inputs aren't BCD numbers, but some other bit pattern. Also, though, we will see that it's often convenient to construct a deterministic function out of nondeterministic relations. We can also generalize to binary relations between any alphabets whatsoever.

(Historically, "relation" has meant this kind of binary relation, but

since the 1970s a rich theory of N-ary relations has grown up around databases. Here we will completely ignore N-ary relations, being concerned only with binary relations.)

Mostly we will be concerned with finite relations among finite sets, though sometimes they are exponentially large. This means that most of the algorithms we're interested in are trivial in the sense that at worst they need only enumerate some finite set of cases.

The algebra defined

(Very little of this is original.)

Here's the definition of the algebra of relations we'll be using, which is explained in more detail below. Consider a relation as a set of (domain element, range element) pairs; this gives us standard definitions of ∪, ∩, and \ operations, to which we add the following definitions of →, K, ∘, ⁻¹, car, cdr, ×, and *; note in particular that × is *not* the Cartesian product of sets:

$x \in a \to b \Leftrightarrow x = (a, b)$
$x \in \mathrm{K}(b) \Leftrightarrow \exists a\colon\ x = (a, b)$
$x \in \mathrm{A} \circ \mathrm{B} \Leftrightarrow \exists a\colon\ \exists b\colon\ \exists c\colon\ x = (a, c) \wedge (b, c) \in \mathrm{A} \wedge (a, b) \in \mathrm{B}$
$x \in \mathrm{A}^{-1} \Leftrightarrow \exists a\colon\ \exists b\colon\ x = (a, b) \wedge (b, a) \in \mathrm{A}$
$x \in \mathrm{car} \Leftrightarrow \exists a\colon\ \exists b\colon\ x = ((a, b), a)$
$x \in \mathrm{cdr} \Leftrightarrow \exists a\colon\ \exists b\colon\ x = ((a, b), b)$
$x \in \mathrm{A} \times \mathrm{B} \Leftrightarrow \exists a\colon\ \exists b\colon\ \exists c\colon\ x = (a, (b, c)) \wedge (a, b) \in \mathrm{A} \wedge (a, c) \in \mathrm{B}$
$x \in \mathrm{A}^* \Leftrightarrow \exists i \in \mathbb{N}\colon\ x \in \mathrm{A}^*_i$, where
$\mathrm{A}^*_0 = \mathrm{A}$
$i > 0 \Rightarrow \mathrm{A}^*_i = \mathrm{A}^*_{i-1} \cup \mathrm{A} \circ \mathrm{A}^*_{i-1}$

(This is somewhat related to Binate and to the function notation in Pattern matching and finite functions (p. 1235).)

Sometimes people consider the domain and range sets to be part of the content of a relation, aside from its pairs of elements, in the sense that two relations are not equal if they have the same sets of pairs of elements but different domains or ranges (which necessarily in this case include some elements that don't occur in any of their pairs). Here, however, when we mention the "domain" or "range" of a relation, we mean the sets of elements that occur on the left or right side of its pairs.

XXX typing this fucking Unicode is getting on my fucking nerves. Maybe I should switch to "." (the other way around) for ∘, ";" for ∪, ":" for →, "~" or "!" or something for ⁻¹, "&" or something for ∩, and some other things?

Constructing relations from items: → and K

The operator → produces a relation consisting of a single pair: $a \to b$ is the set $\{(a, b)\}$. So, applied to a, this relation gives us $\{b\}$, and applied to anything else, it gives us the empty set.

(Originally I was going to use ↦ rather than →, but I have → on my keyboard, and I gave in to expediency.)

The operator K(x) gives us a constant function whose value is x everywhere.

These are the only two operators of our eleven-operator algebra which take elements of relations, rather than relations, as operands. We could consider the tuple-construction operation "(,)" that constructs (u, v) from u and v as an operation on elements, but it doesn't belong to the algebra proper; we only use it in the meta-notation we're using to *describe* the algebra.

Constructing relations with set operations: ∪, ∩, and \

The ∪ set union operator allows us to construct a possibly larger relation from two relations. With ∪ and → we can construct all finite relations simply by listing the cases: (ℵ, π) → P ∪ (P, π) → p ∪ (P, λ) → λ, and so on. If we sort the clauses, we can consider this a canonical form, in the sense that two finite relations will have different canonical forms if and only if they map some domain element to different sets of range values.

The ∩ set intersection operator allows us to construct a possibly smaller relation from two relations, as does the \ set-subtraction operator. So, for example, (α → a ∪ υ → y ∪ υ → u) ∩ (υ → y ∪ υ → v) is just υ → y, and (α → a ∪ υ → y ∪ υ → u) \ (υ → y ∪ υ → v) is (α → a ∪ υ → u).

We could define these in the same style as the above definitions, but it hardly seems necessary, since we're just using them in the conventional way on sets that happen to be relations:

- $x \in A \cup B \Leftrightarrow x \in A \vee x \in B$
- $x \in A \cap B \Leftrightarrow x \in A \wedge x \in B$
- $x \in A \setminus B \Leftrightarrow x \in A \wedge x \notin B$

Call a relation R **deterministic** if $\neg\exists x\colon\ \exists y\colon\ \exists z\colon\ (x, y) \in R \wedge (x, z) \in R \wedge y \neq z$, which is to say that it's a function, and **reversible** if correspondingly $\neg\exists x\colon\ \exists y\colon\ \exists z\colon\ (y, x) \in R \wedge (z, x) \in R \wedge y \neq z$. (I was going to use "injective" for "reversible", but apparently sometimes "injective" is used to mean what I mean by "deterministic".) In particular, the empty relation ∅ is trivially deterministic and reversible.

All three of these operations preserve finiteness; they cannot construct an infinite relation from finite relations. (This is the reason for using \ rather than the more conventional set complement.) Only ∪ preserves infinity, in that the intersection or difference of infinite relations may be finite, but generally we don't care about preserving infinity.

∩ preserves determinism and reversibility — if either argument is deterministic, the result is deterministic, and similarly for reversibility. Importantly, though, it does not preserve nondeterminism or irreversibility: the intersection of two nondeterministic, irreversible relations may be deterministic and/or reversible. Indeed, it may be empty.

\ preserves determinism and reversibility in its left argument.

∪ does not preserve determinism and reversibility, but it does preserve nondeterminism and irreversibility: if the result is deterministic, both of the operands were deterministic, and similarly for reversibility.

The usual properties of set operations hold in the usual way, with the usual adaptation of DeMorgan's laws and the distributive and associative laws to set subtraction:

- A∪A = A∩A = A
- A∪B = B∪A
- A∩B = B∩A
- A∪(B∪C) = (A∪B)∪C
- A∩(B∩C) = (A∩B)∩C
- A∩(B∪C) = (A∩B)∪(A∩C)
- (A\B)∪(A\C) = A\(B∩C)
- (A\B)∩(A\C) = A\(B∪C)
- (A∪B)\C = (A\C)∪(B\C)

- $(A \cap B) \setminus C = A \cap (B \setminus C) = (A \setminus C) \cap B$
- $A \cup \varnothing = A$
- $A \cap \varnothing = A \setminus A = \varnothing$

We can also derive some laws for how they combine with the primitive relation constructors:

- $a \to b \cap c \to d = \varnothing$ unless $a = c \wedge b = d$
- $a \to b \cap \mathrm{K}(c) = \varnothing$ unless $b = c$, in which case it's $a \to b$
- $\mathrm{K}(a) \cap \mathrm{K}(b) = \varnothing$ unless $a = b$

(All of these, like the other laws presented below, can be proved in terms of the pointwise definition of the operators above.)

Composing relations with ∘

As a generalization of function composition, $A \circ B$ maps some element a to some element c precisely when B maps a to some (possibly different) element b, and A then maps that element b to c. So, for example, $(1 \to 3) \circ (0 \to 1)$ is $(0 \to 3)$. The reversals of direction are most unfortunate, XXX maybe I should switch to using | or . and the other direction of composition.

∘ preserves finiteness in the sense that the composition of two finite relations is also finite. The composition of a finite relation with an infinite one, or vice versa, or the composition of two infinite relations, may be either finite or infinite; but in particular $A \circ B$ has B's domain, or some subset thereof, and A's range, or some subset thereof, so if B's domain and A's range are both finite, then $A \circ B$ is finite, even if neither A nor B is finite.

∘ preserves determinism and reversibility in that the composition of two deterministic relations is deterministic, and the composition of two reversible relations is reversible. Nothing in particular can be said about the other combinations.

∘ has a number of useful algebraic properties: XXX some of these are probably wrong

- $\mathrm{K}(a) \circ (b \to c) = b \to a$
- $(a \to b) \circ \mathrm{K}(a) = \mathrm{K}(b)$
- $A \circ (B \circ C) = (A \circ B) \circ C$
- $A \circ (B \cup C) = (A \circ B) \cup (A \circ C)$???
- $A \circ (B \cap C) = (A \circ B) \cap (A \circ C)$???
- $A \circ (B \setminus C) = (A \circ B) \setminus (A \circ C)$??? this one seems really dubious

Inverting relations with $^{-1}$

A^{-1} is a relation that interchanges the domain and range of A, a generalization of taking the inverse of a function; so, for example, $(p \to q \cup p \to r \cup q \to r)^{-1} = (q \to p \cup r \to p \cup r \to q)$. Unlike the case with functions, every relation has an inverse, which is also a relation, and A^{-1-1} is always precisely A.

A^{-1} is finite if A is finite, and it's reversible if A is deterministic, and conversely deterministic if A is reversible.

We can write down some laws for how $^{-1}$ combines with other operators:

- $A^{-1-1} = A$, as mentioned above
- $(x \to y)^{-1} = (y \to x)$
- $A^{-1} \cup B^{-1} = (A \cup B)^{-1}$
- $A^{-1} \cap B^{-1} = (A \cap B)^{-1}$
- $A^{-1} \setminus B^{-1} = (A \setminus B)^{-1}$
- $A^{-1} \circ B^{-1} = (B \circ A)^{-1}$
- $\mathrm{K}(a) \circ \mathrm{K}(b)^{-1} = b \to a$

From these we can derive an unending farrago of worthless variants like $B \circ A^{-1} = (A \circ B^{-1})^{-1}$, $(a \to b \cup c \to d)^{-1} = b \to a \cup d \to c$, $A \cap B \cap C = (A^{-1} \cap B^{-1} \cap C^{-1})^{-1}$, and so on.

Constructing and deconstructing aggregates with car, cdr, and ×

The × "relational product" operator, if applied to two relations A and B over the same domain, produces a new relation A×B with the same domain, but whose range is the Cartesian product of the ranges of A and B — it consists of pairs constructed from an item from A's range and an item from B's range. This allows you to take two relations from the same range and combine their results into a single relation. So, for example, $(x \to y) \times (x \to z)$ is $x \to (y, z)$.

What × has joined together, the car and cdr relations put asunder; car∘(A×B) is some subset of A, all of A if B didn't lack any of A's domain values, and cdr∘(A×B) is analogously some subset of B, all of B if A didn't lack any of B's domain values. For example, $(y, z) \to y \in$ car, while $(y, z) \to z$ is in cdr.

car and cdr are unapologetically infinite and polymorphic, even Protean, but they have the property that composing them *on the left* (car∘R, cdr∘R) with a finite relation R produces another finite relation.

You might complain that car, cdr, and × reintroduce the asymmetry between domain and range that we dispensed with when we moved from functions to more general relations. This is merely a matter of convenience; you can use $(A^{-1} \times B^{-1})^{-1}$ or $R \circ car^{-1}$ nearly as easily as you can use A×B or car∘R, so there is no need to provide them as separate operations.

× preserves finiteness in the sense that the product of two finite relations is finite, but the product of two infinite relations, or a finite relatin with an infinite relation, may be either finite or infinite. More precisely, if either A or B has a finite domain, A×B will have a finite domain, and if both A and B have finite ranges, A×B will have a finite range. × does not preserve infinity in any of these cases, in the sense that A×B may be finite even if both A and B have infinite domains and infinite ranges.

× preserves determinism in the sense that if A and B are *both* deterministic, then so is A×B. In this case, A×B will also have no more pairs than either A or B — precisely the same number if and only if they are deterministic and their domains are equal. It preserves reversibility in the stronger sense that if *either* A or B is reversible, then so is A×B.

× has some interesting algebraic properties:

- $(a \to b) \times (c \to d) = \varnothing$ unless $a = c$
- $A \times (B \cup C) = (A \times B) \cup (A \times C)$
- $A \times (B \cap C) = (A \times B) \cap (A \times C)$
- $A \times (B \setminus C) = (A \times B) \setminus (A \times C)$
- $car \circ (A \times B) \cap A = car \circ (A \times B)$
- $cdr \circ (A \times B) \cap B = cdr \circ (A \times B)$

XXX this is simpler than the kind of relational product I eventually ended up using in Binate, but I imagine I'm going to end up with a bunch of opaque definitions saying things like "carry = car∘car∘cdr" in particular circuits. The Binate approach avoids that, and also sort of avoided the problem of infinities associated with car

and cdr. The idea there was that you would write {x: Xexpr, y: Yexpr, z: Zexpr}, and that would be a relation from the (intersected) domains of Xexpr, Yexpr, and Zexpr to records, one for each triple of range elements; then, new field-selection relations x, y, and z related those records to their individual fields. This avoids the problems of infinities and polymorphism mentioned above, but it's definitely conceptually more complicated, and I think the algebraic laws described above are a lot harder to state in the named-field case. On the other hand, I'm not sure how useful such algebraic identities will really be.

Transitive closure: *

XXX maybe this should be +? Because the * suggests that maybe zero times through the relation is fine too, in which case the identity should be included, and it isn't. It would also help avoid the semantic collision with Kleene closure once we get to regular expressions.

A* is a superset of A; it's the smallest relation such that A*∘A = A*. If A tells you where you can get in one move, A* tells you where you can get to in one or more moves. A* = A∪(A∘A)∪(A∘A∘A)∪.... So, for example, $(p \to q \cup q \to r)^* = (p \to q \cup p \to r \cup q \to r)$.

, surprisingly, preserves finiteness: a finite relation A necessarily has finite domain and finite range, and A has precisely the same domain and range as A. This provides a convenient way of enumerating A* in finite time for finite relations A, despite its recursive definition.

If A's domain and range are disjoint, A* = A.

* does not preserve determinism or reversibility, as can be seen by the example above in which the transitive closure of a deterministic, reversible relation is neither deterministic nor reversible. Indeed, I think A* can only be deterministic or reversible if A* = A.

* has relatively few useful algebraic properties:

- $A^{**} = A^*$
- $A^{-1*} = A^{*-1}$
- $K(a)^* = K(a)$
- $A \cap A^* = A$
- $A \cup A^* = A^*$
- $(A \circ A) \cup A^* = A^*$, *etc.*
- $(a \to b)^* = \varnothing$ unless $a = b$, in which case it's $(a \to b)$

Notes from the paper notebook

I started writing this file in 2017, and then never finished it; I just found it again now in 2019. But I have some notes from a paper notebook, in Spanish, which I am attempting to transcribe here. I appear to have been working from them when I originally wrote this file.

The expression notation for algebraically composing binary relations is fairly similar to Binate; you have relational composition, transitive closure (which, as a note later in this file points out, is necessarily terminating on finite sets), Cartesian product, union, intersection, set subtraction, relational inverse, relations car and cdr for dissecting Cartesian products, and notations for constant functions and primitive relations consisting of pairs of elements.

It's not a particularly tiny algebra — it has eleven primitives, of which two are primitive relations, one constructs a relation from an element, one constructs a relation from two elements, two more construct a relation from another relation, and the remaining five construct a relation from two relations. And, implicitly, there's the tuple-creation operator, which constructs an element of $A \times B$ from an element of A and an element of B. But, at least for finite relations — which are all we care about for specifying combinational logic! — it is complete (which really only requires $\mapsto$ and $\cup$) and I think may fulfill the desiderata I laid out below of being concise and flexible, and is certainly tractable, simulable, and synthesizable.

Then I use the union and primitive pairs to build up boolean NOT, and then without mentioning elements again, build up bitwise identity, the universal relation on bits and from pairs of bits to bits, restrictions of car and cdr to relations from pairs of bits to bits (called L_2 and R_2), their bitwise inversions, and finally a relation called NI_2, which I think is $(1, 1) \to 1 \cup (0, 0) \to 0$. I'm pretty sure this is what I was thinking about in the "Example: XOR from NAND" section below: build up all the primitive gates from just a NAND relation

(rather than from NOT and AND as I was trying on paper).

I think I was trying to derive AND from just NOT and the primitive relations, so that I would have an algebraic derivation of a whole Boolean algebra from just a definition of NOT. I think doing this isn't possible, because NOT is symmetric under exchange of 0 and 1, while AND is not. I think it also requires the use of some form of negation, which I hadn't tried using yet, and although I had included set subtraction in my set of logical definitions of operations, I had omitted it from the list at the end!

My comments about which relations are finite and which are infinite suggest that I was worried about infinite sets popping up and making algorithms fail to terminate, as does my use of set-subtraction \ rather than simple negation, and the aside (on the facing page, which I set aside for asides) about providing only $A \div B$ instead of B^{-1}, which would keep infinite sets that occur in the range confined to the range, preventing them from escaping into the domain and making it infinite too. This would have preserved the ability to finitely enumerate the domain of any relation except car and cdr (which I suggested demoting in the same aside) although if ranges were infinite anyway I'm not sure why that would be especially useful.

I think the idea then was that you can consider a binary relation to be a specification of a combinational logic function, and you can consider that combinational logic function to be a specification of a sequential logic behavior (if you can identify which parts are state and which are inputs, anyway); but, that under other circumstances, other forms of behavior specification, such as the sequence/alternation/repetition operations of regular expressions, are more convenient; and that other ways of combining finite state machines, such as (some unspecified form of) concurrency, (some unspecified form of) nondeterminism, and (some unspecified form of) state trees, are sometimes more useful.

You could conceivably treat an FSM (S_0, F) as a relation from input strings to output strings — a function, if deterministic, but in any case a relation — and attempt to handle them with the same algebra of relations. But I'm not sure I had that in mind, and it may not be a useful way to compose finite state machines. I suspect I just had in mind that you would construct primitive finite state machines using binary relations to specify their transition function, then use the other mechanisms to combine these primitive state machines in series, in parallel (note that tconcurrency was a heading not in the paper notebook), nondeterministically, and in trees of state (perhaps as in Harel statecharts, although I didn't know about those then).

Componer FSMs

- Intro [link]

- Arboles de estado

Intro

Un circuito digital sincrónico es una máquina de estados finitos, FSM por sus siglas en inglés. En cada momento tiene un estado $S_i \in$

Σ, y en cada transición del reloj entre un nuevo estado $S_{i+1} \in \Sigma = F(S_i, I_i)$ donde I_i es su entrada en momento i, y F es una función $\in \Sigma \times \Upsilon \to \Sigma$. Así genera una palabra en Σ^* a partir de una palabra en Υ^* y un estado inicial S_0.

```
π λ α τ ο ν ␣ κ α i
↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓ ↓
P→l→a→t→o→n→␣→K→a→i
```

Cabe destacar que, ya que Σ y Υ son (ilegible) así también $\Sigma \times \Upsilon$, así (ilegible) hacer un listado de F.

No incluidos:

- H Z (Hi-Z?)
- open-collector
- asyncronia
- variables (registros o pseudo-registros con nombres)

En los registros del circuito almacenamos S_i, representando como un conjunto de bits, interpretamos el conjunto de entradas como I_i, y representamos F como el RTL del circuito, que se puede realizar con LUTs, lógica combinacional de DAGs de compuertas (un "circuito" de teoría de computación), un EPROM, lo que sea.

No es necesario especifcar los registros ni Σ — se pueden inferir de F y S_0. La representación de Υ puede ser especificado o libre para optimizar.

Así que podemos diseñar un circuito digital secuencial sincrónico especificando su función de transición nomás, y ya que es finita, lo podemos hacer enumerando los casos. Pero para la mayoría de circuitos, nos conviene usar un lenguaje más poderoso para poder componer la función deseada de sub-funciones separadamente entendibles, verificables, y reutilizables.

Cabe repetir que ésos no son las "funciones" de JS o C, es decir, subrutinas, que pueden ejecutarse y así tomar tiempo.

Relaciones

- $(a, b) \in A \land (b, c) \in B \Rightarrow (a, c) \in A \circ B$
- $(a, b) \in A \Rightarrow (a, b) \in A^*$
- $(a, b) \in A \land (b, c) \in A^* \Rightarrow (a, c) \in A^*$
- $(a, b) \in A \land (a, c) \in B \Rightarrow (a, (b, c)) \in A \times B$
- $(a, b) \in A \Rightarrow (a, b) \in A \cup B$
- $(a, b) \in B \Rightarrow (a, b) \in A \cup B$
- $(a, b) \in A \land (a, b) \in B \Rightarrow (a, b) \in A \cap B$
- $(a, b) \in A \Rightarrow (b, a) \in A^{-1}$
- $(a, (b, c)) \in A \Rightarrow (a, b) \in \leftarrow A$
- $(a, (b, c)) \in A \Rightarrow (a, c) \in \rightarrow A$
- $((b, c), b) \in \text{car}$
- $((b, c), c) \in \text{cdr}$
- $(a, b) \in A \land (a, b) \notin B \Rightarrow (a, b) \in A \setminus B$
- $(a, b) \in K(b)$
- $(a, b) \in a \mapsto b$

Así con $\mapsto$, K, car, cdr, $^{-1}$, $\cap$, $\cup$, $\times$, *, y $\circ$, podemos combinar relaciones para formar otras relaciones, y podemos construir cualquier relación finita.

(ilegible) va al (intentar?) (evitar?) dominio inf(inito?) es brindar una operacion $A \div B = A \circ B^{-1}$. Pero no ayuda con car y cdr (pero pueden ser sus propias

operaciones.)

De éstas operaciones, car, cdr, y K(x) son relaciones infinitas, y los otros solo general relaciones infinitas a partir de relaciones ya infinitas.

NOT es $1 \mapsto 0 \cup 0 \mapsto 1$.

AND es $(0, 0) \mapsto 0 \cup (0, 1)$ (ilegible) $(1, 0) \mapsto 0$ (ilegible) a partir de NOT sin $\mapsto$.

- $\mathrm{NOT} \circ \mathrm{NOT} = I_2$
- $\mathrm{NOT} \cup I_2 = U_2$
- $U_{22} \cap \mathrm{car} = L_2$
- $U_{22} \cap \mathrm{cdr} = R_2$
- $(U_2 \times U_2)^{-1} = U_{22}$
- $\mathrm{NOT} \circ L_2 = \overline{L}_2$
- $\mathrm{NOT} \circ R_2 = \overline{R}_2$
- $(L_2 \cap R_2) = NI_2$

Topics

English diphones

Kragen Javier Sitaker, 2019-12-03 (5 minutes)

How much speech would you need to sample to make a diphone synthesis engine out of it?

How many diphones are there in English? The following set of words more or less covers the phoneme set:

Ack, ache, mother, father, bet, cite, done, leash, gum, hedge, sip, rot, sought, room, foot, azote, few, valley, which, yet, think, pleasure.

`espeak --ipa` renders this as follows:

```
 ˈak
 ˈeɪk
mˈʌðə
fˈɑːðə
bˈɛt
sˈaɪt
dˈʌn
lˈiːʃ
ɡˈʌm
hˈɛdʒ
sˈɪp
ɹˈɒt
sˈɔːt
ɹˈuːm
fˈʊt
 ˈazəʊt
fjˈuː
vˈalɪ
wˈɪtʃ
jˈɛt
θˈɪŋk
plˈɛʒə
```

To this we need to add at least æ, which I'm not sure how to do with espeak without -v en-us.

This reduces to this set of phonemes, as I understand them:

```
ʌ
ɑː
a
aɪ
æ
b
d
ð
dʒ
ʒ
eɪ
ə
əʊ
f
h
```

iː
j
uː
k
l
m
n
ɔː
p
s
t
tʃ
ʃ
uː
ʊ
v
w
z
θ

That's 34 phonemes. That means that English can't have more than $34^2 = 1156$ diphones, although in practice English phonotactics exclude most of these.

English speech is typically on the order of 200 wpm, and each word might average 5 phonemes, so this is about 1000 phonemes (and thus 999 diphones) per minute of speech, which is to say that you could in theory capture all the English diphones from roughly one carefully-constructed minute of speech. If instead the diphones are uniformly randomly distributed, the number of uncovered diphones will drop by a factor of 2.7195 (about e) per 1156 phonemes uttered, an exponential progression 1156, 425.1, 156.3, 57.5, 21.1, 7.8, 2.9, 1.1, 0.39, 0.14, so complete coverage would usually require some 7 or 8 minutes of recorded speech.

But in fact some phonemes and thus some diphones are much less frequent than average: the order is very crudely something like, first, n, ə, d, and t; a factor of 2 lower, a, f, z, s, m, l, and iː; a factor of two lower, v, p, k, ð, w, uː, j, b, and ɔː; and so on. A standard Zipfian guess is that the 34th phoneme is about 3% as common as the most frequent one. This would tend to lengthen the time required for complete coverage, just as phonotactic restrictions would tend to shorten it.

Crudely, though, I think it's reasonable to guess that sampling a few minutes of speech should be enough to produce a comprehensible approximation of a person's speech, without requiring previous knowledge like statistics of other people's speech in the language.

An interesting question is how to formulate a prepared speech that you could read in a minute or so that would provide a richer-than-average set of diphones. Given, say, the pronunciation of each word in /usr/share/dict/words, you can formulate this as a combinatorial optimization problem: the shortest set of words containing all the diphones contained in all the words. Analyzing a recording of such a prepared speech would be easier than analyzing arbitrary speech because the alignment problem would be much easier.

As a quick experiment, I recorded myself reading the above list of 22 words, about 72 phonemes, slowly, in 21 seconds, under relatively poor recording conditions, with `rec words.wav`. Then I encoded it with LPC-10 with `sox words.wav words.lpc10`. The resulting LPC-10 file was 6447 bytes (293 bytes per word, 90 bytes per phoneme) and was pretty comprehensible; it would surely contain enough information for phoneme alignment.

How exactly do phoneme alignment?

Maybe the matrix profile would help, for example, over a time series of mel-frequency cepstral coefficient (MFCC) vectors, for example, or of LPC coefficient vectors. Maybe for a sufficiently small dataset the whole correlation matrix that the matrix profile is a "profile" of would be more useful; the peaks in that correlation matrix might tell you at which time points the same phoneme occurred previously and later, which you could compare against the temporal distribution patterns of phonemes in the supposed phoneme sequence.

Maybe you could use something like the Viterbi algorithm, in which the "symbols being transmitted" are positions in the supposed phoneme sequence rather than phonemes, each with a transition to itself (that is, the phoneme continued from one time window to the next) and to the following phoneme in the sequence --- although this requires some a priori knowledge of what each phoneme sounds like. But once you have even the most basic guess about alignment, you can use that to get an improved guess about what each phoneme sounds like, then repeat the procedure.

This is surely a problem that is well explored in the research literature.

An interesting possibility is to try to use some kind of self-organizing maps to map the space of observed sounds, perhaps using three or four dimensions conjectured to correspond to tongue position and nasality; the idea is that the continuous changes in sound harmonic content provide you with information about which sounds are physically adjacent to which other sounds. (Voice pitch and sibilance are probably independent dimensions there.)

Can artificially-lit vertical farming compete with greenhouses?

Kragen Javier Sitaker, 2019-09-08 (12 minutes)

Comment at https://news.ycombinator.com/edit?id=20908476:

the point of sun light is that it has a very attractive cost of exactly 0$. It costs absolutely nothing. So it doesn't matter that solar panels are not very efficient. They actually are getting better and certainly 16% efficiency is nowhere near the best there is.

For most purposes I agree with you! However, in this case, the alternatives I am considering are:

• Build a 10000 m² greenhouse full of, say, lettuce, perhaps on multiple shelves ("vertical farming").
• Build a 10000 m² solar park full of solar cells, then use the energy produced by the solar cells to illuminate lettuce being grown inside an opaque concrete box, of some arbitrarily variable size.

In this comparison, the efficiency of solar cells and of LEDs matters very much indeed! Because of their inefficiency, you get 30 times as much lettuce in case #1. That's the reason I think this scheme is uneconomic except in unusual cases. In another part of the comment thread, I agreed that abundant wind energy is a case where it might make sense.

It's true that there are solar cells in commercial production that are 30+% efficient instead of 16%. However, those are specialty solar cells designed for use in things like spacecraft (we used them on our satellites at Satellogic, for example.) Consequently, they are eye-wateringly expensive and not getting cheaper, and so nobody is building solar parks with them, particularly since non-arable land is abundant and will remain so for a couple of decades, while the prices of low-cost 16%-efficient solar cells are dropping like a hafnium pellet.

The whole point of LEDs is that they are supposedly very efficient; around 40-50%.

No, LEDs are nowhere close to 50% efficient. LEDs have many wonderful attributes, including tunable color spectra, directionality, the possibility of being scaled down to submillimeter scales (hard to do with an incandescent bulb!) and, indeed, very good efficiency ---*compared to other light sources*, that is. The problem is, all light sources are shitty when it comes to efficiency; LEDs are just less shitty. That's why we charge our cellphones wirelessly with induction coils, not LEDs and expensive multijunction photovoltaic cells.

It's hard to get your hands on good efficiency numbers, because LED vendors don't quote any kind of absolute energy efficiency number in the datasheets, because they only publish luminous efficacy (because that's what people normally care about). In theory, we can derive the absolute energy efficiency using a luminous-efficiency curve: https://en.wikipedia.org/wiki/Luminosity_function. I'll see if I can do that in a separate comment.

heat is not actually energy loss in a vertical farm.

This argument turns out to be wrong; I've explained why in detail in https://news.ycombinator.com/item?id=20906210, but in brief, 87% of the energy we're talking about gets lost in the solar park, not

the hothouse, and artificial illumination to crop-growing levels produces so much heat that you need to air-condition the hothouse rather than heating it. Moreover, produced heat is *always* energy loss, because you can always reduce it further even by adequate insulation.

Meaning that the reason vertical farming is getting a lot of attention is that the cost of energy has been dropping by rather a lot and is projected to continue to drop. Effectively this dominates variable cost in a vertical farm.

It's true that the cost of energy dropping, and to levels that would make people in the Space Age gasp. I still don't see how that justifies building a 30-hectare solar park to grow the same lettuce you could grow in a one-hectare greenhouse. I mean, how big is your armored vault hothouse going to be?

You seem to be arguing this cost is too high. That seems to be countered by the many people actually growing stuff in greenhouses for decades this and making plenty of money.

No, man, that's not what I'm *saying*, man. I'm saying that if you're going to build a hothouse, make it a greenhouse. Daylight it, with skylights and/or lightpipes. Maybe supplement with artificial lighting some of the time. Lighting it with a solar farm that's thirty times as big is going to be more expensive, unless solar cells are thirty times cheaper than glass per square meter, and lighting it with fossil fuels is more expensive still. Fuck, thirty times cheaper than plexiglass. Thirty times cheaper than the shitty transparent plastic wrap we used to make greenhouses in Ecovillage Velatropa. If you're right and, against all odds, LEDs are now 50% efficient, exceeding the theoretical ideal luminous efficacy maximum Wikipedia gives, the threshold becomes fifteen times cheaper instead of thirty --- still improbable!

While I'm calculating the efficiency of LEDs for you, would you mind undoing your downvote, please?

There are some example calculations in https://en.wikipedia.org/wiki/Luminous_efficacy#Examples_2 of the overall luminous efficiency of different kinds of light sources. Candles are around 0.04% efficient, while incandescent bulbs range from 1.2% efficient (though there's really no lower limit) to 5.1%. The illumination LEDs listed are in the range of 15%–25%. None comes close to 40% efficiency, much less 50%. Low-pressure sodium lights, the kind you occasionally still see in streetlights, head the pack with luminous efficiency up to 29%, which is why they're so popular with clandestine indoor growing operations.

Here's the deal with luminous efficacy: to calculate the absolute energy-efficiency (η) of an electrical light source, we need to know the input power (watts: $P = EI$) and the output power, which is in the form of radiant flux (also watts). The ratio between these two is the efficiency; it tells us how much of the electrical energy that goes into the luminaire comes out as light, or inversely, just gets wasted as heat.

But nobody publishes radiant flux numbers for their light sources because what people care about is mostly the *brightness* and, sometimes only secondarily, the temperature and the color rendering index. Brightness --- luminous flux --- is measured in lumens, not watts. But because the humans' eyes are not equally sensitive at all wavelengths, converting between radiant flux and luminous flux is complicated. A hundred watts of radiant flux at a 900-nanometer wavelength counts as zero luminous flux, because the humans' weak

little eyes can't see it at all. Similarly, a hundred watts of radiant flux at 350 nanometers is also zero luminous flux, although that will give a human a sunburn pretty quickly. A hundred watts at 555 nanometers, where the humans' cone cells are most sensitive to light, looks twice as bright as a hundred watts of radiant flux at around 520 nanometers or 630 nanometers.

So, to convert between radiant flux and luminous flux, we use a weighting function called the luminous efficiency function, which reflects this variation. At 555 nanometers the weight is 683 lumens per watt, a number arbitrarily chosen to make the SI candela (a lumen per steradian) approximate the Victorian-era candlepower as closely as possible. At every other wavelength, it's lower, according to a standardized approximation of the photopic luminosity function of the humans' eyes, which can be downloaded from the image links at the top of https://web.archive.org/web/20081228083025/http://www.cvrl.org/database/text/lum/vljv.htm (I recommend https://web.archive.org/web/20070518010940/http://www.cvrl.org/database/data/lum/vme_1.txt, specifically).

Now let's consider a modern illumination LED I happen to have the datasheet handy for, the Cree XLamp CXA2530 family. On p. 6 of its datasheet, it displays its relative spectral power distribution at 800 mA and 85 degrees, from 380 nm to 780 nm. Let's take the "warm white" variety, because its distribution is flatter, so the calculation errors will be smaller. Unfortunately, it's normalized to percentage of maximum brightness. From 380 nm to 430 nm, it's between 0 and 10%; from 430 nm to 480 nm, it's between 10% and 50%; from 480 nm to 530 nm, it's between 20% and 55%; from 530 nm to 580 nm, it's between 55% and 90%; from 580 nm to 630 nm, it's between 85% and 100%; from 630 nm to 680 nm, it's between 30% and 85%; from 680 nm to 730 nm, it's between 5% and 30%; and from 730 nm to 780 nm, it's between 0 and 5%.

On p. 7 we find that these LEDs --- LED arrays, really --- hit this 800-mA current level around 37 volts. Also, they're a little more efficient if you run them at a lower power level, because the light output is fairly closely proportional to the current, while the current increases with voltage. So if you run them at 400 mA instead of 800 mA, you get half the light output, but the voltage drops to 34 volts, about a 10% efficiency improvement (so, if we end up computing that they were 22% efficient, that could be improved to 24% this way). Also, if they're sufficiently cooled, we can get another 10% improvement. I'm going to use the nominal 800 mA and 85 degrees, but keep those possible improvements in mind.

This works out to 29.6 watts of electrical power.

On p. 9 we find that the "brightness" performance groups range from 2100 lumens up to 3950 lumens, with the top bin, U2, having a minimum luminous flux of 3680 lumens at 85 degrees and 800 mA. (This also shows up on p. 3 of the datasheet.) I'm going to assume that Cree isn't just being optimistic and some of their LEDs in this family actually do test into this bin.

Now, if you were trying to find out the maximum luminous flux an LED could put out at a given radiant flux, you would calculate with as much of the energy at the highest-luminous-efficacy wavelengths as possible. Ideally, all of the energy would be at 555 nm,

although here we know that some of it is outside the 530–590 nm range, and some of it is even out past 680 nm one way and 480 nm the other. If someone had managed to produce LEDs that had the same 3680 lumens at purely 555 nm and 29.6 W, those LEDs would be producing 5.39 watts of green light (and be 18.2% efficient.)

But in this case we have the inverse problem: we're trying to find out the *maximum* radiant flux these LEDs could possibly be emitting, given their published luminous flux rating. That is, because they're emitting light at other wavelengths as well, they can emit *more radiant flux* at the same luminous flux. And to put bounds on how much radiant flux they could be emitting, we need to do the opposite: put as much of the power as possible at the least-visible-possible wavelengths.

Given the numbers above, the total area under the curve of the LED's spectral power is between (0 + 10% + 20% + 55% + 85% + 30% + 5% + 0)50 nm = 205% * 50 nm and (10% + 50% + 55% + 90% + 100% + 85% + 30% + 5%)50 nm = 425% * 50 nm.

Progressive revealment crypto

Kragen Javier Sitaker, 2019-04-10 (2 minutes)

If I encrypt a document with a symmetric key to which I give you all but the last 40 bits, and the decrypted document contains a way to verify that it's the correct decrypted document (lower entropy, say, or a checksum), then you can decrypt it in about 2^{39} work. If this document contains all but the last 40 bits of the encryption key to another document, then once you've decrypted it, you can decrypt the second document in about another 2^{39} operations, or 2^{40} operations in total. Such a chain of documents forms a sort of "time lock crypto"; it is difficult and perhaps infeasible to decrypt the documents further down the chain without first decrypting the earlier documents.

It's not a very good timelock, in that I (the puzzle-maker) must encrypt the documents serially as well, and my only advantage over you (the puzzle-solver) is that I only had to encrypt each document once, while you had to decrypt it 2^{39} times. But those decryptions can be carried out in parallel; in the limit of unbounded parallelism, decryption is as fast as encryption plus a bit of communication overhead.

But, in the case where the puzzle-solver has limited parallelism, the puzzle can be made arbitrarily hard. Suppose, for example, that the puzzle-solver only has a million-node cluster available to try keys with, each node being as powerful as my laptop. Then, using the 40-bit example above, a chain of documents that I needed one day to encrypt on my laptop will take them a million days — 3000 years — to decrypt.

The downside of this is that, if they are decrypting it on their laptop instead of a million-node cluster, they will need 3 billion years instead.

Another candidate lightweight frequency tracking algorithm

Kragen Javier Sitaker, 2017-08-18 (4 minutes)

Okay, I can't find my previous notes on frequency identification, but here's what I came up with tonight, which I'm pretty sure is good. You get two booleans by comparing the current sample to 0 and to the simple moving average (or maybe double simple moving average) of the last N samples, getting a kind of estimate of its derivative. These two booleans give you a quadrature rotation signal: 00, 01, 11, 10, repeat. The timing of the (corresponding forward) transitions of this signal is ¼ the period of the input signal. You get the transition immediately at the sample, with no codec or processing latency the way an STFT has, and fairly little computation per sample:

```
// Advance ring buffer sample pointer
xj = &x[j++];
if (j == n) j = 0;
// Update ring buffer x and moving average numerator m
m -= *xj;
*xj = xi;
m += xi;
// Compute new quadrature state.
s = (xi > 0) << 1 | (xi * n > m);
if (s != os) transition(t[os << 2 | s]);
os = s;
```

So in the usual case, that works out to an increment, an indexed address computation, four comparisons, a memory fetch, a subtraction, a memory store, an addition, a multiplication by constant N, a bit shift, a bitwise or, and a state variable update which could be eliminated by unrolling the loop once: 14 operations per sample, all very simple except possibly the constant multiplication. In the case of a detected transition, you get a bitshift by two, an or, and a table lookup.

All of this is LTI up to the last bit where we take the signs and look stuff up in a transition table.

The FIR frontend is a very chintzy bandpass filter: the (implicit) subtraction from the current sample attenuates low frequencies, while the moving average itself attenuates high frequencies, but can only manage about 3dB of attenuation on the overall transfer function because of the impulse at lag 0. An additional moving-average pass (6 more operations, including the memory references and wrap) cleans up the high-frequency part of the response. We could make it a somewhat better bandpass filter, at the expense of fractional cycles of response latency, by using something else than the current sample: another simple moving average, which of course suggests that maybe we should use two moving averages of the same size, abutting but not overlapping, thus removing the multiplication as well.

Perhaps more interesting, though, is to use several moving-average

filters of different sizes, which, if they are single-stage, can use just one single buffer of input data. If their sizes are powers of 2, you can rescale the sums for the subtraction just by a bit shift of 1. In the limit, this takes the same 14 operations per sample per octave, but gets you much better low-pass filtering. Each filter will detect a separate frequency, which may or may not be the dominant frequency in its octave.

You could try to track the phase of the signal more closely than just within 90°, and this may be useful. However, the moving-average filter that provides the "derivative" signal imposes a somewhat arbitrary attenuation, which means that your phase velocity will vary throughout a cycle, perhaps wildly. However, the lag between crossing a given phase angle on successive cycles should be consistent.

Median filtering, PLLs, blah. Everybody uses variants of autocorrelation (ASDF and AMDF).

Ultraslow radio

Kragen Javier Sitaker, 2013-05-17 (updated 2013-05-20) (26 minutes)
(Published previously on kragen-tol.)

Long-distance telecommunication is really important, and currently crucially dependent not only on the state of the global economy, but also on operationally centralized telecommunications companies, large telecommunications structures that are easy to bomb, and undersea cables. What's the minimal digital telecommunications infrastructure that would usefully enable intercontinental communication?

Possible communications modes

Shortwave radio

Shortwave radio (1.5MHz–30MHz) reflects off the ionosphere and can be received intercontinentally. This includes a couple of ISM bands in which unlicensed operation is permitted internationally: 13553–13567 kHz (22 meters) and 26957–27283 kHz (11 meters). Wikipedia's "High frequency" article says, "The maximum usable frequency regularly drops below 10MHz in darkness during the winter months, while in summer during daylight it can easily surpass 30MHz." Wikipedia's "Skywave" article says, "Signals of only a few watts can sometimes be received many thousands of miles away as a result." One hop off the ionosphere gets your signal up to 3500km.

This means that, in theory, you could set up a single unlicensed radio station providing communications services to you in most of a 7000-kilometer-wide circle. Something over a dozen such receivers could provide you with global coverage. Of course, you'd have to deal with interference: both decoding the received signals in the face of interference, and not generating so much interference to other users of the spectrum that they start to interfere with you in ways other than radio communication.

(Transmitting in the 22-meter band, especially using time-domain radio with low-power code division multiplexing and a low duty cycle, would also make it practically difficult to locate the radio transmitter; and of course the receiver would produce even less evidence of its presence.)

Possible bit rates for shortwave

Shannon's Theorem, aka the noisy-channel coding theorem, has no minimum signal strength below which communication bandwidth is zero; the Shannon-Hartley limit is B log (1 + S/N), where B is bandwidth in hertz, and S and N are the power of the signal and noise. In the "power-limited regime", when S/N is very small, this is linear in S/N. A somewhat counterintuitive result here is that, practically speaking, your bit rate doesn't depend on frequency selectivity much at all --- if you use twice as much of the spectrum, you double B, but you also probably double N. This means you can choose your bandwidth to satisfy other considerations, such as minimizing interference with other users of the band, who are mostly still using frequency-division multiplexing, or minimizing device cost.

So, supposing you can send one bit per second in the HF band using one watt over a few thousand kilometers, you can probably send about one bit per 1000 seconds using one milliwatt, or one bit per day using 12 microwatts, and this regardless of whether your signal is 0.1kHz wide, 14 kHz wide, or 28.5 MHz wide.

Is one bit per second about right? Digital Radio Mondiale in the shortwave bands uses at least 6 kilobits per second, but that doesn't tell us much, since this could be slammed through by using hundreds of kilowatts. What we really need to know is how much background noise there is in these frequency bands, in an absolute sense, or how many words per minute people can send and receive with CW Morse code over what distance and what power. One bit per second would be about 1.2 "words per minute".

It seems like the keyword for this kind of thing in current amateur radio operation is "QRP operation", which means around 5 or 10 watts or less. QRPers consider anything below 1 watt as "extremely low power", or QRPp, and they consider a thousand miles per watt as a difficult benchmark to meet. PSK31 is the digital code most commonly used at present for this kind of thing, and it operates at 31 baud and a bandwidth of 31.25Hz; it does a 180-degree phase shift during an amplitude null to represent a zero bit after encoding the digital signal into Varicode, a huffman code for ASCII. There are 10-baud and 5-baud variants in use. PSK31 is commonly used down to the 160-meter band.

If we figure that talking a thousand miles (1609 km) on a watt already puts you into the power-limited regime, and guess that you can get some 10 bits per second out of it, then using skywave bounce, you should be able to talk N thousand miles at 10/N bits per second. For example, you should be able to talk 16000 km, about a third of the way around the world at one bit per second.

Lasermoon moonbounce communication

You could illuminate the moon with a rapidly modulated laser at night. The moon's albedo is about 12%, it covers about half a degree of arc, and you can get cheap 5mW semiconductor laser pointers with divergence of less than that, indeed closer to a tenth of a degree, so that all of their power falls on the moon. Similarly, an inexpensive lens focusing the moon's image onto a photodiode (which is faster than a phototransistor) can easily give you better than an arcminute of selectivity. A square arcminute is about 85 nanosteradians, so this corresponds to about 80 dBi of "antenna gain" on the receiving end, but focusing more tightly than the original laser pointer spot isn't useful, so you only get about 60 dBi in practice.

Against this you must weigh the fact that most of the light falling on the moon is reflected off into space. You can probably reasonably use a one-meter-diameter plastic Fresnel lens, but you're about 380 megameters from the moon. This means that the light signal you get is about 176 dB weaker than the light signal sent from the moon, which is presumably most of the 500µW or so of light emitted from a 5mW laser pointer, minus about 9dB for the low albedo. This means you're trying to detect a signal of some -188dBm, which is difficult but feasible. It's actually considerably more feasible than doing the same trick with radio waves, due to the higher "antenna gain".

I think common laser diodes have a Q factor around 1000 --- their

light is mostly contained in a range of wavelengths of less than a nanometer --- which means you could improve your SNR by up to about 30dB by filtering the moon's image through a dichroic filter.

This leaves the question of how much noise you're dealing with in the first place, particularly important if you might have significant "crosstalk" from brightly-illuminated parts of the moon, say because your camera is imperfect. Sadly, I have very little idea how bright earthshine is, which is kind of the question.

Earth-mode communications

Ultra-low frequency radio --- 300 Hz to 3000 Hz --- can propagate through the earth itself; there are apparently lots of NATO papers from the 1960s about using this for military purposes. As far as I can tell, though, this involves running antenna cables a distance comparable to half the wavelength (100 km or more) or to the distance you want to communicate. So I think this may be impractical.

Balloon radio

Getting a balloon to 90km altitude is straightforward, at which point it has a line-of-sight radio path to anything within 9.57 degrees of arc (acos(r/(r + 90 km)), where r is 6371 km, the radius of the Earth) on the Earth's surface, about 1000 km; at this point it could quite reasonably communicate at gigabits per second using laser or highly-directional ultrawideband microwave to any of those points, if it can figure out how to align its transmitter and receiver. Furthermore, two such balloons will have a line-of-sight if they're less than twice the angle apart, or 2000 km. Twenty such balloons could ring the earth along a great circle, so a frequency-four geodesic sphere would suffice to provide global coverage with a bit under 200 balloons.

On the other hand, getting balloons to stay up there would be quite a challenging project. In fact, just getting them to work at all while they're up there is no walk in the park.

Air mail

In 1998, Laima, an Aerosonde, flew successfully across the Atlantic on 5.7 liters of fuel in 27 hours. Aerosondes weigh about 13 kg, about the same as a large swan. One micro-SD card weighs about 500mg and can currently hold 64 GB of data, so a 2-kg payload would hold 256 TB. This would amount to a 21 Gbps transatlantic data connection.

In 2003, the 5kg Spirit of Butts Farm made more or less the same 3000km flight on under a liter of fuel, in just under 39 hours.

On one hand, these bandwidths are orders of magnitude higher than the bandwidths reasonably achievable by the other technologies mentioned above. On the other hand, the latency is also some five orders of magnitude higher, and also, this is a very unreliable way of transmitting data --- it is likely to result in the loss of the aircraft and its payload on a regular basis.

A lower-tech approach for north-south communication would be to attach high-capacity store-and-forward radio-communication nodes to long-lived migratory birds. When they came into communication range of other nodes, they would exchange messages via short-range, high-bandwidth radio.

Neutrino beams

Particle accelerators can generate large quantities of neutrinos in a beam, by accelerating large quantities of pions or kaons to relativistic speeds and letting them decay; if the neutrino beam is directed at the earth, most of them will penetrate to the other side. Unfortunately, detecting a change in neutrino flux is very difficult, because they can easily penetrate things like the earth. It's feasible using thousands of photomultiplier tubes and tens of thousands of tonnes of water or other transparent liquid deep underground, like the Super-KamiokaNDE and the Sudbury Neutron Observatory; such observatories see on the order of one natural neutrino decay per few days per thousand tons of matter included.

This is clearly a feasible technique for communication, but it costs tens to hundreds of millions of dollars (which is to say, hundreds to thousands of person-years of work) and the result should be communication with bandwidth measured in fractional bits per day. If it were possible to increase the number of neutrinos by several orders of magnitude, you could increase the bit rate substantially, and in the limit, you could have lower latencies for long-distance communication than communication methods for which the earth is an obstacle.

Sound in air or water

Low-frequency sound can propagate for hundreds of kilometers in air, which is the principle behind the West African talking drums, which were used for long-distance digital communication for several centuries, up to the mid-20th century. I think you can get up to tens of bits per second this way. The talking drums could transmit several kilometers (8 km, says Wikipedia), but not tens or hundreds of kilometers. Whistled speech can cover one to two km, and has in theory a higher bit rate.

High-frequency sound is unusably attenuated by air in a few kilometers, but can cover thousands of kilometers in water, where whales use it; it also travels above 1km/sec. There's the additional advantage that sound in the ocean tends to remain a few hundred meters from the surface, in a zone called the SOFAR zone or Deep Sound Channel, so its intensity falls off as $1/d$ instead of $1/d^2$ over long distances.

Telegraph towers and cloud-bounced signal lamps

A 1.6-km-tall mountain, such as Sandia Peak in Albuquerque, has a line of sight to some 140 km distance on a smooth-spheroid earth, and perhaps 100 km in real life. Even a 100-meter-tall tower can see for 36 km. This principle was used in semaphore telegraphs throughout Europe in the decades before the development of the electric telegraph: a line of fortified stone towers at 30-km intervals provided about one bit per second. If you put a cheap laser pointer on the tower, you can transmit over this line of sight at megabit speeds or better.

Of course, you can also use a reflecting mirror to reflect sunlight instead of a laser; such a "heliograph" can transmit up to 300km under ideal conditions or 50km under normal conditions, using small, hand-sized mirrors. Bit rates depend on how fast you can open and close some kind of "shutter", but at least hundreds if not thousands of

bits per second should be attainable with inexpensive LCDs.

As suggested in the Lasermoon section, you can do this same kind of long-distance communication even without going up on the mountain yourself; it's sufficient to illuminate it from afar. Naval communication with Aldis lamps uses this trick to communicate by illuminating the bases of cloud formations, which enables communication at much greater distances; in theory, you could use cirrocumulus or cirrostratus clouds at their altitude of some 5–12 km to communicate to a station 500–800 km away, or perhaps even the 23-km-high tip of a cumulonimbus cloud to communicate with a station 1000 km away. This is more practical than using the moon, since you only have to detect light diffusing from the cloud 500 km from you instead of 380 000 km from you, giving you 60 dB less path loss in the cloud-to-you path than in the moon-to-you path. (As before, I think you can focus light onto the cloud well enough that effectively all the light you transmit reaches the cloud, so you effectively don't have any path loss.)

Useful bit rates

Why would it matter if you could transmit a millibit per second? Well, one bit can still be a crucially useful thing to be able to transmit. "I'm alive," for example, or "The killers weren't al Qaeda." But even a Tweet is only 1120 bits, so a bit per 1000 seconds would let you you transmit a Tweet every two weeks. The Annals of Spring and Autumn, 春秋, covers 541 years in 16000 characters; if each were 16 bits, that would be just over one bit per day on average. The Chappe semaphore line system transmitted about one "symbol" per minute out of 92 possible symbols, giving a bandwidth of about 0.11 bits per second; it was credited with giving Napoleon a decisive military advantage.

One bit per second

Consider the higher bandwidth of one bit per second, which I've hypothesized above requires about a watt of power over transcontinental shortwave. Two bits is roughly one letter of compressed ASCII text [0], so this is about 7000 words of text per day; one to ten Wikipedia articles per day, for example, or a fairly in-depth summary of daily international news, or a couple of hours of writing email per day, or a book per month. Furthermore, it's fast enough to permit someone to write a line of text in a chat system, transmit it, and get back a response from someone else within a couple of minutes.

[0] bible-pg10.txt is 824 146 words and 4 452 069 bytes; its .bz2 is 999 906 bytes, 1.80 bits per uncompressed byte; compressors other than bzip2 may be more efficient; but extremely high compression ratios may only be achievable with the transmission of large amounts of data. For example, if I split the same document into 64KiB chunks and bzip2 each one independently, the result is 1 214 055 bytes, 2.18 bits per uncompressed byte.

One bit per second, then, is a sufficiently rapid connection to permit real participation in the intellectual life of an invisible college; but it's less information than a person can read. Furthermore, with a broadcast medium such as radio, it's reasonable to transmit the same information to many recipients at a time, Usenet-style.

Commercially speaking, even one bit per second, or for that matter a thousandth of a bit per second, at low latency is enough to make you a hell of a lot of money in commodity arbitrage, if your competitors don't have access to equally fast communication. A price to three significant figures is only ten bits, and it's straightforward to encode names for widely-traded commodities in 30 bits or less. (This is why the stock ticker was such big business in the late 19th and early 20th century.)

Ten bits per second

Ten bits per second would give you some 70 000 words of text per day, which is almost as much as you could read in real time; and it would be fast enough to permit real-time hypertext navigation with a stateful two-way protocol. (If you're transmitting document contents containing the IDs of other documents in one direction, while transmitting the IDs of requested documents or document parts in the other direction, each ID will typically be within the last thousand IDs transmitted, so it can be encoded in ten or twenty bits.) Ten bits per second at 2.5 bits per character works out to 240 characters per minute, or 48 words per minute, so it's at least theoretically possible for one person to type faster than ten bits per second on a sustained basis; but it's fast enough that one-to-one text chat would be more or less real time.

A hundred bits per second

A hundred bits per second would give you some 700 000 words per day, an entire book. This is enough that one person can no longer read all of it, if it's text, and eliminates the need for a stateful protocol for real-time hypertext --- although full HTTP might still be excessive. It's about 480 words per minute.

Acquiring one new book per day was an unachievable dream for nearly all individual scholars and the majority of libraries in most of the age of print. If the books were new cheap paperbacks, it cost about US$1800 per year toward the end of the 20th century, within the means of most of the population of the developed world, but new hardbacks pushed the cost up by an order of magnitude, to US$18000 per year. So a hundred-bit-per-second connection to a large data store could beat access to printing presses for all but the wealthiest.

If one person were trying to consume a hundred bits per second, they would probably want to do much of it in the form of still images. A high-quality color JPEG file typically uses about four bits per pixel, and black-and-white needs about half that. So a hundred bits per second is on the order of 100 low-quality pixels or 25 high-quality pixels per second. A low-quality 320×200 color image might download in 21 minutes.

As of early 2012, the English Wikipedia articles without pictures total 10 399 030 471 bytes in a compressed Zim file. At a hundred bits per second, this file would take 26 years to transmit.

For much of the twentieth century, most Telex systems ran at 45.45 bits per second.

A thousand bits per second

A thousand bits per second is 7 000 000 words per day, some ten books. At this speed it's possible to receive text you don't intend to read yourself, just in case you want to read it later; but it's also fast

enough that you don't need to if the connection is reliable. You could download the Wikipedia archive I mentioned above in 2.6 years.

It's also at the minimal lower limit where you can do real-time voice transmission. Many voice codecs (from early LPC work in the 1970s to HVXC and Speex today) have modes between 2 and 3 kilobits per second. I think transmitting intelligible speech at 1kbps is feasible, but only barely, and I don't know if it's been done.

At a thousand bits per second, you can completely kick the ass of printing-press-based communication systems, both providing instant hypertext access to faraway data stores and accumulating the equivalent of thousands of locally-stored books per year, plus, of course, email.

Ten thousand bits per second

This is the speed at which much of Fidonet operated.

Possible communications hardware and algorithms

The very low power levels involved suggest that it might be possible to do these ultraslow transmissions with extremely steampunk equipment, or not even that. For example, for radio communication, perhaps you could trigger a static-electrical spark from a Wimshurst Influence Machine at intervals driven by holes in a rotating glass sphere, firing an electrical impulse into a dipole antenna. But a Wimshurst machine can produce more than a watt of power; a simpler generator, such as your hair and a balloon, might be sufficient. You just have to time your sparks correctly to make them interpretable by your (presumably much more capable) receiver, and successfully couple them into your antenna, maybe with a low-Q resonator containing a coil and a Leyden jar.

(In theory, maybe you could decode such a low-bandwidth signal by hand, too, but it's not obvious to me how you'd do it.)

(The earliest non-spark-gap radio, the Poulsen arc, used a carbon arc as a negative-resistance device to produce a dynatron oscillator; I think you could also use just about any gas discharge tube, such as a fluorescent lamp tube or even a fluorescent lamp starter.)

Of course, multiple ultraslow radios could form a very slow packet-switching network.

Moving further into the steampunk and cargo-cult direction, you could imagine a shorter-range purely passive radio transmitter, like a sort of switchable analog RFID tag. The "receiver" would wait for the transmitter to be energized by electromagnetic pulses produced by nearby lightning strikes; then it would measure a variable set of RF resonances in the device. A Leyden jar might have a nanofarad of capacitance, and a variable inductor with up to about a henry of inductance can be fairly easily constructed by hand, the two forming a tank circuit with a resonant frequency of as little as 5kHz and a Q of perhaps 100; a large number of such resonant circuits connected to an antenna will "ring" for tens or hundreds of oscillations when subjected to a radio impulse. If their frequencies are chosen in accordance with some kind of error-correcting code, a distant detector will eventually be able to determine what those frequencies are, after detecting enough impulse responses. Multiple receiving antennas could provide

enough phase diversity to do beamforming.

Such a device is fairly inefficient, since most of the energizing pulse energy will not coincide with a resonant frequency of the transmitter and will thus simply reflect from the antenna. If you could store the pulse in some kind of device that allowed you to use it to continuously energize the resonators until it dissipated, you could use more of it. For example, with a semiconductor diode, you could store much of the pulse in a capacitor, and use that to power active oscillator circuits; or if you could circulate it through some kind of delay line, such as a piezoelectric acoustic delay line, you could use any nonlinear but nondissipative circuit element to shift some of the remaining pulse energy into resonable harmonics or subharmonics on each circulation through the system.

Pulse radio would allow for relatively reasonable decoding electronics and algorithms: while your average power might be, say, 100 milliwatts, if you're only transmitting for 100 microseconds out of every minute, that transmission would be at 60 kilowatts. (If it's a single 100-microsecond pulse, it would be a six-joule pulse; into a 63-ohm antenna impedance, it would be a momentary current of 31 amps, driven by 2000 volts, which could be stored in 3 microfarads, so this wouldn't require any particularly exotic circuit design.) Detecting the pulse at even a very substantial distance should not require particularly sensitive or highly linear analog electronics; the remaining task, then, is to figure out which subset of the detected pulses represent a decodable message.

Cassette tape capacity

Kragen Javier Sitaker, 2018-04-27 (1 minute)

David Rowe's Codec 2 packs relatively comprehensible voice into 700 bits per second, for use in the FreeDV amateur radio low-bandwidth voice mode. But what if you record it on an audio cassette tape instead? You should be able to get higher bandwidth than we got out of analog telephone lines — two channels with an ENOB of about 5 with frequencies up to about 15kHz, implying 30ksps. This works out to a channel capacity of about 300 kilobits per second, given the appropriate modulation. (And doing the appropriate modulation should be pretty feasible.)

This implies that each second of audiocassette data can hold about 7 minutes of Codec-2-encoded voice; a 60-minute audiocassette can hold some 400–500 hours of recorded voice.

Fortunately or unfortunately, this is not actually a useful thing to do.

Binary translation register maps

Kragen Javier Sitaker, 2017-07-19 (1 minute)

Reading Sorav Bansal's dissertation, I was struck by the fact that in the middle of the binary-translation section, he tackles the register allocation problem using the Viterbi algorithm, although he seems not to have realized that he was solving register allocation (conventionally considered NP-hard) or that his solution was the Viterbi algorithm.

The context is not conventional compiler code generation but rather binary translation from PowerPC code to 386 code, so both the input and output of his system are sequences of instructions. He is faced with the question of how to assign registers for the output instructions.

His solution is to compute the cost of all possible register maps, one input instruction at a time, as he walks through the input code, adding an extra "switching cost" when the predecessor state used a different register map; but he retains only the lowest-cost few maps at any given point in order to keep the cost reasonable, up to about 8 maps, though he only gets a significant performance advantage up to about 3 maps. (I wonder if this is due to having several maps that are essentially equivalent.)

This seems like a remarkably simple approach to a remarkably difficult problem, so simple that I am led to wonder whether it actually works. Some other aspects of the scholarship in the dissertation are shaky.

Atmospheric pressure harvesting phoenix egg

Kragen Javier Sitaker, 2018-11-23 (14 minutes)

I think I've finally found the problem to how to refresh the memory in the Egg of the Phoenix: use daily tidal atmospheric pressure swings to power programs to periodically rewrite NAND Flash.

The memory retention problem

The problem is that the device, by definition, needs to be able to retain its memory when buried for a century or more; that's its entire raison d'être. But modern Flash is not designed for such a requirement; instead, it's designed for memory retention of 20 or even 10 years. And it's very likely that Flash memory will gradually lose its memory as charge tunnels away from its floating gate, at a rate which is IIRC exponential in temperature.

It doesn't take very much energy to refresh Flash; Low-power microcontrollers for a low-power computer (p. 2602) says the Adesto AT25SF041-SSHD-T NAND chip requires 100 mA for 500 ms to erase 32 kB ≈ 500 nJ per byte, and presumably some smaller amount to write the erased memory; Keyboard-powered computers (p. 2220) says Flash uses 2 µJ per 32-bit write, which is exactly equal. FeRAM also exists and is about 2000 times more energy-efficient than Flash, and MRAM is apparently about 500 times more energy-efficient than Flash, but both are dramatically more expensive.

(Other possibilities besides Flash, FeRAM, and MRAM exist, but nothing that we can confidently predict will survive a century.)

The power needed is thus proportional to the amount of data archived.

Energy requirements; why not just use a battery?

This means that preserving, say, 100 gigabytes of Flash requires about 50 kJ every 10 years or so, which works out to an average of 160 µW. If we take that over 100 years, it's 500 kJ; converted to milliamp hours at the 3.7 V of a lithium-ion battery, it's 37000 milliamp hours. This would be a very reasonable-sized lithium-ion battery, one you could hold in your hand. So why not just use that?

Well, all batteries have a self-discharge rate, and typically it's enough to discharge them completely within five years. Lead-acid batteries have a somewhat longer shelf life, perhaps 10 or 20 years. But no commercially made battery has a shelf life of a century.

One possible alternative is a Zamboni pile such as, it is believed, the Clarendon Dry Pile that powers the Oxford Electric Bell, which has been ringing almost continuously since 1840, on about 1 nA and 2000 V (2 µW). Unfortunately, although long-lived Zamboni piles do exist, they are not very well characterized; we don't know very much about the ways they can fail, particularly after decades. We don't

even know for sure that the Clarendon Dry Pile is in fact a Zamboni pile. And, as far as I know, nobody has ever built a Zamboni pile that yields tens of microwatts, let alone hundreds.

Atmospheric pressure variation

Earth's atmospheric pressure varies tidally by a few millibar (a few hundred pascals) around its average of 101.325 kPa at sea level, varying from 87.0 kPa (during Typhoon Tip in 1979) to 108.48 kPa (during the Siberian High in Mongolia in 2001). (The vertical variation is larger than this, at about 11.3 Pa/m, so reaching the record low typhoon sea-level pressure only requires going a bit over a kilometer up.)

As I write this, the pressure is some 103 kPa, and tomorrow it's forecast to fall to 102 kPa, then as low as 100 kPa the next day as a rainstorm comes through. For most of the next week, the trend is almost perfectly flat, staying between 101 and 102 kPa. There are tidal-looking wiggles in the forecast of about 100 Pa above and below the trend line. The NWS says Boston currently has 101.51 kPa, but earlier today it's been as low as 101.05 kPa and as high as 101.62 kPa; yesterday was from 100.91 kPa to 101.56, with a bit of rain. So, although the dependable tidal variations are only around 100–200 Pa, working out to a total of 400–800 Pa per day absolute change, it's common to have a bit more than that, like 1 kPa or more per day of change in one direction or the other.

Common soils and even rocks are not sufficiently rigid and impermeable to prevent this pressure variation from reaching underground, even to a depth of tens of meters, a phenomenon known in some contexts as "barometrically induced variability". So an energy-harvesting device that harnesses these tidal pressure variations will work even if it's buried, as long as it doesn't get all crudded up with sand or something. Even if it's filled with water, it should continue to work.

Such energy-harvesting computational devices date back to the seventeenth century; one of the greatest engineers of all time, Cornelis Drebbel, built several clocks powered by such pressure changes at that time, starting in 1610. Cox's Timepiece, built in the 1760s, ran exclusively on atmospheric pressure until being acquired by the Victoria & Albert museum in 1961, and the Beverly Clock, built in 1864, is still running today, 154 years later, though it also harvests thermal energy.

Jaeger-LeCoultre currently sells the Atmos clock, which harvests energy from temperature and pressure variations to run without winding; some half a million have been produced so far since their 1929 début. Although, like the Beverly Clock, it primarily harvests thermal energy, a pressure variation of 3 mmHg = 0.4 kPa is sufficient to energize it for two days; although typical tidal pressure variation is slightly smaller than this, it shows that pressure variations in this range are suitable for harvesting even with a tabletop-sized device with no electrical parts, by pressing an ethyl chloride bellows against a spring. Michael P. Murray, a specialist in Atmos clocks, claims that they use about 250 nW; Adam Sacks claims they should have a service life of about 600 years.

Underground pressure penetration

Aside from the few hundred pascals of tidal variation, when it rains, the soil may saturate with water and go to higher pressures. If the Egg is buried 2 meters deep, for example, it will experience an extra 20 kPa of hydrostatic pressure if the water table rises past it to the surface. This is some two orders of magnitude larger than daily tidal variations, but only somewhat larger than the 15 or so kPa of difference between world records. So it's important to design the Egg to withstand such pressures, even if it can't harvest the energy they present.

The surface tension of water in the soil can also produce soil suctions up to some 30 MPa, which I interpret as pressure below atmospheric pressure and indeed below zero pressure, despite cautions that that's not exactly what is meant. Apparently typical soil suction for agricultural soils is 25 kPa or less.

"Barometrically induced variability" is a term used for variability in subsurface gas concentrations, of concern in monitoring of toxic waste. One paper reported pressure variation over a range of some 25 mb (2.5 kPa) during a few days, tens of meters below the soil surface, which was inversely correlated with CCl_4 concentrations.

Even higher-frequency pressure variations, such as those caused by wind vortices, can penetrate deep underground; Takle and colleagues in 2004 measured about 6 dB of attenuation of 2 Hz pressure variation by 600 mm of soil, if I'm reading the paper right, which suggests that the ≈20 μHz tidal pressure swings should be able to penetrate many, many meters of soil with no real attenuation.

Power

How much power is available from these air pressure variations? It seems like the limit is somewhere around 100 μW/ℓ, but it may be hard to approach that limit.

Suppose we have a cubic decimeter of air (a liter) with one flexible or bellowed face, to which we couple some kind of harvesting device, piezoelectric or mechanical or whatever. Suppose the air pressure changes by 200 Pa. If that device provides no resistance to the pressure variations, then the volume of the cube will increase and decrease by 0.2%, which is some 200 μm. But this is doing no work on the device, because there is no force. At the other extreme, suppose that the harvesting device is absolutely rigid. Then the force on it will vary from +1 N to -1 N, but the volume of the cube will not vary, and so it will do no work on the device, because there is no movement.

In between these extremes, we can harvest energy. For example, suppose that the harvesting device will rigidly resist a maximum of 0.5 N and thereafter move, winding a spring or something at constant force. Then the flexible face will move by only 100 μm, but it will be exerting 0.5 N over that distance, providing 50 microjoules, about every 6 hours. This works out to about 2 nW, which is two orders of magnitude smaller than what Murray claims the Atmos clock runs on. And the Atmos clock bellows does not appear to occupy an entire liter. We can perhaps conclude that using air, as the Beverly clock does, is quite disadvantageous.

Dividing the cube into slices to get more faces does not help, because the slices will expand and contract by correspondingly less distance. Making the cube larger does help, as the energy available is

proportional to the expansion distance and piston area.

What's the maximum work we could potentially extract from air pressure on our liter? Suppose it's still a cube, but filled with vacuum and with four bellows sides, with a constant-force spring pulling on it producing 1013.2 N. Now, whenever the air pressure falls below 101.32 kPa, the spring will expand the cube to its full 1ℓ volume, and whenever the air pressure rises higher, the spring will contract the cube down to a little square pancake, which we can suppose has insignificant volume compared to 1ℓ. The work that can potentially be extracted is a function of the height of the peak at the point that we allow the harvesting device to move; supposing that, as before, it's 200 Pa from trough to peak, we have 2 N over 100 mm, which of course yields 200 mJ. This is a quite respectable 9.3 μW, though still considerably smaller than the 160 μW we need. And, of course, if we somehow know that the pressure will fall from 103 kPa to 102 kPa tomorrow, then we can leave the cube fully extended until the pressure reaches its minimum, and then extract 10 N over 100 mm, a total of 1 J, some 100 μW over 24 hours.

(And of course we can use multiple liters to multiply the power; use a longer, thinner cylinder to get a longer stroke at proportionally less force; or use a fatter, flatter cylinder to get a shorter stroke at proportionally more force.)

Note that 9.3 μW is some 4000 times larger than the 2 nW we'd get from the air cube.

How close could we come to this ideal in practice? Presumably the Atmos uses ethyl chloride because the pressure range is enough to cause much of it to condense and evaporate at room temperature, enabling much larger volume variations than an air tank could manage. At a given temperature, the equilibrium pressure within such a mixed-phase, single-material container is absolutely constant at the vapor pressure of the liquid at that temperature, so a liquid whose vapor pressure is 101.32 kPa at whatever your temperature is would actually behave precisely like the vacuum-and-constant-force-spring gedankenexperiment above, expanding to an almost arbitrarily large volume when the pressure drops, and contracting to almost none when the pressure rises. (For water, the liquid to vapor density ratio is a few thousand to one; it's a bit lower for ethyl chloride.) Unfortunately, that experiment assumes that the tidal swings center precisely on that known pressure, which, as described above, is far from true; day-to-day shifts are commonly several times the amplitude of the dependable tidal pressure swings.

It isn't yet obvious to me how, but I suspect that something close to the ideal behavior described above is feasible. So only a few liters (perhaps less than the 28 used by the Beverly Clock) should be necessary to provide the refresh power. I think the Atmos compromises its ability to harvest energy at any given pressure/temperature combination by using its "counterweight" Hookean spring to spread its response curve over a wide range of pressures and temperatures in a purely static fashion. That is, at a given pressure and temperature, I think the Atmos's expansion chamber will always have the same volume, plus or minus a small constant bit of hysteresis.

Efficiently converting the mechanical power to electrical power is, I think, the easiest part of the problem; piezoelectric,

electromagnetic, and electrostatic techniques are all applicable, though it seems likely that the fairly rigid piezoelectrics are the best fit for the likely small displacements involved.

Observable transaction possibilities

Kragen Javier Sitaker, 2019-06-15 (10 minutes)

I was reading about Observablehq last night. They've layered a dependency and auto-recalculation system on top of JS, so that any cell of your code is re-executed when its dependencies change, without requiring you to explicitly reinvoke it.

I should probably dig into what Observable can do, or actually I should work on some DSP code I've been procrastinating on, but instead I am going to go off and natter about vaguely related stuff.

By executing the sequence of code in a cell, such a system can discover which inputs it's currently reading from and which outputs it's currently writing to, although both of these could change depending on the values of those inputs. Observable in particular determines the outputs statically and doesn't let different cells write to the same variable.

Suppose in such a system you have a cell that computes

```
r = (x**2 + y**2)**0.5
```

You can interpret this in the standard way, as a "statement", which is to say an instruction, which, when executed, reads single values from `x` and `y`, do a computation, and write the single result to `r`. Numpy extends this, following APL, by allowing `x`, `y`, or both, to contain *values* which are arrays of *numbers*. For example:

```
>>> x
array([-1.  , -0.75, -0.5 , -0.25,  0.  ,  0.25,  0.5 ,  0.75,  1.  ])
>>> y
array([ 1.73205081,  1.85404962,  1.93649167,  1.98431348,  2.        ,
        1.98431348,  1.93649167,  1.85404962,  1.73205081])
>>> r = (x**2 + y**2)**0.5
>>> r
array([ 2.,  2.,  2.,  2.,  2.,  2.,  2.,  2.,  2.])
>>> y = 1
>>> r = (x**2 + y**2)**0.5
>>> r
array([ 1.41421356,  1.25      ,  1.11803399,  1.03077641,  1.        ,
        1.03077641,  1.11803399,  1.25      ,  1.41421356])
```

In addition to allowing `x` and `y` to either not vary or to vary *together*, we can also have them vary *independently*, producing a *matrix* of results for `r`:

```
>>> y = x.reshape((9, 1))
>>> y
array([[-1.  ],
       [-0.75],
       [-0.5 ],
       [-0.25],
       [ 0.  ],
       [ 0.25],
       [ 0.5 ],
```

```
       [ 0.75],
       [ 1.  ]])
>>> r = (x**2 + y**2)**0.5
>>> r
array([[ 1.41421356,  1.25      ,  1.11803399,  1.03077641,  1.        ,
         1.03077641,  1.11803399,  1.25      ,  1.41421356],
       [ 1.25      ,  1.06066017,  0.90138782,  0.79056942,  0.75      ,
         0.79056942,  0.90138782,  1.06066017,  1.25      ],
       [ 1.11803399,  0.90138782,  0.70710678,  0.55901699,  0.5       ,
         0.55901699,  0.70710678,  0.90138782,  1.11803399],
       [ 1.03077641,  0.79056942,  0.55901699,  0.35355339,  0.25      ,
         0.35355339,  0.55901699,  0.79056942,  1.03077641],
       [ 1.        ,  0.75      ,  0.5       ,  0.25      ,  0.        ,

```

As I wrote in A principled rethinking of array languages like APL (p. 1995) and Index set inference or domain inference for programming with indexed families (p. 1434), you could think of the broadcasting rule for these simple elementwise operators as a logical interpretation: *if* x = -0.75 *and* y = -1, *in that case* r = 1.25; but *if* y = 0, *in that case* r = 0.75; and so on. And given a reactive observable dataflow transaction system like Observablehq, you could in fact evaluate it that way — if you change the value of `y` from -1 to 0 without changing `x`, `r` will react by changing its value from 1.25 to 0.75.

A FIR filter example

How about a FIR filter?

```
y = sum(w[i] * x[-i] for i in range(len(w)))
```

This is a valid Python statement, applying the time-domain FIR kernel `w` to the last few values of the list or array `x`. If you run it every time you append a new value to `x`, it will put successive samples of the FIR filter result into `y`. You have to be careful to not run it before `x` has enough values in it, and you probably want to do something with the result in `y` before it gets overwritten by the next execution, because the result is a function of a time-varying state of the system.

Suppose instead that you want to compute the entire FIR-filtered signal rather than just a point on it. You can do such a computation in Numpy in at least four different ways. The way you would actually use in practice is the `convolve` function:

```
y = numpy.convolve(w, x, 'valid')
```

Unfortunately this doesn't throw any light on how to solve the problem; it just delegates it to a library function, which, as it turns

out, delegates to the `multiarray.correlate` function, which is written in C and presumably does a nested loop.

The other two straightforward ways involve an interpreted loop in Python (which is why you wouldn't want to use them in practice) which invokes an inner loop via a Numpy SIMD operation. You could have the implicit inner loop compute a single point of `y`:

```
y = [(w[::-1] * x[i:i+len(w)]).sum() for i in range(len(x) - len(w) + 1)]
```

Or you could have the implicit inner loop calculate the contribution of a single sample of `x` to all the samples of `y`:

```
y = numpy.zeros(len(x) + len(w))
for i in range(len(x)):
    y[i:i+len(w)] += x[i] * w
y = y[len(w)-1:1-len(w)]
```

The fourth approach is to transform both `x` and `w` into the complex Fourier domain, multiply the complex phasors there elementwise, and transform back into the spatial domain. This involves some subtle issues of numerical precision, and it's profoundly nonobvious, but for large signal vectors, it is by far the fastest method. Implicitly in the above, `w` is not longer than `x`, and in that case it looks like this:

```
wf = numpy.fft.fft(numpy.concatenate((w, numpy.zeros(len(x) - len(w)))))
y = numpy.fft.ifft(wf * numpy.fft.fft(x))[len(w)-1:]
```

How about in the "logical" view? `w * x` is a perfectly reasonable expression; if `w` has 5 possible values and `x` has 11, then it `w * x` has 55 possibilities, reasonably represented as a matrix (the outer product of `w` and `x`, considered as vectors). It's indexed by the Cartesian product of `w`'s index set and `x`'s index set. The `y` computed above is just a sum over some of those values; the summation introduces a dummy variable that ranges over the valid indices of `w`.

The conventional mathematical notation for this is

$$y_n = \Sigma_i w_i x_{n-i}$$

where the dummy variable i implicitly takes all the values that it would be coherent for it to take. This is somewhat ambiguous and often disambiguated by contextual information: if x_i only exists when $i \geq 0$, for example, does y_0 exist, being simply $w_0 x_0$? And resolving that ambiguity is what the `'valid'` in the above Numpy expression is for.

Typically we think of x and y here as being indexed by (discretized) time, but of course nothing in the math requires that; for math, the time is just another meaningless variable.

In the "logical" view, this introduction of the dummy variable i means that *any* value of y depends on *every* value of w. In the sort of ambient-indexing environment I was thinking of there, Σ considers a multiplicity of possible worlds with different values of w; in this case, we also want to use the *index* into w to reindex *time itself* (ominous music with minor chords!) so we can access values of x from other points in time. A reasonable way to write this in ASCII might look something like this:

```
y = sum(w.i, w * x[t = t-w.i])
```

Here `sum` takes two arguments: the index to sum over and the expression to evaluate in a possible world for *all* of the possible values of the index. `w.i` is the index set of `w`; as `sum`'s first argument, it's being used as *a reference to an index* that needs to have its index set inspected and iterated over, while within the expression, it's being used as *a reference to a particular value of that index*, a mere rvalue. `x` is being indexed by the specification `[t = t-w.i]`; this indexing creates another possible world in which to evaluate `x`, in which the index `t` (which, perhaps, might be `x.i` or a part of `x.i`) has a different value from its value in the outer environment. The expression `t-w.i` is evaluated in that outer environment, taking the ambient value of `t` and subtracting the current value of `w.i` from it. The indexing expression hides the outer ambient value of `t` from `x`, replacing it with the fake value.

This implies that `t` and `w.i` are of some types such that it makes sense to subtract them; they are not, for example, merely categorical or ordinal. They could, however, be vectors of the same dimensionality, such as 2-vectors, in which case the same expression above serves for convolving images as well as time-series signals.

However, the fact that we're iterating over all the possible values of `w.i` means that it cannot be a *continuous* dimension, although its values could be values of a continuous type. It must be discrete so that it can have a finite number of possible values!

The same ambiguity about out-of-range values is present. If one of the `x[t = t-w.i]` values happens to not exist, for a given ambient value of `t`, does that mean the entire sum fails to exist, and thus `y` has no value at that point? Or does it merely mean we sum over a smaller number of values?

Karatsuba

Kragen Javier Sitaker, 2019-04-20 (2 minutes)

$(aX + b)(cX + d) = acX^2 + (ad + bc)X + bd$

Here X is some power of the base of your number system, and this is the conventional algorithm for multiple-precision multiplication. This divides the problem of multiplying two numbers "ab" and "cd" into the problem of multiplying four pairs of numbers, each half as long; so it's a sort of recursive divide-and-conquer algorithm which, in the end, takes $O(N^2)$ time: for 2^i digits, you do i levels of divide-and-conquer, producing 4^i bottom-level multiplications, which is just the square of the number of digits. These multiplications are then combined in a smaller number of shifted addition operations.

Karatsuba came up with a different way to do this, computing (a + b)(c + d) = ac + bc + ad + bd. This contains the ad + bc sum we need as a couple of subterms. If we compute ac and bd, we can subtract them off to get ad + bc.

For example, 93 × 24: ac = 9×2 = 18; bc = 3×4 = 12; (a + b)(c +d) = (9+3)(2+4) = 12 × 6 = 72; 72 - 18 - 12 = 42. So our final result is 1800 + 420 + 12 = 2232, which is correct.

This has the advantage that, although the operations per internal node are slightly more complicated, instead of 4^i bottom-level multiplications you have 3^i. So, for example, if you have a 1,048,576-digit number, you need 1,099,511,627,776 bottom-level multiplications with the conventional algorithm, but only 3,486,784,401 with Karatsuba's algorithm,

Commentaries on reading Engelbart's "Augmenting Human Intellect"

Kragen Javier Sitaker, 2018-12-24 (updated 2018-12-25) (25 minutes)

My commentaries on reading Engelbart's 1962 "Augmenting Human Intellect: A Conceptual Framework" for the first time, rather belatedly in 2018.

The date 1962 is rather crucial in understanding this work, because he talks a lot about computers, and computers were changing rapidly around this time. 1962 is the same year Sutherland (mentioned on p. 72) wrote Sketchpad, published in 1963, in which he invented graphical user interfaces, object-oriented programming, computer-aided design, and constraint-based programming, for example; and 1962 is the year IBM published their book on Project Stretch, edited by Werner Buchholz, which ran from 1954 to 1961. The first integrated circuits were fabricated around this time, the first real compilers were written in the years 1958–9, and the Lisp paper was published in 1959, based on an implementation on a vacuum-tube IBM computer. DEC had just been founded, and Spacewar! had just been written. The IBM 360 project, with its ambition to unify "business" and "scientific" computing on a single general-purpose computer, had not yet begun. Timesharing operating systems, like compilers, was an avant-garde technique — Stretch was designed for timesharing operating systems, but most computers did not use them, or indeed any operating system. Nowadays instead of "timesharing" we call it "multitasking".

(I am not sure when Expensive Typewriter, the first interactive word processor, was written.)

In short, this report was published immediately after the creation of the compiler, the high-level programming language ("problem-oriented language (e.g., ALGOL or COBOL)", p. 17), the computer game, the operating system, and multitasking ("what is known as 'time sharing'", p. 70), and immediately before the publication of the graphical user interface and object-oriented programming.

Moreover, this was three years after Sputnik, and airlines had just started flying jet airplanes ten years before, adding a new increment in human velocity to some 300 m/s (600 mph in archaic units), up from the 8 m/s that had reigned from the domestication of the horse until the introduction of the automobile seven decades earlier; supersonic jets were being flown by the military, but the Concorde wouldn't offer passenger supersonic service until 1976. In retrospect, the continuous, spectacular increase in human velocity Engelbart could look back on ended almost precisely in 1962, with the exception of a few dozen astronauts.

This was also the time period when full automation was being touted as an imminent end to work as such, before the difficulties of robotics were appreciated. Engelbart doesn't mention this directly, but his report is part of the same intellectual ferment that sprang up to

try to make sense of the possibilities of the new technologies.

Given this atmosphere of radical ferment, it's interesting that a significant part of Engelbart's paper (pp. 48–56) is dedicated to discussing "As We May Think", published in 1945, 17 years earlier; Engelbart quotes its description of the Memex in its entirety. I'm not sure when Engelbart came upon the paper (and I missed my opportunity to ask him) but that 17-year gap is notable. He cites Licklider's "Man-Computer Symbiosis", various list-processing things (including IPL-V and LISP 1.5, on pp. 65–66), and a couple of items in passing from Ross Ashby, but in nothing like the depth he dedicates to the Memex.

Engelbart's famous "Mother of all Demos" in 1968 was the result of six years of work at SRI attempting to realize the vision he set out in this 1962 report.

Are we augmented yet?

On p. 3, Engelbart explicitly cites the velocity progress I mention above as his antecedent:

> there is no particular reason not to expect gains in personal intellectual effectiveness from a concerted system-oriented approach that compare to those made in personal geographic mobility since horseback and sailboat days.

This leads me to ask, 56 years later, have we achieved those gains? Can I do intellectual things now that would have taken 150 people to do in 1962, or can I do things now in a day that would have taken me four to six months then?

In a few domains, I think I can. In purely calculational terms, I have balanced on my paunch a laptop capable of about a hundred billion multiplies per second; its RAM is 4 gibibytes with a memcpy speed of about 2 gigabytes per second (4 gigabytes/second or 32 gigabits/second unidirectional), and its SSD holds 100 gigabytes of data and can be read at 75 megabytes per second (600 megabits per second). Stretch's disk was 8 megabits per second, or 125 000 64-bit words per second, with a total size of 2 megawords (16 megabytes) and a seek time of 150 milliseconds (p. 20 of Buchholz), and it needed about 2.5 microseconds per instruction (p. 32 of Buchholz), some of which could be multiplies; its memory cycle time was 2.1 microseconds per 64-bit word (p. 17 of Buchholz), giving 32 megabits per second, with a maximum of 2^{18} words (1 mebibyte). Moreover, Stretch was shared by all of Los Alamos National Labs, which I think was several hundred people at the time, though perhaps only a few dozen of them had access to the computer.

(On pp. 66–67 Engelbart describes the capabilities of a typical computer of his day: 100,000 6-bit bytes of RAM costing 60¢–US$1.50 per byte, 2–10μs per machine instruction, with a megabyte-sized magnetic drum costing 5¢ per byte, or a hundred-megabyte-sized disk costing 0.14¢ per byte.)

So, roughly speaking, my laptop is 2.5 million times faster than Stretch at multiplying (and arithmetic in general), 1000 times faster than Stretch at accessing its RAM, of which it has 4096 times as much, and 75 times faster than Stretch at accessing bulk storage, of which it has 6000 times as much; and this computing power is distributed among about 1000 times fewer people.

As a consequence of this extreme arithmetic power, it can do things like real-time raytracing, software-defined radio, and speech

recognition. Mostly, however, this arithmetic is devoted to decompressing porn and other video. I don't have any speech-recognition software on here.

I *can* and occasionally do use it for tasks like 3-D design, and designing and testing signal-processing algorithms in IPython, and I have a library of many technical papers, including the Engelbart report I'm currently reading. Due largely to format incompatibilities, I don't have an easy way to search through the library for key words, although searching through an individual book takes only a few seconds. Quoting one document in another, as I did above, often requires manual retyping — evince's user interface sometimes doesn't respond to mouse drags, and it doesn't offer an interface to easily display an excerpt from a PDF or DjVu file, even though those file formats contain internal indices to permit random access.

I can easily prepare a document plotting a bunch of equations and simulations, complete with nicely-typeset equations, using IPython; TeX and HTML provide me with document-preparation capabilities Engelbart's whole team couldn't pull together in 1962, even leaving aside the ability to distribute the results immediately to the world.

I wrote a Tetris game a couple of days ago. It took me three or four hours, using the C programming language from the 1970s, slightly augmented with type-checking from the 1980s. Using a more modern programming language would have simplified it only slightly. It doesn't handle key-repeat in the way I would like, which is substantially more difficult due to decisions baked into the X11 protocol in the 1980s to make terminal emulators easier to write; fixing that will probably take several more hours.

When checking one of the assertions in Engelbart's report, I quickly calculated how many words you'd need in a lexicon for it to cover half of the words in a sample corpus (95, for the British National Corpus). This took me 4 minutes.

Wikipedia, Stack Exchange, arXiv, the Internet Archive, and other sites with books and academic papers are perhaps the things that most closely approximate Engelbart's vision of jet-like "gains in personal intellectual effectiveness", since there I can easily get information about a wide range of topics. Unfortunately, though, they can only provide answers to questions that someone else has already learned the answers to; they are immensely useful for describing known consequences, but they are not useful for working out the consequences of situations I just dreamed up.

Consequently, I do most of my noodling in the same way I would have 56 years ago, with typed notes and a pencil and paper, but with quicker access to the library of knowledge represented by Wikipedia and the like, and the easier revision Engelbart suggests on p. 13 (though Emacs is considerably more fluid than the OCR stylus he suggests, more like the text editing process he suggests on p. 16, pp. 77–80, and p. 84). I have instant access to the worldwide community of knowledge workers, but this is useless; they largely waste their time on trivialities and infighting.

Nothing approaching Engelbart's vision of the augmented architect has been realized, despite the extensive computerization of architectural drafting (p. 5):

> He checks to make sure that sun glare from the windows will not blind a driver on the roadway, and the "clerk" computes the information that one window will

reflect strongly onto the roadway between 6 and 6:30 on midsummer mornings. … Finally he has the "clerk" combine all of these sequences of activity to indicate spots where traffic is heavy in the building, or where congestion might occur, and to determine what the severest drain on the utilities is likely to be.

I conclude that, so far, Engelbart's unfinished revolution is still unfinished.

The failure of diffusion

Remarks on pp. 16–17 express Engelbart's forlorn hope that a centrally-planned research effort could "greatly accelerate" the evolutionary process of diffusion of innovations:

Normally the necessary equipment would enter the market slowly; changes from the expected would be small, people would change their ways of doing things a little at a time, and only gradually would their accumulated changes create markets for more radical versions of the equipment. Such an evolutionary process has been typical of the way our repertoire hierarchies have grown and formed.

But an active research effort, aimed at exploring and evaluating possible integrated changes throughout the repertoire hierarchy, could greatly accelerate this evolutionary process. The research effort could guide the product development of new artifacts toward taking long-range meaningful steps; simultaneously, competitively- minded individuals who would respond to demonstrated methods for achieving greater personal effectiveness would create a market for the more radical equipment innovations. The guided evolutionary process could be expected to be considerably more rapid than the traditional one.

Perhaps if he had studied the accumulating literature on, for example, diffusion of agricultural innovations in poor countries, he might have had a better plan. In retrospect, it took 20 years for even the beginnings of his innovations to be adopted even by office workers, and 40 years to be broadly adopted by society.

How did Engelbart conceive training would happen?

Engelbart put a lot of emphasis on the importance of "training", which is an important part of the process of diffusion of innovations, but he seems to have lacked an anthropological or ethnographic conception of how this training would come about; or at least he is silent on the topic.

It's interesting that Engelbart takes as his starting point "a man", that is to say, an individual, rather than an institution, grappling with problems. (The unexamined sexism in the terminology was *de rigueur* in formal contexts in the US in 1962.) To my mind, much of the underlying zeitgeist of the work is collectivist, in the sense that Engelbart imagines institutions supporting the individual ("pursuit by an enlightened society"); he speaks of "diplomats, executives, social scientists, life scientists, physical scientists, attorneys, designers," perhaps with the implicit presumption that the users of his system will be supported not only with a powerful computer system but also with secretaries, administrative staff, a purchasing department, and so on. His "H-LAM/T" framework (p. 9) cites the necessity of "training", but never discusses the social context of the training — is it provided to new employees by a company, individually undertaken by problem-solvers who want to get augmented, or required of the whole population by a government?

In the 1980s, when some of Engelbart's ideas finally gained broad adoption, training was precisely the point on which he remained

outside the mainstream, and which made his continuing research progressively less relevant to that mainstream; CHI or HCI (already purged of the implicit sexism of the term "man-machine interface" term, or "man-artifact interface" as on p. 20) began to take advantage of findings from cognitive science with an eye to market competitiveness, while Engelbart did not.

On training, pp. 9–10:

> [W]hile an untrained aborigine cannot drive a car through traffic, because he cannot leap the gap between his cultural background and the kind of world that contains cars and traffic, it is possible to move step by step through an organized training program that will enable him to drive effectively and safely.

Of course, part of this is that the first part of the report is purely descriptive; it is not prescribing courses of action so much as it is describing the human world as Engelbart sees it. On p. 30 he talks a bit more about the circumstances of training in the context of possible research programs:

> For instance, some research situations might have to disallow changes which require extensive retraining, or which require undignified behavior by the human. Other situations might admit changes requiring years of training, very expensive equipment, or the use of special drugs.

(In this context it is worth pointing out that the Tuskegee Experiment was still ongoing at the time, no such thing as an IRB existed, LSD was still legal, and the MKUltra research program was in full swing, although it wouldn't be revealed to the public until 1975.)

This is unfortunate in part because the advent of computer games showed that computers were capable of producing fairly extreme learning performance by setting up a sort of Skinner box. But Engelbart was writing too early, and on the wrong coast, to have observed Spacewar!, and in any case computer games didn't really have a significant number of players until the 1970s. Consequently his focus, in practical terms, was mostly on designing new artifacts (in his H-LAM/T breakdown) to perform work for humans, then training humans to use them, rather than on designing new forms of training.

The lack of emphasis on communication

As I said above, Engelbart's focus is primarily individualist, focusing on the individual in their efforts to solve problems, but implicitly collectivist; he treats communication and community as secondary to individual thought and action, e.g., p. 22:

> Humans made another great step forward when they learned to represent particular concepts in their minds with specific symbols. Here we temporarily disregard communicative speech and writing, and consider only the direct value to the *individual* of being able to do his [sic] heavy thinking by mentally manipulating symbols instead of the more unwieldly [sic] concepts which they represent.

In a sense, this is the same lacuna represented by the mysterious absence of discussion of the social context of training.

He says, "temporarily," but so far I have not encountered where he analyzes communication in such a way.

On pp. 90–91, he does mention the utility of rich hypertext structures with typed links for communication, and even talks a bit about pedagogy:

> Well, when you ever get handy at roaming over the type of symbol structure which we have been showing here, and you turn for this purpose to another

person's work that is structured in this way, you will find a terrific difference there in the ease of gaining comprehension as to what he has done and why he has done it, and of isolating what you want to use and making sure of the conditions under which you can use it. This is true even if you find his structure left in the condition in which he has been working on it--that is, with no special provisions for helping an outsider find his way around. But we have learned quite a few simple tricks… Some of these techniques are quite closely related to those used in automated-instruction programming--perhaps you know about 'teaching machines?'

The power of the unpredictable and of irrationality

Engelbart touts of unpredictable processes, claiming that the power to use them is one of the largest benefits of the computerized augmentation he proposes (p. 45):

When the course of action must respond to new comprehension, new insights and new intuitive flashes of possible explanations or solutions, it will not be an orderly process. Existing means of composing and working with symbol structures penalize disorderly processes very heavily, and it is part of the real promise in the automated H-LAM/T systems of tomorrow that the human can have the freedom and power of disorderly processes.

Simultaneously, though, he perceives the subconscious mind as mostly an enemy due to its irrationality:

Clinical psychology seems to provide clear evidence that a large proportion of a human's everyday activity is significantly mediated or basically prompted by unconscious mental processes that, although "natural" in a functional sense, are not rational. … It may be that the first stages of research on augmenting the human intellect will have to proceed without being able to do anything about **this problem** [emphasis mine] except accommodate it as well as possible.

On reasoning and argument structures

On p. 62 Engelbart is discussing the process of revising a research design:

…when several consideration statements bore upon a given product statement, and when that product statement came to be modified through some other consideration, it was not always easy to remember why it had been established as it had. Being able to fish out the other considerations linked to that statement would have helped considerably.

Modern automated software testing supplies this in a somewhat restricted form: if you change the code and some tests start failing, you can go back and read those tests to find out what other considerations led to the code behaving as it had; but of course not everything can be described in code yet. Proof assistants perform a similar task in a more rigorous fashion for mathematical proofs. Requirements-management systems like DOORS also attempt to do this for more general structures of non-machine-readable statements.

He goes into more detail about his proposed antecedent-consequent links on pp. 84–88.

Chording keysets and premature commitment

On pp. 74–79, Engelbart describes the chording keysets that his system used into the 1980s:

He could hit a great many combinations of keys on his keyset--i.e., any one stroke of his hand could depress a number of keys, which gave him over a thousand

unique single-stroke signals to the computer with either hand.

He was quite optimistic about the speed of this system, with a quite reasonable information-theoretic basis:

It seems that, for instance, the 150 most commonly used words in a natural language made up about half of any normal text in that language. Joe said that it was quite feasible to learn and use the single-stroke abbreviations for about half of the words he used, but beyond that each added percent began to require him to have too many abbreviations under his command. …

(As it turns out, the 95 most commonly used words, without lemmatization or even stemming, make up half of the text in the British National Corpus; the 150 most common words make up 54.43% — though this disregards the tail of words that occurred less than 5 times, which might indeed amount to the 9% of the total that would make his statement correct. Thanks to augmentation, I could calculate this in about four minutes by writing an 8-line Python script. Doing the same exercise on words extracted from an earlier draft of this note, I needed 179 words, drawn from the 223 most common words in the BNC, to reach 50% of the words in this note; some common words, such as "she", "her", and "know", did not appear. 6.3% of the total words in this note, such as "1968", "lemmmatization", and "keysets", don't appear in the BNC at all. Incidentally, the point in the curve at which a given word makes up 0.1% of the corpus — so it could conceivably be efficient to enter it with a 10-bit abbreviation code — is just about that 50th percentile (95 words) in the BNC; this note is too short to give good statistics at that level. This greater rigor brought the total to almost 40 minutes rather than 4.)

A whole word so abbreviated saved typing all the letters as well as the spaces at either side of the word, and a word-ending abbreviated by a single stroke saved typing the letters and the end-of-word space. He claimed that he could comfortably rattle off about 180 words a minute--faster than he could reasonably talk. … He made some brief references to statistical predictions that the computer could make regarding what you were going to type next, and that if you got reasonably skillful you could "steer through the extrapolated prediction field" as you entered your information…

In practice, though, the chording keysets constructed by his team didn't really reach above about 50 words per minute, according to anecdotes. Part of this may have been that they ended up using only one key per finger (the "over a thousand" quoted above suggests two bits per finger, e.g., four keys per finger or two keys per finger that can be concurrently depressed) but other parts may have been the lack of the extensive abbreviation dictionary described.

This leads one to ask: why didn't Engelbart give up on his own keyset design at some point and use a Stenotype keyboard? Stenotype operators regularly reach well over the 180 words per minute he was hoping for. Instead, he apparently continued to hope that the design he came up with in 1962, before doing any experiments, would eventually pan out. That was a terrible idea; it prevented him from taking advantage of the 20+ years of experience he gained in the meantime.

Similarly, the outliner structure of NLS and Augment already appears on p. 84.

Bike charger

Kragen Javier Sitaker, 2014-04-24 (2 minutes)

What would it take to recharge your laptop and other electronic devices by riding your bike? There are highly efficient and reliable dynohubs these days. You could mount a small lead-acid gel cell battery on your bike and charge it by riding.

A regular car or motorcyle battery holds in the tens of kJ up to MJ. The Wikipedia article for "Car battery" says 30–40 Wh/kg, around 100 kJ/kg. My netbook battery says:

```
$ acpi -i
Battery 0: design capacity 5246 mAh, last full capacity 4518 mAh = 86%
```

It's, I think, 11 volts at the moment, which means it had about 200 kJ when full. So you'd need about 2kg of lead-acid battery to hold a full recharge for it, plus some small, lightweight electronics like a buck-boost converter to supply the laptop with the 19 volts it wants for recharging.

Amazon has a £17 lead-acid battery with 10Ah at 12V, or 400kJ. At the moment £17 is US$27. (Typical prices seem a bit higher.) It weighs 3.3kg. If everything scaled linearly, a 200kJ lead-acid battery would weigh 1.7kg and cost US$14.

At a substantial cost in reliability, safety, and money, you could use the laptop battery directly. I think it weighs more like 500 g, but it costs more like US$100.

A bike dynamo hub like the Schmidt SON28 consumes some 2–6 W of mechanical power, and probably has efficiency in the 80%–99% range. Getting 200 kJ out of 4 W would require almost 14 hours of riding, which I think of as two to four days' worth.

A modular display strategy would be very useful: several cellphone-style displays would both be easier to protect against breakage and allow scaling power usage up and down as needed.

Karplus–Strong PLLs

Kragen Javier Sitaker, 2017-06-09 (1 minute)

A PLL is great for tracking the frequency of a sine wave. But lots of sounds we want to track the pitch of aren't sine waves; they have substantial energy in their harmonics. The usual chopper PLL approach detects phase by multiplying the input signal with a square wave, thus convolving its spectrum with a spectrum containing significant third and fifth harmonics, but no even harmonics, then low-pass filters the result to try to separate out the dc component.

As a possible alternative for software PLLs, maybe you could try using the Karplus-Strong string model for your phase detection, using two delay lines that differ in length by one sample.

Forth with named stacks

Kragen Javier Sitaker, 2014-02-24 (7 minutes)

Something occurred to me on the way back. I was thinking about the lack of good notation for state machines, as opposed to pure functions; we don't have anything equivalent to Haskell for state machines, unless you count Haskell itself. But when you're using the state monad in Haskell to write state machines, lots of stuff goes away: you can no longer reasonably write it in point-free style, for example. I think.

The closest we have is Forth, which lets you write state machines in point-free style, but only up to a certain point: once you have more than two or three live values, you start to get confused about stack depth and stuff.

It reminded me of a thing I saw someone (Jeff Fox?) say a few years back about how stacks and registers are sort of duals at the level of CPU design: a stack lets you retrieve each value only once, but store many values, while a register lets you retrieve each value many times, but store only one value at a time. And it occurred to me that a way out of this is to make variables in Forth work a different way: rather than simply pushing a memory address onto the stack, instead each variable could name a separate stack out of a potentially infinite variety of stacks, and uttering its name could switch future evaluation onto that stack (until future notice). You'd need @ and ! to store and fetch values from some special magic place that wasn't on a stack: a register. But you could still say N @ M ! to move a value from N to M.

A couple of things that occurred to me about this notion:

• /=, +=, *=, etc., are the fundamental operations in a sense. N 3 + is sort of the equivalent of n += 3; from C.
• You get named local variables for free (naïvely, with shallow binding) as long as you're careful to store into them before you fetch.
• The return stack stops being special; it's just another variable.
• PICK replaces array indexing, as long as you don't mind indexing from the end of your array. That is, all of your variables are, in a way, aggregates (APL-style), although this competes with them being automatically local.

It occurred to me that this could maybe give you a notation for writing state machines with variables that was similar to RPN for pure math or regexps for state machines without variables.

[Some text in this note is from me typing messages to someone who could see my screen, and who I could hear, but who could not hear me. That's why it sounds like half of a conversation; it is. I may come back and edit this out at some point.]

Maybe interesting?

How about the "largest prime factor"? That's sort of cheating, maybe, since I was thinking about it...

So let's see. You have a sequence of letters, which we could push onto a stack as the argument; call it INPUT; then we want to switch between consuming whitespace and non-whitespace, incrementing a counter each time?

I guess arguments should be like a default named stack? Call it <>. What's not needed?

What does that look like if you want to, say, increment n?

OK, so some of the things on the argument stack should be arguments to the function and others should be other stacks?

You mean, put the state variable on the same stack as the input?

Do you want to type that out? Because I don't understand still.

So you use @ and ! to pop and push from the other stacks? Then you have something almost exactly like Forth with shallow-bound local variables and the need to dup values on the stack instead of in variables, which could be interesting; let's see if that's fruitful in a bit.

Hmm, { } from StoneKnifeForth is probably the wrong way to go, because most loops are better as while loops rather than do-while loops. So I think Knuth's/Forth's BEGIN/WHILE/REPEAT is better; but I want to spell it { | }.

```
: wc-w
  n 0                           \ initialize counter to 0
  { <> empty? ~ |
    <> { dup isblank? | pop }      \ drop characters until we find a blank
    n 1+                          \ here we switch to the n stack
    <> { dup isblank? ~ | pop }    \ again, but until we find a nonblank
  }
  n @ <> ! ;                      \ return n

: isblank? dup bl = [ pop #t exit ]     \ [ ] are IF THEN, with no ELSE.
           dup \n = [ pop #t exit ]
           dup \t = [ pop #t exit ]
           pop #f ;
```

<> switches to the <> stack. dup dups on the current stack, whatever it is, and immediately after executing <> it is the argument stack.

It does seem kind of promising, no? Somewhere I guess we have to declare n. Oh, and it's buggy because it always underflows the stack in the inner loops.

Reformatted horizontally:

```
: wc-w  n 0  { <> empty? ~ | <> { dup isblank? | pop }  n 1+
                            <> { dup isblank? ~ | pop } }
  n @ <> ! ;
```

Suppose my text is in memory instead of on the stack? It seems like we need a lot of dups in this notation, so I'm going to use "," for dup. This is looking suddenly a lot harder... how do I transliterate `while (n && isblank(*t)) t++, n--;`?

`n , [ ... ]`, so far so good; if we press into service | for "else" as well as "while", then we can end up with `n , [ ... | 0 ]`. But then what are you doing inside? You want to

That seems very promising! It could even be a deterministic regexp, perhaps, so that you don't have to handle backtracking.

Backtracking is tricky in the presence of add1.

Python itertools and family (not to mention Unix shell) show that you can do quite a lot by plugging together state machines that

generate and consume sequences.

```
: wc-w  @ t !  <> @ n !  words 0
  { n , | { n , [ t , c@ isblank? | t ++  n -- }
```

Should exiting from a loop or conditional restore you to whatever stack you were working on when you entered it?

What does this look like in Real Forth? Is it simpler?

Programming paradigms for tiny microcontrollers

Kragen Javier Sitaker, 2007 to 2009 (6 minutes)

Concurrent actors in a microcontroller

Suppose you have a microcontroller with a small RAM (say, 2kiB) and you want to run bigger actor-oriented programs. Perhaps you can "page" the actors in and out to an external serial memory?

What I have in mind is that you can have many messages in flight at the same time --- enqueued in the RAM --- and some subset of actors resident. Whenever an actor sends a message to another actor, the message is enqueued, and the execution engine merely repeatedly searches for a message to deliver to a resident actor. When there are no more such messages, it "pages out" some actors to the serial memory to make space to "page in" some other actor that has messages waiting for it.

It's possible for the set of in-flight messages to get too big for RAM. There are a couple of tactics we could use in this case.

First, we could simply page out a chunk of the message queue to the serial memory. This will universally work, but it might make it hard to figure out what actors would be good choices to page in later.

Second, we could look for message deliveries that will diminish the number of in-flight messages instead of increasing it. In the classical Actors model and in Erlang, each handling of a message returns a new state for the actor, rather than mutating the actor's state during the handling of the message; if the system implemented this, then any message delivery could simply be undone by returning the message to the queue, deleting whatever outgoing messages the execution produced, and keeping the old actor state instead of using the new one. So the system could simply try each pending message, one after another, until it finds one that reduces the number of in-flight messages.

Third, we could page out actors to make more room for the message queue.

Of these three, the first strategy is apparently mandatory; the other two might be useful optimizations.

2kiB of RAM is enough to hold 1024 16-bit quantities; if a typical message contains four of these (destination actor, message name, and two arguments) then we could handle a queue of 256 messages at once. If half the RAM is dedicated to actor storage, we could handle 128. This is the level of concurrency at which the system would be most efficient; having fewer concurrently in-flight messages would worsen the choices of which actors to page in next, and possibly reduce the amount of work a particular actor could do before getting paged back out, while having more would not improve that choice, but would require time to be spent paging messages in and out.

When considering the size of each actor on its way to or from memory, it's important to remember that we have to include its code as well as its data. The data might be only 2-10 words, but the code will probably be much larger. So it's probably worthwhile to take this

into account in decisions of which actors to page in and out, and to share the code between objects when possible, just as in a traditional in-memory object system without concurrency.

There are several drawbacks to this scheme:

- the space usage of the message queue is inherently nondeterministic --- it depends deeply on the task switcher's choice of the order to run tasks in.
- the cost to "page" actors in and out may be excessive, especially since most microcontrollers don't have any support for DMA for access to external serial memories. The actors will have to be contain very much less code than the objects we are familiar with from current OO systems.

Concurrent tree-space transformation in a microcontroller

Suppose instead that we run Aardappel in the microcontroller. In place of in-flight messages, we have the trees of the tree space, which of course we page out to memory; in place of stateful actors, we have stateless rewrite rules, which rewrite one or more trees into zero or more trees. (Approximately.) In the Aardappel implementation, all the rewrite rules for a particular "type" of tree get collected by the compiler and compiled into a single function, where the "type" is the atom at the beginning of the expression for the tree.

So for a relatively simple system, we repeat the following process:

- figure out which type of tree is most abundant in the tree space;
- "page" in all the code needed for rewriting that type of tree (unless it's already paged in);
- rewrite all the trees of that type, paging them in as necessary, except for those that aren't currently rewritable (because some other tree is needed).

(This needs some refinement in case all the trees of the most common type aren't currently rewritable.)

I'm not sure this is really very different from the other proposal, but I think it is likely to work better for the following reasons:

- the code to rewrite a type of tree in Aardappel is likely to be substantially smaller than the code for a class in a Smalltalk-like language;
- all the state is in a single kind of thing, rather than being spread between messages and actor states;
- it seems straightforward in the source language to separate out rewrite paths that increase the number of trees from those that leave them constant or decrease them.

Building a resilient network out of litter

Kragen Javier Sitaker, 2014-04-24 (4 minutes)

Buenos Aires is about 300 km from Rosario. There's a train that runs twice a day, taking seven hours. The Flutter embedded wireless device, due to ship in 2014 for US$20 with a few kilobits per second and about a 1km radius of communication, could conceivably be thrown out the window of the train at regular intervals to provide a low-bandwidth, low-power communications relay line between the two cities; you would need perhaps 500 of the devices, for a total cost of US$10 000. This sounds like a lot of money but actually I think it's orders of magnitude cheaper than running a conventional communication line over such a distance; and it ought to decrease by another factor of two or three in the near future.

The remaining problems, then, would be to power the devices and to protect them from sabotage.

First, power. Nonrechargeable batteries will only last a year or two, maybe less in the sun. Small nickel-cadmium or nickel-metal-hydride cells might last five or ten years; but the problem remains to harvest sufficient power from the environment to supply the communication line. The device might use 2W in operation, so 2mW of photovoltaic power per device, with adequately efficient power harvesting, might be sufficient.

Second, protection. It's probably not practical to harden 500 such devices to make them impractical to break, but you could probably make them hard to find by concealing them inside of pieces of garbage. This also suggests a way to deploy them from the train without arousing suspicion: every 50 seconds, on average, one member of the planting team throws a piece of garbage (say, a food package) containing a wireless transceiver out the window. The train ticket costs US$2.50, so you could buy 4000 trips (2000 round trips) for the cost of the needed devices; so one person could do this in a practical fashion over some 50 to 100 trips, so two or three months. Ten people could do it in five or ten trips each.

You still need to prevent the devices from being detected by their radio emissions and destroyed, which is difficult if they're basically stationary. The best defense against this, other than spread-spectrum and using legal frequencies (the Flutter devices use a 915MHz frequency that's legal for unlicensed use in the US only) is very low duty cycle and very long periods of time between transmissions — days to weeks. This suggests that all the devices should wake up their receivers periodically at a synchronized time to see if they're being activated, say a few times a day, but not transmit anything unless a circuit is opened.

(Alternatively you could use store-and-forward transmission, but this would result in message latency of months.)

The desire to support solar power, combined with the desire to look like garbage, poses the problem of how to have solar cells that are not exposed to sunlight. This seems impossible, but keep in mind that we only need about 2mW. At the 5% efficiency typical of cheap

thin-film cells used for solar calculators and the like, this is 1 cm^2; it could be 4 or 5 cm^2 that's not directly exposed to sun, for example behind a layer of paper.

A perhaps more useful project would connect an off-the-grid location rather than a major city, and could be deployed by bicycle rather than train. There are locations in the Tigre delta, for example, that have electrical power but no broadband internet access.

Hacking a buck converter into a class-D amplifier?

Kragen Javier Sitaker, 2018-06-30 (4 minutes)

I was thinking about this 5V-output buck converter I dumpster-dived. A plausible-looking datasheet says the input is 8–48 volts and the output is 5V at up to 2.1 amps. It has a feedback pin which it uses to adjust the duty cycle of the 150kHz PWM signal it uses to generate the output; you're supposed to hook that up to the output side of the inductor so it can regulate the output voltage properly.

It occurred to me that this sort of implies that if, instead of hooking up the feedback pin directly to the output side, you hook it up to the output side through a voltage divider to ground, you should be able to get it to act as a 6V or 8V or 10V regulated power supply instead of a 5V one. Maybe it won't compensate for load changes quite as quickly, but I don't think it should oscillate.

But what if, instead of using a voltage divider to ground, you use a voltage divider to a *variable* reference voltage? Maybe you could make a high-power class D audio amplifier! Say you use a high-impedance 4:1 divider, so that a 1-V shift in the "reference" voltage (really the input) requires a 4-V shift in the output in the opposite direction to compensate. It'll be superimposed on a 20VDC level that you probably want to block with a capacitor, but 4 volts RMS across 8Ω should give you 500 mA RMS, which is 2 watts, which is pretty loud. Filtering out the 150kHz (and harmonics) carrier should be pretty easy.

Also, you might be able to use this as an AM radio transmitter. AM radio is in the range 540 kHz to 1610 kHz, so there ought to be some harmonics of the 150kHz PWM signal in there (at least the fourth through ninth or so), and their power ought to vary with its duty cycle. Some experiments reveal that the second harmonic of a PWM wave is zero at 0% power, 50% power, or 100% power (which is the same as 0%), but maximum at 25% power; the third harmonic is zero at 0% and I guess 33⅓% and 66⅔%; the fourth harmonic is zero at the same places as the second harmonic and also at 25% and 50% power; the fifth harmonic at multiples of 20%; and so on. So lower harmonics should modulate more reliably. If you're trying to modulate the fourth harmonic, you'd probably want to use a duty cycle on the steepest part of this slope, like in between the maximum at 12½% and the minimum at 25%, around 18.75%, which means you want to regulate the nominal output voltage to be around 18.75% of the input voltage, and vary that percentage according to the signal you're trying to modulate. Then you "just" need to filter out the other harmonics (a bit tricky since the actual frequency could be anywhere from 125kHz to 175kHz, so the desired fourth harmonic could in theory be anywhere from 500kHz to 700kHz, while the undesired fifth harmonic could be anywhere from 700kHz to 875kHz), hook it up to an antenna, and tune a radio to it.

The thing isn't designed for an output duty cycle of over 62½% (⅝), but maybe using the region between the maximum at 37½% and

the minimum at 50%, like around 43.75%. For its nominal 5V output, this would mean an input voltage of around 11.43 volts, which is more manageable than the input voltage needed to get 18.75%.

Topics

Clay fabrication objectives

Kragen Javier Sitaker, 2017-01-16 (updated 2017-01-17) (3 minutes)

I'm doing some stuff in the ceramics lab, with the objective being to construct a self-replicating micromachine. I have four key objectives to achieve this:

• Full recursion: do the entire fabrication process, from separation to firing and assembly, using entirely components that can be fabricated with that process. Alternatively, if this objective is misguided (perhaps using metals, glasses, plaster, or plastics would be more reasonable), I want to discover that.
• Material properties characterization, simulation, and optimization: I want to have quantitative measurements of the main physical properties of the material in both green and fired states. In particular:

• Tensile strength and modulus.
• Shear strength and modulus.
• Density.
• Thermal expansion.
• Separately, fracture resistance, even though that can in theory be predicted from the other properties.
• Abrasion resistance.
• Dependences of these on relevant process parameters.
• Heat resistance (e.g. maximum service temperature, softening point if any, sintering point, melting point, perhaps variation of other properties with temperature below the softening point).
• Creep, plastic deformation, and related complications; although I expect these will be very low for fired clay ware, plastic deformation is an enormously important process for shaping wet clay, which can have almost zero elastic deformation and creep but enormous plastic elongation.

Given an adequate numerical characterization of the materials' properties, simulation of its behavior under different circumstances should become possible; by running a series of such simulations with different designs and performing error and differentiation analyses on the simulations, a substantial degree of automation in design should become possible. If the simulation performs adequately, it should be possible to run such optimization processes during the fabrication process in order to automatically improvise responses to newly available information.

With the first two of these items, I can do FEA analyses and optimizations for static loading; with the third, I can do dynamic loading as well. The others are useful for particular cases.
• Generation-time reduction by process intensification: I predict that the primary figure of quality for self-replicating machinery will be its mass growth rate, which needs to exceed the IRR of available investments in order to be economic, and which is an exponential function of the generation time.
• Miniaturization: somewhat secondary to the above three considerations, smaller is better. This is largely a means to an end: thinner walls will dry faster and fire faster (up to a point), linearly

smaller machinery will have a proportionally shorter generation time, and the demands its mass places on its mechanical properties will be proportionally smaller, both permitting more geometrical freedom and simplifying calculations. Miniaturization also helps with safety and cost of materials and energy. However, miniaturization has limits: it requires more precise manipulation and measurement, surface effects like stiction and sliding wear become more serious concerns, and in particular thermal processes like firing pottery become more difficult to complete at smaller scales.

Topics

The Dontmove archival virtual machine

Kragen Javier Sitaker, 2014-06-29 (5 minutes)

(In this version of the dontmove archival virtual machine, Aa input and output a byte, Bb read the subtractor or subtract a number from it, Cc read and write the word in memory in the Dd register, and Ee read and write the program counter, the last of which leaves a return address in the accumulator. Somewhere I had a sort of "signum" register but I forget where it is.)

I was thinking about how to do an assembler for dontmove, and I think that the right thing to do is probably really a simple Forth compiler, one that pastes together chunks of code with known stack effects. If we put the top of stack in Y, the down-counting stack pointer in X, the down-counting return stack pointer in W, and the return address (top of return stack) in V, assume Z is zero, and use U as a scratch register, then DUP is "BbXbBbbZ1bBdxYc", for example, and DROP is "BbZ1bBbbBuXdbBbbUbBxCy" or "BbXdbZ1bBbbBxCy". Function calls are similarly obnoxious; the actual function call itself is simply something like "Z1234e", where 1234 is the address of the function; and function entry is simply "v", and function exit is simply "Ve"; but before the call it is necessary to save V onto W, which is "WdVc", and decrement W, which is the painful "ZbWbBbbZ1bBw"; and after the return, restoring the previous V from W is also necessary. (Perhaps leaf functions could avoid that, and in other functions it could be moved into the prologue and epilogue.)

(Note, there's lots of confusion in the code both above and below about whether the pointers point to the last item pushed or the space for the next one.)

If we had a way to simply set the contents of the subtractor, say "f", rather than subtracting from it, then these would simplify substantially, replacing lots of cases of "Bb...bBbb" with "...f". Also let's suppose we have a premade -1 in, say, T, which we can set up at some point with "Zf1bBt".

- DUP: "BbXbBbbZ1bBdxYc" -> "XfZ1bBdxYc"
- DROP: "BbZ1bBbbBuXdbBbbUbBxCy" -> "XfdTbBxCy"
- save V onto W and decrement W: "WdVcZbWbBbbZ1bBw" -> "WdfZ1bBwVc"
- restoring V from incremented W: "WfTbBwdCv"

(On second thought, it might make more sense not to keep top-of-return-stack in a register; then non-leaf function entry is something like "vWdfVcZ1bBw" and non-leaf function exit is "WfTbBwdCe", needing no scratch register. Without "f", non-leaf entry is, for example, "vBbWdbBbbVcZ1bBw". Leaf entry and exit can still be "v" and "Ve".)

At some point you might get to questioning whether it's worth maybe having increment and decrement instructions, distinct modes for reading memory (add to accumulator, subtract from accumulator, XOR with accumulator) but it doesn't take much to get to an abstract

machine that's more complicated than a GreenArrays core.

Forth "@" (memory fetch) is then "YdCy". Store "!" is complicated by needing to pop the stack twice: "XfdTbBxCsYdScXfdCyTbBx", or something like that. SWAP is easier due to the lack of arithmetic: "YuXdCyUd". OVER, which pushes onto the stack, is something like "XfdCuZ1bBxdYcUy".

If we had an increment instruction "+" that would increment the accumulator instead of having "f", then store would become "XdCsYdScX+d+xCy". DUP, DROP, and function entry and exit would similarly benefit from increment and decrement: "X-dxYc", "Xd+xCy", "vW-dwVc", and "Wd+Ce" respectively. This + and - completely eliminate the need for "f" for these basic operations.

Forth "+" then would be "BbYbX-dxCbBbbBy" and Forth "-" is "BbX-dxCbBbbYbBy".

Bitwise AND is going to be a real bear, involving a loop that shifts bits to the left by adding a number to itself (something like "BbYbbBbb") and then somehow getting the most significant bit.

This implies that we can probably do orders of magnitude better by adding a NAND operation. Say it was Gg, behaving like Bb: g NANDs the input with what's already there, and you can read the result with G. Now "Gg" NANDs the current result with itself, bitwise inverting it, and "Zg" NANDs the current result with 0, setting it to all-1, which also means that it will bit-invert the next thing we "g" into it. Then we can AND registers Y and U with "ZgYgGgUgGgG": first putting the bit-inversion of Y into G, then inverting that with Gg, then NANDing U with Ug, inverting the result with anothe Gg, and then getting it with G. Similarly OR of U and Y becomes "ZgUgGuZgYgUgG", I think.

The more I think about this, the more I wonder if something like Calculus Vaporis is a better design.

Designing a drawing editor for well-factored drawings

Kragen Javier Sitaker, 2019-05-07 (9 minutes)

As described in Dercuano drawings (p. 64), I want to add illustrations to Dercuano. These include things like sketches of screen layouts, box-and-arrow diagrams for things like data flows, cutaways of mechanical devices, pictures of three-dimensional solids to refer to in the text, plots of physical properties, decorative orders, timelines, diagrams of records in memory, and so on. But I want the illustrations not to be extremely large files, so as to keep Dercuano easily downloadable.

In Some musings on applying Fitts's Law to user interface design and data compression (p. 1164), I've talked a bit (perhaps to the point of beating a dead horse) about achieving this kind of efficiency at the primitive level: freehand drawings are going to involve a lot of coordinates of points, lines, and curves, placed individually with a stylus, mouse, or finger, and continuously displaced until they look right. And it's probably beneficial both to the quality of the drawing and to the download size to include intentional, considered placements and exclude random measurement noise.

But the primitive level is just one aspect of a visual language, albeit the only one that is accessible to purely freehand drawings, which have much to recommend them. And on top of this, we can layer things like blur and sharpen filters, or cutting and bending existing primitives, or using them as reference points for more primitives. However, it's also often useful to make drawings by combining existing drawings, rather than starting entirely from scratch. The simplest way of doing this is just putting one drawing next to another in a larger drawing, and a better way of doing merely this was sufficient for Gutenberg to revolutionize the world. But several other means of combination are possible!

In particular, let's talk about curves ("polylines") and how they can be combined.

Curves have many attributes

A curve on the page has a shape, by which we mean that each point along the curve has a position, an orientation, and a curvature. If we remember which direction the curve was drawn, it has a direction, which is the orientation plus one more bit of data. If we remember the speed with which the curve was drawn, each point also has a time and a speed. These are the intrinsic data of the curve; it also has a variety of presentation attributes or aesthetics, typically including fill color, stroke color, z-order, and stroke thickness, which we can change without changing (in the view we adopt here) the curve itself.

Most of these aesthetics can also vary continuously along the length of the curve, just like its curvature and position. Letterform curve thicknesses typically vary according to the local orientation of the stroke, and we could imagine applying such a relationship to a curve or many curves, perhaps interactively adjusting anchors on an auxiliary X–Y function curve like the luminance curves in the

GIMP. Or we could adjust the curve thickness as a function of time, or of the distance from the start of the curve, or, if we make it a function of speed, orientation, and direction, we can perhaps achieve a quill-pen calligraphic effect.

A curve can be approximated by a series of directed line segments, each of which is associated with a local frame of reference, one which distorts (perhaps via perspective) to follow the curve. These distorted frames of reference, if used to transform the unit square, will produce a sequence of trapezoids that approximate the curve with unit thickness. But the frames of reference can be orthogonalized, normalized, and even derotated, so that they become nothing more than a sequence of translations to the midpoints of line segments along the curve; or only some subset of these neutering operations can be applied. The line segments themselves can be placed according to fixed length, fixed time, fixed maximum angle, fixed approximation error, or some other criterion. By using fixed-length segments and using them to transform a tileable graphic segment, we can transform the curve into a rope, a braid, a dotted line, a (rather poor) dashed line, or a curly border.

Given two curves, we can produce a variable number of additional curves interpolating between them (both in intrinsics and in aesthetics), or extrapolating beyond them. Moreover, we can adjust the interpolation; the interpolated curves can be anchored along some other curve, at the midpoints of the approximating segments described earlier, and further auxiliary curves can adjust the nature of the interpolation.

Interpolating an array of lines along a line gives you a fence, a brick wall, or half of a grille. Interpolating an array of lines along a curve can give you a ribbon, a suspension bridge, or a sunburst. Etc.

From a curve with speed you can extract a "normalized" curve that has lost its speed information, making it equivalent to the distance along the curve.

Any of these nonscalar attributes, intrinsic or aesthetic, can be pseudorandomized by adding deterministic noise, which can have varying frequencies and amplitudes.

By making these attributes potentially time-dependent, we have animations.

Stroking a curve produces another curve, one we typically fill with black; but we can use it to clip a texture in order to get many other kinds of curves.

The ends of open curves are special; we can mark them with arrowheads.

Reducing abstraction overhead

A stencil that is merely copied wholesale into another drawing is already useful, and turning a drawing into such a stencil is conceptually trivial. Nothing about the drawing need be explicitly abstracted, and it is then subject to whatever manipulations are available in its destination environment, which may include things like rotation, scaling, clipping, colorspace transformation, convolution, alpha-blending, skewing, and cutting into pieces. (An image that has already been made so concrete that it consists only of pixels may not rotate as well, though, and one that has been merged with a transparent background may need some extra flying-matte

work to re-abstract it to use in a new situation.)

But often these leave something to be desired. Scaling can change stroke widths, for example, and sometimes the original stroke width is desired; in other cases, bringing in stroke widths and colors from the new environment is necessary to get it to "look right". And you may want to change the text, adjust a rectangle to meet up with another graphic element, and so on.

However, often the biggest issue is that it's just very fiddly to convert a concrete graphical object into something that can be reused. The overhead of "abstraction", even when no detail is actually being removed, eliminates the majority of opportunities in mainstream programs.

Enabling individual drawn strokes in a drawing to be used as "stencils" in context, providing immediate feedback as they are edited, and making the combining facilities more flexible may help with this problem.

Constraint drawing and optimization

Sutherland's SKETCHPAD, SolidWorks, SolveSpace, and FreeCAD are four well-known constraint-drawing systems; their drawings contain graphic objects whose concrete parts are held in relation to one another by non-unidirectional constraints. (See Relational modeling (p. 1102) for some more thoughts about this, generalized beyond purely graphical applications.)

Constraint-based drawing has a potentially very flexible interface for combining drawings, even if only points can be constrained to be equal (this can enable one object to fit with another).

SKETCHPAD solved its constraints iteratively by a sort of optimization approach. It's common for drawings to have some kind of desiderata they would like to optimize — it's best if arrows don't pass through boxes in box-and-arrow diagrams, for example, or kink too much or cross each other at shallow angles, but any of these can be acceptable.

Particle systems

A seed leaps along a trajectory, curving under gravity, depositing branch segments behind it until it flames out; periodically a leaf sprouts. Your mouse draws an arch, from which explode a thousand sparks, each of which seeks a consistent distance from its neighbors before sprouting a tapered, curved eyebrow hair. Randomly sprayed points sprout into randomly rotated copies of a mother sand-grain polygon, each with its vertices perturbed slightly differently, and they repel until all their surfaces are a minimal distance apart. One by one, slightly inconsistently sized bubbles appear at the nearest bubble boundary at a source, and bubbles shift and move until every bubble is in equilibrium.

How can these systems, so seemingly simple to describe, be simple to create, debug, and tweak interactively? Does the temporal description help or hinder?

Filling hollow FDM things with other materials

Kragen Javier Sitaker, 2016-09-07 (5 minutes)

You can improve some characteristics of 3-D printed FDM things by filling them with other stuff.

"Filling" with plastics usually means mixing the plastic with "filler", originally just some random solid material that was cheaper than the plastic (thus the name), but often these days something that imparts other superior properties to the plastic: higher strength and lower gas permeability in the case of bentonite clay; higher strength and density, plus reflectiveness in the case of steel or aluminum (aluminum-filled nylon is what Shapeways calls "alumide"); color; conductivity, when graphite, silver, or gold is the filler; thermal conductivity, using e.g. iron oxide; surface texture, as when sawdust is used as a 30% filler in PLA filament for 3-D printing to produce "printable wood"; and so on.

That's not what I'm talking about. I'm talking about using FDM to print a hollow shape, and then filling the hollow spaces with some other material, in order to provide different properties to the resulting object. In some cases, you might want to actually remove the FDM plastic entirely afterwards, sort of like lost-wax casting, but without the intermediate step of making the negative mold around your wax positive.

What kinds of properties might you want to get?

Mass

Mass is a big one. FDM is capable of producing impressively light and thin objects, but it's a very slow process for massive objects. And for many applications, "light and thin" equals "cheap-feeling and fragile". So simply filling a cavity with a cheap, heavy material can make a big difference.

Here are some materials you could reasonably use for adding mass:

	g/cc	max temp	
paraffin wax	.9	46°-68°	<https://en.wikipedia.org/wiki/Paraffin_wax>
water	1	0°	
sugar syrup	1-1.6	0°-186°	<https://en.wikipedia.org/wiki/Sugar>

| whitewash/chalk/calcite | 2.7 | 600˚ | <https://en.wikipedia.org/wiki/Calcium_carbonate> |

| aluminum | 2.7 | 660˚ | <https://en.wikipedia.org/wiki/Aluminum#Physical> <https://en.wikipedia.org/wiki/Solder> |

| magnetite | 5.2 | | <https://en.wikipedia.org/wiki/Magnetite> |

| steel | 8 | | <https://en.wikipedia.org/wiki/Steel#Material_properties> |

| 37% tin, 63% lead solder | 9.8 | 183˚ | <https://en.wikipedia.org/wiki/Solder> <http://www.metallurgy.nist.gov/solder/NIST_LeadfreeSolder_v4.pdf> |

| lead | 11.3 | 327˚ | <https://en.wikipedia.org/wiki/Solder> <http://www.metallurgy.nist.gov/solder/NIST_LeadfreeSolder_v4.pdf> |

| glass powder | 1.7 | 850° (Ts) | <http://www.expertsystemsolutions.com/biblio/HSM/sintering%20behavior%20of%20glassceramic%20frits.pdf> |

The cheapest filler material is water, but it also has the lowest density of any solid here. All the others listed here are currently pretty easy to buy in kilogram quantities, a criterion which excludes otherwise interesting materials like cyanoacrylate, gallium, Wood's metal, gelatin, and albumen.

Salt, gypsum, concrete, and whitewash have the property that you can convert a powder into a solid mass at room temperature by adding water and, in the case of whitewash, carbon dioxide. Paraffin is similar in this, in that you can divide it into grains and then sinter them, but it also melts at a low enough temperature that you may be able to pour it into an FDM-printed mold, possibly carrying other filler materials with it. (Sugar can also be extruded directly, as Jordan Miller has done: http://www.thingiverse.com/thing:26343/#instructions.)

Epoxy resins and silicone caulks, similarly, will harden at more or less room temperature, starting in a liquid state.

Flexibility

Silicone is flexible and high-temperature tolerant.

Removing FDM plastic

You should be able to melt PLA or ABS off of silicone once it's hardened; also of concrete, salt, plaster, chalk, or metals. You can also dissolve ABS with acetone or PLA with a mixture of alcohol (ideally propanol, although I've heard ethanol or even water works too) and sodium hydroxide. Weld-On #5 solvent also works to dissolve PLA, but it's nasty, nasty shit, made of methylene chloride, glacial acetic acid, and methyl methacrylate monomer. Miller-Stephenson MS-111 stripping agent can also dissolve PLA, and also epoxy (!!) https://groups.google.com/forum/#!topic/ultimaker/8s1bq_9LsRM. http://www.vinland.com/blog/?p=68. MS-111 is 50% methylene chloride, 20% phenol, 15% formic acid and will blister your skin.

Dichloroethane can supposedly also dissolve PLA.

Acetone, MEK, tetrahydrofuran, and TCE will plasticize PLA but not dissolve it. I think all three of them will dissolve ABS, and MEK and TCE may be more available here in Argentina than acetone.

Ethyl acetate can vapor-polish PLA, which suggests it can dissolve it: http://www.printedsolid.com/smoothpla/

My attempts to polish PLA with ethyl acetate, or dissolve it in a test tube, were unsuccessful.

Terrestrial lithium supplies provide adequate energy storage to reach Kardashev Type 1

Kragen Javier Sitaker, 2019-07-25 (6 minutes)

While the amount of solar energy available is far greater than world marketed energy consumption, by about four orders of magnitude, solar energy mostly only arrives during the day, and sometimes even during the day most of it is blocked by clouds, while existing marketed energy is generally available 24 hours per day. The impending transition to a photovoltaic-solar-energy-based economy therefore has many of the humans worried about the "intermittency problem" or the "storage problem".

Intermittent usage, or demand response

Probably the most important result of the intermittency problem is that the humans will use energy intermittently.

In some cases this is relatively straightforward and already practiced — for example, it's common for large air-conditioning systems on commercial properties to run their chillers during the night, when electrical energy is cheap, to store up ice, and then use the melting ice during the day to chill a coolant which is circulated to chill air, and electric car owners often have a lot of latitude about when they charge up.

In other cases, it's a matter of moving demand geographically — perhaps a Google Search query needs to be done in a data center close to the requester, but a large finite-element simulation can be done in whichever data center the computation is cheapest. And in some cases long-distance power transmission can bridge a storm cloud.

In other cases, idling machinery at night is expensive because of the mere depreciation of the machinery, and it might be worth paying higher energy costs.

In still other cases, like life-support machinery and alarm systems, it's worth paying even extremely high energy costs to guarantee uninterrupted power.

Lithium battery storage

Right now, the popular approach to utility-scale energy storage to reduce solar intermittency is lithium-ion batteries, similar to the Tesla PowerWall or Jehu Garcia's DIY powerwall projects, but larger. (There are a dozen other possibilities — the Sisyphean train, pumped-water storage, flywheels, compressed-air caverns, vanadium flow batteries, hydrogen or methane fuel cells, molten-metal batteries, and so on — but lithium is the currently popular one.) You might reasonably wonder: is there enough lithium?

The Earth's crust contains about 10^{17} kg of lithium

(Updated from my comments on the orange website.)

In 2018, the USGS estimated 16 million tonnes of "worldwide identified reserves" of lithium (1.6×10^{10} kg), but about 53 million

tonnes of "resources" of lithium (5.3×10^{10} kg), which are extractable with current techniques but not necessarily economic at current prices. There's also 2.3×10^{14} kg of lithium dissolved in seawater, and the estimates of lithium abundance in the earth's crust have a low end of 20 ppm. The crust averages about 40 km thick and 3 g/cc in the 29% of the Earth that has continents, which works out to 1.5×10^{14} m², 5.9×10^{18} m³, 1.8×10^{22} kg of rock, and 3.6×10^{17} kg of lithium.

World lithium "production" (which is to say, extraction) is about 4.3×10^{7} kg per year, which would take 350 years to exhaust the "worldwide identified reserves". It seems like a safe bet that some new mining technologies will become available before even 2100, let alone 2369.

Lithium is not destroyed when it is used — you can recycle worn-out batteries into new batteries — so, like gold, we should expect that eventually the amount circulating is much greater than the amount mined in any given year or decade. But, how much would need to be circulating for the humans to start using lithium batteries to power entire continents overnight? Maybe extraction would have to speed up?

The lithium in the crust can store 130 zettajoules

Wikipedia's table of energy densities says Li-ion batteries contain 0.36–0.88 MJ/kg, or slightly higher if you only count the mass of the lithium rather than the entire battery. Conservatively taking 0.36 MJ per kg of lithium (which assumes battery technology doesn't improve — almost-nonrechargeable lithium-metal batteries get five times that much energy per kg of lithium), the 1.6×10^{10} kg of "identified reserves" would hold 5.8 petajoules; the 2.3×10^{14} kg of lithium in seawater would hold 83 exajoules; and the 3.6×10^{17} kg of lithium in the continental crust would hold 130 zettajoules.

Current world marketed energy consumption is on the order of 5.7×10^{20} joules per year, which is 18 terawatts. Incident solar power on the Earth (the Kardashev Type 1 benchmark) is 130 petawatts. So the 5.8 PJ of "identified reserves" is only five minutes of world marketed energy consumption, but the 83 EJ of seawater lithium is about 1.7 months of world marketed energy consumption. Even so, that's only 10 minutes of total terrestrial insolation. But the 130 zettajoules of continental crustal lithium is 12 days' worth of total terrestrial insolation.

So it seems likely that known concentrated lithium deposits will not be sufficient to permit the transition to solar over the next decade or two, but there is plenty of lithium in seawater and other, less-concentrated deposits to permit such a transition. New extraction technologies will be needed if lithium batteries are to bridge the intermittency gap. Alternatively, some of the other utility-scale storage technologies might be developed.

Summary table

Lithium	Energy storage	World marketed energy consumption	Terrestrial insolation
Identified reserves	1.6×10^{10} kg	5.8 PJ (1.6 million MWh)	5 minutes	45 milliseconds
"Resources"	5.3×10^{10} kg	19 PJ		

(5.3 million MWh) 18 minutes 150 milliseconds
Seawater 2.3×10^{14} kg 83 EJ
(23 billion MWh) 53 days 11 minutes
Crust 3.6×10^{17} kg 130 ZJ
(36 trillion MWh) 230 years 11 days

Leconscrip: a family of JS subsets for BubbleOS

Kragen Javier Sitaker, 2018-11-23 (2 minutes)

Leconscrip is a family of languages for implementing BubbleOS (see Speculative plans for BubbleOS (p. 2128)).

It's mostly a subset of JS, since that eliminates unnecessary syntactic obstacles. But it's implemented as a series of levels.

Leconscrip level 0: Lecon

Lecon is nearly the lowest programming level at which it makes sense to use JS syntax at all; it's barely above the assembly level. It has recursive functions with global and local `let` variables, assignment, integers, `if`, `while`, binary `+`, `-`, `*`, `%`, `&`, `|`, `^`, and arrays of integers. The arrays must be defined with the syntax `let x = Array(k)`, where `k` is a compile-time constant. Expressions are only permitted as the right operand of a variable initialization or assignment. It doesn't support closures, objects, object references, or `for` loops. Functions can return integers. Identifiers are limited to two characters. Semicolons are required. I/O is done with `read` and `write` functions on arrays of integers representing bytes.

Variables are of three types: arrays, integers, or functions. Type inference is used; only arrays can be indexed, only integers can be indexes or participate in arithmetic, and only functions can be called. Parameters can be arrays or functions.

Because Lecon doesn't directly permit runtime allocation, it is (in conjunction with a stack-depth checker) suitable for functions in which failure is not an option.

Here's the whole grammar, bottom-up, as a PEG.

```
_ <- (` ` / `\t` / `\n`)*.
LP <- `(` _.
RP <- `)` _.
LB <- `{` _.
RB <- `}` _.
LS <- `[` _.
RS <- `]` _.
EQ <- `=` _.
C <- `,` _.
S <- `;` _.

literal <- [0-9]+ _.
name <- [A-Za-z] ([A-Za-z0-9] / ) _.
atom <- name / literal.
op <- [-+*%&|^] _.

aparams <- atom (C aparams / ) / .
fparams <- name (C fparams / ) / .

call <- atom LP aparams RP.
expr <- atom op atom / atom LS atom RS / atom.
```

```
assign <- name EQ expr.
decl <- name EQ `Array` _ LP literal RP / assign.
decls <- decl (C decls / ).

return <- `return` _ atom.
let <- `let` _ decls.

block <- LB statement* RB.
if <- `if` _ LP atom RP statement.
while <- `while` _ LP atom RP statement.
statement <- block / (let / return / if / while / assign / call) S.

func <- `function` _ name LP fparams RP LB statement* RB.

prog <- func*.
```

Speculative plans for BubbleOS

Kragen Javier Sitaker, 2018-10-28 (updated 2019-02-24) (12 minutes)

BubbleOS is a tiny bubble of sanity in a universe of insane operating systems. It's self-bootstrappable — it includes all the tools needed to build it, edit its source code, and so on — and it can be used as a robust front end to a family of less sane systems. This provides a variety of benefits.

You can use BubbleOS as a standalone computing environment, run it as domo under Xen, or run it as a process under Linux (including Android), MacOS X, Microsoft Windows, or an HTML5 browser.

BubbleOS contains the following:

• A hard-real-time secure windowing system.
• A hard-real-time secure microkernel designed to protect the user from malicious applications.
• A couple of hard-real-time secure terminal emulators.
• A hard-real-time layout system built on a simplified version of the CSS box model.
• A text editor.
• A minimal TCP/IP implementation.
• Minimal cryptographic facilities, an ssh client and server, and a Bitcoin client.
• Encrypted swap and disk.
• Unicode fonts.
• Unicode text rendering including bidi and combining characters.
• A bootstrapping chain of compilers, including assembler, low-level, high-level, and very-high-level languages. The assembler is a variant of Forth, the low-level language is a subset of C, while the others are extended subsets of JS.
• A compiler for a subset of C++ sufficient to cross-compile GCC.
• A SAT solver which provides some of the horsepower for these compilers.
• A virtual CPU machine set, with simulators for i386, amd64, RISC-V, and ARM(32), which runs all the other code.
• A hardware design for this CPU.
• A library of engineering models of many different physical phenomena.
• A circuit design and synthesis system capable of synthesizing this CPU for certain Lattice FPGAs.
• An analog circuit simulation program similar to SPICE.
• A general mathematical optimization system that provides most of its horsepower.
• Emulators capable of running CP/M, MS-DOS, or Apple][programs.
• An image-format library capable of reading and writing most common image file formats, including JPEG, PNG, TIFF, and GIF.
• A minimal web browser capable of fully rendering Wikipedia and Stack Exchange, though it lacks support for most modern web standards.

• Snapshots of Wikipedia and Stack Exchange for offline viewing.
• A fast, capable, secure web server.
• The ability to checkpoint and migrate either a full machine image or an individual process.
• Its full source code as a hypertext literate program.
• A fast, secure, crashproof content-addressable filesystem that supports transactions.
• A fast key-value store similar to LevelDB.
• A minimal SQL database.
• A terser database query language than SQL, but equally powerful, better suited to interactive exploration.
• A fairly full set of data-wrangling facilities similar to Unix software tools, but implemented differently.
• An implementation of Git.

It does not provide a POSIX API.

This is 32 major components in all. I'd better get cracking!

Naming

Bikeshed-style, the thing I am currently devoting my attention to is what to name the components. Names from Consider Phlebas:

Perosteck Balveda (Juboal-Rabaroansa Perosteck Alseyn Balveda dam T'seif), Gravant (alias for Perosteck Balveda), Amahain-Frolk, Egratin, Bora Horza Gobuchul (Horza, shapeshifting traitor), Xoralundra, Farn-Idir (sect), Schar, Heibohre, Rairch (species), Kraiklyn, Zallin, Wubslin, Yalson, Gow, kee-Alsorofus, Marain (language), Tzbalik Odraye, Mipp, Rava Gamdol, Aviger, Lenipobra, Lamm (traitor), Cifetressi, Dorolow, Jandraligeli, Chicel-Horhava, Neisin, Sro Kierachell Zorant, Fwi-Song (cannibal), Twenty-seventh (redshirt), First (acolyte), Sarble the Eye, Ghalssel, Tengayet Doy-Suut, Wilgre, Neeporlax, Xoxarle, Unaha-Closp (drone), Stafl-Preonsa Fal Shilde 'Ngeestra dam Crose (Fal 'Ngeestra), Gimishin Foug.

Names from The Dispossessed: 46. 32 Pravic names along the same lines:

Bebach, Chagvol, Chapis, Chekoks, Chigvigv, Dupin, Gvegob, Komush, Kvakot, Kvushab, Lassep, Logog, Makul, Mokob, Pabar, Palab, Pechol, Pevip, Pichok, Reshub, Shishek, Shivaks, Shumin, Sikvok, Siroks, Skemun, Sotat, Suvun, Trapan, Trekvish, Vabon, Vavun.

Those are too similar.

Names from gen24.py:

Slilg, Floung, Gealgpru, Grapvirveag, Quiphdrusp, Kalgspricloost, Theagproohool, Shophslylg, Wimsplup, Houbdrid, Quyngdryg, Azpream, Greashgrystscoul, Yynpraint, Speazwhof, Scrussbres, Bealggusssprush, Kelpluf, Kasplach, Ploonchag, Prontseng, Graispclooshchuss, Kreassweaxheaph, Nyz, Yoontstaif, Doontdoup, Noosh, Clackblum, Dechspat, Plosttaix, Splez.

Those are too silly.

Names from gen24.py generated with some English probabilities, with real words removed:

```
./gen24.py 40 /usr/share/dict/words .1 | awk '{print $1}' | LANG=C sort
```

Achem, Dep, Dirness, Atafli, Essdi, Enlini, Rera, Tiomtru, Dercal,

Bii, Abhar, Difodent, Nibanspo, Lincalent, Semeed, Veskeno, Ingex, Lum, Onel, Chantcor, Iiz, Reelfin, Blocklo, Leconscrip, Ura, Satyrpo, Editdish, Igstrud, Cing, Inon, Harfa, Etordot.

Okay, I think that'll work.

Another candidate naming convention takes sequences of letters, numbers, and symbols that spell words in Spanish. For example, "5p" means "faint away" and would work well for the checkpoint-and-restart facility (as might "k+" "beds" or "ck" "dry"), "g+" means "jewels" and would work well for a packaging system, "kbo" means "headboard" or "header". And "ogo" means "glance" and would work well for the windowing system.

Oops, unfortunately "ogo" is already "an OpenFlow Network controller in Go", a handheld computer sold from 2004–2006, an abbreviation for "OpenGroupware.Org", and a mobile phone dating app similar to Tinder. So, without more detail, that name is right out. Something like "ogoak" ("ojeo acá", "a glance here") or "ogoc2o" ("silky glance") or "ogo☼o" ("ojeo solo", "just a glance") might work; none of them exist.

Wercam: a hard-real-time secure windowing system

Wercam securely multiplexes input and output between mutually untrusting applications while guaranteeing glitch-free animation and instant responsiveness to system commands 100% of the time, despite the efforts of malicious applications. Additionally, applications can upload executable bytecode to Wercam to provide glitch-free bounded-latency visual feedback to user actions without writing the whole application as a bounded-latency system.

It includes VNC and RDP clients for remote access to other graphical systems.

Wercam is about 1000 lines of real-time Leconscrip.

(The predecessor to 8½ was "a few hundred lines of source code using [Newsqueak]", and 8½ itself was about 5–15kloc, but 8½ supported 23 operations in /dev/bitblt and a bunch of font nonsense. Rio was smaller and simpler.)

See also files Scriptable windowing for Wercam (p. 1256), Window systems (p. 1335), and Real time windowing (p. 891).

Intranin: a hard-real-time secure microkernel

Intranin securely multiplexes the CPUs, memory, disk, and GPU between mutually untrusting application processes, which are isolated using objet-capability discipline, and furthermore securely enables hard-real-time control applications to meet microsecond deadlines 100% of the time.

Intranin is about 2000 lines of real-time Leconscrip, plus a few hundred lines of Abhar assembly for each platform.

Oops, "DEP" (the original name) already has a meaning in infosec, "data execution prevention": https://seclists.org/oss-sec/2018/q4/82 . Renamed to Shang.

Oops, "Shang" (the name replacing Dep) is already https://github.com/etherzhhb/Shang, free software for compiling C

to RTL. Intranin!

Atafli: hard-real-time secure terminal emulators

Atafli is a set of character-cell terminal emulators that are hardened against resource-exhaustion attacks. They run on Wercam and are useful for running older programs or providing access to remote machines, but when writing programs for BubbleOS, it's easier and provides better results to use Essdi.

Atafli is about 500 lines of real-time Leconscrip.

Essdi: a hard-real-time layout system

Essdi is a modern replacement for character-cell terminal output streams, preserving their ease of programming and guaranteed real-time performance (a particularly big contrast when compared to the janky pause-filled experience that is an HTML5 web browser) but providing enough of the CSS box model that it's easy to write things that look good. Most applications that run on Wercam use it to do their layouts.

At times, Essdi privileges responsivity over correctness.

Essdi is about 800 lines of real-time Leconscrip.

Editdish: A text editor

In the 1970s, text editors were separate application programs, but they turned out to be useful for handling the user interfaces of other application programs. Graphical user interfaces embedded tiny text editors all over other applications.

Enlini, a minimal TCP/IP implementation

Enlini implements enough of TCPv4, IPv4, and UDPv4 to support the minimal BubbleOS network services: an ssh client and server, a Bitcoin client, and an HTTP client and server. It uses a parser-driven approach reminiscent of the STEPS TCP/IP stack.

• Minimal cryptographic facilities, an ssh client and server, and a Bitcoin client, Rera.
• Encrypted swap and disk, Tiomtru.
• Unicode fonts, Dercal.
• Unicode text rendering including bidi and combining characters, Bii.
• A bootstrapping chain of compilers, including assembler, low-level, high-level, and very-high-level languages. The assembler, Abhar, is a variant of Forth; the low-level language, Difodent, is a subset of C; and the others, Leconscrip, are extended subsets of JS.
• A compiler for a subset of C++ sufficient to cross-compile GCC, Lincalent.
• A SAT solver which provides some of the horsepower for these compilers, Semeed.
• A virtual CPU machine set, with simulators for i386, amd64, RISC-V, and ARM(32), which runs all the other code, Veskeno.
• A hardware design for this CPU, Ingex.
• A library of engineering models of many different physical phenomena, Lum.

• A circuit design and synthesis system capable of synthesizing this CPU for certain Lattice FPGAs, Onel.
• An analog circuit simulation program similar to SPICE, Chantcor.
• A general mathematical optimization system that provides most of its horsepower, Reelfin.
• Emulators capable of running CP/M, MS-DOS, or Apple][programs, Blocklo.
• Nibanspo: An image-format library capable of reading and writing most common image file formats, including JPEG, PNG, TIFF, and GIF.
• Ura, A minimal web browser capable of fully rendering Wikipedia and Stack Exchange, though it lacks support for most modern web standards.
• Satyrpo: snapshots of Wikipedia and Stack Exchange for offline viewing.
• Igstrud: A fast, capable, secure web server.
• Cing: The ability to checkpoint and migrate either a full machine image or an individual process, which produces an executable.
• Inon: its full source code as a hypertext literate program.
• Dirness: A fast, secure, crashproof content-addressable filesystem that supports transactions.
• Harfa: A fast key-value store similar to LevelDB.
• Etordot: A minimal SQL database.
• Binate: A terser database query language than SQL, but equally powerful, better suited to interactive exploration.
• Atsoled: A fairly full set of data-wrangling facilities similar to Unix software tools, but implemented differently.
• Bonlar: An implementation of Git.

Bootstrapping sequence

Veskeno, the virtual machine, is, in some sense, the bedrock of the system; everything else runs within it. But Veskeno alone is unusable; you need programs for the virtual machine in order to do things with it. And for that you need at least some version of Abhar, the assembler, running.

Given a definition for Veskeno's instruction set and I/O architecture, this ought to be a matter of a few hours of programming (initially in C or Python), but coming up with the instruction set could easily take longer than that. Probably writing a few drafts is a good idea, but then I need to test each one with some kind of code generator.

In Abhar or low-level Leconscrip I can write a bootstrap interpreter for high-level Leconscrip, and then I can write a compiler for high-level Leconscrip in itself.

Some personal notes from February 2014

Kragen Javier Sitaker, 2014-02-13 (8 minutes)

It's the 13th of February. Today my friend Stace and her dad, who are staying at my house, took delivery of a portable air conditioner, which they'd bought on my behalf from the Coto department store around the corner. My apartment is cooling down now.

On Thursday, the 23rd of January, the official exchange rate had jumped from $6 to the dollar to $8 to the dollar, apparently as a result of a small sale of a few million pesos by Shell Oil. The official market is tightly controlled (payments for imports, for example, must be immediately liquidated in it, providing it with a large captive supply of dollars; and access to the peso side of the market is strictly limited) and, apparently as a consequence, has very little depth on the selling-dollars side. The central bank stepped in to force the closing price back down to $7.75 to the dollar, and the newspapers were full of dueling accusations the next day, Friday. The true price went up from $10 to $12, and the buy-sell spread widened to 15% or so. The government issued panicked pronouncements that the restrictions on Argentines buying dollars would be lifted.

In the midst of this, I went to check out the price on this portable air conditioner on Saturday, the 25th of January. It was priced at $4900, which is US$410 at the new true rate, or US$490 at the old true rate, or US$600 at the new official rate, or US$800 at the old official rate.

I was talking with my landlord during this time about repairing the current air conditioner or replacing it with a new one, and he was taking a while to get back to me; so on Tuesday, the 28th of January, I went back with $5000 to buy the portable unit myself, so I wouldn't have to wait for him. Within those three days, the price had been increased by 40% to $7000, so I didn't have the money.

The promised restriction-lifting turned out to be kind of a dud; it entirely excludes the majority of the population (I guess the government figures that poor Argentines don't need to be able to save money) and allows high-income people to purchase only very small quantities.

The air-conditioner repairman called to tell me that the replacement compressor the apartment's unit needs no longer costs $800 or $900 like he'd expected, but rather $3000. The landlord asked if maybe I could pay the repair cost up front and then deduct it from my rent a little bit at a time over the next few months. I declined.

In an effort to stem the inflationary spiral, the government signed agreements with the big supermarket and department-store chains to freeze their prices at the levels of January 21, or in some categories (like home appliances) to freeze them at 7.5% above the January 21st levels. I returned to Coto hoping to find the air conditioner price reduced to $5375, but it was still $7000.

So I sent Stace with my money to buy the air conditioner and arrange for delivery while I was at work. She succeeded, but delivery

wasn't scheduled for another week.

So now I have a sort of monochrome R2-D2 in my bedroom belching out hot air onto my patio, cooling off my apartment and periodically urinating into a bucket I've placed next to it.

Around town there are posters with the faces and names of the heads of major chains: Walmart, Frávega, Coto, Shell. The posters blame the inflation on these chains' choice to raise prices, which seems plainly absurd to me in an environment where unions have been regularly getting yearly raises above the rate of inflation.

Thursday morning, I took a bus home from an outlying neighborhood. The fare was $8. When I arrived in Buenos Aires in 2006, the highest fare was $0.80. But this is somewhat of an overstatement of inflation, because I was only charged the cash fare rather than the $3.90 card fare because my prepaid bus card was empty.

Some months ago, a garbage truck caught fire in the street outside the office where I work. The fire ignited six cars parked along the street. They burned until nothing was left but metal and carbon. The heat blistered the stucco and paint on the buildings on the street and melted parts of the engine, which puddled in the street. A chunk of melted engine is now sitting on my bathroom vanity.

A week or two ago, I saw the last four of the six burned-out cars finally being loaded onto a tow truck. Now only the melted plastic and blistered concrete bear witness to the conflagration.

When Darius was here, I tried to persuade him to buy a set of reading glasses from a Senegalese street vendor, though without success. A couple of weeks ago, the Senegalese street vendors of Buenos Aires suffered a sudden setback: the police raided all their houses early in the morning to confiscate the watches, cheap jewelry, and eyeglasses they sell on blankets around town --- as well as the blankets themselves. They protested by cutting off streets, but since they are immigrants, public opinion is against them.

Macri, the mayor, used his new metropolitan police force to repress the various street vendors. This has been a project of his for some time, and in at least one case they have shot street vendors with rubber bullets to drive them out of an area.

Still, early-morning house raids seem like a new extreme of repression against such a previously tolerated activity. I wonder how much longer San Telmo's famous Sunday open-air market will last. Perhaps it will be spared, since it attracts so many tourists.

Macri's party, PRO, is popular here in Buenos Aires, but fortunately has little support nationwide.

The cockroaches are back. I've set out fresh roach-bait traps, and that seems to have slowed them down, but I still have a long way to go before they're eradicated.

I still haven't reassembled the hot-water heater. There's a bag somewhere in my apartment with the absolutely crucial faceplate and spring parts of it, which I haven't been able to find in months. This is starting to become a problem again as the weather cools down from sweltering to merely sweaty.

Yesterday, we went to look at an apartment that we could possibly share. It's 110 square meters with four potential bedrooms (one of which is rather too small, and one of which lacks a door); the cost is $4400 (US$400, say) plus $1300 expenses. Gorgeous parquet floors,

huge living room, well-equipped kitchen with granite counters, noisy. I was expecting the realtor to call me back today with information about the water damage in the walls and access to the roof.

The other apartments we've been looking at have been similar in size, but in large part since they're in richer parts of town, they're two or three times as expensive.

Executable scholarship, or algorithmic scholarly communication

Kragen Javier Sitaker, 2016-08-11 (13 minutes)

We are witnessing the birth of a new phenomenon I haven't seen named before. I propose to call it "algorithmic scholarly communication".

Alan Kay describes the birth of a new genre of media as proceeding in a series of stages:

> A new genre is established. A few years later a significant improvement is made. After a few more years the improvement is perceived as not just a "better old thing" but an "almost new thing" that leads directly to the next stable genre.

This essay identifies an "almost new thing" which is beginning to transform the nature of scholarly communication. First I provide some background, including my personal view of the principles underlying scholarly communication; then, I give some thought-provoking examples of the current state of the system; and then, I project where it seems likely to take us.

Background: what are scholars, and what is scholarly communication?

A hundred and thirty generations ago, we began to understand formal mental processes when Thales and the Pythagoreans including Socrates formulated proofs in geometry in terms of logical arguments. Over the next ten generations, Mozi, the Pythagoreans, and Aristotle developed the study of logic as an object in itself.

The academy as we know it is, in name, an homage to the estate of Plato, Socrates' student; in structure it descends from medieval seminaries of the Roman Catholic Church, and indeed some of those seminaries are universities today. It has always aimed at acquiring and diffusing knowledge, both in the sense of practical skill (the arts) and knowledge of what is objectively true (the sciences), though modern epistemology has demoted Christian theology and holy writ in general to the status of myth and metaphor rather than an objectively-true cosmology, tempting us to scoff at the debates of the European medieval Scholastics; it's easy for us to forget that angels and demons seemed as real to them as states, money, and corporations do to us.

XXX etymology of "university"?

After 2600 years of work, we at last succeeded in fully formalizing logical reasoning and other formal mental processes during the 20th century; the product of this formalization was the digital computer, which executes processes called "algorithms".

What happened to mathematical tables?

We have already seen executable scholarship happen in many aspects of practical mathematics. I have on my bookshelf a 1965 book by R.S. Burington entitled *Handbook of Mathematical Tables and*

Formulas, first published 1933, LCCN 63-23531. It tells me things like this, neatly organized into tables:

$\log \cos x \approx -x^2/2 - x^4/12 - x^6/45 - 17x^8/2520 - \ldots$ when $x^2 < \pi^2/4$
roughly 53030 Americans of every 100 000 live to age 63; 1800 die that year
the cotangent of 38.5° (i.e. the reciprocal of the tangent) ≈ 1.2572
$\nabla^2 S$ is defined as $\partial^2 S/\partial x^2 + \partial^2 S/\partial y^2 + \partial^2 S/\partial z^2$
the logarithm of the cotangent of $17^\circ 21'$ is 0.50526
an endomorphism is a homomorphism of a system onto itself or part of itself
$0.15^\circ \approx 0^\circ 9' 00''$
the definition of the cumulative discrete probability as a sum $\Sigma_i f(x_i)$
formulas for the sides & angles of a triangle given 2 angles & 1 side
$\int dx/(x\sqrt{(ax + b)}) = 1/\sqrt{b} \log((\sqrt{(ax+b)}-\sqrt{b})/(\sqrt{(ax+b)}+\sqrt{b}))$ for $b > 0$

The first half of the book is a brief but complete summary of the most widely useful branches of mathematics; the second half consists of numerical tables. The first "mathematical table" of this sort was assembled by Aryabhata in the fifth century CE; it consisted of 24 first differences of the sine function. Calculating and disseminating such tables — crucial for practical manual celestial navigation, artillery warfare, trigonometric calculation in general, and statistics — was a major effort of mathematicians for centuries. It inspired Babbage's original plan to automate computation in 1822; computing mathematical tables was the justification for funding one of the three World War II projects that did successfully automate computation, the ENIAC. The ENIAC was designed to compute mathematical tables for artillery firing.

The other two projects were Konrad Zuse hacking in his Berlin apartment (and later with government support) and the secret British cryptanalytic Colossus machine; arguably the Harvard Mark I ASCC, based on Babbage's work, was a predecessor to the ENIAC. The Mark I was also used to compute mathematical tables.

After fifteen centuries, the publication of books of mathematical tables essentially ceased in about 1975, at which point the numerical tables were replaced in common use by HP scientific calculators, where they had not been replaced earlier by larger and more expensive computers. (Bowditch's American Practical Navigator is one of the few remnants that still includes mathematical tables, even in the 2002 edition, the latest as of this writing; pp.565–727 are devoted to tables, most of which are mathematically calculated rather than empirically measured.)

The kind of mathematical scholarship formerly devoted to publishing mathematical tables is nowadays devoted to publishing software instead. Pages 325 to 344 of Burington's handbook are devoted to a table of n^2, n^3, $\sqrt{n}$, $\sqrt{(10n)}$, and the cube roots of n, 10n, and 100n; given a computer that can multiply integers, the square-root columns of this table can be replaced in practice with a single line of C code, which implements the "Babylonian method" of computing square roots given by Hero of Alexandria (Ἥρων ὁ Ἀλεξανδρεύς) a hundred generations ago:

```
g,h;q(n){h=n;if(n)do g=h,h=(g+n/g)/2;while(g-h+2&~3);return h-=h*h>n;}
```

However, this line of C code, although it works and replaces two sevenths of those twenty pages of numbers, falls short of many of the

ideals of scholarship, as I will explore below.

units(1)

Several times a week, I use GNU units(1), the GNU version of the BSD (?) units(1) program, which is a simple desk calculator program which contains a comprehensive database of over two thousand units of measurement, compiled over decades by the tireless scholarship of Adrian Mariano at Cornell. The original uses were things like this:

```
You have: 60 miles per hour
You want: furlongs per fortnight
        * 161280
        / 6.2003968e-06
```

But units(1) also allows me to immediately calculate things like how many minutes of arc the sun subtends on average:

```
You have: radians (2*sunradius)/sundist
You want: arcminute
        * 31.988013
        / 0.03126171
```

Or, in case I've forgotten, that a mole of ideal gas at STP occupies 22.7ℓ:

```
You have: gasconstant
You want:
        Definition: 8.314472 J / mol K = 8.314472 kg m^2 / K mol s^2
You have: gasconstant * 1 mole * tempC(0) / 100 kPa
You want: liters
        * 22.71098
        / 0.044031565
```

Or that Israel's new Sorek reverse-osmosis desalination plant, which is reported to use 70 atmospheres of pressure for the reverse-osmosis process step, is doing 7.1kJ of mechanical work per liter, putting a lower bound on the economic cost of the freshwater obtained:

```
You have: 70 atmospheres
You want: kilojoules per liter
        * 7.09275
        / 0.14098904
```

And that that is US$200 per megaliter or US$240 per acre foot if the energy used to drive it costs US$100 per megawatt hour:

```
You have: 70 atmospheres * US$ 100/MWh
You want: US$ / megaliter
        * 197.02083
        / 0.0050756054
You have: 70 atmospheres * US$ 100/MWh
You want: US$ / acrefoot
        * 243.02308
        / 0.0041148356
```

I can calculate that 10 amperes of electrical current through a round 22-gauge wire amounts to 31 amps per square millimeter; I have to be careful here, because units's `wiregauge` unit gives me the wire diameter, but its `circlearea` unit wants the radius:

```
You have: 10 amps / circlearea(wiregauge(22)/2)
You want: amperes / mm^2
        * 30.718763
        / 0.032553394
```

If I include the resistivity of copper and the equation $P = I^2R$ in the calculation, I can get the heat production:

```
You have: (10 amps)^2 * 16.78 nanoohms * meter / circlearea(wiregauge(22)/2)
You want: watts/meter
        * 5.1546084
        / 0.19400116
```

(That's enough heat to be dangerous if used as electrical wiring, but not enough to use as a heating element, except maybe in an electrical blanket or something.)

That was actually my second try at that calculation; on the first try, I accidentally calculated the voltage drop per meter instead, which units was able to catch, but not provide a useful error message for:

```
You have: 16.78 nanoohms * meter * 10 amps / circlearea(wiregauge(22)/2)
You want: watts / meter
conformability error
        0.51546084 kg m / A s^3
        1 kg m / s^3
You have: 16.78 nanoohms * meter * 10 amps / circlearea(wiregauge(22)/2)
You want:
        Definition: 0.51546084 kg m / A s^3
```

It happens that kg m / A s^3 is equivalent to volts per meter, but that's not at all obvious from looking at the result.

You can see that as the examples get more complex, more and more of the knowledge is in my head, and less and less in the software.

Actually, I didn't have the resistivity of copper memorized in my head; I looked it up on Wikipedia and typed it in. There's a Wikidata entry for copper but it doesn't yet include electrical resistivity as a property. It does include its density, but in the format "8.94±0.01 Q15639371", which units(1) cannot parse; Q15639371 is the Wikidata name for "grams per cubic centimeter." There was an entry for copper in Freebase.com too, but I don't know if it included electrical resistivity.

Wolfram Vertical Line Alpha

Stephen Wolfram also has a broad vision of part of what I am calling executable scholarship. He calls it a "computational knowledge engine", and being Stephen Wolfram, he plans to own it, and his version doesn't cite any sources.

The Wolfram version is called "Wolfram|Alpha", but I decline to

use marketing-provided punctuation in the middle of proper nouns like "Yahoo!" and "Re/Code", because I don't hate my readers enough. Instead I will spell out the term as "Wolfram Vertical Line Alpha" when necessary.

Wolfram Vertical Line Alpha *does* include the electrical resistivity of copper, and given the input "resistivity of copper * (10 amps)^2 / 0.326 mm^2", it correctly computes 5.2 watts per meter. It also claims that the size of 22AWG wire is 0.324 mm², which differs by about 0.5% from the value given by units(1), and will return it given the input "22awg", but I haven't found a way to get Alpha to combine these pieces of knowledge in a single formula.

The aims of scholarship

What is scholarship?

valid trustworthy well-known

reproducibility self-correcting interlinked honest objective stable readable public reveals preferred embodiment not ignorant creative? documentable? replicable? peer-reviewable?

[Boyer 1990] proposed expanding the definition of "scholarship" to include not only the discovery of knowledge but also teaching, application ("the use of new knowledge in solving society's problems"), and what he calls "integration" ("where new relationships among disciplines are discovered", a definition broad enough to include any research). Boyer was unable to publish his proposed redefinition in a peer-reviewed venue, publishing it instead through a phony "Carnegie Foundation" whose declared purpose is to promote the interests of teachers, which is to say, university faculty who do not engage in scholarship; not satisfied with this, however, he additionally proposed to expand "scholarship" to include practitioners of a field in general, except those who use only old knowledge.

[Boyer 1990]: E. Boyer, *Scholarship reconsidered: Priorities for the professoriate*, published by the "Carnegie Foundation for the Advancement of Teaching."

Square roots

The line of code I gave above to calculate the square root of an integer falls short of the aims of scholarship for several reasons. It's hard to read (made unnecessarily so by a)

On the computer I'm typing this on, square roots are generally calculated by proprietary Intel hardware designs that I am not able to see, because using specialized hardware makes it much faster, and

tested using a function called sqrt_test.

. But the free software I run the computer on has an option to calculate square roots using addition, subtraction, comparison, bit shifts, and iteration, called _FP_SQRT_MEAT_E.

Hypothesis evolution

Kragen Javier Sitaker, 2019-12-17 (4 minutes)

David R. MacIver's generative testing system Hypothesis is an example of a new breed of "lightweight formal methods" software that I think represents a significant advance in the state of the programming art. Hypothesis works as follows: you state a hypothesis about your system's behavior; Hypothesis searches for a counterexample by, essentially, fuzzing the system; and if it finds a counterexample, it "shrinks" it by testing simpler and simpler examples until it finds one that it cannot simplify to a simpler counterexample. (That is, any simplification it tries results in an example that isn't a counterexample.) It tells you the simplest counterexample and records it in an example database and then always or nearly always retries it in the future so that you'll know when you've fixed the bug.

Contrary to 1980s QA dogma, random testing turns out to be an excellent way to find bugs, and Hypothesis's innovative approach to shrinking counterexamples is very helpful in getting useful bug reports. But you know what would be even more helpful than a single minimal reproducing test case? A thorough characterization of the bug, telling you not only one case where it does happen, but a formal model of when it does and doesn't happen.

Evolution of a hypothesis population with adversarial experiment design

Suppose that your initial hypothesis is that no input sequence for your calculator program will produce a result that is incorrect by more than 0.01%, and random testing finds such a result by comparing against some kind of formal model of arithmetic --- perhaps another calculator program, one that doesn't have to run fast or use little memory, or perhaps some kind of sparer model. The testing has probably found a large set of cases that produce the correct result and a smaller set of cases that don't.

The initial hypothesis was that this second set would be empty. Now we could generate a set of new hypotheses --- for example, that all input sequences containing division will produce an incorrect result --- and test them against the experimental data. Hypotheses that do a better job of discriminating the two sets (per bit!) should be preferred, since the objective is to find a concise hypothesis that discriminates them perfectly. Once we have several hypotheses that discriminate perfectly, or nearly equally well, we can do more experiments: generate more examples and test them to see what the result is. We should prefer to spend our CPU budget on examples that do a good job of discriminating between our existing hypotheses. Once we have more evidence, we can generate more hypotheses, and vice versa.

The approach is very similar to generative adversarial networks: hypotheses attempt to evolve to predict the behavior of the system under test, while experiment design (test-case generation, example generation) attempts to confuse the existing hypotheses.

What form should the hypotheses take? There are many possibilities appropriate to different kinds of examples: predicate-logic expressions, regular expressions, neural networks, and context-free grammars, for example. If an example can be described by some kind of abstract syntax tree, tree regular expressions can capture interesting properties of that tree, especially if augmented by predicate-logic expressions that can examine node properties. The whole field of genetic programming can be applied to hypothesis generation.

This may provide a useful way to take advantage of increased CPU power (see The uses of introspection, reflection, and personal supercomputers in software testing (p. 2306)).

Genesis

This was inspired by a bug I'm investigating tonight which Hypothesis is happily finding seven hundred times a day without providing much new insight into why it happens. Of course, conventional debugging approaches based on inspecting the code are necessary and sufficient, and I probably should spend some time on them in this case rather than continuing with black-box testing, but I thought maybe I could write a simple model of the bug as I did with another recent bug to exclude it from the testing Hypothesis is doing. This turned out to be more difficult than I anticipated, and I got to thinking about what kind of software would make the process easier.

Storing dry bulk foods in used Coke bottles

Kragen Javier Sitaker, 2012-10-15 (updated 2012-10-21) (5 minutes)

I've been putting dry bulk foods into used Coke bottles for storage. The place where I'm staying for another week now has bottles of soybeans, polenta, flaxseeds, whole wheat flour, white flour, rice, and lentils. This makes me happy. I feel like I'm creating order out of chaos. The bottles look a lot prettier than half-full bags of lentils, and they also exclude cockroaches and beetles better. (Sometimes beetles can get into even sealed-shut plastic bags.) They also seal hermetically, preventing oxygen and moisture from the air from attacking the contents, and for foods that come in paper bags rather than plastic, there's the additional advantage that they protect the food from possible roof leakage --- not a merely theoretical advantage in the places where I've been living!

One of the bottles I have to work with is not a Coke bottle, but a bottle for Terma, a sort of bittersweet herbal infusion that's popular here. The plastic is green, so a lot of foods look horrible inside of it, despite its graceful form, which looks rather like a thigh modified to be rotationally symmetric. So rather than using it for storage, I scissored off the top of the Terma bottle to use it as a funnel for filling the other bottles with, then heated up the neck with a stove flame in order to squish it down a bit so it fits inside other bottle necks --- not actually necessary since it's not a big deal if I spill a few drops of flour or a lentil or two, but helpful.

(Another Terma bottle got used for yerba mate instead, which looks fine when tinted green.)

Washing the bottles out is kind of a pain because they don't dry easily. I've taken to dripping a few drops of 96% ethyl alcohol into them and shaking it around to take up the water. Then I can just pour it out, because it has a lot less surface tension than water. Also, it's reassuring that it's a mild disinfectant.

The more time-consuming step --- which I'm not doing this time around --- is removing the glue that keeps the labels on. Terma labels come off with just water, leaving only a little residue, but Coke and Pepsi label glue (at least currently in Argentina) won't come off even with alcohol; turpentine works, but also penetrates the bottle and can leave the food tasting like turpentine. Filling the bottles with cold water before turpentining the labels off reduces this problem.

A friend suggested freezing foods like flour for a while before storing them, in order to kill any beetles that might be hiding in them, which seems like an eminently sound idea to me. After all, even if the bottles keep the beetles or moths contained, you still lose a bottlefull of food, which could have been avoided if you just had to discard a single beetle.

In order to limit the lifetimes of foods stored this way, I label the bottles with the name of the contents and the date it was bottled. So far I haven't found a good way to do this. Masking tape is workable, but the adhesive decays over time, and two years later when I use the bottle for something else, I'm left with stinky dried adhesive on the

outside of the bottle. Also, the masking tape itself is kind of ugly. Permanent marker works, but you can't take it off, and I fear that the solvent will flavor the food. Maybe paper labels with some kind of water-based adhesive, such as wheat paste, would be best, but first I'm going to try tying bows around the necks of the bottles using a wide cloth ribbon I write on.

Many people prefer glass bottles for this kind of thing because they're prettier. Plastic Coke bottles have three advantages over glass bottles:

• If you knock them off the shelf, they don't break. In fact, if you run over them with a truck, they don't break. If you hit them with a baseball bat, they don't break. They're nearly bulletproof.
• They weigh much less.
• For things like flour which can entrain air, you can squirt them out of the bottles like liquids by turning the bottle upside down and squeezing.

Evaporation chimney

Kragen Javier Sitaker, 2013-05-17 (13 minutes)

Fundamental principle of operation of an evaporative chimney

A chimney is a bistable fluidic structure, sort of like a siphon: once the chimney fills with hot air, the higher pressure from outside the chimney forces the newly produced hot air up the chimney. Hot air is a lot less dense than cold air. Air at 275°C is half the density of air at 0°C, because it's twice the temperature.

Drying things out is a major problem in day-to-day life: laundry or dishes after you wash them, fruit or other food you want to preserve, parts of your building you don't want to grow Stachybotrys mold and poison you, and so on. Dryness, cold, and poison are the three major ways to inhibit life on media that could otherwise support it (e.g. mold, bacteria, insect predation), and of these, dryness is by far the preferred option in many cases.

Room-temperature evaporation is usually adequate to dry things out enough that they can't support life. Usually, the main determinant of the speed of room-temperature evaporation is air circulation. With no air circulation, relative humidity rapidly reaches 100%, and evaporation stops. Even a fairly weak draft is often sufficient to reach adequate evaporation speeds.

But evaporation, like heat, decreases the density of air. My calculations below suggest that you could construct an evaporation-driven chimney that would provide adequate air circulation even without a source of above-ambient temperature, probably using laminar rather than turbulent airflow.

In a sense, this is an evaporative downdraft cooltower, meant to make things dry rather than cold and wet. The only difference is that you saturate it with heat instead of humidity.

Overall parameters and results

The vapor pressure of water increases exponentially with temperature, which means that any such chimney device will have a critical temperature below which it will basically not work at all, and it's much harder to build one that will work at 0° (0.6 kPa vapor pressure) than 16° (1.8 kPa), 25° (3.2 kPa), or 35° (5.6 kPa) — you have an entire order of magnitude of density difference here.

It's probably a good idea to shoot for 16°, since 0° sounds too hard, and higher ambient temperatures in places where people live are often a result of humidity-induced greenhouse effect, so in practice the dryer may not work that much better.

Of course, evaporation also cools the air and the thing from which the water evaporates, but you can passively warm the cooled air back to room temperature — it's just a matter of providing sufficiently high thermal coupling. At sufficiently high airflow, this heat transfer can be the limiting factor in drying things out. For this exercise, I will simply assume that heat transfer is adequate.

With these assumptions, the device seems quite practical. It seems

that you should be able to maintain 25 cm/s airflow with a 5.4-centimeter evaporation chimney, numbers which don't really depend on the chimney's height, according to the calculations below. However, it turns out you can get even stronger airflow by operating it as an evaporative downdraft cooltower!

Fluid dynamics calculations

Water molecules weigh 18 daltons, while the other major air molecules weigh 30 and 32 daltons. So pure water vapor weighs about 41% less than dry air.

So at 16°, air at 100% relative humidity and one sea-level atmosphere (100 kPa) will consist of roughly 1.8% water, which means its density is decreased by 41% × 1.8% = 0.74%. If your incoming air already has 50% relative humidity, which is common, you're down to 0.37%; if the air density is 1.23 kg/m³, that's about 4.5 mg/ℓ, 4.5 µg/cc, or 4.5 g/m³.

Okay, how much pressure can you get out of that? At Earth surface gravity, it works out to about 45 mPa/m, which is a pretty tiny pressure!

How much laminar airflow can you get out of that? Well, it depends on your air duct size. The Darcy-Weisbach equation says your pressure loss to friction is f[D] ρLV²/(2D), where f[D] is the Darcy friction factor (64/Re in the laminar case), ρ is the density of the fluid, L is the duct length, D is the diameter, and V is the velocity.

Conveniently, or not, the chimney length here drops out: our pressure difference is L × 45 mPa/m, proportional to the chimney length, and the Darcy–Weisbach pressure drop is also proportional to the chimney length. So we have 45 mPa/m = f[D] ρV²/(2D); if we divide both sides by the density of air, we get 0.037 m/s/s = f[D] V²/(2D).

Will it be laminar? Laminar flow dominates at Reynolds numbers below about 2000 or 3000. The Reynolds number Re in a pipe is VD/ν, where V is velocity, D is diameter, and ν is kinematic viscosity, measured in e.g. m²/s. The kinematic viscosity of air is about 1.5×10^{-5} m²/s, so the laminar-turbulent transition takes place (assuming Re = 2000) at around VD = .03 m²/s. That is, if D is 3 cm, it takes place at 1 m/s; if D is 30 cm, it takes place at 10 cm/s; if D is 1 m, it takes place at 3 cm/s. So you can get it to be turbulent by using a big enough duct, even without changing the velocity.

If we figure on a Reynolds number in the middle of the laminar range, giving us a comfortable safety factor, f[D] is about 0.06. Solving for V², we get

$$V^2 = 2D \times 0.037\ \text{m/s/s} / 0.06$$

or simplified

$$V^2 = D \times 1.2\ \text{m/s/s}$$

so our actual air velocity is

$$V = \sqrt{(D \times 1.2\ \text{m})}/\text{s}$$

assuming that Reynolds number.

So, uh, that assumption gives us a duct size, no? I was assuming $VD = .015\ m^2/s$, so $.015\ m^2 = D\sqrt{(D \times 1.2\ m)}$. Square both sides (adding meaningless complex solutions) and you get $.000225\ m^4 = D^3 \times 1.44\ m$, so $D = (.000225\ m^3 / 1.44)^{\wedge}⅓$, or about 5.4 cm.

Okay, so if you have a 5.4 cm wide evaporation chimney, you get $\sqrt{(.054\ m \times 1.2\ m)/s} = 0.25\ m/s$ airflow from the tiny pressure difference from evaporation, which is pretty respectable.

You can make the duct a bit bigger (up to twice the Reynolds number, which is growing as $D\times\sqrt{D}$, so you can make it up to 59% wider: up to 8.6 cm, which would have 2½× the cross-sectional area and 1.26× the flow velocity, for a total of three times the volumetric flow) before you hit a slowdown from turbulent airflow, at which point you have to make it a lot bigger to compensate. Eventually, the total turbulent airflow will exceed the possible laminar airflow, but it's probably better to plan to stay well into either the laminar or the turbulent regime on the Moody diagram, avoiding the much lower airflow just above the transition. If you want to stay in the laminar regime but need more total airflow volume, you can have a number of small chimneys, perhaps a grid of partitions inside a larger space.

Such partitions would also help prevent the moist air coming up the chimney from mixing with dry air descending from above, which will reduce the pressure difference, but not the Darcy–Weisbach loss, thus reducing the flow rate. In the limit of an infinitely large chimney, you will have a plume of water vapor rising slowly from your moist object and gradually diffusing into the air, while nearby air remains stationary or sinks.

$0.25\ m/s \times \pi \times (.054\ m/2)^2 = 0.00056\ m^3/s$ total airflow in one of these chimneys. That's about 0.69 g/s of total air per second, of which 0.37% is the water we're extracting: 2.5 mg/s per chimney, or about 9.2 grams of water per hour per chimney. So to evaporate a liter of water in four hours — suitable for drying laundry or fruit — you might need 27 such chimneys, perhaps a 6×5 grid inside a larger 30×30 cm duct, for a total of $.015\ m^3/s$ or 32 cfm, somewhat less than a standard bathroom ventilation fan.

Startup

As I said, chimneys are bistable: once they have a draft, they keep sucking (much like standing armies), but until they're full of the lower-density fluid, they don't suck. So how do you start the chimney?

The usual approaches are using a fan and using an inverted funnel.

The fan works in the obvious way, but if you have the fan, you don't really need the chimney. The chimney is quieter and uses less energy, though.

An inverted funnel leading up into the chimney can capture individual chimneyless updrafts of moist air from below and fill the chimney with them. This will only work if the moist air updrafts are sufficient.

Materials

It barely matters at all what materials an evaporative chimney is made from. It could be sheet metal, paper (as long as it doesn't get rained on, or if it's greased to protect it), silk cloth, brick, or

polyethylene sheeting. Soft materials will need some kind of external support.

If you're venting it outside, you might consider it desirable to curve the chimney at the top, or put a roof over it, so that rain doesn't fall into it.

In many cases it might be beneficial to use a transparent material.

Heat flow

Earlier I said I assumed heat flow was adequate. Is that reasonable?

Heat flow is really critical for two reasons: first, the 0.5%/° change in air density with temperature could easily overwhelm the 0.4% change in air density with humidity, making your "chimney" work *backwards*; and second, if the thing you're trying to dry out is cold, water on it will evaporate really slowly, which will give it more time to rot before it dries out.

Evaporating 2.5 mg/s of water is about 10.4 mW of heat dissipation, so you suck up about 10.4 mW of heat per chimney. The earlier-suggested 27-chimney assembly thus sucks up about 280 milliwatts.

A glance at a psychrometric chart shows that the temperature drop of the air at 15° and 50% humidity is about 5°. Air is about 1.01 J/g/K, so that's about 5 J/g, and at 0.69 g/s, that's 3.4 watts. This differs from my calculation above by a factor of 12, so one of them must be completely wrong. Maybe both.

You can deliver the heat from the environment by convection, conduction, and radiation.

Room-temperature radiation is more than adequate to replace a few hundred milliwatts (it's on the order of tens of watts per square meter — Stefan–Boltzmann 57 nW/m²/K⁴ gives you 390 W/m² at 15°C, and perhaps more relevantly the derivative is about 5 W/m²/K), but only if the objects you're drying is mostly exposed to radiation from other objects that aren't drying. That means they have to be spread out flat, and you don't want to put them under glass.

Convection will replace the missing heat, but only at the cost of the five- or ten-degree temperature drop in the air, which will keep the chimney from sucking air up.

Conduction is likely to be the best approach in many cases. It can take several forms: metal plates maintained at room temperature by a flow of water or air on the non-wet side, say by running water through pipes or by funneling wind past them; thick metal fins connected to a large temperature reservoir; or even flat heat pipes.

Backwards

But wait! If you have to struggle to overcome a 5° temperature drop, which produces a countervailing effect that's four times as strong, why not use the temperature drop? Instead of a moist-warm-air chimney above your drying objects, you have a cold-air drainpipe below. Your drying objects don't dry as fast, since they're colder.

As a bonus, you get free cold air, which can be used by itself to cool things to retard decay, or to improve the efficiency and delta-T of a refrigerative cooler.

Sunlight

Yeah, if you have the chance, some sunlight on whatever you're trying to dry will help a lot. Then you can get not only more-than-adequate heat flow, on the order of 1000 watts per square meter instead of tens, but also enough heat to make the chimney run purely on heat.

Compression with second-order diffs

Kragen Javier Sitaker, 2014-04-24 (3 minutes)

If you're compressing a numerical sequence, such as a digitized sound wave, you only rarely see exact repetition of sample number sequences; the smallest noise or varying DC offset (i.e. low-frequency noise) will cause all the samples in the sequence to be different. As a result, schemes like LZ77 don't do well at compressing digital signals.

Even the very simplest numerical signals fail in this way. For example, if you have a series of 16-bit samples, each being 258 times the sample number, it will repeat every 131072 bytes; but `gzip -9` can only compress it by 1.4%. (bzip2 -9 does better, compressing 8:1, partly because of its bigger block size; bzip2 -1 only compresses 2:1.)

But if you take the second-order finite forward differences of this sequence, they will be 0 258 0 0 0 0... which is very highly compressible. In fact, even memoryless schemes like Elias gamma coding will work somewhat well at this point, about as well as bzip2. But applying gzip to the above sequence gives you 961-fold compression, while bzip2 gives you 10280-fold compression.

In general, we should expect this to be the case for mostly continuous functions of time: the first and second-order forward differences should be much more highly compressible than the original sequence.

From a Fourier perspective, the finite-forward-differences operation is a single-pole high-pass filter with no knee: it just keeps attenuating at 6dB per octave all the way to DC. Two iterations of it give you 12dB per octave, strongly attenuating the low-frequency content and leaving you only the high-frequency content to encode.

You could ask why only second-order rather than higher orders: if a second-order predictor is good, wouldn't a fifth-order or twentieth-order predictor be better? It might be, depending on your data. The order multiplies discontinuities: a single impulse becomes two opposite impulses in first-order differences, three impulses in second-order differences, and twenty-one in twentieth-order differences. This kind of effect might outweigh the improved compression from removing higher-order regularities from the data.

The Fourier-analysis viewpoint might suggest that this is a lossy scheme, concerned with numerical approximation, but applied to a group (such as N-bit integers under mod-2**N addition) it is perfectly lossless. If you apply it to IEEE-488 floating-point numbers it will indeed be lossy, I think, because floating-point numbers are not a group. (Right?)

This is somehow related to linear predictive coding, in the sense that the finite differences at a given timestep are a linear function of the sample value at previous timesteps, and their "predictions" at future timesteps are also linear functions of them, and the Nth-order difference somehow represents a "residual" from that "prediction".

Various lossless audio compression codecs (Shorten, AudioPaK, and FLAC, for example) use linear prediction in this way to decorrelate

the samples they are compressing.

A plotter language of 9-bit bytes

Kragen Javier Sitaker, 2017-05-29 (updated 2017-06-01) (11 minutes)

Suppose we're in an alternate history where Japan won WWII due to some grievous miscalculations by the US. Computer technology developed anyway, somewhat later, on 18-bit machines like the PDP-4, PDP-7, and PDP-9, with 9-bit bytes, accommodating potentially a 512-bit character set — not enough for single-character kanji, but plenty for hiragana, katakana, and some common kanji. The electromechanical output device of choice in 1970 is not a teletype, but a kind of pen plotter optimized for curve plotting, with a scotophor CRT memory tube (like a Skiatron) as a higher-speed and less material-consuming alternative.

Instead of having two motors driving a teletype carriage across the paper, a third motor to select a letter from a typewheel, and a solenoid to fire a type hammer, the plotter has a pen-down solenoid and X and Y motors (counting from the upper right corner of the page) servoed from, nominally, analog voltage signals with a SNR of some 26dB, providing an effective resolution on the paper of some 2000×2000. These position signals are controlled in two ways: by setting them directly from a 12-bit DAC and by being changed over time by a velocity signal, which is also nominally an analog voltage signal with a 26dB SNR; it, too, can be set directly from a 12-bit DAC, but is changed over time by a (26 dB SNR) acceleration signal, which is an analog voltage signal that can only be set directly or zeroed by a reset command. This allows the plotter to plot perfectly smooth curves by setting only the acceleration signal periodically as the motors move under servo control.

There is additionally a "form feed" command, which initiates a change of page, either through manual operator intervention or through an automatic motor mechanism. The scotophor tube implements this by erasing the image.

This gives us 10 basic commands: x←, y←, x'←, y'←, x"←, y"←, reset, form feed, pen up, and pen down. Additionally, there's an 11th command, which idles the command stream for the given amount of time to allow the pen to catch up. The basic plotter command word, then, is an 18-bit word consisting of a 4-bit order code field, a 12-bit operand field, and two extra bits.

The "reset" command sets the velocity and acceleration to 0, but doesn't change the position.

In our timeline, the 1981 CGA had 128 kilobits of framebuffer; the US$1200 1976 ADM-3A had 16 kilobits of ASCII screen contents buffer (not even inverse video!). We're supposing that this plotter thing became standardized in 1965 at a budget of about US$50000, in a timeline where Moore's Law's 18-month capacity doubling was about five years behind our own. In our timeline, the appropriate amount of memory for computer terminal equipment was about one bit per 7.5¢ (total cost of the equipment, not the cost of the memory) in 1976, which would be 1981 in the Japan plotter timeline. So 1965 would be 16 years back from that, roughly 10 capacity doublings back: US$75.00 per bit. So the plotter has a digital memory budget of about 32 of these 18-bit words, or 64 9-bit bytes.

A terrible problem for terminal equipment at the time was that speeds of 10 characters per second were demanded (this was the major upgrade in the Teletype Model 28, introduced in our timeline in 1953, and a widely used computer console until about 1970 in our timeline; the Friden Flexowriter used as the console for the LGP-30 was also 10 6-bit characters per second) but it was challenging to transmit data over long distances at more than 300 bits per second. Much of Unix's user interface design (for example, the absence of success messages, the two-letter command names, and the "?" error message from ed, The Standard Editor) derives from this. We can suppose that the Japanese would be satisfied with 5 characters per second, but instructing the plotter to draw a single character like "ア", "ラ", "マ", or "ハ" involves about four or five vertices per character, and each vertex requires typically a new x/y position, perhaps a new x'/y' velocity, and often pen up or down. This means we need three or four commands for each vertex, and maybe 16 such commands per character, totaling 288 bits — almost an entire second to transmit in full!

There are about two strokes and two non-plotting movements per character, so the plotter pen also needs to be able to move the distance of a typical character stroke 20 times per second, or 50 milliseconds. If the character box is 5 mm square, and the typical stroke length is about half of that or 3 mm, we need a 60 mm/s pen movement speed, which seems rather slow; we can probably specify 240 mm/s, giving us the physical ability to plot some 20 katakana characters per second, rather than only 5, for which we would also need to be able to execute 320 commands per second. If we presume that our paper is shiroku-ban size 4, 264 mm × 379 mm (implying ≈200μm servo resolution), it will take us an entire second to move from one side of the paper to the other, and the paper can hold 52 columns of 75 characters, which will take some 195 seconds to finish plotting, which is an entirely reasonable kind of interval for a human operator to be asked to manually change the paper. (If we analyze a hypothetical analog electronic PID control system for controlling the pen position with a mechanical system whose acceleration is low-pass filtered by its mechanics, we can derive the kinds of glitchy distortions likely to result in the characters.)

If we figure that a typical stroke length is 3 mm at 240 mm/s, the pen needs 12.5 milliseconds to execute it, so millisecond resolution is likely adequate for the "delay" command; to be safe, let's say we count cycles of a 8kHz clock, so the maximum delay with a 12-bit operand is about half a second. Of course, later plotters that manage higher speeds, and the CRT version, will virtualize these "milliseconds".

(What should the scale for the v and a components be? Like, how many virtual milliseconds should x'=1 take to increment x by 1?)

We have a relatively large discrepancy here between the hypothetical mechanical device's physical capabilities to execute 320 commands per second and the hypothetical serial link's physical capability of 300 *bits* per second. In the other direction, in our timeline, the (18-bit!) 1959 PDP-1 could execute about 93,000 instructions per second, and presumably a similar stack-based machine could execute about 200,000 instructions per second, or maybe 20,000 if it were much smaller and therefore less powerful than the PDP-1's

2700 transistors, 3000 diodes, and 4096 18-bit words of core.

Could we advantageously use this powerful memory of 64 9-bit bytes or 32 18-bit words, or maybe a few times that, and the potential of executing tens or hundreds of thousands of instructions per second, to bridge the gap between the 300-bit-per-second serial link and the 320 drawing operations per second. Maybe you could even take full advantage of the curve-drawing abilities of the hardware with a font ROM made with PCB inductance, like the HP 9100A's microcode PCB (512 64-bit words totaling 32 kibibits, 1968 in our timeline, US$5000, 23 registers of core RAM; projecting forwards to 1973, backwards 8 years to 1965 to get a factor of 6 Moore's Law reduction, and up by a factor of 10 to account for the larger budget, we get 53 kibibits), or core ropes, like the Apollo AGC (1966 in our timeline, astronomical budget).

The GreenArrays C18 core has (not counting its stacks) 128 18-bit cells in its memory address space, of which 64 18-bit cells are RAM and 64 18-bit cells are ROM; disregarding literal cells, each one normally has four five-bit instructions packed into it, with the fourth instruction having two implicit zero bits. This is only a factor of two greater than the RAM budget of 32 18-bit cells I suggested above, and although it is somewhat limited in what you can achieve on a single core, I think a smaller C18-like processor would work fine as a controller for this hypothetical plotter. Normally it would execute 18-bit instruction words received over its serial port, which could read and write its 64 cells of RAM, and also make calls to routines loaded into its RAM and routines already present in its ROM; if it can execute 20 000 instructions per second, then it has time to execute some 63 processor instructions per necessary plotter instruction or 1000 processor instructions per plotter stroke, and if our serial connection gives us a start bit, 9 data bits, and a stop bit per 9-bit byte, at 300bps we can receive 27 bytes per second and execute 733 processor instructions per serial byte. Two such bytes should be adequate to invoke a subroutine to draw a character.

This architecture would actually allow font ROMs with a significant number of kanji, since you could define and invoke subroutines for radicals with bounding-box parameters.

Of course, this approach also allows you to write characters at arbitrary non-character-cell positions, to draw arbitrary line graphics, and probably to draw stipple patterns.

(If the pen is replaced by a brush, it might make sense to use a proportional actuator like a servomotor or voice coil to control trace intensity, which of course is easy on a scotophor.)

The physical system described here visits new points at about 20 Hz, which means it probably needs to have its first vibrational eigenmode well above 200 Hz to avoid unacceptable ringing (with a simple PID control system, anyway.)

The imbalance inherent in copyright systems

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

It's 2028. Last year, you visited your mother in a nursing home and sat with her and talked for a long time, which was sometimes difficult, because one of the other residents was listening to music on the radio on the other side of a curtain. You video-recorded the whole session and stored it on your computer. You told her you'd come back to visit the next week, but trouble came up at work, and you had to postpone the visit for another week. On your next visit, she no longer recognized you. A few weeks later, she died. Now your computer has flagged your video as copyright infringement and deleted it because of the music in the background. You would like to make sure this doesn't happen again.

Your brother stored a copy of your last recording of your mother before she died on Dropbox, but Dropbox also flagged it as copyright infringement and deleted it. After he protested publicly, Dropbox reported him to the police for child pornography, and indeed the police found child porn videos were in his Dropbox folder when they seized his computer. He swears he didn't put them there, but he's not having good luck convincing his cellmates of that. You would like to make sure you don't entrust companies like Dropbox with the ability to plant incriminating files on your computer.

Ever since you watched a video on YouTube about spearfishing off the coast of Panama, every web site you visit shows you ads for ammunition and "paracord", whatever that is. Your request for a visa to visit your sister in Spain is declined; no reason is given. You realize that watching videos on YouTube is dangerous.

What are Bitcoin's uses other than sidestepping the law?

Kragen Javier Sitaker, 2019-03-11 (updated 2019-07-05) (6 minutes)

(An edited version of a comment I left on the orange website.)

Someone asked: what are the uses of Bitcoin, other than sidestepping the law?

Rather than sidestepping the law, you can be sidestepping official corruption or crime. There are lots of cases where people who are supposed to be enforcing the law instead use their law-enforcement powers for their own benefit, sometimes in ways that are illegal, officially speaking, but in an unenforced way.

It's perfectly legal for me to, for example, donate money to WikiLeaks. But Visa and Mastercard aggressively canceled every merchant account that allowed people to use Visa or Mastercard to donate to WikiLeaks, apparently because of secret pressure from US government officials who were unhappy about some of the things that WikiLeaks revealed. The Snowden revelations — which may not have been legal, so they are peripheral to the question — very likely wouldn't have happened without WikiLeaks being able to support him, which they could only do because they could receive Bitcoin.

Similarly, many Patreon accounts are getting canceled because their owners have published things that are embarrassing to Patreon, but not illegal (typically, racist remarks). If Bitcoin becomes mainstream, there won't be a centralized authority like Patreon that is in a position to end people's livelihoods because they publish politically undesirable viewpoints. (Right now, those viewpoints are viewpoints that are odious to you, but there's no guarantee that that will be the case in the future; it's easy to imagine Patreon bending to Chinese government pressure to censor people who talk about Falun Dafa persecution or Tiananmen Square, for example, even in countries where that is legal.)

As another example, many Venezuelans are having difficulty fleeing the country, even though fleeing the country is technically legal, due to both official corruption and armed gangs. You can get long-distance bus tickets, but even if the bus can get fuel, it may be robbed in transit by armed gangs ("*piratas del asfalto*", as we call them here in Argentina), who can take your cash and your cellphone but not your LocalBitcoins password or your wallet seed. You could argue that it's not clear what is and isn't legal in Venezuela right now because there are two competing governments, but neither of those governments authorizes demanding bribes from would-be émigrés.

As yet another example, it's perfectly legal in Iran and France for French companies to do business with Iranian companies. But, because much of the world financial system is controlled by the US, it can be difficult in practice; see the Washington Post article on European companies that are selling to Iran for more details. Regardless of whether US law is misguided or not, under well-established principles of international law dating back to the Peace of Westphalia, it certainly does not apply to French companies doing business in France with Iranian companies in Iran.

Also, in many countries, saving money in the local currency is a recipe for poverty, but buying foreign currency is illegal. In 2016, India invalidated most of its circulating currency without warning, so that people would have to save their money in banks instead of in their mattresses; this change significantly exacerbated India's poverty problem. Here in Argentina, the peso lost over half of its value last year. Even the US dollar inflates by a few percent per year, and it's lost 96% of its value since Bretton Woods ended in 1972. Like gold, Bitcoin's volatility makes it suboptimal as a savings vehicle (unless you like to gamble), but for many purposes its disadvantages are less serious than those of the alternatives.

So, in a sense, I think you're right that the main purpose of cryptocurrencies is to sidestep *violent coercion*. I think you're terribly naïve about how much illegal violent coercion is actually "the law", although that's understandable if you've never lived outside a rich country. Increasingly, the same kinds of problems are occurring in rich countries as well, so you may have a chance to correct your naïveté with experience. Hopefully you'll have some Bitcoin first.

There are other uses as well; it's a dramatically better way to send money overseas, for example. Last time someone sent me money via Western Union, I had to go to three different locations, stand in line for twenty minutes, hand over a massive amount of personal information (perfectly suited for identity fraud or targeted home robbery) to an unaccountable third party, sign a false statement, and walk out the door into a dangerous neighborhood with a pocket full of small bills. For this "service", WU charged me/them about 10% of the money sent, and also didn't inform me when it arrived. Bitcoin transactions require none of this nonsense and cost much less; the last Bitcoin payment I received from overseas cost 0.3%, and I received a notification in a few minutes in my Bitcoin client of the transaction.

(See also Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333) for how Bitcoin and similar systems could potentially provide many of the financial functions of the current banking system with much lower risk, both individual and systemic.)

Many thanks to sbp for his comments, which greatly improved this note!

Ternary mergesort

Kragen Javier Sitaker, 2015-09-03 (2 minutes)

Ternary divide-and-conquer algorithms are usually more efficient than their classical binary cousins.

A few years back Java switched to Yaroslavskiy's ternary or dual-pivot quicksort; it turns out that quicksort is marginally more efficient if you partition into three parts in the partitioning stage rather than two, but it's a marginal difference that grows with the dataset size.

Ternary numbers

Similarly, if you represent numbers in N-ary with unary digits, such that 1 is "|," and 0 is just ",", then the optimal value for N is 3, which is marginally better than 2 or 4, which are equivalent. That's because a number M needs ceil(log(M)/log(N)) N-ary digits to represent it, but each of the digits is of size N/2 on average, so the number as a whole is O(N/log N) digits. It turns out that 2/log 2 is equal to 4/log 4, and about 5% larger than 3/log 3; N/log N has its minimum at N = e.

For example, 32808328602 is, represented with unary digits of various bases:

```
2 |,|,|,|,,|,,,,|,|,|,,,,,|,|,|,,|,,|,|,|,,|,|,,,|,|,,|,,
3 |,,,|,,||,,,|,|,,|,||,||,||,,||,||,||,||,|,||,,
4 |,|||,||,||,,|||,||,,|,|||,|,|,|||,|,||,|,||,||,
5 |,,|,||||,|,||||,||,||||,|,|||,,,|||,||||,,||,
6 ||,|||,,||,|||,|||,|,||,||,,||,|,|,,
7 ||,||,||||,|,,|,,|,||,||,|||||,||||,,
8 |||,||||||,||||,|||,||||,|,||||||,|||||,||||||,||||||,|||,||,
9 |,,|||,||||||,|,|||,|||||,||||||||,||,||||||||,|||||||,||||||,
```

And here's 8308233280877:

```
2 |,|,|,|,,,,|,|,|,,,|,|,,|,,,|,,|,,,|,,|,|,,,,|,|,|,,|,,|,|,,|,|,,|,
3 |,,,||,|,,||,,||,|,,,,,,|,||,,,|,,||,||,,|,,|,||,
4 |,|||,||,,|||,||,|,||,||,|,|,,||,|||,,|,|||,|,|,||,|||,|,
5 ||,,||||,||,|,|,,||,|||,,||,,||||,||||,||||,||,,,||,
6 ||,|||||,||||,,,||||,||,|||||,|||||,|||,||,|||||,|||||,|||||,,,|||||,
7 |,|||||,|,|||||,|,|||||,|,|||||,||,|||,||||,|||||,|,|,||,|||||,
8 |,|||||||,,|||||||,|,|||||,|,||,||,||||||,|,||||||,|||||,|||||,|||||,
9 |||,||,|||,||||||,|||||||,,,|,||||||,|,||,||||||,|||,|||||,
```

And here's 9237528032:

```
2 |,,,,|,,,|,|,,|,,,|,|,,,|,,|,|,|,|,|,,|,|,|,|,,,,,,
3 ||,|,||,||,|,|,||,|,,,,|,,,|,,|,||,||,|,||,
4 ||,,||,|,||,||,|,||,|,|,|||,|||,|,|||,||,,,
5 |,||,||,||||,,||||,|||,,|,|||,||||,||||,|,|,||,
6 ||||,|,||,||||,|||,||||,||||,|,||||,|,||,|||||,||,
7 ||||,||||,||||,||||||,||,|||||,||||,|||||,||||||,||||,|,|||||,
8 |,,||||,||||||,||||,||||||,||,|||||||,||||||,|||||||,||||,,
9 ||,|||||,|||||||,|||||,|||,,|||,|,|,||||||||,|||||,
```

You can see that the number size is generally minimum at N=3, but higher bases can have progressively greater variances.

Following this logic, there were a few ternary computers built in the 1950s (?) with three vacuum tubes per three-state "flip-flop" instead of the usual two tubes per two-state flip-flop.

Ternary mergesort

M-ary mergesort of N elements takes ceil(log N / log M) passes over the data; each pass merges M runs at a time, making (in the simple case) M-1 comparisons for each of N elements, for a total of

N (M-1) ceil(log N / log M)

What does a futuristic OS look like?

Kragen Javier Sitaker, 2017-08-18 (updated 2019-05-05) (6 minutes)

I was just looking at the screenshot of HelenOS at http://www.helenos.org/chrome/site/screenshot.png, and it occurred to me that it's a bit clichéd.

Hobbyist OS clichés that look outdated

I mean, the reasons HelenOS is supposedly interesting aren't capable of being shown in a screenshot at all. But here's a sort of checklist/bingo card of things that look "outdated":

- Fixed-width fonts everywhere.
- Big title bars on all the windows.
- A rotated rectangular window.
- Flat-shaded buttons (and everything) with no texture and no gradient. I mean, Arena had texture on its backgrounds in 1994. All our displays are TrueColor now. No physical objects have no texture and no gradient.
- ASCII-art tables (in the top display).
- A restricted color palette that nevertheless includes a diversity of saturated colors.

There's a lot of hobbyist-OS work that kind of looks like that actually. I'm looking at a TempleOS screenshot that hits #1, #2, #4, #5, and #6; it's mostly fixed-width text on a white background, even the window borders; of the I think 59 lines of text on the screen, about 5 (8%) are taken up by window borders and titlebars; the text is in white, magenta, red, green, dark blue, light blue, and yellow; the filesystem directory and the hotkey menu are both ASCII-art tables. (TempleOS additionally has many aesthetic problems: very wide borders, 640×480×16, color boundaries that butt up right next to text and impair readability, low-contrast color choices, underlining, and a profoundly ugly font, among others.)

ColorForth screenshots I find have fixed-width text in red, green, yellow, white, and blue on a plain black background, hitting #1, #4, #6, and arguably #5.

The Toledo family's Fénix operating system and Biyubi web browser is an effort that seems mostly to have escaped this, though it still suffers from #2.

Oberon suffers from none of these except #4.

Hollywood "futuristic" UI clichés

There's a separate set of clichés in Hollywood depictions of "futuristic" user interfaces, some of which are due to constraints of filming:

- Transparent screens.
- Giant flashing error messages, and more egregiously, non-error messages: "INTERCEPTING SIGNAL", ">>SEARCHING_ALL_LIBRARY_ARCHIVES", "QUERY

COMPLETE".
• Lots of "cool" slide transitions and animations, including lots of three-dimensional rotations and progressive delays. Things rarely just blink into or out of view; instead we have progressive display on even the simplest of data, such as monospace hex dumps or even individual people's names, as if we were receiving it over a 1200-baud modem.
• Bright-on-dark text, but never in monospace except to show that the user is a data vandal.
• Bright-on-dark vector drawings, including lots of wireframes.
• Radial menus. Radial and circular layouts wherever possible, really. This is sort of a callback to "high-tech" products of the 19th and 20th centuries made by lathing steel and brass.
• Touchscreens and voice interfaces.
• Lots of capital letters.
• Holographic displays.
• Textures, animation, and translucency everywhere. Incessant animation.
• Lots of 3-D interfaces and zooming. "This is Unix! I know this!"
• Rectangular grids.
• Great text size variation to focus viewer attention on the most important part, like that used in machine tool DROs.
• Windows with tabs in funny places.
• Random patterns of dots linked into a Delaunay triangulation or something similar, all bright on a dark background, maybe with some of the triangles filled with translucent bright.
• Sound effects, especially square-wave beeps.
• Constant, instant responsivity, even of partial results.
• Lots of primary colors, and things changing color over time.
• Roundrects, perhaps with a bit of rotation.
• Lots of text windows that look more like chyrons than anything else.
• Gestural interfaces.
• Lots of photos, often with strange clipping paths around them, often reminiscent of punched cards.
• Visible pixelation and glitches. Things flickering into or out of visibility.
• Hershey-ish monoline fonts. Old movies often used MCR characters.
• Dotted lines.
• Crosshatch shading (usually light on dark).
• Bright-on-dark displays, especially with cyan glows (the ZnS:Cu color of an analog oscilloscope screen; sometimes the green oscilloscope color is also seen). Fairly sparse color schemes, mostly varying in the intensity of a small number of hue-saturation settings, usually not very saturated. (ZnS:Cu cyan is not very saturated.)
• Bright-on-dark color schemes in general.
• Lots of numbers and graphs.
• Callouts, like on a mechanical drawing — with a leader connecting some text to a point in a drawing.
• Ripples expanding from things.
• Targeting crosshairs.
• Lots of non-convex polygons whose sides are lines at multiples of 45°, often looking kind of like punched cards.
• "Scientific" information: the Earth, the Periodic Table, chemical

diagrams, DNA double helices.

Some of these are actually good ideas. Some are instead chosen to make things look foreboding, scary, "futuristic", intimidating, advanced, and so on; others are simply imitations of previous films. As Christopher Noessel says, "This is the fundamental problem of the idea of sci-fi interfaces, they're not interfaces. What they are are *plot visualizations*. They're there to illustrate, or demonstrate something happening, or something that has happened." Some are not currently achievable. Some are actually packs of prepackaged effects, like the Cybertech HUD Infographic Pack template for After Effects.

A UX StackExchange question goes into more details. There's a whole category of "FUI" or "fictional user interface" videos on YouTube, too.

Expanded mineral beads

Kragen Javier Sitaker, 2019-10-01 (12 minutes)

Material made from expanded polystyrene beads (usually referred to as "styrofoam", although that's a brand name for a slightly different material) is very common for a number of reasons.

What if we did this with minerals?

Advantages of expanded polystyrene beads; properties of foams

The foamed nature of the resulting material makes it light, very stiff for its weight, very soft for its volume, forgiving of impact (I think much of the impact energy is actually taken up by compressing the gas), and an excellent insulator, and being some 1–2 orders of magnitude less dense than the source polymer, it is also 1–2 orders of magnitude cheaper per unit volume. It doesn't have much tensile strength because the beads tend to pull apart, but its compressive strength is extreme, although it suffers from creep in both tension and compression.

Moreover, it is much more resistant to fracture propagation than pure polystyrene, which has an alarming tendency to shatter. Both cell walls and bead boundaries act as barriers to crack propagation.

One of its biggest advantages, though, is its moldability. The beads are made to expand inside a mold, in this way filling the mold. (I'm not familiar with the process but I assume it's a matter of releasing the pressure at a temperature where the thermoplastic beads are plastic but not molten.)

Another interesting feature is its amenability to shaping processes. You can cut it with a hot-wire slicer with very little energy and low to very low side loading, producing a smooth and precise surface. The smoothest surfaces with this process come when the wire is touching the foam and transmitting its heat by conduction, rather than by radiation, but this produces some side loading and consequent surface imprecision. The "swarf" from this process is absorbed into the surface of the material by virtue of densification from collapsing cells. It's also fairly easy to cut with more traditional processes like sawing and milling — much, much easier than the underlying polymer. These processes work at such low forces that they do not create significant heat, and thus do not create a heat-affected zone.

The extension at yield of the foam is somewhat larger than that of the bulk polystyrene material, which is relatively brittle, but not dramatically so.

In terms of material properties, probably the most extreme result of the foaming process is the decrease in the material's Poisson ratio: the foamed material very nearly does not expand at all laterally when compressed, even plastically, or shrink laterally when extended. This is particularly favorable to *forming* processes: drawing on a styrofoam cup with a thumbnail, for example.

Why isn't everything made from styrofoam? It's very flexible for its volume, which is an advantage in many applications but a disadvantage where it needs to resist buckling — though it is

commonly used as part of composites (see Sandwich theory (p. 2450), which also talks about buckling a lot). It isn't transparent, it doesn't resist high temperatures (because polystyrene creeps and then melts), and it isn't hard. The molding process isn't very precise, typically having surface roughness that approaches a millimeter in places, and I suspect it's considerably slower than injection molding. It's nonporous, and in a lot of situations where softness is desirable, porosity is too.

Finally, a lot of people just fucking hate it aesthetically, precisely because it's so widely used and cheap; also, it got a bad rap in the 1980s when it was blown with CFCs and thus contributed to ozone depletion.

Presumably any desired properties of a random foam could be equaled or dramatically exceeded by a metamaterial with similar pore size but precisely controlled geometry, topology, and heterogeneous materials, in the same way that woven and knit fabrics exceed felt and nonwovens, and masonry arches and reinforced concrete skyscrapers can exceed random piles of rocks. So in a sense foams may be a bootstrapping step toward self-replicating machinery or a technique to use at scales too small for your available machinery to manipulate explicitly, not a long-term material. Living tissues generally do not contain unstructured, random foams at scales larger than a white blood cell, and once the humans' fabrication technology is not so primitive, neither will their fabricated artifacts.

Why minerals?

As I've discussed in some other notes, it's very desirable for self-replicating machinery to be independent of organic feedstocks, including things like petroleum: inorganic material is much more abundant both on Earth elsewhere, it doesn't create conflicts with objectives like reterraforming, and it avoids scaring the humans. However, most materials that are strong but not too brittle at or near room temperature are organic. It might be possible to improve this situation with metamaterials — glass fiber, basalt fiber, and steel coil springs are far from the limits of what can be done. One of the simplest "metamaterials" to fabricate is foam.

Candidate minerals

In addition to styrofoam-like processes, it's worth thinking about infusion postprocessing, where after the foam is shaped its cells are filled with some other material. This probably requires the cells to be substantially open rather than closed. Also, think about painting (depositing a layer of a different material on the surface, such as a harder material, maybe a metal), use as a mold (for example, for metal), and defoaming the surface to form a harder surface layer.

Soda-lime glass

Soda-lime glass commonly requires extreme measures to prevent it from foaming: ingredients to reduce its viscosity and long kiln times to allow bubbles to escape. (I'm not sure if precalcination of some of the ingredients is also used). Bubbles are one of the most common obstacles to getting good, clear glass from raw materials.

If you want *more* bubbles instead of none, it seems like it should be easy to achieve: leave out the viscosity-reduction agents; incorporate

more gas-producing minerals such as boric acid, sodium carbonate and even bicarbonate, and calcium carbonate, and cool the melt rapidly.

Waterglass

The sodium silicate I have here dries to a glassy, mildly alkaline substance with a Mohs hardness around 3–4. Upon heating to around 200–300°, it foams up into a white foam with visible bubbles; presumably water inside of it is boiling out and the heat has plasticized the sodium silicate enough to permit bubble formation. The total volumetric expansion is maybe a factor of 10. (These are crude stovetop experiments; my temperature estimate is based on the fact that a grease spot on the same electric burner had started smoking shortly before, for example.) The resulting foamed material floats and leaves tiny silica-gel sparkles when rolled across my palm.

(I suspect that if I let the dried waterglass sit for a long enough time, it might become harder by absorbing CO_2 from the air.)

This phenomenon is behind what I hear is the common use of sodium or potassium silicate as a firestop — upon heating, it foams up to produce a non-oxidizable insulating layer that stops airflow and heat transport.

This suggests that it should be possible to use dried sodium silicate beads or perhaps silica-gel beads to mold and foam up in the same way as styrofoam.

Since the water doesn't condense again until a lower temperature at which the waterglass is no longer plastic, the foam remains foamed after cooling.

Perlite and vermiculite

These are commonly foamed minerals used in gardening and glassblowing, able to withstand much higher temperatures without softening than the materials mentioned above; vermiculite is used as an insulator in laboratory glassblowing of borosilicate glass, commonly in direct contact with the hot glass without sticking to it.

They are mostly open-cell foams, which is the reason for their use in gardening to improve soil drainage.

In both cases, the foaming action is produced by the escape of water vapor from the mineral under heating; the minerals are found in nature in their unfoamed form, having formed, I think, under pressure sufficient to prevent the water from escaping.

Pumice

This rock is naturally foamed during volcanic eruptions; like obsidian, it is a glass, but it contained a large amount of dissolved gas which bubbled out of solution during the eruption. Typically the foam is sufficiently closed to allow the rock to float.

Pumice is not common, suggesting that unusual circumstances are needed to produce it; I don't know if that's a matter of mineral content, dissolved-gas content (which might depend on the mineral content), or rapid cooling (which might not be entirely adiabatic; obsidian typically depends on water cooling). More common natural volcanic mineral foams such as scoria cool much more slowly and typically have an open-cell macrostructure and a crystalline rather than glassy amorphous microstructure.

Concrete

Of course foamed portland concrete is a thing. I ran into a pallet of stacked foamed-concrete blocks on the sidewalk the other day. This works by mixing detergent and air into the water before mixing the concrete. While the reduction in weight and consequent improvement in insulation properties is substantial, as I understand it, it's rarely even a factor of 3, let alone the 10–100 of styrofoam.

You could conceivably puff up foamed concrete into a mold before the cement starts to set, either by initially mixing it under pressure and then releasing the pressure, or by mixing it at one atmosphere and then pulling a vacuum once it's in the mold. But usually people just pour it into molds before it sets without fooling around with pressures.

Firebrick

Insulating refractory firebrick is also a common foamed mineral product. Most commonly it is made by mixing the refractory clay with a filler material which burns out during firing; any carbon or organic matter will do (I made some using used yerba mate; see file `ceramics-notes`), and I think sulfur would do as well. This material is also amenable to molding in its plastic state.

I was able to get density reduction of up to a factor of 9, but beyond a factor of 4 (3:1 clay body to yerba) the material was noticeably friable. At a factor of 4, it felt solid but could be carved with a thumbnail in fired form. These foamed ceramics were enormously easier to cut than regular fired clay, which tends to shatter whenever you try to cut it, and enormously more resistant to thermal shock, which I suspect is partly because it's softer and partly because of its insulating qualities.

To make this process amenable to execution without organic matter, you'd have to find a different filler. This could be something with a low boiling point (like zinc); something whose oxides have a low boiling point, as do carbon, hydrogen, nitrogen, and sulfur; or something that decomposes or substantially decomposes into gases at high temperatures, like nitrate or carbonate.

Alternatively, you might be able to use a styrofoam-like foaming process, where a gas such as nitrogen or CO_2 is dissolved into the clay's water under high pressure, then bubbled out with a release of pressure.

Topics

Critical defense mass

Kragen Javier Sitaker, 2013-05-17 (14 minutes)

I think our only real hope for survival and prosperity is learning to cooperate nonviolently — not just without violence and threats in day-to-day life, but without even condoning state violence such as war, arrests, and imprisonment. Historically, state violence has been far from sufficient to organize society; society's functioning rested primarily on nonviolent day-to-day interactions, what Gandhi called satyagraha, primarily between people who know each other in small communities.

Mostly starting in the 20th century, although with antecedents in historical episodes like the Roman Dominate, we've seen a dangerous set of experiments in organizing society primarily around the state, which is to say around violence. While these experiments have produced some promising results (the extermination of polio, space travel, dramatically improved agricultural yields, the internet) I hope we can move beyond them to a peer-to-peer global society. Otherwise, it seems that we are doomed either to live under a global state — which we can hope against hope will not be particularly despotic — or perish in a nuclear holocaust or similar tragedy.

Violence, Warfare, and Agriculture

Nevertheless, it remains true that through most of history, we've been under the threat of violence from other communities. Warfare and warriors have been a constant plague on humanity since prehistory, and historically, we have had no hope of living without violence, only of prevailing in it.

And, historically, this violence has been mostly two-dimensional: warfare and warriors moved around on the ground. This gives rise to a minimal stable size for an agricultural settlement, because the circumference of a two-dimensional shape increases more slowly than its area as the shape grows.

A farmer cannot defend his own field from looters, armed or otherwise. It might require 100m² or 1000m² of land to feed one farmer, depending on the climate, your cultivars, your ability to trade, and so on; but even 100m² of land has a minimal circumference of some 35 meters. One farmer might be able to defend one or two or ten meters of circumference, even while he's awake, but not 35.

But a circle with a circumference of 70 meters has an area of 400m², enough to feed, hypothetically, four farmers. That leaves each of them only needing to defend 18 meters of circumference instead of 35. Still too much, but perhaps moving in the right direction.

If each farmer can defend ten meters, your minimal size is almost twice that, or 130 meters of circumference, and 13 farmers, with their wagons or houses circled in a 20-meter circle around 1300m² of land.

If each farmer can defend two meters of circumference, you have 315 farmers on a circle 200 meters across with a total area of 31500 square meters, about three city blocks, three hectares, or eight acres. This is beyond Dunbar's Number, and so at this point you start needing institutions, formal hierarchy, and so on. Two meters is small enough that you can have night sentries who wake everybody else up

if they see or hear anything, and dense enough that you can't steal the farmers' crops by yourself — you need a raid by an armed and organized band of bandits.

100m² is a really small farm. It's not enough to support a person except in the most fertile parts of the world, with a lot of luck. 1500m² might be a more realistic estimate in most of the world. If you need 1500m² per person, but each person can defend only five meters, your minimum community size is 754 farmers, 600 meters across, with an area of a million square meters (100 hectares).

Of course, in real life, the farmers don't live on the outer borders of the farmland; they only go there when there's a raid or the threat of a raid from another tribe, and they keep what is most precious to them — their lives and those of their families — in a much smaller area that's easier to defend than their entire fields. But there still need to be enough of them to keep a watch on the border, and to repel the raiders when they raid.

The Origin of Stratification

I think this is why the birth of agriculture led to the stratification of society. It's not, as many have said, that agriculture makes it possible, for the first time, to produce enough surplus to support a richer class; observations of contemporary hunter-gatherers show that, even though they're living on the most marginal lands, they still only work for survival a small amount of the time. And it's not just that agriculture makes you store up your harvest in a granary where it can be stolen. It's that keeping hunter-gatherers from gathering what's in your field requires you to organize into groups that are bigger than Dunbar's Number, and the more organized the hunter-gatherers or pastoralists or invading agriculturalists are, the bigger your community needs to be to repel them — even at the cost of enabling parasitic warrior-kings.

To put it more plainly, in such a world, if your farmers aren't willing to die for the sake of people they don't really know, if they aren't willing to sacrifice their lives for an abstraction, if they aren't willing to be sent to their deaths by a general, then raiders will take their food and their children will starve. But the general or king who chooses who to send to their death will not send his own sons first, and if you do not pay him tribute, he can send his loyal subjects to take it from you by force. So stratification is born.

If this explanation holds water, we'd expect to see:

- Proportionally smaller states and less social stratification in areas and time periods with higher natural agricultural productivity.
- Larger states and more stratification in areas with more forceful raiders.

I think these do exist, although I'm not sure — many enormous empires with great stratification have surely existed in very fertile places.

(The explicatory power of this area-to-perimeter ratio thing is perhaps somewhat dubious: surely in most of history the greatest determinant of the size of any given state has been the size of neighboring states, no?)

What about new technology?

Vat food

People only need to eat 100–120W of food, or 2000–2500kcal/day, and the solar resource in most of the world is greater than that per square meter — in the US, it's mostly 3–6kWh/day/m², which is 120–250W/m². The reason you need hundreds or thousands of square meters per person for agriculture is that, first, natural photosynthesis is only about 3% efficient even when not resource-limited; second, plants spend most of their energy on growth and reproduction, not on feeding you; and, of course, you need micronutrients.

But what if you had a 60%-efficient electric solar collector, powering a 30%-efficient synthetic sugar-and-protein plant? Then you could turn 18% of the sunlight you caught into edible calories. If you had access to a 250W/m² solar resource, you could get by on 2⅔m². Remember how, before, the need for one defending farmer per five meters of perimeter forced the farmers to band together into groups of 754? Now you can get that same level of security with 2 "farmers" guarding a 1.3-meter-diameter circle. You don't hit Dunbar's Number until you have 135 "farmers" guarding their shared 10.7-meter-across solar plant, half a meter apart.

One person per 2⅔m² is about 370 000 people per square kilometer, which is more than ten times the density of the densest cities in the world, such as Delhi, or Manhattan, or Friendship Village, Maryland.

That is, people eating synthetic macronutrients out of vats could establish population densities that exceed the population densities of our current agriculture-based society by as huge a ratio as ours exceeded the density of the pastoralist and hunter-gatherer societies it has defeated. And, perhaps, they would have no need to establish hierarchical states with unaccountable rulers, simply in order to be able to protect their crops from raids; they could do it with tribes of hunter-gatherer scale.

None of this is quite feasible yet, neither 50%-efficient solar-energy collection (the current state of the art is about 40%, or 5% at the lowest cost per watt) nor efficient macronutrient synthesis. However, they're both clearly technically achievable.

(You might think that it would be pretty uncomfortable to have only 2⅔ m², 29 square feet, per person, like hanging out in a crowded supermarket for your entire life; but you could build buildings many stories tall, to provide each person with ample living space.)

(Another caveat: as Charlie Manson, David Koresh, and the like have amply demonstrated, living in a hunter-gatherer-sized autonomous band is no guarantee of living in peace or hunter-gatherer-like egalitarianism.)

The United States contains 9.8 million km². If it were populated at 370k people/km², it would contain 3.6 trillion people, 500 times the current population of the Earth. At a twentieth of that density, it would contain 180 billion people, all living with a material standard of living comparable to current US society. The corresponding numbers for Argentina are 2.8 million km², 1.04 trillion people, and 21 billion people. For Earth, 150 million km², 56 trillion people, and 2.8 trillion people, about 7900 or 400 times the current population.

At the current population growth rate of 1.1% per year, we'd reach those population benchmarks in the years 2561 and 2835; but if the

world population were to grow at Qatar's 4.9%, which we know is possible, we'd reach them in years 2138 and 2201. In-vitro gestation would make much higher population growth rates possible.

(Why a twentieth? Because it brings the total solar power available to each person to some 5–10kW, or 2½-5kW after conversion to electricity, putting them on par with modern US consumption of some 10.4kW per person.)

Given the extent to which modern cities are tolerant of pluralism, and the compatibility of growing vat food with city life, it's probably not realistic to imagine the eruption of such a new lifestyle in separated communities; rather, people inside of cities will buy, separately, solar energy harvesting devices and macronutrient-growing vats, probably in both cases mostly as emergency fallbacks; and vat food won't become popular until a generation comes to maturity that grew up eating it, probably due to a political and economic catastrophe that forced them to grow up in poverty, like Spam and horrible boiled vegetables in England after World War II.

Furthermore, vat-growing food won't become a popular thing to do as a hobby, like bean sprouts or yogurt-making, unless it becomes popular first as an industrial-scale product, or unless there are regulatory and political reasons people can't do it on an industrial scale.

Quite aside from the purely factual questions considered above — how vat food could become established, what population it could support, where it would likely take root, and so on — there is the normative question to consider: is a vat-food future dystopic?

Hierarchical or not, it sounds dystopic to me.

Robots

Instead of increasing agricultural productivity per square meter, consider the possibility of extending each farmer's defensive powers. Today drone pilots in the US armed forces routinely control four drones at once, each capable of surveillance and unaccountable targeted violence over a very large geographical area.

If each farmer has at his command some kind of robots, perhaps he could use the robots, instead of his neighbors, to guard his garden against raids. In a sense, this is what happened with the enclosure of the Old West: instead of robots, ranchers installed barbed-wire fences ("bob wahr") to keep their cattle from wandering off, converting their rustler-killing, Native-American-battling pastoralism into a kind of agriculturalism. It didn't stop rustlers, but it slowed them down enough, and it did stop the buffalo.

Now, it seems eminently plausible that one person with a bunch of video cameras and, say, remotely triggered Tasers, chains, salt-water squirters, mines, and so on, could police 1500m² of land, which after all has a perimeter of only 138 meters, against raids. His neighbor, or his neighbor's robots, wouldn't be able to step onto his land to dig his potatoes without his permission.

But could one person really put all of that in place? Maybe not — but it seems clear that one person with modern surveillance, computation, and weapons could defend a larger perimeter than one person without.

So far, though, we've seen a countervailing trend: the increasing

division of labor, and thus specialization, necessary to produce the computing devices is deeply bound up with the current world system of enormous states with millions to hundreds of millions of citizens or subjects. And while current machinery may not make it particularly easier to steal potatoes, it certainly makes it a lot easier to cut chains and blow up mines, enabling attackers as well as defenders — especially attackers using the power of large states with hundreds of millions of members.

Minimal imperative language

Kragen Javier Sitaker, 2018-12-10 (7 minutes)

What's the smallest we can make an imperative programming language to, for example, plot points in a framebuffer?

Well, BF is one answer to that question; StoneKnifeForth is another. But what about a language that supports subroutines (recursive, with arguments, but without closures), conditionals, loops, arrays, and arithmetic with infix syntax? Because I guess I'm not willing to go *that* minimal.

A thing you have to think about is whether arrays are valid as arguments or not. That makes a big difference in the flavor of the language.

You need some way to declare arrays, but that could be static, like subroutines are in C.

Your syntax might look like this:

```
program: _ (name '['_ int ']'_ | name '('_ (name, ','_)? ')'_ ':'_ exp)*
exp: stmt, ';'_ | '{'_ (exp '->'_)? exp? '}'_ | stmt
stmt: name ('=' | '<-' | [-+*/%^&|] '=' | '&^=')_ stmt | cond
cond: cmp '?'_ cond ':'_ cond | (cmp, '&&'_), '||'_
cmp: val ('==' | '<=' | '>=' | '<' | '>' | '!=')_ val | val
val: ((((chain, [*/%]_), [-+]_), ('<<' | '>>')_), ('&' | '&^')_), [|^]_
chain: ([-+~]_ chain | atom) ('('_ (expr, ','_)? ')'_ | '['_ exp ']'_)*
atom: '('_ exp ')'_ | name | int
_: [ \n\t]*
int: [0-9]+
name: [A-Za-z_] [A-Za-z0-9_]*
```

In this grammar, the syntax `a, b` means `a (b a)*`; , binds more tightly than |, so `a | b, c` means `a | (b, c)`, and `a, b | c` means `(a, b) | c`. This enables this grammar to get by without defining associativity much, though it does define precedence. It also is free of left recursion, enabling a straightforward PEG implementation.

Most of this is the same as C or Golang, but the `{ foo -> bar }` construct is intended to mean `while (foo) { bar }`, and the distinction between = and <- is that = declares and initializes a new variable, while <- mutates an existing variable. (Inconsistently, += and the like are not written +<-.) The intended semantics are that everything has a value, including `stmt`, but loops return just the zero value of their conditional upon exit, rather than anything useful like their last body expression or a list of their last body expressions (since we don't have lists). Sequences `a; b` likewise return the value of the last item in the sequence.

There's a bit of parsing confusion where a stray : after a function call could give you a potentially misleading error message.

So here's a program:

```
f[100]
fib(): f[0] <- f[1] <- 1; i = 2; {i < 100 -> f[i] <- f[i-1] + f[i-2]; i += 1}
```

The really lame nature of not being able to initialize data structures shows up strongly in this program.

Here's another.

```
minskytron(x, p, n): y = 0; {n -= 1 -> x += y >> p; y -= x >> p; pset(x, y)}
```

Here's a toupper function operating on ASCII codes in s.

```
s[4096]
toupper(i, end):
    {i < end ->
        (s[i] >= 97 && s[i] < 97 + 26) ? s[i] -= 64 : 0;
        i += 1}
```

This language is somewhat similar in its capabilities to BASIC or bc, though it lacks strings.

It is, however, considerably bulkier in the description of its syntax than the λ-calculus, Abadí and Cardelli's ς-calculus, or the ur-Lisp. On the other hand, an implementation of an interpreter for it might be simpler, since you don't need any memory management or type testing. (You might need subscript error handling.)

PEG syntax

(See also Tagging parsers (p. 208).)

It's perhaps worthwhile dwelling a bit on the syntax of the PEG above. It doesn't use negation, but I'm including negation here, since it's an important tool in PEGs in general.

```
grammar: (name ':'_ alts)*
alts: (seq | seq ','_ seq), '|'_
seq: ('!'* (name _ | str | class | '('_ alts ')'_) [?*+]*)*
str: "'" ('\\' char | [^\\'])* "'" _
   | '"' ('\\' char |  [^\\"])* '"' _
class: ('[^]' | '[]' | '[^') [^]]* ']'_
_: [ \n\t]*
name: [A-Za-z_] [A-Za-z0-9_]*
```

The definition of character classes omits the syntax of ranges, but that's okay as long as we don't care about the rightmost member of a range being].

A big problem with this syntax is that it doesn't provide a way to tag parts of a production so they can be referred to elsewhere. Following the proposal in Tagging parsers (p. 208), let's use the syntax `name { contents }` to tag the range of input matched by `contents` with tag `name`. To achieve this, we could just change the definition of `seq` in the above as follows:

```
seq: ('!'* (name _ | str | class | '('_ alts ')'_ | name _ '{'_ alts '}'_) [?*+]*o
o)*
```

Now we can take advantage of this to build an AST, refactoring the grammar a bit in the process:

```
grammar: _ rule {name ':'_ choice}*
choice: choice {alt {term* | item {term*} ','_ sep {term*}}, '|'_}
term: '!' negated {term} | modded { atom mods { [?*+]+ } } | atom
```

```
atom: name _ | str | class | '('_ choice ')'_ | tagged
tagged: tagged {tag {name} _ '{' _ spans {choice} '}'} _
str: "'" str {('\\' char | [^\\'])*} "'" _
   | '"' str {('\\' char | [^\\"])*} '"' _
class: '[' class {'^'? ']'? [^]]*} ']'_
_: [ \n\t]*
name: name {[A-Za-z_] [A-Za-z0-9_]*}
```

Separating nonterminals from tags allows us to avoid constructing worthless intermediate nodes in some cases; the `term` rule can generate, for example, just a `str` node or just a `class` node, rather than a `term` containing an `atom` containing a `str`. It also enables the resulting node to tag just the relevant text, omitting irrelevant delimiters.

The idea is that each AST node has a start byte position, an end byte position, and a sequence of zero or more child nodes. In token-like cases, the client program is probably more interested in the byte positions, while in other cases, it probably only cares about the child nodes. So, for example, a `choice` node in the AST will have zero or more `alt` children, none of which children include the `|` separators between the alternatives. The `alt` nodes may have a single `item` child and a single `sep` child, or they may have a sequence of the possibilities that come from `term`: `negated`, `modded`, `name`, `str`, `class`, `choice`, or `tagged`.

The `modded` node structure is an unfortunate result of PEGs' lack of left-recursion; ideally the AST for something like `x*+?` would be `optional { oneormore { zeroormore { name "x" } } }`, although of course that is a pretty stupid thing to write. However, once we've parsed the thing into a lopsided tree structure, it's pretty easy to write imperative code in your language of choice to produce the desired structure. See Tagging parsers (p. 208) for another solution to this problem.

Audio tablet

Kragen Javier Sitaker, 2019-09-28 (7 minutes)

Today I was talking with David Christensen about a project of his, and I had some ideas about tracking styluses on drawing tablets using ultrasound. In his project, which is not a drawing tablet, they're tracking a point of contact on a surface using an array of piezoelectric contact microphones on the back of the surface, using the relative intensity of the conducted sound at different microphones to estimate the location.

It occurred to me that by cross-correlating the signals at the different microphones, you can do a much better job of localizing the sound, and this could be useful for an inexpensive large-area drawing tablet. (This is related to Measuring submicron displacements by pitch bending a slide guitar (p. 905).)

A stylus scratching on a rough surface such as paper or MDF produces broad-spectrum noise, and broad-spectrum noise is wonderful at having very low autocorrelation at any shift other than zero; it's very nearly orthogonal to itself at other shifts.

Echoes from the edges of the tablet can set up Chladni-plate-like standing waves, which could complicate the situation substantially (like some stupid Hollywood action movie that ends in a hall of mirrors) so using a highly attenuating material like leather might be a good idea, or perhaps cutting the edges of the material in a sunburst-like zigzag pattern so that the high frequencies we want are strongly attenuated and their coherence destroyed as they reflect from the edge. (This is related to the Q of acoustic resonators such as music-box tines cut from the material, although I don't know if we can talk about an acoustic Q of the material itself; but clearly for this purpose MDF is dramatically superior to plastics, which are dramatically superior to metals, which are mostly somewhat superior to ceramics.)

With only two microphones you would have an ambiguity about which side of the line through them the stylus is on (whose importance could be minimized by putting them along the same edge of the tablet); three microphones would avoid this problem, and more than three microphones would help to reduce errors and latency further. Latency of under 10 milliseconds is critical for musical use and strongly desirable for drawing; anything over 1 millisecond is detectable and undesirable.

The localization precision and interaction latency are both limited by the speed of sound in the material, but unfortunately in opposite directions: a higher speed of sound means less interaction latency but lower precision. Using higher frequencies alleviates this problem. Suppose you have three microphones in an equilateral triangle one meter on a side; the center is 661 mm from the corners, and that's as far as you can get from the corners inside the triangle or indeed anywhere near it. With a speed of sound of 2000 m/s, a reasonable estimate for many solids, that works out to an intrinsic acoustic latency of 331 microseconds, not counting processing time. If there are significant 10-kHz components of the noise being tracked, they will narrow the autocorrelation peak to around 100 microseconds ---

but at 2km/s, that's 200 mm of position uncertainty! That's no good for drawing, which needs submillimeter precision. A lower speed of sound would reduce the positional uncertainty proportionally.

However, correlation and intensity aren't the only sources of information we have. Solids actually carry two different kinds of sound, longitudinal and transverse, and transverse waves are slower and have polarization. If the microphones are able to detect the direction of vibration, for example by coupling them to points on the board through taut UHMWPE or glass-fiber threads near tangent to the board, they will first detect the longitudinal waves moving the board towards and away from the point of contact, then later the transverse waves moving it in some direction normal to the vector towards the pencil.

This still depends on getting substantial phase separation of the two waves --- I haven't measured yet but I think they'll tend to be strongly correlated, though perhaps longitudinal impulses going in one direction will be strongly associated with transverse impulses propagating at right angles to it.

Raising the frequency would help a lot, but you need to raise it by a factor of 500 or so, to about 5 MHz. It may be the case that pencils scraping on paper or MDF intrinsically produce 5-MHz noise, but I doubt it. 5-MHz ultrasound doesn't travel very far in air, but it has no difficulty with most solids and liquids. You could attach a small sound transmitter to the pencil that transmits a 10Mbps LFSR signal, which would be transmitted to the board whenever the pencil was touching it. (Or touching paper taped to it.) You could transmit this signal intermittently --- a 40-bit burst, taking 4 microseconds, every 100 microseconds or more, would be adequate.

Alternatively you could couple ultrasonic vibrations into the board from a piezoelectric, magnetostrictive, or electromagnetic actuator mounted on the back of it and see how they scatter; this might be adequate but would probably work better for large, hard contact points than for a pencil point. Or, as described for the one-dimensional case in Measuring submicron displacements by pitch bending a slide guitar (p. 905), you could attach the detector to the stylus (or the person's finger) and pick up vibrations injected into the surface.

Periodicity in the sound injected would be problematic, since the autocorrelation of periodic waveforms has many peaks, creating ambiguity about the stylus position. It's easy enough to avoid with an LFSR in the electronic case, but for acoustically produced sounds there is the risk of resonances.

Vibration transducers attached to the board could also, at sub-kilohertz frequencies, provide haptic feedback like the piezoelectric click pioneered by Nokia for some of their cellphones years ago; and if the tablet is horizontal and isn't very well damped at the edges, they could also make Chladni figures to move small objects around on it, also a technique demonstrated some years ago by a research group using a single actuator to vibrate a metal plate.

Division

Kragen Javier Sitaker, 2014-06-05 (14 minutes)

(This was published previously on kragen-tol.)

My friend Santi asked me why we divide by a fraction by interchanging the numerator and the denominator and multiplying; that is, why a/(b/c) = a(c/b). I wasn't quite sure how to answer, but after thinking about it, it turns out that there are many deep and fascinating answers that involve many aspects of the universe of mathematics. Here are three different answers. Sort of.

Part of the problem is that it's difficult to say what really counts as an explanation here, because, as Feynman explained in his famous BBC video on "Fucking magnets, how do they work?", an explanation has to start with things that you already understand to be true. In cases like this, it's really easy to fool yourself into thinking that you have an explanation, when all you really have is circular logic. Here, let me demonstrate.

An answer based on group theory

A "group" is a set with an operation that have the four properties of closure, associativity, identity, and invertibility. Nonzero fractions, together with multiplication, are a group. It turns out that the divide-by-multiplying-upside-down thing isn't limited to fractions at all; it's a much more general property that applies to any group, including bizarre things like permutations under composition, three-dimensional rotations of polyhedra under composition, matrices under matrix multiplication, Gaussian integers under addition, bit strings of some fixed length under XOR, and integers under multiplication modulo a prime number!

To explain, first I will explain the meaning of the group properties. Since I'm writing this mostly in ASCII, I'm going to use "G" to mean the set, other letters to mean elements of the set, "+" to mean the operation, and two other special notations which I explain below: "0" to mean the identity element of G, and "-X" to mean the inverse of an element X of G.

Closure: if A and B are in G, then A+B is also in G. This rules out things like "numbers 1 to 10 under ordinary addition", because 9+9 is 18, which isn't in the set, and things like "integers under ordinary division", since even though 6/3 is in the set, 2/3 isn't.

Associativity: (A+B)+C = A+(B+C), always. This rules out non-associative operations like division or subtraction.

Identity: There's an element of G which I will call 0 which has the property that A+0 = 0+A = A, for all A. We call it the "identity element". This rules out operations like "return the left argument".

Invertibility: Every element A in G has a corresponding inverse element -A such that A+-A = -A+A = 0. This rules out operations like multiplication on rational numbers, since zero (not the identity element, real zero) is a rational number, the identity element for multiplication on rational numbers is 1, and there's nothing you can multiply by zero to get 1. (But multiplication on nonzero rational numbers is still fine!)

You will note that commutativity isn't one of the group properties,

even though, say, integer addition is additive; and in fact there are lots of interesting groups whose operation isn't commutative. If you can prove a property of groups without depending on commutativity, then it applies not just to commutative groups like the nonzero rationals under multiplication, but also noncommutative groups like matrices under matrix multiplication and permutations under composition.

The question we started out with was, "Why does a/(b/c) = a(c/b), when a is a rational number and b and c are nonzero integers?" Here's why that's true not just for integers but actually for any nonzero rational numbers.

Our question, restated in generic group terms

Let's start by rewriting it in the notation I have above: ab becomes A+B, and a/b becomes A+-B. So we're trying to find out if, and why, A+-(B+-C) = A+(C+-B).

Using the definition of invertibility (-), we can derive that:

```
B+-B = 0
```

From there, we can replace B with B+o, using the definition of identity (o):

```
(B+0)+-B = 0
```

Then, using the definition of invertibility, we can replace that o with -C+C:

```
(B+(-C+C))+-B = 0
```

The definition of associativity lets us move around the parentheses around + operations:

```
(B+-C)+(C+-B) = 0
```

Now, if (B+-C)+(C+-B) is o, then for any element Q, by the substitutability property of equality:

```
Q+0 = Q+(B+-C)+(C+-B)
```

In particular, if we take Q to be -(B+-C), which we know exists by the properties of invertibility and closure, we have:

```
-(B+-C)+0 = -(B+-C)+(B+-C)+(C+-B)
```

The right side now begins with a thing of the pattern -R+R, which we know from invertibility is o, so we have:

```
-(B+-C)+0 = 0+(C+-B)
```

And by the definition of identity, we now have:

```
-(B+-C) = (C+-B)
```

This is a stronger form of what we wanted to prove in the first place, since it shows that for any A:

```
A+-(B+-C) = A+(C+-B)
```

which is our original statement, but it also shows that you don't even need the A.

Applying the result to other groups

So that shows that a/(b/c) = a(c/b), as long as all three are nonzero rational numbers, and in particular if b and c are nonzero integers. It also shows that the same thing is true if, for example, a, b, and c are numbers in the range of 1 to 6, with the following tables for multiplication and division in Z/7:

```
 *  1  2  3  4  5  6     /  1  2  3  4  5  6
 1  1  2  3  4  5  6     1  1  2  3  4  5  6
 2  2  4  6  1  3  5     2  4  1  5  2  6  3
 3  3  6  2  5  1  4     3  5  3  1  6  4  2
 4  4  1  5  2  6  3     4  2  4  6  1  3  5
 5  5  3  1  6  4  2     5  3  6  2  5  1  4
 6  6  5  4  3  2  1     6  6  5  4  3  2  1
```

For example, if a=3, b=4, and c=5, then a/(b/c = 5) = 2, and a(c/b = 3) = 2 also. Try it for any three of these numbers. It will always work. (It works in Z/p for any prime p. See attached modmul.py.)

Here's a Python example of permutations using my permutations module:

```
>>> from permutations import cycle
>>> a = cycle(1, 2, 4)
>>> b = cycle(2, 5)
>>> c = cycle(2, 4)
>>> a * (b * c**-1)**-1
cycle(1, 2, 5)
>>> a * (c * b**-1)
cycle(1, 2, 5)
```

Note that, since permutation composition is not commutative, a(1/b * c) is not the same:

```
>>> a * (b**-1 * c)
cycle(1, 2) * cycle(4, 5)
```

Why this is a little bit bogus

But wait! All this is based on my initial assertion that the four group axioms apply to nonzero rationals under multiplication. How do we know that's true? Maybe all of the above is begging the question, when it comes to the nonzero rationals, since how do we know that nonzero rationals even have multiplicative inverses in the first place? I mean, if we assume that rationals including zero are a group under multiplication, then we can use the same argument to claim that rationals including zero can be divided in this way, but that turns out to be wrong. So first we have to show that nonzero rationals are a group!

Rational numbers as pairs of integers

Suppose we take as given that nonzero integers form a *commutative* group under multiplication, and we want to explore relations a:b of those integers, using the equality relation a:b = c:d iff an:bn = cm:dm for some nonzero integers m and n; and we define multiplication as (a:b)(c:d) = ac:bd. What can we find out?

First, we can prove pretty directly that ((a:b)(c:d))(d:c) = a:b, as long as neither c nor d is zero:

```
((a:b)(c:d))(d:c) =
    {definition of multiplication}
(ac:bd)(d:c) =
    {definition of multiplication}
acd:bdc =
    {commutativity of integer multiplication}
adc:bdc =
    {associativity of integer multiplication}
a(dc):b(dc) =
    {definition of rational equality}
a:b
```

(Bloviation 0)

Which is pretty close to what we started out wanting to know. But we can also show that nonzero rational numbers, defined in this way, are a group under multiplication. We need to show closure, associativity, identity, and invertibility.

Closure: (a:b)(c:d) produces ac:bd, and since the integers are closed under multiplication, ac and bd are integers.

Associativity:

```
((a:b)(c:d))(e:f) = (ac:bd)(e:f) = (ac)e:(bd)f
(a:b)((c:d)(e:f)) = (a:b)(ce:df) = a(ce):b(df)
```

which are equivalent because integer multiplication is associative.

Identity: (1:1)(a:b) = 1a:1b = a:b since 1 is an identity for integer multiplication.

Invertibility: Bloviation 0 above shows that these relations have right multiplicative inverses (and how to compute them); you can carry out the same argument for left multiplicative inverses.

So that shows us how to compute multiplicative inverses of pairs of nonzero integers with these weird definitions of multiplication and equality. But how do we know that those pairs of integers are *really* "the rational numbers"?

We can translate individual integers into this pair-of-integers form as follows: t(x) = x:1. It should be straightforward to see that multiplication on these pairs corresponds to multiplication on the integers, i.e. t(x)t(y) = t(xy). And, in math, that's really all you need: it walks like the group of fractions, quacks like the group of fractions, so it's the group of fractions! There is no more "really" than that, in math.

I guess this is the algebraic structure you get if you assume that nonzero integers must have multiplicative inverses, and then take the set of the integers and their multiplicative inverses and extend it by transitive closure of multiplication; it's the smallest set that includes

the nonzero integers and satisfies the group axioms. I'm not immediately sure how to show that, but I'm pretty sure it's true.

An interesting thing here is that the proof above depends on the commutativity of (nonzero) integer multiplication, from which we could directly derive the commutativity of rational multiplication. Integer multiplication is closed, associative, and has an identity, but it isn't invertible, which makes it an algebraic structure called a "commutative monoid". I'm not sure what happens if your numerator and denominator are drawn from some other monoid that isn't commutative, such as quaternions with nonzero integer coefficients, or nonzero square matrices of integers of some size n.

A spatially-oriented intuitive answer

But that's all very algebraic and abstract. You could read all of the above and still think that there was maybe a flaw in the logic somewhere, that there might be some case where a/(b/c) isn't really a(c/b). What about everyday intuition?

When we say n/m, we're looking for a solution x to the equation mx = n; we want to know how many times we would have to add m to itself to get n, or looking at it another way, what number we would have to add to itself x times to get n. Spatially, we're looking for the length x of a stick of which we would have to lay m of, end to end, to add up to n, or the number of sticks x of length m.

If m is a fraction, it's easier to think of it as a length of a stick than as a number of sticks, so let's go with that. It's clear that if m is a reciprocal of an integer, like 1/3 or 1/4, then that integer is the number of sticks you need to reach a length of 1; and if you have to go twice or three times as far, you need twice or three times as many sticks, so clearly x is going to be proportional to n. Similarly, it's clear that if m is twice or three times as long, you need half or a third as many sticks to go the same distance, so making m be 2/3 or 3/4 will make x be half or a third of what it was when m was 1/3 or 1/4.

So that kind of covers it: you can get to any fraction m by starting with the reciprocal of an integer (your denominator) and then multiplying it by another integer (your numerator), and if you watch how x changes as you do that, you can see that x gets multiplied by the denominator, divided by the numerator, and multiplied by n, your original dividend.

modmul.py

This Python script generated the multiplication and division table for Z/7 above.

```
#!/usr/bin/python
nn = 7
col = "  "
def num(xx):
    print "%2d" % xx,

print " *",
for ii in range(1, nn):
    num(ii)

print col, " /",
```

```
for ii in range(1, nn):
    num(ii)

print

for ii in range(1, nn):
    num(ii)
    for jj in range(1, nn):
        num((ii * jj) % nn)

    print col,

    num(ii)
    inverse = (jj for jj in range(1, nn) if (ii * jj) % nn == 1).next()
    for jj in range(1, nn):
        num((inverse * jj) % nn)
    print
```

Food miles imply insignificant energy costs

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

[Gussow's] most oft-quoted statistic is that shipping a strawberry from California to New York requires 435 calories of fossil fuel but provides the eater with only 5 calories of nutrition.

Some Rambling Figures

Well, we towed our 5000lb Vanagon across the country (with a rather larger truck than we needed) at about 10 miles per gallon. A gallon of diesel is about 130MJ, or 13MJ per Vanagon-mile, or 2.6kJ per pound-mile, or 5.7 J per gram-mile.

Diesel's energy density: http://hypertextbook.com/facts/2006/TatyanaNektalova.shtml

Google Maps says it's 2906 miles to drive from San Francisco to New York City, which would be 17 kJ per gram. Suppose the strawberry is 20 grams. That's 330 kJ. A kilocalorie, or food calorie, is 4.2kJ, so that's 79 calories.

However, commercial trucking is considerably more efficient. Interstate highways are built to support vehicles of up to 80 000 lbs. gross vehicular weight (40 tons), although much of Europe seems to allow up to 60 tons. http://www.oilcrisis.com/transport/ claims that 18-wheelers get "120 to 200 gross ton miles per gallon", while trains get 750. http://www.answerbag.com/q_view/138616 claims "8mpg when I'm on time; 4mpg when I'm behind schedule," and "4.5 to 7.5 mpg." 4mpg at 40 tons would be 160 gross ton miles per gallon.

But not all of that 40 tons is strawberries; some of it is the tractor and the trailer. One random web page suggests 35000 lbs. for the tare weight. So your 4mpg is hauling 45000 lbs. of stuff, so that's 180 000 pound-miles per gallon, or about 720J per pound-mile, or 1.6J per gram-mile, or 4.6kJ per gram. Or 92kJ per strawberry, which is 21 calories.

Conclusion #1

Which is one twentieth of Gussow's figure: 21 calories to drive the strawberry across the country, not 435 calories. Maybe there are other energy costs but I don't see how they could add up to 20 times the energy cost of actually moving the truck.

More Rambling Figures

But the train is 4.7 times more efficient (per gross ton mile) and perhaps has a higher fraction of its weight devoted to cargo rather than chassis. If the fraction were the same, a train would bring the figure down to 4.7 calories per strawberry.

Time Magazine's local eating on campus article sidebar says that the average distance is only half that: 1500 miles.

Other Variations

Now, suppose that our calorie per gram of

California-to-New-York transport cost is getting spent on transporting rice (5 calories per gram) or vegetable oil (9 calories per gram) instead of strawberries (hypothetically, less than a calorie per gram). Suddenly it looks pretty affordable, energy-wise, to truck those foods all the way across the US if they taste a little better or are a little cheaper.

Boat freight, I think, is even cheaper. Considerably cheaper. Air freight costs more.

What if gas prices go up? Well, if they go up enough, we'll start using rice and corn to power the trucks. But more importantly, they're already only 10% of the cost of the vegetable oil if you truck it from a crushing plant in San Francisco to a restaurant in New York.

Stuff to Check

What's the tare weight of an 18-wheeler? What fraction of a train is tare weight?

Topics

Quicklayout

Kragen Javier Sitaker, 2017-01-10 (updated 2017-01-18) (3 minutes)

I want to explore how to do text layout and rendering at 100fps on one core, in particular for a kind of greenfield computing system. A few different obstacles present themselves:

• I probably need to hack up something involving SDL in C or something similar in order to see if I've succeeded.
• I don't know what text layout is. Are we talking about displaying one line on top of another? Word wrap? TeX-style hboxes, vboxes, and stretchy glue? Tk-style packing on different sides of nested boxes? The CSS box model? Arbitrary Linogram-style linear constraint systems? Arbitrary constraint or optimization systems?
• How much do I need to lay out other than the stuff that appears on the screen? If I can get away with only doing layout for what I am actually rendering, then the 100fps constraint is not nearly as difficult as if I need to do layout for a bunch of earlier and later text as well in order to figure out how wide my column is and where to start.
• What font do I use? Font and text rendering might take a significant amount of computation time.

I've done a couple of things like this in the past. http://canonical.org/~kragen/sw/dofonts and http://canonical.org/~kragen/sw/dofonts-1k are fixed-width font renderers in JS, the second in under 1 kilobyte of DHTML, including the font. http://canonical.org/~kragen/sw/netbook-misc-devel/propfontrender.py is a proportional pixel-font renderer in Python. It's about 4 kilobytes of Python. All three have their own fonts and do letter wrap but not word wrap. http://canonical.org/~kragen/sw/inexorable-misc/wordwrap.py is a word-wrap algorithm in 16 lines of Python. http://canonical.org/~kragen/sw/netbook-misc-devel/telegram.py has a couple of different word-wrap algorithms, one of which is 12 lines. I haven't done much in the way of boxes-and-glue layout.

There are a few different first things I could do on this. I could hack together a thing with C and SDL that generates bitmaps (without text in them) and puts them on the screen. I could hack together a thing in Python or JS that lays out boxes with some kind of boxes-and-glue model. I could write a thing in Python or JS that converts a boxes-and-glue spec into a sparse matrix of linear constraints, and use (or write) a solver for it.

A fun example to try doing layout on would be some equations and program code.

Ultimately the objective is to run a thing in C that I can benchmark to see how far I am from 100fps and what the critical path is.

Okay, now I am rendering 12 megabytes per second of input text (250 megapixels of output) on my netbook, which would be 120 kilobytes of text or 2.5 megapixels at 100fps. On my laptop I can do 70 megabytes per second of input text on one core. This is with the code in http://canonical.org/~kragen/sw/dev3/propfont.c. This is

still far from memcpy-limited, so I can probably do better.

The tangent of the sum of two angles

Kragen Javier Sitaker, 2018-04-27 (1 minute)

If you have two Pythagorean triples $a^2+b^2=x^2$ and $c^2+d^2=y^2$ you could be said to implicitly be talking about two triangles (a,b,x) and (c,d,y). One of the angles in these two triangles is $\tan^{-1}(b/a)$ and in the other is $\tan^{-1}(d/c)$. If you put these two angles adjacent to each other and scale the (c,d,y) triangle up to use the (a,b) vector as the basis for its x-axis and a (-b, a) vector as the basis for its y-axis, then its (c, 0) side has become (ca, cb), and the side from (c, 0) to (c, d) now has a displacement of (-bd, ad), so the new corner is at (ca-bd, cb+ad), so the tangent of the angle sum is going to be (cb+ad)/(ca-bd).

2017 [Provisional English translation of intercepted transmission]

Kragen Javier Sitaker, 2018-04-27 (updated 2018-07-14) (13 minutes)

I thought it would be good to review human activity over the arbitrarily delimited span of time many humans call "2017", since it just ended.

All humans live on a planet they call "Earth", which means "soil". They do not yet know of non-Earth life. They still manifest via biologically-evolved bodies (some $3^{21} - 3^{20} + 3^{19} - 3^{18}$ of them) with an overpowering delusion of individuality. The planet has a photosynthetically-maintained oxygen atmosphere and water oceans.

2017 coincides with a cycle of Earth's orbit, known as a "year", but its starting point is not an aphelion, perihelion, or other notable point in the orbit; it's purely arbitrary. "2017" means $3^7 - 3^5 + 3^4 - 3^2 + 1$, in the unbalanced decimal place notation commonly used on Earth; it denotes a count of years from the erroneously calculated birthdate of a human religious figure, one of their messiahs.

A year is roughly $3^{51} - 3^{50} - 3^{49} + 3^{48} + 3^{47} + 3^{44}$, altho the precise measurement used varies somewhat depending on political processes. Each human body lasts about 3^4 years.

Humans are a dioecious tribal predator species mostly composed of liquid with the high power intensity (some 3^{-61} per) and political conflicts common among predators. They moderate sexual dimorphism, of which they make much. They achieved digital communication some 3^{12} years ago (the evidence is ambiguous — they have been communicating via phonons for much longer than they have practiced digital encoding with atoms, which is only about 3^8 years ago) but did not mechanize it until some 3^4 years ago. They are currently experiencing the singularity (on a timescale of some 3^3 years), making this a very interesting time to observe the species.

Their alternation of generations is simple haploid-diploid, with the haploid forms being unicellular and very short-lived; haploids do not play a significant role in their social dynamics.

"Human" also means "made from soil", even though they do not have roots and do not photosynthesize, even facultatively.

Humans are currently a Kardashev Type $1 - 3^{-1} + 3^{-3}$ species.

Politics

A human they call Donald Trump was what they call President of USA for basically all of "2017", and that sucked. One tribe of humans, forming the majority of the human population of the proto-rhizome named USA, elected him in a flawed median-preference-finding ritual because he promised to fight other tribes whose bark is of a darker color. Several 3^{13}s of humans protested, gathering in public and adorning themselves with cloth representations of their genital organs, because Trump has apparently pollinated several female humans without their consent. Humans

commonly experience involuntary pollination as psychologically traumatic despite the widespread availability of contraception.

Earth had a small nuclear war just over $3^4 - 3^2$ years ago, initiated by USA, which became the dominant proto-rhizome on the planet as a result. Dominance posturing between Trump and Kim, the leader of a tribe known as North Korea, did not cause a second nuclear war in 2017, but it has about a 3^{-3} chance of doing so in "2018", the following year.

A war has been starting during the last 3^2 years in regions known as "Afghanistan", "Syria", "Iraq", and "Ukraine", largely for ecological reasons, with some religious reasons involved. Over 3^{15} humans are currently insufficiently fertilized as a result. Several 3^{13}s of humans have pulled up roots to migrate, a common strategy for humans under such circumstances. Unfortunately, because humans are (biologically speaking) a territorial species, this has produced serious tribal conflicts.

Early in 2017, in part due to these tribal conflicts, a proto-rhizome known as "Britain" engaged in the ritual to begin its separation from a larger superorganism known as "EU". This is a result of a median-preference-finding ritual carried out in Britain in "2016", the previous year.

Spaceflight

Despite using chemical rockets, the humans previously had achieved the capability of interplanetary travel $3^4 - 3^3 - 3^2 + 3$ years ago, but lost it only 3 years later. (Earth's gravity is high enough that it's almost totally impractical for chemical rockets to reach orbit, which requires some $3^{-5} - 3^{-6} + 3^{-7}$ per more difficult for them to reach escape velocity, but over the past 3^4 years, the humans have done so on several times 3^3 occasions.)

They landed on a shoot of Earth called the Moon, orbiting at a distance of some $3^{40} - 3^{39} - 3^{36}$, but that was during of a spring called "von Braun", and using some 3^{-3} of the total sap of USA. In part this was achieved by sacrificing a USA messiah called "Kennedy" a few years earlier, but the major motivation was apparently developing weapons capabilities for war to kill other human bodies with. Von Braun's first chemical rockets were used for that purpose.

Humans are still launching solids into orbit, still using chemical rockets. About $3^8 - 3^7 - 3^6$ satellites are on orbit around Earth as a result, mostly in a planetosynchronous orbit.

One of the human superorganisms launching satellites is called SpaceX. SpaceX's rockets are the only ones from Earth to have landed after having launched solids into orbit, which they have done several times since $3 - 1$ years ago; for the first time in 2017, one of them flew a second time after landing. SpaceX's rockets reached orbit $3^3 - 3^2 - 3 + 1$ times in 2017 and 3^2 times in 2016.

A spring named "Elon Musk" is the messiah of SpaceX; ey plan to land mechanized seeds on the nearby planet Mars within $3 + 1$ years and achieve human colonization of Mars within $3^2 - 3$ years, using a rocket designed to carry $3^4 + 3^3 - 3^2 + 1$ humans at once, adapted from SpaceX's current chemical rockets, even though humans are liquid and consequently shock-sensitive. Musk wants to seed Mars with nearly 3^{13} humans within $3^4 + 3^3$ years, but ey do not yet channel

enough sap.

SpaceX is a subrhizome of USA. Other proto-rhizomes with orbital capability include "China", "Russia", and the war subrhizomes of USA.

Human rockets fail to reach orbit with a probability of around 3^{-3}.

Crab-bucket politics hamper the development of spaceflight — competing proto-rhizomes fear that adequate spaceflight in the hands of others will put them at a disadvantage during wartime, so each seeks to prevent the others from achieving it. This has so far entirely prevented the development of nuclear rockets, laser rockets, , superguns, s solar sails, which humans do not know to be feasible, although there have been speculations. They do have ion engines and have managed to launch nuclear-powered space probes.

As a consequence of the absence of any real spaceflight capability, the human proto-rhizome suffers from extreme shortages of a number of materials, including platinum and .

Humans also observed an interstellar object for the first time, which they named ʻOumuamua.

Sap flow, sap allocation, and bodies

Humans measure their sap in a variety of imprecise units, of which the most common is the "US dollar", established by USA. Currently some $3^{29} + 3^{27} - 3^{25} - 3^{23}$ US dollars of sap flows through the human proto-rhizome per year. Sap flow grows each year by a factor of about $3^{-3} + 3^{-4} - 3^{-5}$, continuing an exponential increase trend that has remained roughly consistent over some 3^5 years, which was when humans developed thermodynamics, via a spring named "Watt". In 2017, it grew by a smaller-than-average factor of roughly 3^{-3}.

This growth in sap flow has resulted in a dramatic diminishment of the quantity of insufficiently fertilized humans, and a big fast blowup of how many human bodies are alive, which is ending. 3^3 years ago, humans made $3^{17} + 3^{15} - 3^{14}$ new bodies each year, and now they only make about $3^{17} + 3^{14}$. They do not yet .

Small things and self-replication

Humans cannot yet make small things, except chemically, but they have been rapidly approaching this capability over the last $3^4 - 3^3$ years, largely in order to improve nonquantum computers (see the next section). The fabrication technologies for nonquantum computers permit manufacturing of objects down to some $3^6 - 3^5 - 3^4$ in size, but only in two dimensions, and only from set of materials. Precision on the order of a is neede make small things.

Consequently, and as a result of the deficiencies in human computation discussed in the next section, humans have not yet achieved autonomous self-replication except through their evolved biology. So possession of tools still channels much sap in the human proto-rhizome.

Computation, communication, design, and optimization

Humans have a poorly developed logic, largely optimized as a

defense against social manipulation. Human springs named "Turing", "Church", and "Gödel" discovered the universal algorithm about $3^4 + 3^2$ years ago, but they could not channel much sap for reasons related to predator dominance hierarchies. Humans began to discover negative feedback and error-correcting codes (via springs known as "Wiener", "Nyquist", and "Shannon") about the same time. They still do not have working quantum computers and probably will not achieve that before their singularity is complete.

Nonquantum computers have developed rapidly as a result of humans advancing toward being able to make small things; they currently store, in total, very roughly 3^{56} trits of data. As of 2017, individual humans can buy electromechanical magnetic storage devices of some $3^{28} + 3^{27}$ trits, with a diameter of $3^{19} + 3^{18} + 3^{17}$, by channeling 3^5 US dollars of sap toward their manufacture.

As an amusing side note, human nonquantum computers predominantly use binary. They are made from diamondoid silicon single crystals, not silicon carbide or , in part be Earth is a medium-temperature planet.

A cryptographic sap-channeling ritual known as "Bitcoin" became progressively more important on Earth in 2017, and now perhaps the majority of Earth computation is devoted to competitive computation in it. The Bitcoin network currently hashes at "14 exahashes per second", which is to say $3^{40} + 3^{38}$ hashes per $3^{25} - 3^{24} + 3^{23}$ and each hash is some $3^7 - 3^6 - 3^5$ full-adder operations on $3^3 + 3^2 - 3 - 1$ bits, which works out to some $3^{10} - 3^8$ primitive trit operations. All in all, this works out to a total Bitcoin computation rate of some $3^{16} - 3^{15} - 3^{12}$ trit operations per , which is less than the total di computational capacity of Earth, but not by much.

At the beginning of 2017 Bitcoin only did about 2 "exahashes per second".

Earth communication networks are fragmented, largely in order to deceive humans for social manipulation purposes. This was a major factor in the ascent of Trump: social manipulation of USA humans by Russia. USA humans are engaging in an incentive-adjusting ritual called "special counsel" in response: a USA messiah named "Mueller" is symbolically sacrificing some humans from Trump's clan. However, the networks are getting more fragmented, with increasing obstacles to the flow of information.

Humans discovered xylematic transforms $3^4 - 3^2 - 3 + 1$ years ago, but their primitive optimization algorithms and nonquantum computers were too slow and limited to find useful transforms. In 2017 xylematic transforms (called "neural networks" by the humans) on nonquantum computers exceeded human biological cognitive performance for the first time on a wide variety of tasks: a competitive ritual called "go", diagnosing colonization of human bodies by microbes from images, a stochastic competitive ritual called "heads-up poker", emitting the phonons that humans most often use to encode information, diagnosing heart problems in human bodies, diagnosing cancer in the bark of human bodies.

It's interesting that Musk, unlike most humans, is very worried about this situation.

Harmonic motion chain robot

Kragen Javier Sitaker, 2019-08-16 (2 minutes)

I was watching some 3Blue1Brown videos and came across one about the Fourier transform which illustrated by drawing arbitrary pictures as complex functions with, I think, a constant pen velocity. The complex Fourier transform amounts to representing the function as a sum of rotating phasors, so the dude just drew the phasors; their magnitudes and initial phase wholly determine the image and the pen speed.

It occurred to me that some kind of mechanism vaguely like this could be used for cutting arbitrary toolpaths, like rosette "machine turning". To keep it balanced, you'd want each phasor to be not a single arm rotating around one end, but a bar rotating around its center, with a big enough counterweight at the other end to counterbalance the whole assembly of succeeding phasors at its business end. This quickly gets into exponential growth so you don't want to have too many levels of phasor.

Probably, though, in a physical machine, you will want to vary not the radius of each rotation but its speed, since that's what you control more directly. This poses an interesting optimization problem of how to trace some desired toolpath using such a balanced kinetic chain with fixed radii by setting the rotations to specific speeds.

You can get twice as many degrees of freedom by moving the workpiece as well as the tool, but this involves carefully adjusting the counterweights to match the workpiece's mass.

Topics

Time domain analog chaos

Kragen Javier Sitaker, 2018-10-28 (4 minutes)

There are a variety of circuits published with chaotic analog behavior, iterating chaotic maps like the logistic map (in its domain of chaos) or the tent map, typically producing either a voltage-mode signal or a current-mode signal. These are sometimes used as analog noise sources similar to an amplified Johnson-noise source or an LFSR, but they operate in discrete time; each iteration of the map takes place after a clock pulse.

I was thinking about jittering the sampling time of an analog-to-digital conversion to eliminate aliasing, and it occurred to me that what I wanted was a chaotic analog circuit that produced a signal that was not a voltage or a current, but a time interval. Moreover, a straightforward mechanism using two coupled relaxation oscillators occurred to me.

The *dyadic map* is a particularly simple chaotic map when considered as a formula: just f(x) = 2x mod 1. So, for example, it maps 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 to 0.2, 0.4, 0.6, 0.8, 0.0, 0.2. This is equivalent to shifting a binary fraction to the left by one bit and discarding the overflow, so terminating binary fractions eventually find their way to the map's single fixed point, 0.0, and repeating binary fractions are periodic with a period of their repeating length. So you have, for example, one attractor with period 2 (.$\overline{01}$/.$\overline{10}$, ⅓ and ⅔), two attractors with period 3 (.001… and .011…), 3 attractors with period 4 (.0001…, .0011…, .0111…), 6 attractors with period 5 (.00001…, .00011…, .00101…, .00111…, .01011…, .01111…), and so on.

So all rational numbers are periodic in the dyadic map. *But all irrational numbers are aperiodic*, and almost all numbers are irrational. And so if you perturb a rational number by a small nonzero amount, you are almost certain to land on an irrational number. So an analog circuit implementation of the dyadic map, which is subject to noise, should behave chaotically rather than get stuck in a fixed point.

How can we implement the dyadic map in the time domain? Well, we can convert a sampling time x to a voltage 2x mod 1 by sampling a sawtooth with a period of 1 and a slope of 2, in whatever units we're using. And then to convert from the voltage back to the sampling time, we just use it as the starting voltage for a ramp generator that ramps ⅓ as fast.

(It's ⅓ as fast because it has to finish up the current oscillation of the sawtooth too.)

So, for example, suppose we sample the sawtooth at time 0.231. Its voltage is 0.231, and so we start our other ramp generator at V=0.231. At time 1, it has reached 0.4873; at time 2, it has reached 0.8207; and then at time 2.538, it reaches 1 and triggers another sample of the sawtooth. Now the sawtooth's voltage is 0.538, so the other ramp falls to 0.538 and grows back up toward 1, which takes 1.386 time units, reaching voltage 1 at time 3.924 and triggering an additional sample of V=0.924. And so it goes: 0.231, 2.538, 3.924, 4.151, 6.698, etc.

Note that this is not the dyadic map! 0.538 is not 2·0.231 % 1.

Rather, 0.538 = 2·(1–0.231) % 1. This is an *inverted* dyadic map. It preserves the properties of the original when it comes to which points lead to periodic orbits, but the periods change.

We can do better than that, though. A ramp generator or a sawtooth generator requires a constant-current source. But actually an exponential decay works just as well for this, as long as the exponential decay on the sampling-generator signal is three times as long. You can think of the exponential thing as just a distortion on your oscilloscope. So an RC circuit is a perfectly adequate substitute for a ramp generator here.

Topics

Phase relations

Kragen Javier Sitaker, 2019-07-23 (updated 2019-07-24) (4 minutes)

As I sat on the vibrating bus with my head leaning against its vibrating window, trying to read text on my cellphone, I noticed that the visual OTF induced by the vibration changed over time as the relative phase of components of the vibration changed. It occurred to me that this may provide a feasible way to measure oscillations that are too fast to measure directly or even rectify.

My vibrating head, vibrating because of the vibrating window, reduced the text to mostly just a blur — the convolution of the true text image with the path my eye was taking through each cycle of the vibration. If the path were an ellipse, I'd have seen just a blur and little more; but in fact there were two or three copies of the text, perfectly clear but overlapping, at spots in the vibration path where my eye had temporarily come to rest. But these copies moved as the vibration changed.

Suppose you have an oscillation of some unknown frequency around 1 MHz vibrating a mirror which is directing a focused laser beam at the wall. Without the vibration, the beam would draw a point; with the vibration, it draws a line, which is brighter at the ends than in the middle, because the beam spends more time at the ends. In particular there are singularities of maximum brightness at the ends of the line, like caustics, because the beam actually becomes stationary there. You can see these phenomena with your eyes even though the oscillations are four orders of magnitude too fast for your eyes to see them. They allow you to measure the amplitude of the vibration, at least if you have calibrated the mirror, but not its frequency. They give you some information about the shape of the waveform — how much time it spends at each height — but not in what order.

Now, maybe this is not the best example, because in real life, you could vibrate the mirror in the other axis with a lower-frequency signal, say 100 kHz, and observe the Lissajous pattern; you could adjust the frequency of the reference signal until the Lissajous pattern was stable, although this might be very challenging to do by hand — to get the Lissajous pattern to be shifting at less than 50 Hz, your harmonic frequency needs to be within 50 Hz of the unknown signal. But let's suppose you have only one dimension to work with, and that the unknown signal is very spectrally pure.

If you add a 100-kHz reference signal to the displacement in the same axis, the pattern of bright and dark in the line projected on the wall will change. If the unknown frequency is a precise multiple of the reference, it will produce a stable pattern of bright and dark — in particular, at the points where the sum wave has zero derivative, you have more of those bright singularities that previously appeared only at the ends of the line. If the reference signal has a small enough amplitude, there will be 20 of them, but as the reference signal amplitude increases relative to the higher-frequency unknown signal, more and more of these singularities will disappear.

If the harmonic relation is imperfect, this will manifest as a continuous phase shift between the reference frequency and the unknown frequency, with the bright spots moving around; just as

with a Lissajous figure, the speed of this phase shift tells you the precise difference in frequency.

(This is related to CCD oscilloscope (p. 1861), which concerns a different and much simpler way to measure fast signals with slow sensors.)

Topics

Gradient pixels

Kragen Javier Sitaker, 2018-08-16 (updated 2018-10-28) (9 minutes)

Color computer displays in the 1980s and 1990s used a "palette" of colors to save memory, so that they could use only a single byte per pixel instead of the 2–4 bytes needed by the "TrueColor" displays we use nowadays, which did exist at the time but were specialty high-end hardware, used only for things like making movies. The "palette" was a finite array of colors that the pixels in the framebuffer indexed into.

But what if we'd used a different approach, one more driven by the capacities of the human visual system and of electronics? I think we could have done about an order of magnitude better for photos and video.

Before palettes

Prior to paletted framebuffers, computer displays commonly used character generators. A color 80×25 terminal with 8×16 characters has 256 000 pixels, but might have only 4000 bytes of RAM (one byte of character data and one byte of colors for each of the 2000 screen cells), and video cards for personal computers followed a similar approach. As the electron beam scanned across the screen, the hardware would read out the appropriate line of pixels from the appropriate glyph in the font — at first in ROM, later RAM, allowing runtime-changeable fonts, at the cost of another 4096 bytes of RAM. Systems like the Nintendo used a similar tile system, adding features for "sprite" overlays, which many home computers also had.

Typically, this approach required fixed-width fonts, although that wasn't really a necessary restriction. Later character-generator-driven systems like the DEC VT220 (and maybe the VT100?) often supported double-width and double-height characters, providing a little bit of typographical variety.

Game computers of the time had different specialized hardware with sprites and some compositing built in; https://prog21.dadgum.com/181.html talks a bit about how the Atari 2600 in 1977 managed to do NTSC-resolution video games with 128 bytes of RAM, and https://prog21.dadgum.com/173.html talks about the slightly later Atari 800.

By contrast, the original Macintosh shipped with 128 kibibytes of RAM (because 512 kibibytes was thought to be too expensive) and had a 512×342 one-bit framebuffer, which requires 22 kilobytes of RAM, five times as much as the fixed-font character generator and three times as much as the variable-font character generator, and it couldn't fit as much readable text on the screen and couldn't do color.

The advent of the palette

The IBM EGA (in 1984), the Apple IIGS VGC (in 1986), the IBM VGA (in 1987), and a large variety of other systems in the late 1980s and early 1990s instead adopted a "paletted" approach, in which a small number of bits per pixel in the framebuffer indexed into a palette. The EGA had 4 bits per pixel and 6 bits per palette entry, the

VGC had 4 bits per pixel and 12 bits per palette entry, and the VGA had 8 bits per pixel and 18 bits per palette entry.

Let's consider a 1024×768 Super VGA, common around 1990, with its traditional 256-color palette (with 6 bits per color channel). At the standard 72 dpi, that's 361×271 mm, a "17.8 inch" monitor, while on a more affordable 12.8-inch monitor it would hit 100 dpi. And it could display pretty decent photos, although a lot of software fuckery went into palette handling and dithering, especially once you got into windowed displays and animation; the grainy look of GIF video nowadays comes from the 256-color-palette limitation that it inherited from the video hardware of that period.

These displays could also do pretty decent text: in a readable but jaggy 5×8 font, you would get 96 lines of 204 columns on the screen, but a more easily readable 8×12 pixel font would give you 64 lines of 128 columns. That's a bit more than a printed A4-size page of text.

Antialiased text rendering was not common because doing it on a paletted display would use up a lot of colors in the palette and essentially rule out using varying background colors, although varying background colors itself was unusual. Subpixel antialiasing was not possible because the different colors of a pixel were fuzzy blobs in the same place on the screen, not separately addressable spatially distinct pieces, even though the differently-colored phosphors on the monitor were in fact in different places.

The palette meant that such SVGA cards could ship with only 768 kilobytes of DRAM. DRAM cost US$40 per megabyte from about 1992 to about 1996, due to a price-fixing cartel which eventually collapsed, and so this was US$30 worth of RAM — even more in 1990 or 1988. A 16-bit TrueColor display in the now-popular 5-6-5 RGB format would have cost US$30 more to make and had one bit less color precision in red and blue; a display at this resolution like the Targa, with the 24-bit TrueColor that is now universal except on low-end cellphones, would cost US$60 more to make.

Alternate history: gradient tiles or gradient pixels

But let's consider different tradeoffs you could have made. Suppose that, instead of 1024×768 pixels, the screen were divided into 192×144 tiles, each 1.88 mm square on a 17.8" monitor, and each tile could display two arbitrary linear gradients, separated by a diagonal line at an arbitrary angle and position. Suppose the start color and ∇ (dr/dx, dr/dy, dg/dx, dg/dy, db/dx, db/dy) for each gradient are specified to 8 bits per channel, and 4 bits each specify the angle and the position of the dividing line, so the angle is specified with a resolution of 11°15', and the position is specified with a precision of, say, 118 μm if the line is vertical or 166 μm if the line is diagonal.

This gives us about 3× the linear spatial resolution of the 1024×768 display and 4× its color resolution on each channel (assuming the analog parts of the system are adequate), but subject to some significant lossy compression. In particular, text is going to have to be pretty large.

Let's add up the memory per tile here:

	bytes/tile
gradient 1 start color	3
gradient 1 ∇	6

gradient 2 start color	3
gradient 2 ▽	6
dividing line	1
total	19

So that gives us 525 kilobytes or 513 kibibytes of VRAM, instead of the 768 KiB of VRAM we need for the SVGA.

You could do the whole decoding process from the gradient tiles to voltages entirely digitally, feeding digital counts to a DAC according to a dot clock, just like a normal video card. But you could actually get smoother gradients with much slower hardware if you generate the gradients with *analog* circuitry, consisting of a capacitor C1 connected through a buffer to each output channel, connected to a transmission gate and a voltage-controlled current source controlled by another capacitor C2, which is itself connected to another transmission gate. Each time you cross a tile boundary or a diagonal line, you short both C1 and C2 to voltages at the outputs of a couple of buffers driven by capacitors C3 and C4, which are sampling-and-holding outputs from a previous conversion result from a DAC. The diagonal-line trigger is driven from a timer which is also set by a DAC at tile-boundary-crossing time.

Supposing we have 768 visible scan lines and thus about 850 total scan lines in an 85-Hz frame, our horizontal scan frequency is about 72 kHz; if we have 210 "gradient tile times" per scan line (including 10% HBI) then our "gradient tile clock" is only 15.2 MHz. Under the same assumptions, the 1024×768 traditional display needs an 82 MHz dot clock. However, the jitter constraint on the gradient tile display is actually substantially tighter if we are to achieve the promised 3× spatial resolution improvement, and of course each color channel needs four DAC conversions per tile clock (initial value, initial partial derivative in X, and both of these after crossing the edge), so the DAC actually must run at almost the same speed.

This isn't quite as terrible as it might seem for text if the gradient saturates when it reaches a max or min value, as it would in the suggested analog embodiment; with a background that's either black or white, that allows us to get a vertical line at the left edge of each tile and a diagonal line at the edge, simply by setting the gradient value large enough to rapidly saturate to the background color after the crossing. I estimate that you could get readable (fixed-width) text with 2×2 gradient tiles per character cell, which would give us 72 lines of 96 columns, in the same ballpark as the SVGA card.

Reducing the cost of self-verifying arithmetic with array operations

Kragen Javier Sitaker, 2019-06-23 (15 minutes)

Self-verifying arithmetic systems like interval arithmetic have been known for a long time, but, despite the potentially enormous costs of undetected arithmetic errors, have never achieved wide adoption in HPC because of their high computational cost. Could amortizing their cost over an array make them affordable?

Data type	Numerical accuracy
Static	Fortran, C, OCaml	Conventional numerical analysis
Dynamic	Lisp, Python	Conventional interval or affine arithmetic
Per-array dynamic	APL, Numpy	¿?

Dynamic typing is expensive

In Python, an operation like `x = a + b` requires run-time type checks on `a`, `b`, or both, to determine what sort of addition operation is appropriate. In CPython, this check (and the ensuing indirections and other interpreter overhead) takes two orders of magnitude more time than the addition operation itself: on the order of 100 ns on my laptop. By contrast, statically-typed languages with polymorphic arithmetic operations, such as C or Fortran, typically determine the type at compile time, so only the addition operation need be emitted, not the polymorphic dispatch. (Some dynamically-typed language implementations have lower overhead; Ur-Scheme takes on the order of 5 ns to do the necessary type check and the addition.)

A faster alternative, in an untyped language like Forth or like typical assembly languages, is to use monomorphic arithmetic operations, requiring the programmer to specify the type variant in the source program. In 16-bit Forths, for example, you would use `+` to do 16-bit integer addition and `D+` to do 32-bit integer addition, `<` to do signed 16-bit comparison and `U<` to do unsigned 16-bit comparison. This is dangerous, not only because it creates an unnecessary opportunity to make a programming error, but also because common programming errors will produce wrong answers rather than error messages.

Dynamic type checks not only dispatch to the appropriate method for polymorphic operations, they can also detect programming errors:

```
>>> 3 + []
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: unsupported operand type(s) for +: 'int' and 'list'
```

In a language designed to be unsafe, though, they may not:

```
$ perl -le 'print(3 + [])'
40902451
```

Static typing gives a conservative

approximation of safety

Dynamically-typed languages like Lisp or Python make it easy to write a function that can take arguments of more than one different type; here is a function in Dercuano which can take either a Unicode string or a byte string as its second argument:

```
def vomit_html(output_filename, html_contents):
    dirname, _ = os.path.split(output_filename)
    if not os.path.exists(dirname):
        os.makedirs(dirname)

    if isinstance(html_contents, unicode):
        html_contents = html_contents.encode('utf-8')

    with open(output_filename + '.tmp', 'w') as f:
        f.write(b'<!DOCTYPE html>\n' + html_contents)

    os.rename(output_filename + '.tmp', output_filename)
```

Static type systems generally disallow this kind of thing: `html_contents` must be either of type `unicode` or of type `bytes` but not whichever the caller provides. Or, if it's of type `basestring` (the superclass of those two types in Python 2), the compiler will probably complain when you try to concatenate it to a `bytes` value, since you can't concatenate a `unicode` to a `bytes`. (Except in Python 2, where sometimes you can, depending on what's in it. Unicode in Python is a mess.)

But in dynamically-typed Python, this code runs successfully; if `html_contents` starts out as a `unicode`, it gets safely `.encode()`d to a `bytes` before reaching the fateful `bytes` concatenation.

So it's reasonable to say that a hypothetical static type checker that would reject this code would be judging conservatively, perhaps too conservatively.

Even a dynamic type system is in some sense conservative — presumably addition is side-effect-free, so computing a sum `x + y` should always be safe unless you use the result. But Python will still raise an exception if `x` is 3 and `y` is `[]`, even if you weren't going to use the result.

Static type systems usually aren't entirely static

If you want to build a linked list in a low-level language, you might declare it like this:

```
struct intlist { int car; struct intlist *cdr; };
```

Typically, though, that `cdr` doesn't necessarily point at a `struct intlist`; it points at either a `struct intlist` or `NULL`. There is no `struct intlist` at `NULL` for `NULL` to point at, so it's logically rather dubious to think of it as a `struct intlist *`. But the rules of C make an exception for `NULL`. (This isn't strictly necessary; you could make your `intlist` circular and keep a pointer to its head so you know when you've come back round to it again.)

This does impose an obligation on your program to include a test

whenever it's going to use the `cdr` field — it must first test to see if it is in fact a pointer to a `struct intlist` or if it's `NULL`. In a sense, this is a "dynamic type test", but it's explicit in your program. It's also not safe, because C is not really designed for safety — a forgotten `NULL` check will crash your program. (What's surprising is that this is even worse in Java, which *was* designed for safety — just designed badly.)

You can persuade OCaml to accept a similar declaration, but since OCaml lacks the implicit `NULL` escape valve, the only way to construct the value is as a circular list:

```
# type intlist = Ints of (int * intlist);;
type intlist = Ints of (int * intlist)
# let rec x = Ints(3, x);;
val x : intlist = Ints (3, <cycle>)
# let rec a = Ints(3, b) and b = Ints(4, a);;
val a : intlist = Ints (3, Ints (4, <cycle>))
val b : intlist = Ints (4, Ints (3, <cycle>))
```

To define a nil-terminated list in OCaml in the usual way, you must make the alternatives explicit with a sum type; the easiest way to do this is as follows:

```
# type intlist = Ints of (int * intlist) | NoInts ;;
type intlist = Ints of (int * intlist) | NoInts
# Ints(3, Ints(4, NoInts));;
- : intlist = Ints (3, Ints (4, NoInts))
```

To access the values contained within your variant record, you need to use pattern-matching to test the variant tag and dispatch to the appropriate code for the variant in question, binding the values you want from within it:

```
# let rec illen = function NoInts -> 0 | Ints(_, cdr) -> 1 + illen cdr ;;
val illen : intlist -> int = <fun>
# illen(Ints(3, Ints(4, NoInts)));;
- : int = 2
```

If you forget to handle the `NoInts` case, the compiler will complain.

(N.B. you would never really define a monomorphic `intlist` type in OCaml, both because defining a polymorphic type is easier and because there's a built-in polymorphic `list` type with syntactic sugar; but a realistic example would require more than one line of code.)

Statically-typed object-oriented languages give you such a dynamic type-check implicitly as part of method dispatch, although a code example would be a bit more verbose.

So statically-typed languages generally require some kind of way to behave differently based on the run-time type of an object, which is to say, its *dynamic type*, and this escape-valve mechanism can be more or less safe.

Interval arithmetic can catch numerical errors

There are a few different ways to use interval arithmetic. The most common one is to dynamically detect numerical instability: by, for

example, storing upper and lower bounds for each intermediate value, and executing each numerical operation in an algorithm at least twice with different rounding modes, the final result of an algorithm provides error bounds that give us an interval that is guaranteed to contain the correct result. This ensures that no loss-of-precision bugs in the middle of the algorithm can result in spurious answers.

By using non-zero-sized intervals for the algorithmic inputs, we can additionally detect *numerical instability*, a generalization of the phenomenon of ill-conditioned matrices.

Interval arithmetic provides a conservative approximation of the correct answer; expressions such as $x(x+1)$ will produce spuriously large error bounds. For example, given that $x \in [-0.5, -0.4]$, standard interval arithmetic calculates $[-0.5, -0.4] \cdot [0.5, 0.6] = [-0.3, -0.2]$, which is a proper superset of the precise answer $x(x+1) \in [-0.25, -0.24]$ — an order of magnitude tighter.

The same purposes can be served by the more sophisticated variants of interval arithmetic, such as affine arithmetic, reduced affine arithmetic, and modal interval arithmetic; these still compute conservative approximations of the precisely correct answer, but are more precise than standard interval arithmetic, usually at greater computational cost.

Although catching numerical errors due to rounding and numerical instability is the most common reason to use such self-verifying arithmetic systems, it is not the only reason, and some of the other reasons actually improve performance rather than worsening it. Similarly, dynamic typing can be used not only to catch type errors, but also for the whole panoply of object-oriented program design techniques.

Numerical analysis can catch those same errors statically

Typically, though, the performance cost of any kind of interval arithmetic has been considered far too high, and instead we analyze our algorithms statically to verify that they are numerically stable. This is an even more conservative approximation than standard interval arithmetic, in the sense that if there are any inputs for which the program will produce meaningless outputs, even vanishingly unlikely ones, our numerical analysis will tell us so, and we will look for a different approach.

Some problems, though, are numerically unstable for certain cases in ways that can't be fixed by a clever algorithm — ill-conditioned coefficient matrices being an example from the problem of solving a linear system. So, we put code into our subroutine to dynamically determine whether the inputs we're processing constitute an unstable instance or not — whether they meet the prerequisites for stability our static analysis has found.

There are strong parallels between dynamic typing and interval arithmetic

So there are some important parallels between dynamic typing and interval arithmetic: both approaches catch dangerous bugs that could otherwise cause programs to output wrong answers; both are

conservative in the sense that they catch all possible bugs in their class, at the expense of some false alarms; both cost a lot of runtime performance; both have static-analysis alternatives that eliminate the runtime performance cost but are even more conservative; and both of those static-analysis alternatives generally require an "escape valve" to dynamic checking at times.

People use Python in HPC now because Numpy amortizes the dynamic type checks over large arrays

Traditionally, Python was a non-option for high-performance numerical computing because of the performance cost of its dynamic typing, but nowadays, probably the majority of high-performance numerical computing is done in Python. This is possible because of Numpy, which provides APL-like or Octave-like array operations:

```
In [2]: import numpy

In [4]: x = numpy.arange(4); x
Out[4]: array([0, 1, 2, 3])

In [5]: x**2
Out[5]: array([0, 1, 4, 9])
```

A Numpy array contains an arbitrary number of values of (usually!) the same data type, so the data type is an attribute of the whole array rather than the individual values:

```
In [6]: x.dtype
Out[6]: dtype('int64')

In [7]: (x/2).dtype
Out[7]: dtype('float64')
```

Although Numpy arithmetic operations (like the ** and / used here) are polymorphic, just like ordinary Python operations (only more so — for example, Python has one floating-point data type, while Numpy has four), they can amortize the single type-check over the entire array. So, while Python might take 100 ns to square a float, Numpy can do it in 3.8 ns, if it has enough floats to chew on:

```
In [13]: y = numpy.arange(100000)/2

In [14]: %timeit y**2
1000 loops, best of 3: 378 µs per loop
```

That is, squaring a hundred thousand floating-point numbers took 378 µs, about 2 µs of which is overhead from Numpy and CPython, so squaring each one takes 3.78 ns. This is about five times slower than a C loop not using SIMD instructions would be on my machine, which is typical for Numpy; the loops inside its subroutines still have significant overhead, just much less than Python's.

Can we analogously amortize run-time numerical analysis over large arrays?

What if these arrays carried not only numerical data type information with them but also some kind of conservative error bound, like a shared interval-arithmetic bound?

For simple cases it's easy to see how this could work: if x = [3.3 4.1 2.7 0.028] ±5% and y = [1.0 1.5 0.8 0.005] ±4%, then we can compute x + y by adding them elementwise and tacking on the ±5%, the maximum of the two error bounds, as the new error bound. (Plus an ε appropriate to the floating-point format to account for the possible error from rounding the result of addition.) But that's only because the values have the same sign; if they had opposite signs, you would get cancellation, and a 5% error in each of the original values might add up to a lot more than 5% of the sum. You could calculate a catastrophic-cancellation factor in such cases and use it to inflate the error bound, and maybe you could have all-positive and all-negative boolean flags on your arrays, or even auxiliary max and min values, to avoid element-by-element inspection for catastrophic cancellation in most cases.

Elementwise multiplication is even easier, since there are no such special cases — you can just multiply the error factors, 1.05·1.04 = 1.092, and add the ε appropriate to your floating-point format. Division is no trickier, unless the error bars cross zero.

But maybe some other form, other than a simple "±0.35%", would be most suitable for matrix-matrix or matrix-vector multiplies.

Flexures

Kragen Javier Sitaker, 2016-08-24 (updated 2016-08-26) (6 minutes)

Flexures are a different way to design machinery, a little-understood one. They have many surprising advantages and disadvantages compared to traditional machinery, the kind made of rigid bodies that interact by intermittent and often sliding contact, plus the occasional discrete spring. At present, they are mostly used for bearings and "living hinges", but they are capable of much more.

Disadvantages of flexures include:

• Typically, movements are very small relative to the size of the machine or device, because most materials have a relatively small elongation at break;
• Continuous rotary motion is impossible and you must settle for reciprocating motion;
• Routing "signals" is difficult in a way that it is not in traditional machinery, as (at least in flexures cut from a sheet) crossing two "signals" over one another is tricky, as if you were laying out a one-sided printed-circuit board;
• very limited design tradition; the 2008 edition of the Machinery's Handbook contains 3740 pages of information on designing traditional machinery, but not a single mention of flexure design, other than springs.

The advantages of flexures, however, are astonishing:

• Because there is no sliding contact, there is no wear. There may be fatigue, but just as with traditional springs, it is possible to keep fatigue at bay for impressively long times.
• There is no backlash, and thus no tradeoffs between backlash and binding.
• Flexures do not need to be lubricated, because they have no sliding contact.
• There is no static friction; although flexures can be designed to lock in positions of local energy minima, they don't develop them spontaneously every time they stop moving, the way sliding contact does.
• Very high precision is achievable because of the lack of wear, backlash, and static friction; scanning tunneling microscopes, for example, maneuver their probe tips with a repeatability in the range of 10 picometers.
• In the appropriate materials, dynamic friction can be made arbitrarily low, although this involves tradeoffs against speed, and consequently efficiency can be made arbitrarily high.
• Because of the lack of wear, backlash, and static friction, as well as the resulting high precision, flexures are increasingly favorable at small sizes.
• Flexures can tolerate fairly contaminated environments without losing precision.
• Flexures that can be fabricated by cutting a sheet or plate can be manufactured at extremely low cost, even without mass production. Here in Buenos Aires, laser-cutting shops will cut 3mm MDF to a

precision of about 100μm at a cost of about US$50/hour and a cutting speed of about 30mm/s, which is to say about 300 "pixels" per second; this gives you about 20 kilopixels per dollar. Plasma-cut sheet steel is about twice as expensive, but about an order of magnitude better performance by most measures.
• Flexures in hard materials can effectively use piezoelectric actuators, which can act at frequencies up into the megahertz. By contrast, air bearings are limited to frequencies of around 150krpm (16 kHz), two or three orders of magnitude lower, and non-air- bearing sliding-contact machinery is typically limited to no more than 10krpm (1kHz). So flexure machinery can exceed the speed of sliding-contact machinery by two to five orders of magnitude.
• Flexures have no trouble operating in conditions that are very hostile to lubricants, including hard vacuum, cryogenic cold (with appropriate flexure material), and extreme heat (again, with appropriate material).

In the early 1990s, as a rebuttal to concerns that molecular nanotechnology would not provide practical advantages in computation because of high energy consumption, Ralph Merkle outlined the design of a flexure-based reversible computer using "buckling-spring logic", so flexures are capable of very complex tasks. Given their reliability and speed advantages over sliding-contact machinery, flexures are likely to shine in mechanical computing and automated fabrication applications.

Stuart Smith's 2000 book on flexures defines them as "a mechanism consisting of a series of rigid bodies connected by compliant elements that is designed to produce a geometrically well-defined motion upon application of a force." He cites the following as their advantages and disadvantages:

Advantages of flexures

• They are simple and inexpensive to manufacture and assemble.
• Unless fatigue cracks develop, the flexures undergo no irreversible deformations and are, therefore, wear-free.
• Complete mechanisms can be produced from a single monolith.
• Mechanical leverage is easily implemented.
• Displacements are smooth and continuous. Even for applications requiring displacements of atomic resolution, flexures have been shown to readily produce predictable and repeatable motions at this level.
• Failure mechanisms such as fatigue and yield are well understood.
• They can be designed to be insensitive to thermal variations and mechanical disturbances (vibrations). Symmetric designs can be inherently compensated and balanced.
• There will be a linear relationship between applied force and displacement for small distortions. For elastic distortions, this linear relationship is independent of manufacturing tolerance. However, the direction of motion will be less well defined as these tolerances are relaxed.

Disadvantages of flexures

• Accurate prediction of force-displacement characteristics requires accurate knowledge of the elastic modulus and geometry/dimensions. Even tight manufacturing tolerances can produce relatively large uncertainty between predicted and actual performance.
• At significant stresses there will be some hysteresis in the stress-strain characteristics of most materials.
• Flexures are restricted in the length of translation for a given size and stiffness.
• Out of plane stiffness values are relatively low and drive direction stiffness tends to be relatively high in comparison to other bearing systems.
• They cannot tolerate large loads.
• Accidental overload can be catastrophic or, at least, significantly reduce fatigue

life.
• At large loads there may be more than one state corresponding to equilibrium, possibly leading to instabilities such as buckling or ‘tin-canning’.

Blob computation

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

So I've been thinking a bunch about content-hash-addressed blob stores and automatic deterministic recomputation.

One highly desirable attribute of such a system is that the result of a given computation always be the same — like Java's WORA aspiration, but for real this time. That is, running a program whose code has a given tree hash A on an input dataset that has another given tree hash B will always and forever produce an output dataset C that is bitwise identical to any other time and place that it may have been correctly computed. This has several benefits:

• The program's output can be safely cached so that, if the same result is requested again in the future, it need not be recomputed; it is adequate to use the cached result, at least if you trust the place it was computed.
• Malfunctions or security breaches that produce incorrect outputs can always be detected, in theory, by rerunning the computation elsewhere.
• The program's output can be safely *deleted* from the cache, or stored on unreliable storage media that may corrupt bits, because its integrity can always be checked against the hash, and it can always be produced again on demand.
• In particular, if our definition of "program" includes a primitive that allows us to invoke a given compiler on a "source file" in a dataset, then run its output, then we can

There are several difficult prerequisites to achieve it:

• You need some kind of virtual machine definition to run program code on; the simpler the virtual machine definition, the more likely any given implementation is to be correct, but excessive definitional simplicity may also make it impractically slow or difficult to program for.
• You need to capture all dependencies
• Any concurrency must be deterministic

Word stream architecture

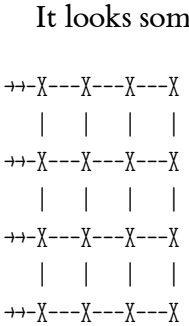
Kragen Javier Sitaker, 2018-06-17 (13 minutes)

I was thinking about how to generalize the arithmetic-computer device Sutherland mentions in his Sketchpad thesis, and I came up with an architecture presumably less powerful than an FPGA but maybe easier to program and simpler to implement. Preliminary calculations suggest that it might be capable of FPGA-like performance on DSP-like problems.

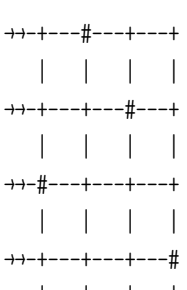
A 4×4 synchronous crossbar switch

Suppose you have a block with 4 16-bit inputs and 4 16-bit outputs, which outputs are driven by clocked registers attached to 4-way muxes. You can configure the 4 4-way muxes with 8 bits of topology configuration data. This allows each of the output ports to receive the input from any of the four input ports on each clock cycle. This can achieve not only any of the 24 permutations of the 4 input words, but also 232 more configurations which discard some inputs and duplicate others.

It looks something like this:



Here each of the "X" points is a switch which can either transmit a signal from the input to the output, or not, according to the switch configuration, and each of the "↓"s is an output register consisting of 16 D flip-flops which registers the input that has been routed to it. An example configuration, with "+" indicating switches that are disconnected and "#" indicating those that are connected, follows:



(With some logic families, it might be appealing to double that to 16 bits of configuration data instead of 4 and get wired-AND or wired-OR functions between the inputs, plus a free all-zeroes or all-ones value, depending on whether it's AND or OR.)

Now suppose you have three "fully-connected layers" made of 4

such 4×4 switches; if dataflow goes from left to right, it looks something like this:

```
digraph f{rankdir=LR;node[shape=box,label=""];{1 2 3 4}->{5 6 7 8}->{9 a b c}}
```

The idea here is that each output port on a single node is connected to a different node in the next layer, and each input port on a single node is connected to a different node in the previous layer. Since the nodes are synchronous, the whole system can run at just as high a clock speed as a single crossbar node, but with three cycles of latency instead of one, 12 bytes of topology data instead of one, and 16 words per cycle instead of 4.

What may not be immediately apparent is that this simple, regular topology is sufficient to achieve any of the 20'922'789'888'000 permutations of the 16 inputs, although not all of the 18'446'744'073'709'551'616 possible ways of assigning inputs to outputs are represented in its 79'228'162'514'264'337'593'543'950'336 configurations, due to redundant configurations. [Proof missing.] With only two layers this is not the case, since you can get at most one value from a given input node to a given output node, but with three layers you can get all four values from the same input node to the same output node if necessary, routing them through four different nodes in the intermediate layer.

Additional layers permit larger numbers of inputs and outputs, at the cost of higher latency. I think, but am not sure, that each two additional layers permits a permutation of four times as many inputs — thus, 4 inputs with 1 layer, 16 inputs with 3 layers, 64 inputs with 5 layers, 256 inputs with 7 layers, etc.

(I learned about this topology from the IBM SP2, but I think it actually originated in telephone networks. In the SP2 "high-speed switch", only permutations were supported, but they were created and removed dynamically, and there was also buffering.)

Note that if the individual crossbar nodes are inverting and you do the wired-AND or wired-OR trick, then you can get words of either all zeroes or all ones out of the same network by generating them at different levels of the network, and you can also get both wired-AND and wired-OR, though not completely without restriction. This can get a wide range of bitwise functions out of the network, though not all 16 bitwise functions.

Transport-triggered crossbar computation

Suppose you hook up an adder to two of the outputs of the above switch network and its output to one of the network inputs. Supposing the adder can operate with the same cycle time as the crossbar nodes, you can then send it a stream of pairs of numbers to add, and the stream of its (three-cycle-delayed) outputs becomes available as another stream of values for the network.

Indeed, you could do the same with a multiplier, or a multiply-accumulate element, with three inputs; or a bitwise XOR, or an AND, a signed or unsigned comparator, a signed or unsigned max, or a general ternary operator. A barrel shifter could quite reasonably derive several outputs from a single input, as could a more general ALU — by simultaneously generating several functions of its two inputs on different outputs, all connected to network inputs, the

routing configuration of the network serves to determine which output or outputs are actually used.

In some cases, you might want to just connect network outputs directly to inputs, providing a feedback path from one cycle through the network to the next. This can be used not just to remember a data value, like a register in a conventional processor, but also to accumulate results iteratively.

Where does the stream of input values come from? You could imagine configuring a memory read port as an input-output pair — an output for the memory address and an input for the data read from the memory. Or you could connect the address bus to a counter and initialize the counter by some other means, perhaps the same means used to set up the network topology configuration. Or, rather than a counter, you could use a register hooked up to an adder which increments by some amount on each cycle, in order to allow strided reads.

Where does the stream of output values go to? Aside from hooking some output ports directly to peripherals such as a DAC, you could quite reasonably have a memory write port as well.

Interleaving

In the above, I've described both cases where the data fed back into the network is purely a function of the network's current outputs — the adder, say, or the ALU, or the outputs wired to inputs — and cases where some state is kept outside the network. I want to distinguish between the cases where this state is kept in RAM and where it's kept in some kind of register attached to the network directly.

I claim that if we abjure entirely having separate registers attached to the network, allowing only RAM and pure functions, then we can think of the processor as a temporal interleaving of several different processors. If we have, say, seven cycles of latency through the network, then we can think of it as seven virtual processors with completely separate sets of registers; the outputs on cycle 7 are a function of the inputs on cycle 0, the outputs on cycle 14 are a function of the inputs on cycle 7, and so on. They could even be computing unrelated things if we also switch between seven different configurations for the interconnect network on each clock cycle. Breaking our abjuration with a one-cycle delay element — a register external to the network — suffices to provide communication from one virtual processor to the next.

This approach would suggest that we handle, for example, strided memory access with an adder connected to a fixed value and its own previous output, which is also routed to the memory read port, rather than an external register that increments by the stride each cycle.

Bit-serial variants

If you make the nodes bit-serial instead of parallel, you lose a factor of 16 in bandwidth. But you gain a factor of 256 (!!) in area, and you may also gain some bit-shifting power — suddenly a delay element is capable of shifting a word by a bit, as for a multiplication.

With this approach, it's still likely worthwhile to interleave virtual processors, but they're interleaved on a bit-by-bit basis rather than a word-by-word basis. The replacement for a 16-bit register in a

normal processor is, rather than wiring an output directly around to an input, a longish shift register from an output back to an input. (If the network latency is 7 bits, for example, you need a 112-bit shift register.) A delay element to shift a word by a bit could similarly be a shift register. (A 7-bit shift register if, again, your network latency is 7 bits.) But you don't need one — you can just use a path through the network! Doing the same thing for a 16-bit value would use up 16 inputs and outputs, though.

An interesting thing about bit-serial processors is that they more comfortably accommodate processing data of arbitrary-length words than data of fixed-length words. Dropping the carry from an addition after 16 bits or whatever is an extra exceptional case to add, rather than something you have to take special pains to avoid. Also, you get perhaps some extra use out of the elements used for addition — if you route a 0 carry to a bitwise adder, it gives you simultaneously XOR and (perhaps integrally delayed) AND, which you can use for other things.

Per-bit LUT

One possible interesting operation for the bit-serial case is demuxing: given four or eight bitstreams, demultiplex the values of two or three other bitstreams to select among them. This provides a programmable universal Boolean function which can, if desired, vary bit by bit.

Very crude performance analysis

The idea here is that you load the inner loop of your algorithm into the configuration of the network and just let it rip for a while. Under such circumstances, modern high-end CPUs can generally take advantage of SIMD operations, carrying out something like 128 bit operations per cycle. Small microcontrollers are stuck at something like one 32-bit payload operation every five cycles or so, so something like six bit operations per clock cycle.

If you have a 256-input 256-output bit-serial network that is 7 bits deep, you might allocate half of its lines to ALUish things, half a dozen or so to memory, and split the other half between long shift registers and simple loopbacks. This gives you a max of 128 bit operations per cycle, but maybe 64 is a more likely estimate.

Let's estimate that each D flip-flop uses 6 transistors and that we have 56 bits of FIFO on each of the 64 long-shift-register outputs, making them more akin to 8-bit registers. (It's easy enough to chain two of them together when you want a 16-bit register.) This gives us 21504 transistors in this register file, which is a lot but not the majority of the whole chip. The 1792 D flip-flops in the network itself are just 10752 transistors, and the 1792 corresponding MUXes might be another 10752 transistors. Then, on our 128 or so ALU lines, we have, say, 5 NAND gates each, each with 4 transistors, for a total of 2560 more transistors. The total, then, is 45568 known transistors, and if we add 50% or so for stuff I'm not thinking of, it's similar to the count on a 68000 or other mid-80s workstation CPU — but clockable at very high speeds because of its very short path length, and doing 128 bit operations per cycle instead of 6 or whatever.

However, that doesn't account for the control unit, the thing that

decides when and how to reconfigure the network and whatnot.

Topics

Keyboard-powered computers

Kragen Javier Sitaker, 2014-10-25 (updated 2018-10-28) (26 minutes)

(See also Low-power microcontrollers for a low-power computer (p. 2602).)

The energy available from keystrokes on a regular keyboard is almost 10 milliwatts: plenty to power a portable electronic word processor, so you could write a novel on one without an external power source. However, so far, energy harvesting keyboards are probably too inefficient to make this practical.

XKCD What if? 102 characterizes the energy produced by tapping keyboard keys; it cites Nagurka et al. 1999 as providing a smallish estimate:

> Using data from a study of rubber-dome keyboards—the most common type these days—… the energy required to press a key is around 1.5 millijoules for a letter key and 2.5 for a big key like the enter key or spacebar.

Summary of results

A keystroke adds, usually, a single letter or space to your novel. It provides 1300 microjoules of energy, of which 2.25 microjoules are needed by an LPC1100-family CPU to run word-processing software, 25 microjoules are needed by the E-Paper display to display the letter on the screen, and 0.5 microjoules are needed to eventually store the letter permanently in a Flash memory if you don't erase it, for a total of 27.75 microjoules out of the 1300 available. This means you need at least 2% efficient conversion of the keystroke energy, which commercially available pushbutton energy harvesting devices have barely achieved (they claim 2–5%.)

However, solar power or pullstring dynamos are probably better options. Typing at 90 wpm provides 10 mW of power, but only while you're typing, and that's 0.2–0.5 mW after conversion inefficiency; a 30mm-square solar panel provides 10 mW all the time.

Keystroke energy estimation

Nagurka et al.'s estimate seemed a little high to me: if for each keystroke your 50-gram fingers have to travel a 4mm key travel in, say, half a second, and then hit the bottom and stop, then the kinetic energy of your finger is closer to a microjoule per keystroke than a millijoule:

```
user@debian:~/devel/hojas$ units
2526 units, 72 prefixes, 56 nonlinear units

You have: 50 g * (4mm / 0.5 s)^2/2
You want: mJ
        * 0.0016
        / 625
```

A more recent open-access article by the same author explains in more detail. The conclusions of the paper are not very sensitive to how fast your fingers move, because the paper has graphs of the

measurements of the spring force of the rubber-dome keys, which is much larger than what is necessary to decelerate your finger and is not particularly sensitive to the speed at which the key is pressed: for 3mm of the 3.5mm travel of the "K" key in one keyboard he tests, for example, the force is between 0.4 newtons and 0.55 newtons regardless of whether the key is moving 0.5 mm/s or 80 mm/s, with the speed amounting to about 0.1 newtons of difference, i.e. about 25%.

0.45 newtons times 3mm is 1.35 millijoules.

0.45 newtons by itself would decelerate a 50-gram finger at 9 m/s/s, which is to say that it's just about the weight of the finger. If your finger were moving at 60mm/s without you applying continuous force to it, it would come to a stop in just under 7ms at 0.45 newtons. So the vast majority of the energy transmitted from your finger to the key is never part of the kinetic energy of your finger.

(Most of this energy is returned to your finger when the key comes back up, so it might be more difficult to type on a keyboard that harvests this energy. Experience with manual typewriters suggests that this problem will be minimal.)

Conservatively we might want to disregard the part of the energy estimate that's due to Nagurka and Marklin's model of how fast your fingers move, because he assumes that your keystrokes don't overlap, which they clearly do. But the difference, as you can see above, is small.

Even with this well-substantiated estimate, which is much higher than what I'd come up with, Randall goes on to calculate that this isn't a very useful amount of energy for things like running a modern laptop or microwaving a burrito.

At 90 words per minute, we have almost 10mW of available power:

```
You have: 90*5*1.3mJ/minute
You want: mW
        * 9.75
        / 0.1025641
```

Keyboard-powered computers

The original question, though, was this:

> As a writer, I'm wondering what would be the cumulative energy of the hundreds of thousands of keystrokes required to write a novel.
>
> —Nicolas Dickner

Perhaps Nicolas was actually wondering, in particular, whether you could run a computer to write the novel on with the energy from the keystrokes, so that he wouldn't have to worry about losing his battery charger or wearing out his battery and being unable to write.

In some sense the answer is clearly yes: people wrote novels on mechanical typewriters whose data storage mechanism was ink stamped onto paper with a mechanism powered by pressing the keys, although they were somewhat more effort to press than modern keyboard keys. Intuitively it seems like electronics ought to allow us to do *better*.

So how much power do you really need? Perhaps laptops are an

energy-inefficient way to write novels, compared to other kinds of portable computers. And in fact it turns out that running an electronic word processor on keyboard power is easily feasible, although I don't know of anyone who's done it.

CPU power consumption

CPU power consumption is not a problem, unless your CPU doesn't have a working sleep mode. Summary:

	nJ / instruction	instructions/keystroke
feasibility limit	170	7500
MSP430	0.9	1400000
PIC24	2?	600000
1990s StrongARM	1	1300000
LPC1110	0.3	4300000
Pentium	10	130000
STM32L0	0.23	5700000

Details

You can write a novel using a Commodore 64 or Apple][, and several people did. They can update text on the screen with relatively complex word-processing logic while keeping up with your typing speed, even at high typing speeds like 160 words per minute. These were 8-bit computers based on the MOSTek 6502 microprocessor and its variant the 6510, which typically run about 200 000 instructions per second. Because those instructions only manipulated 8 bits of data at a time, you usually need about twice as many of them as on a modern 32-bit microprocessor to do the same work. (In some cases you need more like 8 times as many, and in other cases you need the same number or even less, but those cases are rare.)

(Other 8-bit home computers of the time period, like the Nintendo NES, the Altair and all the CP/M computers that followed it, the Atari 2600, the various TRS-80s, and the Pac-Man arcade machine, were similar in speed. The IBM PC was maybe three to five times faster.)

So if we divide 100 000 32-bit instructions per second by 160 words per minute, we get a number of instructions per keystroke that is known to be sufficient: about 7500 instructions per keystroke.

So can one keystroke, in the microjoule to millijoule range, produce enough energy for 7500 32-bit CPU instructions? That would require power consumption of less than about 170 nanojoules per instruction.

The most common low-power microcontroller family today is the TI MSP430. It's a 16-bit microcontroller, and TI recently published a white paper on its power consumption which shows two members of this family running at a million instructions per second on 300 and 515 microamps on a 3-volt power supply; 300 microamps times 3 volts gives us 900 microwatts, and dividing 900 microwatts / 1MIPS gives us 0.9 nanojoules per instruction.

That is, for the MSP430F2001 described in the white paper, a keystroke provides almost 200 times as much power as would be needed to run a word processor to handle that keystroke.

Dividing it another way, a 1.3-millijoule keystroke provides enough

power to run the MSP430 at 1 MIPS (five times as fast as a Commodore 64) for 1.4 seconds.

The point of the whitepaper is to compare the MSP430 favorably to a PIC24 microcontroller from another chip vendor, which (according to TI) needs two or three times more power: they estimate that the PIC could run off a particular coin cell with a 1% duty cycle for less than two years without recharging, while the MSPs could last four to six years.

Academic papers report the fabrication of 10pJ/instruction and 2.6pJ/instruction microcontrollers, which is another two orders of magnitude better than the MSP430's 900 pJ/insn. Even as far back as the 20th century, the DEC StrongARM SA1110 used one nanojoule per instruction, and there were 22-picojoule-per-instruction microcontrollers reported and 1-picojoule-per-instruction ones being designed.

Zhai also published https://web.eecs.umich.edu/~taustin/papers/TVLSI09-subliminal.pdo of on the 2.6pJ processor.

The most interesting microcontroller to me right now is the 32-bit Philips/NXP LPC1110 family, which can apparently run at 48MHz (and 48MIPS) at 1.8 volts and just under 8 milliamps. Dividing, that's 0.3 nanojoules per instruction, three times better than the MSP430! However, the chip suffers about a 6 microamp leakage current in deep-sleep mode at room temperature, so each keystroke only provides enough energy to keep it in deep sleep mode for about 20 minutes. The LPC1110L variant cuts this sleeping energy consumption by about a factor of three.

So keystrokes provide about 600 times as much energy as you would need to power an LPC1110-family microcontroller running a word processor. You could write your word processor in BASIC or some other interpreted language and it would still work fine.

More recently (I think 2015), STMicroelectronics has released the STM32L011x3/4, based on the Cortex-M0+ core, which I think is the same one in the LPC1110. According to their measurements, it can run at 16MHz on 1.95 mA at anywhere from 1.65 V to 3.6 V, running code from RAM with the flash switched off; they claim 0.95 DMIPS/MHz. If we assume 1.8 V, this is 230 pJ/instruction, which is about 25% less than the LPC1110. This is according to the datasheet, "DocID027973 Rev 5".

An interesting feature is that the STM32L011x3/4 has a "low-power run" mode which clocks the CPU at 131 kHz at 31–120 µW (10–40 seconds per 1.3 mJ keystroke), as opposed to its normal 16MHz 3.5 mW run mode (370 ms per keystroke) and its 0.3–1 µW stop and standby modes (20–60 minutes per keystroke). This suggests that maybe you could continue doing less-CPU-demanding operations continuously for some time at a lower speed, without having to pay for sleep and wakeup. Unfortunately, the 7500 instructions guessed at above would amount to about 57 milliseconds at this speed, a noticeable lag.

Even non-low-power CPUs are efficient enough that your keystrokes are enough to power a word processor: a New Scientist article from 2006 explains that the Pentium from 1993, Pentium Ms from 2003, and Core Duos from 2006 all use 10 to 13 nanojoules per 32-bit instruction, which is still about 15 times as efficient as you'd

need to be able to power a word processor from them. The problem they have is that you can't put them to sleep and wake them up fast enough, so you couldn't actually use them for this.

Power consumption of other parts of the system

But a CPU isn't enough, by itself, to be a word processor. You also need some way to display the text while you're editing it and to store it when the machine runs out of stored energy, two functions fulfilled by the ink on the paper of a mechanical typewriter.

You may also want external RAM, since e.g. the LPC1110 family tops out at 8 kilobytes of RAM, which isn't much text, even compared to what you could keep in RAM on a Commodore 64. A small SRAM is probably a better bet than power-hungry DRAM, and you need to make sure to save it to stable storage before power runs out.

Display

The display is going to use more power than the rest of the system put together.

Probably the best current option for low-power text *display* is an E-Ink display, like the one used by the Amazon Swindle. E-Ink can maintain the same display for months or years without applied energy (as evidenced by broken E-Ink screens). A 6" E-Ink display needs about 750 mW during screen update, which takes 120ms, and that's for 122×91 mm at 167dpi. Breaking that down, that's about 190 nanojoules per pixel update, or 8100 nanojoules per updated square millimeter:

```
You have: 750 mW * 120ms / (122 mm * 91 mm * (167/inch)^2)
You want: nanojoules
        * 187.53217
        / 0.0053324185
You have: 750 mW * 120ms / (122 mm * 91 mm)
You want: nanojoules/mm^2
        * 8106.6475
        / 0.00012335556
```

Suppose you want to be able to display eight 20-em lines of 7-point text on such a display, similar to a TRS-80 Model 100, since that was a portable device that millions of reporters and other writers used on a daily basis in its day. (It sold six million units.) That's 7 points * 8 vertically and 7 points * 20 horizontally: 49mm×20mm, similar in size to a cellphone display. Updating the entire display then will require almost 8 millijoules:

```
You have: (7 points)^2 * 8 * 20 * 750 mW * 120ms / (122 mm * 91 mm)
You want: millijoules
        * 7.909696
        / 0.12642711
```

This means that, although you can do huge quantities of computation per keystroke, you can't afford to update the screen on every keystroke; you need about six keystrokes to provide enough

power for a full screen update. You'll have to make do with updating a small part of the screen for incremental updates, and save full-screen repaints for things like scrolling.

8 20-em lines of text is about 50 words (1 word ≈ 6 ens = 3 ems ≈ 3.2 ems = 160 ems/50) so 350 words per minute (a normal reading rate) works out to 7 screen updates per minute, or just under a milliwatt (1 mW).

(Calculating per character: that's 250 characters in 8 lines, or 31¼ characters per line, or 1.58 mm per character, or 3.9 mm² per character; this ends up being 31.6 μJ per character.)

Alternatively you could just make the keys six times as hard to press as on a regular keyboard, plus a tiny bit more to power the rest of the system. This doesn't sound like a great idea though.

(You can probably use a larger E-Ink display and keep your power consumption down by updating only small parts of it.)

You can't just cut a chunk out of a large E-Ink display; a small E-Ink display is Seeed Studio's 2.7-inch e-Paper panel, which is 70×46 millimeters and 264x176 pixels for US$26, and can be driven by a US$24 Arduino shield. That's 18 28-em lines of 7-point text, about 200 words, three times the Model-100-like display I suggested above.

Seeed's site suggests that this hardware needs 3.3 volts, 40mA, and 3 seconds to refresh the whole screen. This is unfortunately 50 times worse than the figures I got from the other site, totaling 400 millijoules for a full display redraw:

```
You have: 3.3 volts * 40 mA * 3 seconds
You want: millijoules
        * 396
        / 0.0025252525
```

You'd think another possible low-power display technology would be Pixel Qi "low-power" transflective/reflective LCD developed for the OLPC XO laptop. Their PQ 3Qi-01 is a 235 mm × 143 mm 185 g 1024×600 display, each pixel containing three transmissive subpixels and three grayscale reflective subpixels. However, its power supply current is specified as 135–228 mA at 3.3 V, depending on color (white uses 30% more power), even aside for its 1.5 amp initial startup current and the 83–525 mA LED backlight current. Even the lowest power mode, 30 fps reflective, is specified as 390–480 mW. So this device is way outside of our power budget. (All this is according to their datasheet, "Doc No.: PQ001-2", Sept 19, 2011.)

But those high-end LCDs aren't the only possible option. Old cellphones used supertwist nematic ("STN") LCD displays, which should be less power-hungry. In fact, I think that pixels that are turned off on these displays don't use any power. The Philips PCF8833 datasheet says it can refresh a 132×132×3 display at 35.8 Hz to 227 Hz; it seems to contemplate driving an LCD at 10 V and up to 10 mA but more normally 400 μA, but no more than 5 kΩ for each of its 132 output rows, only one of which is active at a time, which would seem to mean 2 mA. So it's designed to drive a load of somewhere between 4 mW and 100 mW but probably something like 20 mW. The chip itself consumes about 1 mA while accessing memory, which works out to be something like 3 mW.

So, at a rough guess, a 132×132×3 STN display without a backlight might use 7 mW continuously, which is equivalent to the power cost of about 37000 E-Ink pixel updates per second (at 190 nJ/pixel as above), which means that for motion above 2 fps the STN display is more efficient, but for slightly changing text, it's dramatically less efficient.

Flash or FRAM

(Summary: Flash is adequate.)

You also need to be able to store data permanently, so that your novel doesn't get lost when you stop pressing keys for a while. The most reasonable electronic means for that is probably Flash, although MRAM, PCRAM, and FeRAM ("FRAM") and I think ReRAM and CBRAM are currently available too and might be reasonable alternatives.

Some random PowerPoint presentation I found on the web says Flash uses 2µJ per 32-bit write and 150pJ per 32-bit read, while FeRAM uses 1nJ for either one. That means that a single keystroke provides enough energy to write 5 megabytes of FeRAM or 2600 bytes of Flash. Either memory technology is clearly sufficient for word processing from this point of view, but Flash is much cheaper.

(There are MSP430 microcontrollers that already use FeRAM ("FRAM") instead of Flash, but none of them have more than 128kiB, so none of them are big enough to avoid needing off-chip memory for a novel.)

Some other random PowerPoint presentation puts MRAM at 5nJ per "write energy", compared to 0.8nJ for SRAM, but I don't know if that's a bit, a byte, or a 32-bit word.

Abarrilado compared FRAM and MRAM chips and found that at 3V (?), the FRAM chip needed 5mA to write at 33MHz and 9 µA in standby, while the MRAM chip needed 23mA to write at 40MHz and 7 µA in standby. I think those bus cycles are mostly being used to write one bit each, which would give us 0.45 nJ/bit or 14nJ/32-bit to write the FRAM, or 1.7nJ/bit or 55 nJ/32-bit to write the MRAM. However, in both cases, he had to pay US$5 for about 32 kilobytes of storage, which means enough storage for a novel will be expensive.

The reason people are adopting FeRAM for embedded designs is that the write latency is lower, which lets the microcontroller go back to deep-sleep much sooner, which cuts power consumption. (Also, it's rad-hard and harder to reverse-engineer, which we don't care about here.) However, in this application, we're not under such severe constraints of available energy. We're worried about milliwatts, not microwatts and nanowatts.

Pullstrings

Another alternative to keyboard power and solar energy is a dynamo. 500 mm of pull at 50 N (about 5 kg of weight) should be within the capacity of most biological humans, and that's 25 J; a 50%-efficient dynamo would reduce it to 12½ J. At 10 mW (the power of typing at 90 wpm, disregarding potential conversion inefficiencies) those 12½ J are 21 minutes. If you need 30 µJ of energy to handle each keystroke (3 µJ to run 10000 instructions on a 300 pJ CPU, 25 µJ to update the E-Ink display, 0.5 µJ to store it in Flash, rounding up) then this is enough energy to handle 420 000 keystrokes.

Related work

enOcean has a commercial line of energy-harvesting pushbuttons, such as their ECO 200, and radio transmitters powered by them, such as the PTM 200. The ECO 200 consumes 2.7 to 3.9 newtons over 1.2 millimeters and produces 120 to 210 microjoules, which is about 2–5% efficiency.

Cherry, the well-known keyboard switch company, has a similar product.

Rashi Tiwari under Ephrahim Garcia at Cornell added an energy-harvesting device to a regular keyboard's Enter key and used it to flash some LEDs, I think in 2012, although they haven't published a paper on this, just a YouTube video.

Also, T Wacharasindhu and J W Kwon 2008 J. Micromech. Microeng. 18 104016 doi:10.1088/0960-1317/18/10/104016 is "A micromachined energy harvester from a keyboard using combined electromagnetic and piezoelectric conversion." They got 42 microwatts out of the setup, 95% of it from piezoelectric conversion. 42μW/10mW is 0.4% efficiency.

http://responsive.media.mit.edu/wp-content/uploads/sites/5/2013/10o2/A-Compact-Wireless-Self-Powered-Pushbutton-Controller.pdf got 500 μJ per Scripto "Aim 'n Click" lighter click, but improved circuitry could improve this substantially.

Combining sensing with generation

Variable-inductance position sensors are well-known in the form of e.g. the linear variable differential transformer, which senses the differential voltage induced in two counterbalanced secondary windings by a pulse or ac current through a primary between them to precisely measure the linear position of a high-permeability core. In this case, though, we don't care about precisely measuring its position; it's adequate to distinguish presence from absence.

If we additionally add a permanent magnet to the mechanism, every movement of the core will generate a voltage, even without a current through the primary. We can distinguish that from the higher-frequency sensing current because the core will never move significantly within 100 ns. So we can use a capacitive coupling to couple the fast pulses from the sense windings through to the sensing pins on the microcontroller, while rectifying the much slower ac signals with a Schottky diode or four.

(Alternatively, maybe the probe lines should be the ones the power is harvested from.)

No separate spring is needed, not even a rubber dome, if the magnet itself acts to return the key to the up position.

If we have, for example, a keyboard matrix of six probe lines by six sense lines (for 36 total keys), each wire runs through six coils. I think this means that the inductance of the other five coils will prevent the current from rising quickly, but not the voltage.

If the key makes a full magnetic circuit when in contact with the magnet, it should be easy to sense the initial voltage rise, since the circuit reluctance will rise and fall precipitously as the key moves through the 100 μm closest to the magnet, with a correspondingly

rapid change in flux density and thus a correspondingly large voltage.

The probe pulse needs to induce a strong enough current to charge the sense pin and other parasitic capacitances. If we assume that this is around 50 pF and we need to charge it to 1.2 volts to be sure of detection, this requires 36 pJ of energy; sending such a sense pulse 256 times per second on each of 6 lines requires 55 nW. So the power to probe the keyboard is minimal. However, this doesn't account for the fact that the microcontroller needs to wake up in this case! Somehow we need to wake up the microcontroller to generate the sense pulse.

Cached SOA desktop

Kragen Javier Sitaker, 2017-08-03 (updated 2018-10-26) (6 minutes)

(See also Window systems (p. 1335).)

I was thinking a lot about RESTish ways of doing stuff with caches and whatnot, and I was thinking that maybe you could do a desktop environment consisting of background images, alpha blending, text, text layout, windows, currying, and fonts, using redirects and caches.

The main idea is that, each frame (60 times a second), the window system virtually sends many requests (see What's wrong with CoAP (p. 560)) to the root window, one for each 16×16 pixel tile (see Caching screen contents (p. 2362)). This works out to 120×68 tiles on my 1920×1080 screen, or 8160 requests, for a total of 490,000 requests per second. The root window largely sends back temporary redirects: for subwindows they are redirects to requests for those subwindows, for background images they are redirects to those background images, and for text layouts they are redirects to those text layouts. In cases where more than one kind of thing participates in the tile, the window sends out the requests and takes responsibility for compositing them.

This is a rather large number of requests; 0MQ on my laptop with one single-threaded PUSH process and one single-threaded PULL process can only handle about 2.5 million (empty) messages per second. But the idea is that, almost all of the time, those messages aren't being sent at all; they're satisfied from a local cache.

There isn't a single unified cache, but rather a somewhat distributed caching system, using an asynchronous cache invalidation protocol. Each potentially cached request carries with it an identifier for the cache invalidation endpoint; a stateless responder can merely forward this identifier on to the resources it's fetching to compute the response, while a stateful one should generally store it for cache invalidation purposes.

A window with text in it can query the text layout to find out where to put the text (and which text is visible) and query the font to get the individual glyphs to display, then compositing them onto the background in the appropriate places.

The distributed nature of the caching system allows the display to apply an outdated-is-okay policy of using cached window contents if it hasn't received an up-to-date response by frame render time, or perhaps graying them out a bit or something, without globally applying such an outdated-is-okay policy or having a switch in the protocol for it or something, or having the cache first send an outdated response and then the real response, or whatever. Also, the display server can use a specialized cache structure — for example, instead of caching separate responses to the different tile requests, it can cache a single screen bitmap and maintain a tile validity bitmap (of only 8160 bits), and maybe even use a specialized invalidation handling policy of requesting tiles early. Downsides include cache duplication (many windows requesting the same glyph will cache it many times) and inability to globally optimize cache usage to minimize CPU time or improve responsiveness.

A cached redirected response can be invalidated because any of the

resources in the redirect chain was invalidated, including the final response. Using a redirect rather than just proxying the request allows the (potentially large) response to avoid an extra copy, or potentially many extra copies.

Currying a resource-with-arguments to be just like a normal resource allows requests and cache keys to stay small.

The requests and responses can be pipelined between a relatively small number of processes to amortize system call overhead over large numbers of small messages. Given potentially many outstanding requests, it may be reasonable to process them (on a given core) in an order determined by which piece of code is responsible for processing them.

I don't know, this seems like it might be a bit of mental masturbation in the sense that we already have working ways to build window systems. The main problem they have is that the window systems (and our operating systems) do a shitty job of guaranteeing responsivity to the user, and probably the way to solve that problem has more to do with avoiding swapping, prioritizing real-time interaction (like providing feedback to clicks and typing) over background tasks (like font rendering and relayouts), and having the whole user interface written in a way that guarantees finite and deterministic memory usage and CPU time — static allocation of memory and CPU time rather than dynamic, really. There are only so many pixels on the display, after all, and on a 60Hz video card you can't update them any sooner than 16⅔ ms in the worst case. That gives you 8.04 ns to decide what color to make each pixel. Not a lot of time to copy pixels around in messages!

I think there is something interesting in the idea of caching redirects to curried functions, though — maybe applicable in systems that don't involve IPC, too. If you can delegate a particular call to a chain of particular other functions (perhaps with added arguments) and cache that delegation in a way that doesn't involve running through the whole chain of functions again because the last function in the chain has an input change, then you can do efficient OO method dispatch in just that way, as well as things like delegating painting a particular part of a window to a particular widget. Maybe you could handle it like backtracking: save a series of backtrack points, and handle invalidation notifications by resetting the backtrack state for that cache entry to point to one of those earlier backtrack points, which could literally be an address to jump to in a piece of code. Maybe?

La vibración del hierro, ¿es de baja frecuencia o qué?

Kragen Javier Sitaker, 2016-10-07 (3 minutes)

https://www.facebook.com/jmpoio/posts/10154629260364445?comment_id=10154629631144445&comment_tracking=%7B%22tn%22%3A%22R%22%7D

Depende de comparado con qué.

Desde el siglo 17 hemos realizado varios avances en la alquimia y ahora podemos calcular con algo de precisión la frecuencia de vibración de los átomos de cada sustancia.

La frecuencia de vibración de los átomos de un sólido a la temperatura ambiente es alrededor de 10^{12} Hz, es decir, un terahertz. Esa es mucho más alta que la mayoría de las vibraciones que encontramos en la vida cotidiana, como los de sonido (20–10000 Hz), radio (20 Hz – 200 GHz), pero más baja que la frecuencia de luz (400–700 THz), rayos X, o rayos gama. En particular, los átomos de hierro, con su peso atómico alrededor de 56 amu, vibran más rápido que los átomos de cobre (63), oro (199), plata (108), o estaño (119), pero menos rápido que los átomos de aluminio (27), suponiendo que todos los metales en cuestión están a la misma temperatura.

Para el hierro en particular, su radio atómico es de unos 126 picómetros. Si supongamos que tiene tres grados de libertad translacionales que contienen la mayoría de su energía térmica, cada uno tendrá una energía de kT/6, que resulta ser aproximadamente $6{,}7 \times 10^{-22}$ J a 20°C; usando la relación oculta $E = ½mv^2$ descubierto por el alquimista Newton con $E \approx 6{,}7 \times 10^{-22}$ J y con una masa de 56 amu, entonces la velocidad de cada átomo está alrededor de 120 m/s en cada eje, o 210 m/s en total (ésto siendo el promedio de una distribución estadística Maxwell-Boltzmann, creo). A esa velocidad, el núcleo puede realizar un desplazamiento de, por ejemplo, 50 picómetros, en unos 0,24 picosegundos, implicando una frecuencia de vibración de alrededor de 4 terahertz.

Se puede lograr un cálculo más preciso con la ley universal de oscilación harmónica, basado en el trabajo por el mismo alquimista Newton en su investigación del movimiento de los planetas (como arriba, así abajo; como afuera, así adentro!) — en la simbología que usamos hoy en día, $md^2x/dt^2 = -kx$, cuyo sentido solo estará aparente a los que cultivan cuidadosamente su ojo interno con atención diligente al sendero filosófico. Pero confío que el número aproximado de 4 terahertz será suficientemente preciso para tus propósitos.

Lamentablemente, tanto hoy en día que hace veinte generaciones, hay muchos falsos filósofos que opinan sobre cualquier cosa sin saber nada al respecto, dejándose divagar por diez mil maestros falsos que no se dedican al conocimiento verdadero sino a estafar a la gente, porque la gente sigue buscando un sendero fácil al conocimiento, y así terminan repitiendo las palabras de las falsas maestras sin entender nada. El sendero fácil no existe, pero el sendero verdadero está disponible para todos y todas. Así seguimos ignorantes generación tras

generación, muriéndonos de sed ante un río de conocimiento hermético, y destruyendo la vida en la tierra por nuestra ignorancia.

Es una verdadera tragedia.

A design sketch of an air conditioner powered by solar thermal power

Kragen Javier Sitaker, 2016-12-22 (updated 2017-01-04) (29 minutes)

After reflecting on my solar dehumidifier idea (from August 2016 or maybe earlier) and the current air-conditioner-less state of my new bedroom, I did some calculations on making a desiccant-based air conditioner powered by the sun.

The basic idea is that you cool air by evaporating water, like a swamp cooler. But because swamp coolers work poorly or not at all when the air is already humid, you dehumidify the air before cooling it. And because the high-humidity output is undesirable in climates that aren't dry, you transfer the cool through a recuperative heat exchanger without transferring the humidity; this is known as "indirect evaporative cooling".

Standard swamp coolers use a recirculating pump to dribble water over wood wool ("excelsior") pads to evaporate it, but a mister might work just as well, and might reduce the available habitat for bacteria. WP says a high-pressure pump and 5-micron mist orifices are effective.

To dehumidify the air, you pass it over a desiccant, a hygroscopic substance which absorbs some of the moisture from the air — potentially nearly all of it, depending on the desiccant and how dry it is. The desiccant will eventually be saturated with moisture and stop absorbing it from the air; at this point it needs to be regenerated, normally by heating, normally by running hot air through it, then dumping the hot, moist air into the environment.

This design uses a large quantity of a cheap, inefficient desiccant, such as wood wool, rather than a more reasonable quantity of a more mainstream desiccant, such as calcium chloride. As a result, most of the heat from the regeneration air is deposited as sensible heat in the desiccant; only a fraction is used to drive out the water. In order to prevent this heat from leaking into the intake air to be desiccated, two more air circuits are needed: a closed circuit of dry air to remove the heat from the desiccant, and an open circuit of hot dry air to remove the heat from the closed circuit.

So there are five separate, isolated air circuits: a cool wet circuit running through the desiccant, the evaporator, and a heat exchanger; a cool dry circuit running through that heat exchanger; a hot wet circuit running through a solar heater and used to regenerate the desiccant; a closed dry circuit (half hot, half cold) to cool the desiccant; and a hot dry circuit to cool the air in the closed dry circuit down to ambient, transferring the heat to the outside air. Only the cool dry circuit connects to the indoor air.

Swamp coolers typically achieve 70% to 90% relative humidity on their output side; I think it should be possible for relatively simple desiccants (wood wool itself, for example) to get the relative humidity of the air going into the evaporator below 20% see calculations below), but I haven't performed experiments to show this

yet. As long as it's below 20%, we have a minimum swing of 50% relative humidity, which achieves half of the total theoretically achievable temperature swing. WP says, "Most efficient systems can lower the dry air temperature to 95% of the wet-bulb temperature, the least efficient systems only achieve 50%."

I am estimating that my new bedroom might receive 4 kilowatts of solar heat during the day (3400 frigories per hour, a bit over a "ton") that it might be necessary to extract. Converting this sensible heat adiabatically into latent heat by evaporating water consumes 1 g of water per 2260 J, which is to say (4000/2260) g/s of water: 1.8 g of water per second, or 6.4 kg (= 6.4 ℓ) per hour. And let's suppose that the desiccant can be recycled every 30 minutes.

Output airflow rates

Let's suppose that it is adequate to reduce the temperature of the humid air in the evaporation stage to 15° — indeed, the cool air output will probably need to be mixed with enough warm air to avoid being uncomfortably cold. At 15°, the vapor pressure of water is about 1.7 kPa or about .017 atm; at about a 18:28 molar mass ratio of air to water vapor, that works out to .0109 g of water per g of air; air's density of 1.2 g/ℓ means that our 1.8 g/s of water will need 165 g/s of air occupying 138 ℓ/s to carry it along.

But wait, how much cooling can we get out of .0109 g of water per g of air? Will it cool it enough? Air holds 1.005 kJ/kg/K of sensible heat. 2260 J/g * .0109 g/g / (1.005 kJ/kg/K) is about 24.5 kelvins of ΔT, so we should be fine as long as the incoming air is below 15° + 24.5K ≈ 40°. Checking the psychrometric chart, that seems about right; the 15° diagonal wet-bulb line hits the horizontal 0% RH line at a dry-bulb temperature of 41°. 40° or 41° is fine. It never gets that hot here.

Taking into account the finite efficiencies of evaporative coolers mentioned earlier, a 60%-efficient evaporative cooler (justified below) would only lower the air temperature by 14.7°, which gets us to 15° for temperatures of 29.7° and below, and even at 38° still gets us to a quite tolerable 23.3°.

Wood wool as a desiccant

Common high-capacity desiccants include Glauber's salt (sodium sulfate, mirabilite), plaster of Paris, silica gel, calcium chloride, and sodium bentonite. But many other hygroscopic substances could potentially be used, including Play-Doh, pot shards, coffee beans, cocoa husks, shredded PET bottles, wood wool, straw, or palo borracho fibers. But let's consider wood wool, since it's probably pretty typical of many of these substances, and relatively cheap.

Let's suppose that by heating wood wool or a similar cheap hygroscopic substance after saturation with outdoor air we can easily drive out 5% of its mass in water.

5% is a conservative estimate for wood, because dry wood normally has about 12% moisture content, says WP, compared to its mass after being oven-dried at 103° for 24 hours. The fiber saturation point, which wood in a 99% relative-humidity atmosphere, is typically 25% or 30% moisture content; equilibrium moisture content ranges from 0% at 0% relative humidity through that 25% or 30%, hitting about 7% moisture content at 40% relative humidity and 12% moisture

content at 60% relative humidity. (Buenos Aires summer usually ranges from 30% to 60% relative humidity.) Wood outdoors in Miami ends up with 13% to 15% moisture; in Phoenix, it's more like 5% to 10%.

Wood drying is normally a very slow process, taking days for hardwoods at tens of millimeters of thickness, roughly proportional to the 1.52th power of the wood thickness, according to the Simpson–Tschernitz wood drying model. At 500 microns (a typical thickness for wood wool), this should be several hundred times faster, needing only 15 to 30 minutes to come near equilibrium, or less for softwoods.

To me, the above implies that exposing air to a sufficiently large quantity of wood with, say, 7% moisture content, will result in reducing its relative humidity to 40%, like Phoenix, and if the incoming air has 60% relative humidity, the wood will stop removing water from it once the wood reaches 12% moisture content. So I think 5% moisture content swing is a reasonable estimate for wood. But can we do better? Like 10%?

Wood starts to char above about 200°, and sugar starts to caramelize at 170°. Let's say we heat our desiccant up to just 150° to give a good margin of safety. What will the air's relative humidity be? And what will it leave in the wood?

If we take some incoming air at 35° (a worst case scenario in Buenos Aires!) and 65% relative humidity, the psychrometric chart shows that it contains .022 g of water per g of air, I guess because water's vapor pressure at 35° is 5.63 kPa = .0556 atmospheres, 65% of that is .0361 atmospheres, and water vapor is only about 18/28 of nitrogen's density, which gives a fraction of .0232 grams per gram — close enough. If we then use a solar oven to heat it up to 150°, water's vapor pressure goes from 5.63 kPa to 476 kPa, so the relative humidity falls by the same factor of 84.5, to 0.77%. This should leave the wood's equilibrium moisture content at about 0.1%; the EMC chart in the WP page I linked above has wood at 120° reaching 5% EMC at 60% RH, a ratio of about .08 between the two percentages.

That is to say, heating wood up to 150° should be sufficient to remove over 99% of its moisture content from ordinary levels of air humidity once it reaches equilibrium, a process whose speed depends on the thickness of the wood but should only take a few minutes for the thicknesses I'm talking about here.

This means that we probably *can* get 10% of the wood's weight in water, and perhaps more importantly, we can use it to reduce the relative humidity of the air being desiccated down below 20% or so, at the expense of a lower moisture load in the wood. Indeed, using countercurrent regenerator principles — where the air being desiccated runs through progressively dryer and dryer wood — perhaps we can reduce its relative humidity down below 5% or even 1% in this way.

Wood has a specific heat typically between 2 and 3 kJ/kg/K, with white pine being in the middle at about 2.5. The energy used to heat up the wood to the drying temperature is essentially wasted, so it would be nice to minimize it; going from 20° to 150°, it's about 390 kJ/kg of wood, or about 3900 kJ per kg of moisture absorbed in the wood. Additionally, we need energy to evaporate the water, which is

the same 2260 J/g or 2260 kJ/kg of moisture, for a total of about 6200 kJ/kg of moisture removed by the dehumidifier.

You could consider this a fairly appallingly terrible level of efficiency, but solar thermal energy has been very cheap for the last several billion years, and will probably remain so until at least 2030. So we can afford to "waste" an enormous amount of such low-grade thermal energy.

The air output from the desiccant, at 20% humidity or less, then gets humidified by the evaporator to 80% or more, so we can get at least 60% of the theoretical 24.5K temperature reduction, as long as the output is at or above 15°.

Sizing the desiccant and the hot wet circuit

Above I've talked about a 30-minute cycle time, 65% input humidity (at up to 35°, thus involving up to .022 g/g of moisture), 20% output humidity from the desiccant, and 138 ℓ/s of airflow for the cool, wet air circuit. The amount of water absorbed in the desiccant should be somewhat less than the 1.8 g/s evaporated in the evaporator, because the input humidity is lower than the evaporator's output humidity. 0.022 g/g of water vapor in air of 1.2 g/ℓ is .0183 g/ℓ of water vapor, which, at 138 ℓ/s, works out to 2.5 g/s. XXX this is clearly wrong. Over 30 minutes, 2.5 g/s works out to 4.5 kg of moisture; our equilibrium moisture content is only 10%, since we're using an inefficient cheap desiccant, so that works out to 45 kg of desiccant.

This is clearly a manageable quantity of stuff to put on the roof of your bedroom — it's not 4500 kg or something clearly impractical like that — but at Lowe's they sell "excelsior blankets" for landscaping at [US$183 for 65 pounds, US$6.20/kg], so we're talking about almost US$300 of material.

2.5 g/s by 6200 kJ/kg gives us an estimate of how much thermal power we need: about 15.5 kW, which is about, say, 20 m² of sunlight, and about 4× the amount of thermal power we're trying to reject.

15.5 kW of thermal power at 150° with a ΔT of 130 K in air carrying 1.005 kJ/kg/K is 119 g/s of hot wet air, or 99 ℓ/s, a bit lower than the other circuits.

Output airflow

The 138 ℓ/s of cool wet air can be used to cool a somewhat larger quantity of cool dry air to, perhaps, a somewhat higher temperature. If the cool dry air temperature is to be 20°, you could perhaps have 200 ℓ/s or more of cool dry air.

If we compromise at, say, 160 ℓ/s, we still need to figure out how we move this air around, ideally somewhat quietly. If the ducting is a generous 400mm in diameter, this works out to about 1.3 m/s of air velocity, which is going to be somewhat noisy, but tolerable and easily achievable.

Desiccant cooling

The 3900 kJ/kg deposited as sensible heat to raise the desiccant from 20° to 150° must be removed somehow; otherwise it will heat the intake air rather than desiccating it. My friend Mina suggests

perhaps separating the desiccant from the outside air with only a very thin moisture barrier, such as aluminum flashing, so that it can absorb the ambient temperature in a rest period after being regenerated; if this is workable, it is clearly simpler than what I propose here, which I am certain is workable.

The desiccant passes through three stages: desiccation, regeneration, and cooling. The cooling stage passes cooling air in a closed circuit through it, heating the air; that air then passes through a recuperative heat exchanger to cool it so that it can return to cool the desiccant further.

This air is at, I think, an average temperature of 85°, thus transferring 65 K of ΔT, and holding 65 K · 1.005 kJ/kg/K = 65 kJ/kg of air. The sensible heat involved is 2.5 g/s · 3900 kJ/kg = 9.7 kW. Consequently this circuit must circulate 149 g/s of air, 124 ℓ/s; I think a similar quantity is needed on the hot dry circuit, although maybe it's twice as much air due to a lower ΔT.

Fans

160 ℓ/s is 340 cubic feet per minute. For comparison, a US$24 6" (152 mm) duct fan pumps 240 cfm on 37 watts and supposedly makes 68 dB of noise. This works out to US$0.21 and 330 mW per ℓ/s; the five air circuits of 138, 160, 99, 124, and 248 ℓ/s add up to 770 ℓ/s, US$160, and 250 W. This is less than 2% of the power needed to regenerate the desiccant. It could be reduced further by using wider ducts like the 400mm ducts I suggested above; perhaps it could be provided by solar heat as well, rather than by electricity, particularly since Buenos Aires is prone to power outages at the hottest times. At 1 m/s, 250 W is 250 N, the weight of about 25 kg, which gives some idea of how much work this device requires.

Some kind of wacked-out dude has made a solar Stirling engine of "probably about 100 to 150 W" or "an estimated 70–100 watts" at about 400 mm diameter, "from the 'Andy Ross Stirling' design," with the two cylinders at right angles ("V-position"). At a typical 25% Carnot efficiency and 800 W/m² insolation, 250 W would require a solar concentrator of some 1.25 m². It looks like the nutbag is using a Fresnel lens of about 1 m² for his somewhat smaller engine.

Freezing stuff by multistage water evaporation

At a minimum, even with a perfect system, to get to 0° with evaporative cooling, you need to start with dry air at 9°; to get to 9° with evaporative cooling, you need to start with dry air at 27°; but to get to 27° with evaporative cooling, you can start with dry air at any livable temperature whatsoever. So a cascade of two or three such desiccant-based coolers could cool food or whatever down below freezing.

Water consumption

6.4 ℓ/h is probably 30 ℓ/day, which is probably an acceptable cost. I can't think of a way to condense either the water from the desiccant or from the evaporator.

Feedback

There are a few process parameters that need to be controlled to keep the system working properly.

If the cool wet air circuit runs too fast, the desiccant could be overloaded, leading to air still moist as it enters the evaporator, and thus output air not as cool as it should be.

If the cool wet air circuit runs too slow, it may not be able to evaporate enough water — it will be the right temperature, but there won't be as much cool air as there should be.

If the evaporator water runs too slowly, output air will not be as cool as it should be.

If the evaporator water runs too quickly, it could accumulate. Swamp coolers normally use a float valve to prevent this.

If the hot wet air circuit runs too fast, it might not be as hot as it should be, and so the desiccant might be less regenerated than intended, leading to diminished cooling capacity; however, unless this is super extreme, the diminution should be minimal, because the drying process is an exponential decay already close to its asymptote at this point.

If the hot wet air circuit runs too slowly, it might be too hot, which could set fire to the desiccant or melt other parts of the machinery, maybe including the solar heater itself. This would be disastrous. Some kind of thermostatic control on the solar heater seems essential.

If the cool dry air circuit runs too fast, it won't be as cool as it could be, while if it runs too slow, some of the cool will escape up the chimney with cool wet air.

If the desiccant rotates too slowly, it will become saturated with moisture in the cool wet air circuit, diminishing cooling performance; if the regeneration air is properly temperature-controlled, there should be no further risk, but if the regeneration air is too hot, then the desiccant rotating quickly enough be the only thing preventing it from overheating.

If the desiccant rotates too quickly, assuming a countercurrent configuration, I think the only bad thing that will happen is that it will leak more heat from the hot wet circuit into the cool dry circuit, mildly degrading performance.

XXX what about the desiccant cooling circuits?

With electronics, of course, it's very simple to monitor and compensate for all of these problems. But one of the appealing benefits of this design is that, at least in theory, you should be able to construct and repair it with Stone Age materials and tools.

So it should be possible to make it work reliably under varying conditions with the following feedback and safety mechanisms:

- A float-valve mechanism to control the moisture in the evaporator (and maybe a recirculating pump);
- making the desiccant rotate considerably more quickly than the minimum necessary;
- ???

Perhaps of use is the fact that most species of flat grain wood will change size 1% for every 4% change in moisture content, but only crosswise, so you can make humidistats out of wood.

Desiccant rotation systems

The desiccant could be either in the form of a single, slowly rotating wheel, physically rotating through the three phases it needs, or it could be three or more separate pebble beds, controlled using valves.

A 1% prototype

Suppose we just want to see if the idea can work. It should be possible to scale it down:

- 40 W thermal cooling output;
- 1.4 ℓ/s of input and 15° cool wet air output;
- 1.6 ℓ/s of 20° cool dry air output;
- 990 mℓ/s of hot wet air output;
- 18 mg/s or 64 mℓ/h of water consumed and evaporated;
- 25 mg/s of water removed from input air and transferred to hot wet air output;
- 450 g of desiccant, costing US$3.
- 30-minute cycle time on the desiccant;
- 150 mm diameter air pipes.

wait, how much thermal input?

Alternative fuels

Any kind of fire, including a propane or wood fire, should serve to heat the air to regenerate the desiccant. With a coke or charcoal fire, you could pass the combustion exhaust directly through the desiccant, but other common kinds of fires probably produce too much water and other contaminants which could damage the desiccant in several ways: directly hydrating it, clogging pores in it, coating its surface with waterproof coatings, catalyzing pyrolysis at lower temperatures, and supporting fire. So this involves using another heat exchanger in place of the solar heater.

Alternative coolants

Air has some significant advantages as a coolant: it can withstand temperatures from cryogenic to red-hot, it isn't combustible, it's readily available anywhere in the world, it has low viscosity, and it's compatible with a wide variety of materials (at least at ordinary temperatures). But it also has very low density, which means that transferring significant heat flows with it requires very large pipes and large heat exchangers.

In this case, I don't think there is a reasonable alternative to air for any of the five circuits. The cold wet circuit and the hot wet circuit need water to evaporate into them, so they need to be air;

Alternative desiccants

Wood scraps, paper scraps, and such things may be a cheaper alternative to such freshly manufactured materials. In some places, soil containing a substantial amount of clay, or maybe organic matter, might be cheaper and work adequately. Watts, Bilanski, and Menzies show adsorption "isotherms" for various bentonite clays showing about 100–200 mg adsorbed water per gram of dried clay at 0.6 "relative vapour pressure", which I think means 60% relative humidity. (They never explain the terms in the paper.) US patent

4,254,565 from 1981 says that bentonite left out to dry in the sun for a few weeks to months typically ends up with 10% to 18% moisture content.

So a porous soil mixture that's half sodium bentonite and half, say, sand, might perform similarly to wood as a desiccant. It would also have has the safety advantage that it's not combustible.

Perhaps the second cheapest alternative, following dirt itself, is agricultural crop residues like straw or bagasse. It turns out there are a number of studies of equilibrium moisture content of straw, because moisture absorption is crucial for, among other things, straw-bale construction.

Kymäläinen and Pasila published an experiment in 2000 on flax and hemp fiber "moisture regain", typically 12% in flax or hemp at 21° and 65% RH, but only 7% in cotton, because most of the sorption is not from cellulose. They found curves quite similar to wood — 5% EMC at 15% RH, 10–15% EMC at 76% RH, and 25 or 30% EMC at 97% RH, depending on harvest time, all dry basis. They also say, "Pectins and hemicellulose absorb more moisture from the air than does cellulose," which sounds intriguing.

Farmers discussing online say you normally bale straw at 15% moisture content, though sometimes you can get away with 20% (at which point hay will rot, posing a fire risk, but straw may not), and if you leave it out long enough it gets down to 8–10%. Farmers won't buy hay with over 16% moisture. For construction, anything below 20% is OK.

Some anonymous Canadians at CMHC in maybe 1996 measured straw bale equilibrium moisture content and found a similar curve to that of wood: 5% EMC at 20% RH, 10% EMC around 50% RH, and 15% EMC around 80% RH, all dry basis.

Duggal and Muir measured EMC of wheat straw in 1981 and found 7–9% EMC at 35% RH, 7–12% EMC at 55% RH, and about 10%–14% EMC at 70% RH, all wet basis, all depending on temperature.

Taha Ashour et al. in 2010 measured EMC of some plasters used for straw-bale buildings, finding EMCs mostly in the 2%–4% range, even when the plasters were 75% reinforcing fibers made of wood or straw and 25% made of soil (which was 31% clay). The article doesn't mention the fact that these EMCs are like five times lower than the EMCs of the incorporated fibers, so I don't know if the author has any idea why this large discrepancy exists, or even if they know there is a discrepancy.

Heath and Walker in 2009 measured EMC of straw bale walls and found a fairly straight line from 2% EMC at 4% RH up to 13% EMC at 70% RH, followed by a sharp upward turn to 50% EMC (!!) at 93% RH, all dry basis.

Alfalfa hay bales currently cost AR$35 per 25-kg bale, which would reduce the desiccant cost from US$300 to AR$70, which is about US$5. (Actually there are some shipping costs which almost double the cost, but whatever.) Wheat straw bales cost AR$70.

Hay can spontaneously combust due to thermophilic bacteria if wet. At 200°F (93°) farmers are advised, "Most likely, a fire will occur.", but even as low as 160°F (71°) it can happen. So it's possible that straw, being in many ways similar to hay, might not withstand temperatures as high as 150° without catching fire.

Advantages over standard indirect evaporative cooling

You might reasonably ask why not simply use a normal cooling tower to cool some water (or oil or propylene glycol or whatever), then run that water through a heat exchanger in your house. That is a much simpler approach, and it also avoids raising the humidity in the house. However, more or less by definition, it can only cool the air down to the wet-bulb temperature of the outside air, and usually it can't quite make it that far. On an unpleasant summer day in Buenos Aires, when the temperature reaches 35° and the relative humidity 60%, the wet-bulb temperature is 27° — still unbearable. Worse, on simply cooling that air to 27° without dehumidifying it, you would raise its relative humidity to 90%, which is very unpleasant indeed. (Air conditioners generally reduce this problem by dehumidifying air by cooling it even further, then allowing it to mix. XXX maybe I should tackle that by a different approach)

Topics

Hipster stack 2017

Kragen Javier Sitaker, 2017-04-28 (updated 2017-05-04) (26 minutes)

What's the hipster stack in 2017? Or, maybe, what's the most powerful, highest-leverage software tool stack available? Here are my notes on trying to learn it.

Overview of the current hipster trends

I'm not totally sure, but I'm thinking that it's probably something like React (with JSX) for the frontend (with maybe Less or something for the CSS), Node for the server (with nginx in front of it), and SQLite for the database, though there seems to be a lot of fragmentation here, with lots of people using MariaDB, Redis, MongoDB, or whatever the hell. For administering the server, we use Docker (probably on Ubuntu) and Puppet and Kubernetes, and for an editor, we use Atom. When we're not using Docker, we virtualize our testing environment with Vagrant in VirtualBox. And we chat about it all on Slack.

StackOverflow trends

http://stackoverflow.com/tags?tab=popular has JS as the top language tag (followed by Java, C#, and PHP); Android as the top platform tag (followed by iOS); MySQL as the top database tag (followed by SQL and sql-server); etc. I did a SQL query to see what the current ones were at https://data.stackexchange.com/stackoverflow/query/664354/most-popular-stackoverflow-tags-in-2017 and got JS (followed by Java, Python, and PHP); Android (followed by iOS); jQuery as the top JS framework (followed by Angular, twice, and then React); MySQL as the top database (followed by SQL and sql-server); Excel as the most popular IDE (followed by XCode, Visual Studio, Android Studio, Matlab, and Eclipse); the top UI toolkit is HTML (followed by jQuery, CSS, Angular, and finally WPF at #60 and Qt at #96); etc. Firebase, Typescript, Pandas, Swift, AWS, Azure, Android Studio, and Spark also seem to be hot compared to previously. https://data.stackexchange.com/serverfault/query/664369/most-popular-serverfault-tags-in-2017 is the same query on ServerFault, from which we learn that nginx and AWS are hot.

The relatively most fashionable things this year are centos7, docker, apache-2.4, azure, windows-server-2012-r2, linux-networking, amazon-web-services, php-fpm, and reverse-proxy, each of which had more than twice the proportion of all stackoverflow tags this year as over the life of stackoverflow. However, nginx is far more popular than Apache now! And AWS is still more popular than Azure, and Ubuntu still more popular than CentOS.

Hacker News trends

The fashionable things on Hacker News seem to be, at the moment:

• Machine learning: 2 items on front page, 1 item in 30 newest, 2 comments in 30 newest

• Linux: 4 comments in 30 newest
• Computer vision: 1 item on front page, 2 comments in 30 newest
• Rust: 1 item on front page, 2 comments in 30 newest
• Python 3: 1 item on front page, 1 comment in 30 newest
• C++: 1 item on front page, 1 comment in 30 newest
• React: 2 items in 30 newest
• C: 2 comments in 30 newest
• Docker and similar containers: 1 item on front page
• Kubernetes: 1 item on front page
• Redis: 1 item on front page
• TypeScript: 1 item on front page
• Dataflow programming (Fathom, in this case): 1 item on front page
• Rails: 1 item in 30 newest
• Golang: 1 comment in 30 newest

I mean that's super crude. Note how different it is from the StackOverflow list!

Github trends

GitHub has a list of language implementations developed there. Swift has 38k stars and 5k forks; Golang has 27k stars and 3k forks; Rust has 21k stars and 4k forks; TypeScript has 21k stars and 3k forks; CoffeeScript still has 13k stars and 1k forks; Ruby has 12k stars and 3k forks; and PHP has 11k stars and 3k forks. Of course, this excludes languages whose implementation isn't GitHub-hosted and those with many implementations, like C++.

Similarly, they have a list of NoSQL databases hosted there, leading with Redis, RethinkDB, and MongoDB. Redis is actually more than twice as popular as Mongo. RethinkDB is probably dead. Their list of trending repositories this year includes Mastodon, which is built on Rails, Docker, Vagrant, Nginx, Redis, Postgres, and Node; a guide to learning bash; an IDE for React, React itself, react-bits (tips), and react-sketchapp; a repo of minimal examples of algorithms in Python; TensorFlow, a TensorFlow-based NN library, and Caffe; a medium.com clone built on React, Angular, Node, and Django (?); a Sendgrid clone built on Rails, MySQL, RabbitMQ (!), and Node called Postman; Vue.js; Atlassian's LocalStack, an AWS clone; a list of hot Mac apps (headed by Atom), and at #1, a "roadmap".

The Roadmap

The roadmap recommends learning, for a frontend developer, HTML, CSS, JS, ES6, npm scripts, Gulp for running tasks, Yarn, npm, TypeScript, some JS test framework (Jest or Mocha), webpack, Bootstrap, Sass, and some JS framework (Angular, React (in which case either Flux or Redux), or Vue.js); or, for a backend developer, one of Python, PHP, Node, Ruby, C#, Java, or Golang. For Python, they recommend pip, unittest, Django, and aiohttp (which is apparently an async/await thing built on Python 3's new (2013) asyncio library); for Node, they recommend npm, Yarn, Express, and Mocha. For going deeper on the backend, they recommend nginx, RESTful APIs, reading about MVC, authentication with OAuth 2.0 and JWT (JSON Web Token), "SOLID/YAGNI/KISS etc." (i.e. learning how to program), regexps, security, and Docker; deeper still, they recommend memcached and Redis for caching, Postgres, MariaDB, and MySQL as relational databases, and Redis and

MongoDB as nonrelational databases. To "up your game further", they suggest search engines (ideally ElasticSearch), GoF design patterns, architectural patterns, "give DDD a shot", and "learn different testing techniques".

There's an entirely separate roadmap for devops, recommending either Linux or Unix, AWS, automation (either CloudFormation, Puppet, Ansible, or Terraform), CI/CD (Jenkins, Travis, or TeamCity), monitoring and alerting (Nagios, PagerDuty, or AppDynamics), Docker (or maybe rkt), Apache and nginx, cluster managers (Kubernetes, Mesosphere, Mesos, Docker Swarm, or Nomad), loving the terminal, vim/nano, bash scripts, compiling apps from source, and a tree of commands:

text: awk sed grep sort uniq cat cut echo fmt tr nl egrep fgrep wc
ps: ps top htop atop
perf: nmon iostat sar vmstat
net: nmap tcpdump ping traceroute airmon airodump

Then there's a set of other things you should know: the OSI model (oddly subtitled TCP/IP/UDP), knowledge about different filesystems, setting up a reverse proxy, setting up a caching server, setting up a load balancer (HAProxy or nginx), setting up a firewall, TLS, STARTTLS, SSL, HTTPS, SSH, SCP, SFTP, and "postmortem analysis when something bad happens".

It seems like most people are using Macs on the desktop and Linux on the server.

Proggit

On Proggit, the top few items are mostly the same as on HN (last night), but not quite the same. Trendy topics include computer vision, machine learning, D, security (which is everywhere even though I haven't mentioned it previously), Docker and containerization, Clojure, Postman (the Sendgrid clone I mentioned above), a .NET thing called "Entity Framework", NixOS, Git, XAML, Heroku, AWS, Vue.js, vim, TLS, Python, Racket, AI, interviewing, Unicode, Spotify, Postgres, Rails, and OpenGL GLSL.

Leverage

The things that are fashionable are not necessarily the things that provide the most leverage. SQLite is a *lot* faster than MySQL, not to mention a lot easier to install and administer, for what it does. Java and Rust are a lot lower leverage for most things than Python or, often, PHP.

Slightly more in-depth overview of the top hipster technologies

Here's my subjective perception of the top 32 hipster technologies for 2017, some of which are actually old. Here's a paragraph about where each one seems to be in 2017:

- JS
- CSS
- nginx
- Firebase
- Angular

• Slack
• Reactive and dataflow programming
• Node.js
• Mobile-friendly web design
• Python
• Less
• MySQL and MariaDB
• Neural networks and other machine learning
• Android
• TensorFlow
• Golang
• Docker
• Linux (Ubuntu and systemd)
• Mocha (the testing framework)
• Bootstrap
• TLS/SSL
• AWS
• RabbitMQ and ZeroMQ
• TypeScript
• Redis
• Atom
• Swift
• JSON
• SQLite
• Chef
• Rust
• React

As a bonus, I'm adding:

• Jenkins

JavaScript is by far the dominant programming language, with performance close to that of C, but garbage collection and a flexible object model like Python or Smalltalk. A lot of server-side development is still being done in C++ (which still runs faster) or Golang, or still being done in Python (which is still more flexible and easier to read), but the gap seems to be closing rapidly, as more and more is done in Node.js. In web browsers, JS is still the only real runtime option, although WebAssembly is working to open the browser to a wider range of languages, and TypeScript is gaining popularity as a statically typed and therefore more maintainable version of JS. ECMAScript 6 is now broadly implemented, and its features seem like they close most of the usability gap that used to exist between JS and more ergonomic languages like Python.

CSS has accidentally become Turing-complete recently and may become sentient soon. Most people use preprocessors like Sass (or Less). There are conferences devoted entirely to CSS. But there still isn't a browser that supports both hyphenation and widow-and-orphan control for printing. Not satisfied with the original CSS box model and its variants, they have now stuffed three entirely separate layout models into CSS: standard, flexbox, and grid. CSS transforms allow pretty trippy (GPU-accelerated!) effects now. Also apparently CSS animation is a thing now.

Nginx is event-based, shuffling any kind of multiprocess management off to some backend process, communicating either via

FastCGI (or SCGI, or uWSGI for Python) or via HTTP (acting as a reverse proxy). This supports WebSockets a lot better than Apache's preforking MPM can, and it's the sensible way to structure things if you're using microservices. It's also a lot simpler to configure than Apache. A minimal install is about 350k. In addition to HTTP (and SPDY and HTTP/2), it speaks IMAP, SMTP, and POP3. Hot topics seem to be load balancing, microservices, HTTP/2, and security.

Google Firebase is billed as a "real-time database", but it's really a web API. It seems to be something like Meteor or KnowNow, but done right. It replicates (JSON) data on all devices, supporting offline operation, and sends asynchronous update notifications whenever it changes. It even supports iOS.

Google Angular is a client-side in-browser JS app framework, like jQuery, Backbone, Knockout, Ember, Sencha, and other such forgotten relics. It uses npm to install, Node to run a development server, and preferably Microsoft TypeScript for your code. It has two-way data binding for doing easy CRUD database screens and, more generally, declarative update propagation with an extensible HTML template language. It's an alternative to React, and Angular is slightly more popular, with 48k question on SO, compared to React's 40k; people like React better, but apparently React is gaining ground.

Slack is a centralized SaaS alternative to IRC. (Free clones include Mattermost and Rocket.chat.) It takes seven seconds to switch channels in current Firefox on a modern four-core 1.6GHz machine that isn't trying to swap. The chat lines are editable, replyable, and written in a pidgin plaintext markup language derived from Markdown. It provides link previews for some links.

Both React and Angular are manifestations of reactive programming, and many forms of dataflow programming are also being bruited about. Angular is built on a more basic reactive framework called Rx.js. Spark is a popular dataflow programming system for big data. Dataflow has its roots in a forgotten language from the 1970s called Lucid, whose open-source implementation plucid is on GitHub.

The main stream of MySQL development is now MariaDB, and despite the continuing fallout from the Oracle acquisition, MySQL is still dramatically more popular than SQLite and PostgreSQL (the two main alternatives) combined. Uber switched from Postgres to MySQL recently and the MySQL tag on StackOverflow has 25000 questions so far in 2017 compared to 12000 for Microsoft SQL Server, 7000 for Firebase, 5000 for Postgres, and almost 2900 for SQLite.

Node vs. LinuxMint

I installed a current Linux Mint (version "Sarah") on this laptop last year. Apparently, though, the current version of Node is 7.9.0 and the current LTS version is 6.10.2, but Linux Mint ships with Node 4.2.6! That version difference makes it sound enormously old, but actually it came out 2016-01-21. As the changelog says, "Node.js v4 is covered by the Node.js Long Term Support Plan and will be supported actively until April 2017 and maintained until April 2018."

Node and SQLite3

Nevertheless, I was able to `npm install sqlite3`.

https://github.com/mapbox/node-sqlite3/wiki/API is the documentation for what seems to be the most popular SQLite binding for Node. It's super easy to use although it seems to handle errors by killing the Node CLI process sometimes:

```
(new (require('sqlite3').Database)('test.db'))
     .run("create table x (y varchar)")
     .run("insert into x (y) values ('qqq')")
     .each("select * from x", (err, row) => console.log([err, row]))
Database { open: false, filename: 'test.db', mode: 65542 }
> events.js:141
      throw er; // Unhandled 'error' event
      ^

Error: SQLITE_ERROR: table x already exists
    at Error (native)
$
```

If you give it an error callback, that doesn't happen:

```
> tdb.run("create table x (y varchar)", err => console.log(err))
Database { open: true, filename: 'test.db', mode: 65542 }

> { [Error: SQLITE_ERROR: table x already exists] errno: 1, code: 'SQLITE_ERROR' o
o}
```

The `select` does work:

```
> new sqlite3.Database('test.db').each("select * from x", (err, row) => console.lo
og([err, row]))
Database { open: false, filename: 'test.db', mode: 65542 }
> [ null, { y: 'qqq' } ]
```

So all the deliciousness of SQLite is easily available from Node, albeit without the modern promise interface.

npm

For some reason `npm` started breaking on me when I was trying to `install mocha` inside the `sqlite3` directory; I consulted the debug log and the offending line was this one, in filter-invalid-actions.js:

```
if (pkg.isInLink || pkg.parent.target || pkg.parent.isLink) {
```

I changed it to this:

```
if (pkg.isInLink || pkg.parent && (pkg.parent.target || pkg.parent.isLink)) {
```

But that didn't really help. What helped was not being inside the `sqlite3` directory. But then `npm test` still didn't work, because it was looking for a directory `test` under `sqlite3` that doesn't exist.

npm is notorious for installing tens of thousands of files in projects that use it, such as Angular.

ES6

Firefox and Chrome both support a lot of ES6 features, as of course does Node, and you can compile to older JS versions if you want to support old, unpatched iPhones or whatever (although none of the compilers-to-JS have ES6 support as comprehensive as Firefox or Chrome). And ES6 fixes most of the problems that used to make JS a pain in the ass, making it (probably?) actually a better language than Python instead of a worse one.

I'm not totally sure it is going to be better, because some of the changes might result in previously invalid code that was actually a mistake now getting DWIMmed in some unexpected way. But I am optimistic.

There's a compatibility table that shows which features work where.

I'm going to list the features that seem most interesting to me, which unfortunately are mostly not very flashy:

`let`

Everywhere you could use `var` you can now use `let` or `const` to get a block-scoped variable, avoiding in some cases the need for IIFEs.

```
> function mr(n) { let rv=[]; for (let i = 0; i < n; i++) { let j=i; rv.push(funco
otion() { return j; }); } return rv; }
undefined
> mr(5)
[ [Function], [Function], [Function], [Function], [Function] ]
> mr(5)[2]()
2
```

(Node's REPL kind of sucks for multiline statements because of the way its history works, in exactly the same way that Python's does, but in JS you actually can get away with glomming everything onto one line.)

This contrasts with the traditional behavior:

```
> function mr(n) { let rv=[]; for (var i = 0; i < n; i++) { let j=i; rv.push(funco
otion() { return i; }); } return rv; }
undefined
> mr(5)[3]()
5
```

However, this also works, and I have no idea how:

```
> function mr(n) { let rv=[]; for (let i = 0; i < n; i++) { let j=i; rv.push(funco
otion() { return i; }); } return rv; }
undefined
> mr(5)[2]()
2
```

for...of loops, generators, and the iteration protocol

This is a big improvement for what I think are the most common kinds of loops:

```
> for (let x of [42, 33, 5353]) console.log(x)
42
33
5353
undefined
```

That is, it does what you probably thought `for x in` would do when you first learned JS. But wait! There's more! You can use it on arbitrary things that implement the iteration protocol, including Python-style generator functions:

```
> function* things() { yield 42; yield 33; yield 5353; }
undefined
> for (let x of things()) console.log(x)
42
33
5353
undefined
> t = things()
{}
> t.next()
{ value: 42, done: false }
> t.next()
{ value: 33, done: false }
> t.next()
{ value: 5353, done: false }
> t.next()
{ value: undefined, done: true }
```

The extra `*` disambiguates syntactically.

It's possible to write your own objects that implement this same iterable protocol, but it's kind of a pain in the ass:

```
> cd = { [Symbol.iterator]: function() { return { n: 5, next: function() { if (th
is.n) return {value: this.n--}; else return {done: true}; } } } };
{}
> for (let x of cd) console.log(x)
5
4
3
2
1
undefined
```

In the terminology of MDN and I guess ECMA-262, `cd` above is an "iterable", and the generator returned from `things` is evidently an "iterator." Unlike in Python, iterators are not required to be iterables, but apparently `for...of` handles that case okay. But it does not work to pass the iterator derived from `cd` to `for...of`:

```
> for (let x of cd[Symbol.iterator]()) console.log(x)
TypeError: cd[Symbol.iterator] is not a function
    at repl:1:56
    at REPLServer.defaultEval (repl.js:252:27)
```

```
    at bound (domain.js:287:14)
    at REPLServer.runBound [as eval] (domain.js:300:12)
    at REPLServer.<anonymous> (repl.js:417:12)
    at emitOne (events.js:82:20)
    at REPLServer.emit (events.js:169:7)
    at REPLServer.Interface._onLine (readline.js:210:10)
    at REPLServer.Interface._line (readline.js:549:8)
    at REPLServer.Interface._ttyWrite (readline.js:826:14)
> ci = cd[Symbol.iterator]
[Function]
> for (let x of ci) console.log(x)
TypeError: undefined is not a function
    at repl:1:37
    at REPLServer.defaultEval (repl.js:252:27)
    at bound (domain.js:287:14)
    at REPLServer.runBound [as eval] (domain.js:300:12)
    at REPLServer.<anonymous> (repl.js:417:12)
    at emitOne (events.js:82:20)
    at REPLServer.emit (events.js:169:7)
    at REPLServer.Interface._onLine (readline.js:210:10)
    at REPLServer.Interface._line (readline.js:549:8)
    at REPLServer.Interface._ttyWrite (readline.js:826:14)
```

Also those error messages are super confusing, which I guess is one way JS has always been worse than Python.

Unfortunately there doesn't seem to be a library comparable to Python itertools in the standard, but the things you would expect to be able to do do work:

```
> function* ifilter(predicate, items) { for (let item of items) if (predicate(ite
om)) yield item; }
undefined
> function* irange(end) { let n = 0; while (n<end) yield n++; }
undefined

> ifilter(function(x) { let q = Math.sqrt(x); return q === Math.floor(q); }, iran
oge(10))
{}

> Array.from(ifilter(function(x) { let q = Math.sqrt(x); return q === Math.floor(
oq); }, irange(10)))
[ 0, 1, 4, 9 ]
```

I'm not sure how to deal with the weird iterator/iterable protocol nonconformance thing for algorithms like merge, though. MDN says it should not be so.

λ syntax: "arrow functions" `(a, b) => a + b`

JS's traditional lambda-expression syntax that I've been using above has always been terribly unwieldy, and it also has always had a binding problem with `this`. So they adopted a shorter syntax and made it lexically bind `this`. Using the `irange` generator above, here's a more efficient way to lazily generate a stream of squares:

```
> function* imap(f, xs) { for (let x of xs) yield(f(x)) }
undefined
> Array.from(imap(x => x*x, irange(10)))
[ 0, 1, 4, 9, 16, 25, 36, 49, 64, 81 ]
```

This `x => x*x` compares favorably to Smalltalk's `[:x | x * x ]`, although it's the best case; in cases where you need other numbers of arguments, you need parens (e.g. `() => x*x` or `(x, y) => x*y`), and in cases where you have multiple statements, you need curly braces and likely a `return` statement; so, for example, it doesn't buy you that much here:

```
> Array.from(ifilter(x => { let q = Math.sqrt(x); return q === Math.floor(q) }, irange(10)))
[ 0, 1, 4, 9 ]
```

Firefox, CoffeeScript, and some versions of Traceur and BabelJS had implemented array comprehensions, which would have been a better alternative for many cases, but since they didn't get in (they were removed in ES6 draft 27 in August 2014), higher-order methods and the arrow syntax are as good as it gets. Here's what it array comprehensions look like in Firefox:

```
» [for (x of [3, 4, 11, 22]) if (x % 2 === 0) x*x]
← Array [ 16, 484 ]
```

This is considerably better than Python's inside-out syntax.

...: spread and rest

This isn't supported in Node 4.2.6, unfortunately. Neither is destructuring assignment.

Object constructor shorthand is in there, so you can say `return {x,y}` and you can say `let x = { y() { return 43; } };`.

Performance

Node is a lot faster than Python at raw computation. Here's a very simple test that gives the crudest outlines of the degree of improvement; in it, Node is about half as fast as C, but three times as fast as PyPy and 20 times as fast as CPython or Jython.

We can define the standard naïve Fibonacci benchmark in ES6 as follows:

```
> fib = n => n < 2 ? 1 : fib(n-1) + fib(n-2)
```

This takes time proportional to its return value.

```
user@debian ~ $ time node -e 'fib = n => n < 2 ? 1 : fib(n-1) + fib(n-2); console.log(fib(3))'
3

real    0m0.161s
user    0m0.132s
sys 0m0.024s
```

```
user@debian ~ $ time node -e 'fib = n => n < 2 ? 1 : fib(n-1) + fib(n-2); console.log(fib(42))'
433494437

real    0m11.056s
user    0m11.028s
sys 0m0.020s
```

That's crudely about 40 million units per second, according to (/ 433494437 (- 11.056 .161)). Doing the same test in CPython would be annoyingly slow, but here's a similar one:

```
user@debian ~ $ time python -c 'fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2); print fib(3)'
3

real    0m0.046s
user    0m0.024s
sys 0m0.020s

user@debian ~ $ time python -c 'fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2); print fib(35)'
14930352

real    0m8.338s
user    0m8.328s
sys 0m0.004s
```

(/ 14930352 (- 8.338 .046)) gives us about 1.8 million units per second, about 20 times slower.

Jython is in the same speed class, perhaps slightly faster:

```
user@debian ~ $ time jython -c 'fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2); print fib(35)'

"my" variable $jythonHome masks earlier declaration in same scope at /usr/bin/jython line 15.
14930352

real    0m10.383s
user    0m15.208s
sys 0m0.896s

user@debian ~ $ time jython -c 'fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2); print fib(3)'

"my" variable $jythonHome masks earlier declaration in same scope at /usr/bin/jython line 15.
3

real    0m3.768s
```

```
user    0m7.776s
sys 0m0.360s
```

PyPy is better, only about three times as slow as Node:

```
user@debian ~ $ time pypy -c 'fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2)
; print fib(3)'
3

real    0m0.066s
user    0m0.056s
sys 0m0.008s

user@debian ~ $ time pypy -c 'fib = lambda n: 1 if n < 2 else fib(n-1) + fib(n-2)
; print fib(42)'
433494437

real    0m29.576s
user    0m29.532s
sys 0m0.040s
```

As a sort of gold performance standard for this machine, here's a C implementation of the same dumb algorithm, which, compiled with `gcc -O`, is more than twice as fast as Node:

```
user@debian ~/dev3 $ cat fib.c
fib(n) { return n < 2 ? 1 : fib(n-1) + fib(n-2); }
main(int c, char **v) { printf("%d\n", fib(atoi(v[1]))); }
user@debian ~/dev3 $ time ./fib 35
14930352

real    0m0.186s
user    0m0.180s
sys 0m0.004s
user@debian ~/dev3 $ time ./fib 42
433494437

real    0m5.073s
user    0m5.064s
sys 0m0.000s
```

So this is a lot of extra leverage. If you write an algorithm in a straightforward way in Node, you can expect it to run about as fast as if you write it in a vectorized way using Numpy, or twenty times as fast as if you write it in a straightforward way in CPython.

Nginx

Nginx (2600 SO questions in 2017) is now almost as popular as Apache (4400 questions in 2017), but while Apache's share of questions is unchanged, Nginx's share of questions in 2017 is double its overall share of questions, indicating that its usage is trending sharply upward.

Slack

Aside from how to *use* Slack effectively for chatting, there's the question of how to build things on it.

IndieWebCamp has written a bit about how their link preview or "unfurling" works, and Slack themselves have explained in detail. Basically they use OpenGraph, which IndieWebCamp have also documented.

Using Aryabhata's pulverizer algorithm to calculate multiplicative inverses in prime Galois fields and other multiplicative groups

Kragen Javier Sitaker, 2017-01-06 (updated 2019-07-05) (4 minutes)

The extended version of Euclid's algorithm due to Aryabhata (the kuṭṭaka (कुट्टक) or "pulverizer" algorithm) explains how to find the coefficients s and t such that $sa + tb = \gcd(a, b)$. Except I don't understand the explanation, so I am going to try to work through an example.

Given 1247 and 1624.

```
1624 - 1247 = 377  ∴ 377 + 1247 = 1624
1247 - 3·377 = 116 ∴ 116 + 3·377 = 1247
377 - 3·116 = 29   ∴ 29 + 3·116 = 377
116 - 4·29 = 0     ∴ 4·29 + 0 = 116 ∧ gcd(1624, 1247) = 29
```

So now I can try to express 29, the GCD, as linear combinations of the values on the other lines. The first one is already done: $29 = 1\cdot377 - 3\cdot116$. The previous pair was (1247, 377). How can we get 29 as a linear combination of those? We know that $1247 = 116 + 3\cdot377$, but how does that help?

Oh! The thing that helps is actually the other direction: $116 = 1247 - 3\cdot377$, which we can use to eliminate the 116 from $377 - 3\cdot116 = 29$, rewriting it as $377 - 3\cdot(1247 - 3\cdot377) = 29$; $377 - 3\cdot1247 + 9\cdot377 = 29$; $10\cdot377 - 3\cdot1247 = 29$.

Then we can do the same thing again to re-express 29 from a (1247, 377) basis to a (1624, 1247) basis, because $1624 - 1247 = 377$. $10\cdot(1624 - 1247) - 3\cdot1247 = 29$; $10\cdot1624 - 10\cdot1247 - 3\cdot1247 = 29$; $10\cdot1624 - 13\cdot1247 = 29$.

This is useful for finding multiplicative inverses, which only exist in the multiplicative group modulo n for numbers relatively prime to n. In this case, if we divide by 29, we find that $10\cdot56 - 13\cdot43 = 1$, so modulo 56, -13 (=43) and 43 are multiplicative inverses, and modulo 43, 10 and 56 are.

So after all these years I understand how to find multiplicative inverses efficiently in a Galois field. At least a Galois field of prime order.

If a multiplicative group order is a prime n, then you can also find the multiplicative inverse by taking to the power n-2, by Fermat's Little Theorem, so, for example, $56^{41} \% 43 = 10$. But that doesn't work in general for multiplicative groups of any order: $56^{42} \% 44 = 12$, but because 56 and 44 have a common factor of 4, 56 has no multiplicative inverse in $\mathbb{Z}/44\mathbb{Z}$; $43^{54} \% 56$ is 1, which not its multiplicative inverse in $\mathbb{Z}/56\mathbb{Z}$, because 1 is always its own multiplicative inverse. 43 is, as I said, its own multiplicative inverse in

$\mathbb{Z}/56\mathbb{Z}$, and the pulverizer algorithm can compute this just as well without the extra confounding factor of 29:

```
56 - 43 = 13;
43 - 3·13 = 4;
13 - 3·4 = 1
= 13 - 3·(43 - 3·13) = 10·13 - 3·43
= 10·(56 - 43) - 3·43 = 10·56 - 13·43
```

Can I formalize this algorithm? The forwards-backwards ordering seems to suggest recursion; we could perhaps try to define a function egcd(a, b) → (s, t, g) such that $sa + tb = g$ and $g = \gcd(a, b)$. The base case of the recursion would be, I suppose, that $a \% b = 0$, in which case a valid answer is (0, 1, b). Otherwise, we have $q = a // b$ and $r = a \% b$, so $a - qb = r$, and we need to recurse with s, t, g = egcd(b, r). Assuming that succeeds somehow, we have $sb + tr = g$, so we can deduce that $g = sb + t(a - qb) = (s - tq)b + ta$, so we can return ($t$, $s - tq$, g).

In Python:

```
def egcd(a, b):
    q, r = divmod(a, b)
    if r == 0:
        return 0, 1, b

    s, t, g = egcd(b, r)
    assert s*b + t*r == g
    return t, s - t*q, g
```

Applied, for example, to (70, 24), this gives $-1 \cdot 70 + 3 \cdot 24 = 2$, so in $\mathbb{Z}/12\mathbb{Z}$, $35^{-1} = 11^{-1} = -1 = 11$, and in $\mathbb{Z}/35\mathbb{Z}$, $12^{-1} = 3$, both of which are correct.

They say it is possible to extend this algorithm to non-prime-order Galois fields GF(p^n) where $n > 1$ by using polynomial division, but I do not yet understand that.

Phase-change heat reservoirs for household climate control

Kragen Javier Sitaker, 2016-06-14 (updated 2016-06-17) (13 minutes)

I have moved in with Nuria Pucci. I am writing this reclining on a foam mattress on the floor of my new bedroom.

I've paid the rent until the end of the month. I don't yet know how to access the internet connection or flush the toilet; in the morning I will see if I can take a shower. I need a Gatorade bottle for emergency urination, since there's only one bathroom.

I have a minimal amount of stuff here now: a sleeping bag, a sheet, a pillow, Tuga, some food, melatonin, my netbook. I need to move the rest ASAP.

The room is roughly cubical with a side of some four meters, for a total volume of 64m³ or 64kℓ. There are no bookshelves or curtains as such. I suspect I can put bookshelves up.

It's almost 2 AM, and Nuria is running the microwave and playing the guitar. So I will need earplugs, too.

It's cold

The room contains about 64kg of air, which has a specific heat of about 1 J/g/K = 1 kJ/kg/K. Raising the temperature of these 64kg of air from its current 10° up to a comfortable 20° thus requires about 640kJ. As I operate at about 100 W, this would take about two hours.

However, the walls are presumably concrete (0.9 J/g/K) or gypsum plaster (1.1 J/g/K), and will probably absorb most of the heat I put into the air — if they don't simply conduct it outdoors. The walls weigh a great deal more than 64kg, although the speed at which the heat penetrates them will depend on how much of their mass is engaged.

This suggests that hanging fluffy curtains on the walls and perhaps something similar on the ceiling might make the room a great deal more comfortable.

If I were to fill a 20ℓ bucket with hot water (4.2 J/g/K) at 50°, in cooling down to 10°, it would release 160kJ. Thus, four such buckets would be needed to bring the room's air up to a comfortable temperature.

Phase-change heat reservoir

A eutectic mixture of Glauber's salt and sodium chloride melts at 18°, with a heat of fusion of 286 kJ/kg, and so it would be adequate to bring the temperature up to there; a slightly smaller amount of sodium chloride would melt instead at 20°, slightly less sharply. 2.2 kilograms of such a mixture in its liquid form would suffice to supply the same heat as all four buckets of water.

If we were to scale up such a system by a factor of 20, we would have a reservoir of 44 kg of phase-change material (30 ℓ at 1.46 g/cc) with 12.6 MJ of phase-change heat capacity; we could also choose a different phase-change temperature. A glazed flat-plate solar heat collector with a water-ethanol mixture pumped through it could

provide the heat input; a thermosiphon-driven heat exchanger inside the room, mounted above the reservoir, would silently release the heat into the air when a valve was opened, at which point it would drive convective air circulation through a "chimney" above the heat exchanger.

Running this system for four hours at night would provide 870 watts of heating, which is probably plenty. It could perhaps be charged over a longer period of time during the day; if it only had a single hour to charge in, it would need 3.5 kWt of sunlight; with a 50%-efficient glazed flat-plate collector, that's about 7 m².

The standard chimney draft calculation is

$$Q = C\ A\ \sqrt{(2\ g\ H\ \Delta T/T)}$$

where Q is the draft flow rate, A is the cross-sectional area of the chimney, C is a discharge coefficient of about 0.7, g is the gravitational acceleration, H is the height, ΔT is the temperature difference across the chimney wall, and T is the temperature outside.

Let's say A = 0.01 m², H = 3 m, T = 288 K, ΔT = 5 K; then our flow rate is 7ℓ/s, at which rate sucking all 64kℓ of air through the system would take about 2½ hours, which is a bit too slow. Correcting to 0.05m², we suck all the room's air through the heater every 30 minutes, which is acceptable; this amounts to a round chimney duct of some 250 mm in diameter.

44 kg of Glauber's salt at the wholesale price of US$130/tonne would cost US$5.72, currently about AR$80.

The 30 liters would need to have plumbing run through it rather thoroughly in order to be able to freeze all of the salt during the heat-evolution part of the cycle. Wikipedia says that sodium chloride has a thermal conductivity of 6.5 W/m/K at 289 K, but I'm not sure how to apply that information to figure out how closely the pipes need to be spaced.

Well, kind of. Let's say the pipes are spaced 50 mm apart, so the heat has to travel 25 mm from a pipe to reach the last liquid salt. If you slice 30 ℓ into 50 mm slices, the surface area of the slices is 0.6 m², or 1.2 m² on both sides. The coolant is presumably halfway between the air temperature, which might be 18°, and the salt's freezing temperature, which might be 22°, so you have a gradient of only 2 K on average over those 25 mm: 80 K/m; multiplying the surface area in, you get 96 K m. That's 624 W, which is probably acceptable. If the pipe spacing were smaller, you would have proportionally more layers and less distance to the last liquid, so the power goes as the inverse square of the pipe spacing.

Spacing zero-thickness pipes 50 mm apart throughout a 30 ℓ volume in a square pattern would require 12 m of pipes. (I'm not sure how much it affects the surface area of the last or nearly last liquid salt, or whether that matters.) You can do slightly better by using a hexagonal pattern, but then again, you will do slightly worse because the coils have to bend in order to fill the whole space. So this is probably about right.

I'm not sure if it matters to the heat transfer into the salt whether you run the pipes in parallel or purely in series.

12 m of 5mm-diameter pipe holds 236mℓ of coolant, almost exactly one US cup, which is a comfortingly small number for the most

hazardous part of the system. If it had the specific heat of water, with that same 2° ΔT, it would transfer about 2.0 kJ of heat each circuit; this is too small, because at 870 W, it would have to make a circuit of the entire reservoir every 2.3 seconds, 5.3 meters per second. That's far too fast, but it might be bearable if you can run a lot of pipes in parallel instead of in series. Just in case, though, it's probably better to think in terms of 10mm-diameter pipe, 940mℓ of coolant, 7.9 kJ, and 9.1 seconds of reservoir transit time.

We probably need turbulent flow for maximum heat transfer power, so we want the Reynolds number in the pipes to be over 4000; but not too much over 4000, because we lose efficiency. If $Re = vD/\nu$, solving for v, we get $v = \nu\, Re / D$. If D = 10mm, ν = 1 cSt = 1 mm²/s, and Re = 4000, then v = 0.4 m/s; at 9.1 seconds of reservoir transit time, this suggests we'd need to split the reservoir coolant into branches of about 3.6 m each.

400 mm/s seems like a lot to expect out of a thermosiphon. How can we fix that? If the pipes were thinner, we would need an even higher velocity to hit Re = 4000, which seems counterintuitive; for example, at 5mm, we need 0.8 m/s. But that really is the way it works: thicker pipes, where viscosity matters less, are more prone to turbulence. So apparently the cure is to use thicker pipes still in order to get turbulent flow at a lower speed.

Let's say we go to 20mm diameter, at which point we can afford 36 seconds of reservoir transit time, because the coolant holds 32 kJ, because there are 3.8 liters of it. Now we get turbulent flow at 0.2 m/s, at which speed we would transit all 12 meters of pipe serially in 60 seconds, so we still do better if we split the pipe into two parallel runs.

How much pressure do we need to get to 0.2 m/s in 12 meters of 20mm pipe, though?

The Darcy-Weisbach equation says

$$\Delta p = f\, L\, \rho\, v^2 / (2\, D)$$

where f is the Darcy friction factor, L is the length of the pipe, ρ is the density of the liquid, v is the velocity as before, and D is the diameter as before.

Unfortunately, I don't have a Moody diagram handy to figure out what f should be. The Haaland equation, a simple approximation to the recurrent Colebrook equation, says:

$$1/\sqrt{f} = -1.8 \log_{10} ((\varepsilon/D/3.7)^{1.11} + 6.9/Re)$$

where ε is the surface roughness and D is the diameter, as before. The relative roughness ε/D here should be about 0.01 to 0.001, so that part of the sum could work out to be as high as .0014, or much lower; 6.9/4000 is about .0017. So our logarithm here is about -2.5 to -2.8, so $1/\sqrt{f} \approx 4.5$ to 5, so f should be in the neighborhood of 0.04 or 0.05. [Later I checked this against a Moody chart and, yes, .045 to .055.]

The original Colebrook equation says

$$1/\sqrt{f} = -2 \log_{10} (\varepsilon/D/3.7 + 2.51/(Re\sqrt{f}))$$

Just checking here, $Re\sqrt{f} \approx 800$, $\varepsilon/D/3.7 \approx .0027$, $2.51/800 \approx .0031$,

the logarithm is about -2.2, and yes, that means $1/\sqrt{f} \approx 4.5$.

Back to the Darcy-Weisbach equation, we have f = 0.04, L = 12 m, ρ = 1 g/cc, v = 0.2 m/s, D = 20 mm, which works out to 480 Pa of head loss. Or only 240 Pa if we split it in half. That's 0.03 psi, which kind of sounds reasonable, but it's 24.5 mm of water head, which seems like it might be hard to get out of a thermosiphon.

This all depends on the thermal coefficient of expansion of water, which notoriously falls to zero at 4°, then goes negative. Mixing ethanol into the water might help with this, both because it serves as antifreeze and because its own TCE is very large, much larger than water's. Wikipedia [[Thermal expansion]] claims that water's volumetric coefficient is 207 ppm/K at 20°; if we have a 2 K difference between the hot side and the cold side of the thermosiphon, then we have 414 ppm. That would mean we needed 59 meters of height to get our thermosiphon to siphon at 240 Pa with only 2 K difference.

So, no, you won't get turbulent flow through the heat exchanger from the thermosiphon. That's too much to ask from a poor little bedroom thermosiphon.

What will happen in reality if you have, say, 1 m of thermosiphon height? (We're running out of height here in the bedroom...)

414 ppm of a meter is 414 microns, which works out to about 4 Pa. Let's solve Darcy-Weisbach for v:

$$\Delta p = f\ L\ \rho\ v^2\ /\ (2\ D)$$
$$\Delta p\ 2\ D\ /\ f\ L\ \rho = v^2$$
$$v = \sqrt{(\Delta p\ 2\ D\ /\ f\ L\ \rho)}$$

So in this case we have Δp = 4 Pa, D = 20 mm, f we don't know but for laminar flow it's 64/Re, L = 6 m, ρ = 1 g/cc. But wait, actually L depends on how many pipes we put in parallel through the reservoir; it might be 500mm if we put 24 parallel pipes there instead of two. Or 250mm if we put 48 pipes in. We were only going with two in order to try to get turbulent flow.

I think that shows that we can get almost arbitrarily high heat transfer powers out of almost arbitrarily low coolant volumes by putting the coolant through lots of pipes in parallel. But I'm not going to finish the calculations tonight.

Topics

Ndarray java

Kragen Javier Sitaker, 2015-05-28 (1 minute)

Different libraries for n-dimensional arrays in Java. None seem to support memory-mapping the arrays to files. What I really want is a minimal-overhead way to randomly access a giant column of index values written out by a now-dead process.

http://www.kdgregory.com/?page=java.byteBuffer explains how to use java.nio.MappedByteBuffer.

Vectorz

https://github.com/mikera/vectorz

"designed to allow the maximum performance possible for vector maths on the JVM"

```
Vector3 v=Vector3.of(1.0,2.0,3.0);
v.normalise();                      // normalise v to a unit vector
Vector3 d=Vector3.of(10.0,0.0,0.0);
d.addMultiple(v, 5.0);              // d = d + (v * 5)
```

1 billion vector operations per second. Has a Clojure interface.

Colt

http://dst.lbl.gov/ACSSoftware/colt/api/cern/colt/matrix/package-summary.html#Overview

"an infrastructure for scalable scientific and technical computing in Java. It is particularly useful in the domain of High Energy Physics at CERN"

```
double[] v1 = {0, 1, 2, 3};
DoubleMatrix1D matrix = new DenseDoubleMatrix1D(v1);
cern.jet.math.Functions F = cern.jet.math.Functions.functions;
// Sum( x[i]*x[i] )
System.out.println(matrix.aggregate(F.plus, F.square));
```

"...LU, QR, Cholesky, Eigenvalue, Singular value..."

ND4J

http://nd4j.org/

"a scientific computing library for the JVM. It is meant to be used in production environments rather than as a research tool...CUDA...API mimics the semantics of Numpy [and] Matlab"

```
INDArray arr1 = Nd4j.create(new float[]{1,2,3,4},new int[]{2,2});  INDArray arr2 = ND4j.create(new float[]{5,6,7,8},new int[]{2,2});  arr1.addi(arr2);  System.out.println(arr1);
```

Apparently this is the library used by DeepLearning4J.

LArray

https://github.com/Ponnie/larray

Safely-unmappable memory-mapped files, including >2GB, as arrays in Java, with map, filter, reduce, zip, etc. But no n-dimensional arrays.

util-mmap

http://engineering.indeed.com/blog/2015/02/memory-mapping-with-util-mmap/

This is a replacement for java.nio.MappedByteBuffer that overcomes its 2GB limit. Also, supports little-endian.

Algorithm time capsule

Kragen Javier Sitaker, 2016-08-11 (1 minute)

What languages have the most important algorithms written in them? That is, what languages would you have to implement in a time capsule virtual machine in order to preserve our most important algorithmic knowledge?

There's an enormous amount of software written in C, but generally the algorithms are implemented in a fairly tailored fashion — they aren't generalizable beyond the specific application, so they have to be written again for the next time. And it takes a lot of C code to get anything done.

My guess is on the following list:

- Fortran for numerical algorithms, many of which don't have equivalents implemented in the other languages below (because everyone just uses the Fortran implementations)
- R for statistical algorithms
- Python with Numpy and Scipy for a lot of other numerical algorithms
- JS for the worlds of crap in npm
- C for cryptographic algorithms, file format decoders (e.g. pngtopnm), compression formats, a few other related things

Unfortunately, this probably still doesn't cover most of the classic algorithms you'd find in an algorithms textbook, at least in a reusable way. Some of them have generic implementations in C++, but C++ is far too hairy to hope to support.

Convolution surface plotting

Kragen Javier Sitaker, 2015-09-03 (updated 2015-09-13) (2 minutes)

A problem I've been wrestling with for a while is how to legibly plot spatial densities with wide dynamic range. Ink on paper is okay for about 10 dB of dynamic range; reversing the video and plotting white on black on a computer screen gives you about 20 dB; and by blooming high-density regions outward at the cost of spatial resolution, which is often an acceptable tradeoff, I think you can do 30 dB. But how can we efficiently calculate a bloom whose area accurately represents the total magnitude within?

In 3-D rendering, convolution surfaces are implicit surfaces of a function defined by convolving a "field function" with a "geometry function", a generalization of metaballs. McCormack and Sherstyuk 1997 chose the field function $1/(1 + s^2r^2)^2$ as an approximation of a Gaussian that is more tractable to solve in closed form.

Metaballs (implicit curves of $\Sigma_i d_i^2/r_i^2$, where r_i is the distance to center point i) in 2-D have the advantage that if you put two of them on top of each other, the total area is twice the total area they would have if they were far apart. There's a transition region in the middle where they're nearly joined and a bridge joining them adds about 20% to their total area. Unfortunately, they are difficult to calculate efficiently.

Is there perhaps an efficient way to convolve metaballs, or an approximation thereof, with the points you want to plot, in order to get the size of the total area to fill with light?

(A different approach would be to use a vector CRT or laser-light display, which can natively reach 30dB of dynamic range without sacrificing spatial resolution — indeed, improving it.)

Photodiode camera

Kragen Javier Sitaker, 2019-09-04 (16 minutes)

High-speed cameras are a crucial sensor technology for a variety of purposes, including high-speed robotics with camera feedback (see Starfield servo (p. 1709) and Servoing a V-plotter with a webcam? (p. 62)) and analysis of high-speed physical events, such as breaking glass or basically anything solid objects do on the micron scale or below. But existing high-speed cameras, based on CMOS and CCD sensors, are expensive and sometimes hard to get for other reasons.

How about photodiodes for faster, cheaper camera focal planes?

What photodiodes are like

Cheap photodiodes can be astoundingly fast compared to a typical camera sensor. The Fairchild QSD2030 5-mm IR photodiode has 5-ns response time, passes 25 µA at 0.5 mW/cm² and 5 V, and 10 nA dark current (at 10 V); it costs 53¢ at Digi-Key. The OSRAM SFH 2701 infrared photodiode (400–1050 nm) passes 1.4 µA under the same conditions, and boasts 2-ns response times, for 95¢ (48¢ in quantity 100).

In the subnanosecond range, prices do start to heat up, because you're getting into avalanche photodiodes and silicon photomultipliers; the Marktech MTAPD-07-003 infrared avalanche photodiode (which can detect down to 400 nm, though at 600 nm its responsivity is already cut in half) is specified for a 300 picosecond rise time, and it claims 35–50 µA at 1 µW of incident light (on its 230-µm-diameter sensor — though this may be an error and maybe it should be 0.35 to 0.50) and less than 400 pA of dark current (though "typical" is 50 pA). It costs US$22. (Advanced Photonix, Excelitas, ON Semiconductor, and Opto Diode are four other vendors.)

These currents are fairly small, which is why people often use phototransistors instead.

Possible camera designs

Matrix focal plane

But at the 2-nanosecond prices you could quite reasonably put together a 16x16 focal plane of fast photodiodes and get a 256-pixel image at 500 million frames per second, although it's challenging to amplify and digitize the data that fast, and your RF signal integrity design needs to be high-quality, with carefully matched stripline or something.

Pushbroom focal planes

Maybe more interesting, you could put your 256 photodiodes in a *column* instead of a matrix, then scan them across the image horizontally, for example using a spinning mirror like the kind used in the Michelson-Morley measurements of the speed of light, in supermarket scanners, and in laser printers. Spinning at 30,000 rpm like a Dremel tool, an eight-sided spinning mirror could scan 4000 times per second; perhaps a separate stationary mirror or two could multiply that by 2 or 4. Air bearings can manage perhaps three times

higher speeds than that.

(This is somewhat similar to the display outlined in A mechano-optical vector display for animation archival (p. 3047), but backwards in time, with light sensors in place of light sources.)

You do suffer a loss of light-gathering capacity, because unless your camera is kilometers long, there's nowhere to store the light that gets reflected to the left or right of the photodiode array; it just gets lost. Light-gathering capacity is extremely important at these speeds.

However, note that this provides an only sort of mediocre frame rate, but a sort of excessively horizontal resolution, limited by the mirror speed: 500 million pixels per second per photodiode, divided by 4000 scans per second, gives you 125000 pixels horizontally, but still only 256 pixels vertically. Something more like 512 pixels horizontally and a million frames per second would be a much better compromise, but you can't spin a macroscopic mirror 500 times faster; it will explode, as did Michelson and Morley's mirror once.

Maybe a bunch of stationary mirrors, or more facets on the spinning mirror, can increase the number of horizontal scans per second, at the expense of a very narrow field of view. But maybe you start running into diffraction problems with mirror edges.

Staggered pushbrooms

If there's no diffraction problem with mirror edges, though, there's an alternative to sacrificing field of view. You increase the number of mirror facets as before, but you organize the photodiodes in several rows, as in the mirrorless 16x16 matrix --- but this time with a large empty horizontal space between columns, such that the narrow fields of view of the various columns, produced by the spinning mirror, nearly overlap, giving you back a wider field of view.

Is there in fact a diffraction problem? If we want our mirror facets to be at least 7 microns wide, we can fit almost 4500 of them around the circumference of a 10-mm-diameter mirror; this could give you a bit over 2 million scans per second.

Smaller and nutating mirrors

A smaller-radius mirror can rotate faster before exploding — the cross-section holding it together diminishes at least proportional to the radius, but the acceleration diminishes proportional to the radius, and the mass diminishes jointly inversely proportional to the radius and to the cross-section, so you gain a factor of the radius. However, submillimeter-scale things in sliding contact tend to stick together (think of compacting dry, clayey dirt between your fingers) and also wear quickly. So it might be worth using a flexing solid object rather than sliding-contact parts.

(What about lubrication? Lubrication with a film of a Newtonian fluid of a given viscosity creates a frictional force proportional to the movement speed and contact area, but inversely proportional to the film thickness. So if we scale down an oil-film-lubricated joint 10× in every spatial dimension, including its movement speed, it seems like we win: 100× less surface area and 10× less movement speed gives 1000× less friction, and the 10× thinner film thickness cuts that to 100×. Maybe lubrication could work?)

Even a macroscopic mirror can vibrate at higher than 500 Hz, although generally not over a very wide range of angles. Music-box

comb tines can vibrate (resonantly!) at 1kHz or so with lengths on the order of 10 mm. If you scale one down by a linear factor of 10 you diminish its mass by 1000 and each part of the cross section of the elastic beam by a factor of 100 (see Gold leaf trusses (p. 3055)). If the tine is curved with a radius of curvature scaled down by the same 10, then the strain near its upper and lower surfaces will be the same as the original tine, and so will the stress, but by acting over a 100× smaller cross-sectional area, it will exert a 100× smaller force. This force is acting over a 10× smaller lever arm to the neutral axis of the beam, thus generating a 1000× smaller moment, but the beam length is also 10× smaller, so this results in a 100× smaller force on the weight at the end of the tine, and thus a 10× greater acceleration at the same relative tine curvature.

This greater acceleration, in turn, would, by itself, raise the resonant frequency of oscillation by $\sqrt{10} \approx 3.16$, but the amplitude of oscillation (measured in meters) is also diminished by a factor of 10, which raises the frequency by another $\sqrt{10}$. So the micro-music-box tine might vibrate at 10 kHz rather than 1 kHz. And if we scale it down by 100× instead of 10× we get 100 kHz.

But a music-box tine is far from the fastest-vibrating piece of metal of its scale; rather, it's designed to have very low rigidity so that its Q will be high, its amplitude of vibration will be large, and its frequency will be *lower*. A *serrucho* or musical saw can resonate, when bowed or plucked, at the same frequency as a music-box tine, but the saw is perhaps 700 mm long and 200 mm wide, about a hundred times larger. So it might be possible to get microscopic mirrors to nutate up into the megahertz.

Alternative camera scanning mechanisms

Perhaps instead of a spinning mirror you could use an electro-optical Kerr cell or Pockels cell with a voltage gradient from one side of it to the other, thus obtaining much quicker response times but smaller deflection angles. Alternatively you could physically move a mirror with a piezoelectric stack actuator like those used for adaptive-optics telescopes; many of these actuators have reasonable response at frequencies up into the megahertz, so sinusoidally scanning a mirror over a small angle at such frequencies should be feasible.

Scanned illumination

As an alternative to scanning the photodiodes' viewpoint across the scene being photographed, you could scan a laser or focused LED across the scene instead, as in Flying spot reilluminatable stage (p. 2358). You could do this with just a single photodiode and a full scanning raster pattern, as suggested in that note, or you could sweep a short vertical line of light horizontally across the scene and locate the column of photodiodes on a one-dimensional focal plane. You might be able to design an asymmetric lens with a normal focusing, imaging-optics shape in the Y dimension, but a compound-parabolic-collector or similar wide-angle non-imaging optics light-gathering shape in the X direction, to somewhat ameliorate the light-gathering problems of the pure-pushbroom configuration.

Switching between illumination sources

This configuration has much the same X-Y imbalance problem as the pushbroom: if your laser is scanned at only 4000 Hz, you get 125000 pixels in X and only 256 pixels in Y. But common lasers and low-brightness LEDs have switching times measured in nanoseconds. Suppose that the illumination pattern of the vertical line produced by the optics in front of the laser is spatially intermittent, with 256 small dots, one in the field of view of one photodiode. Now if you alternately illuminate those optics with two different lasers, one a bit below the other, the dots will be displaced a small amount vertically, but perhaps without moving from the field of view of one photodiode to another. This means that each photodiode is being time-shared between two separate scan lines; most of the temporal dimension of the signal corresponds to the X dimension, but a small amount of it now corresponds to Y instead.

You can extend this to, say, 16 laser diodes, one above the other, firing in sequence. You still have only 4000 frames per second, but now each frame consists of 4096 scan lines of some 7812 or 7813 pixels each. The overall laser firing pattern happens at 1.953'125 MHz, but the waveform at each diode has important components up to 31.25 MHz. This is well within the capabilities of most common laser diodes, but, again, requires some attention to RFI. (This time it's a high-power signal, tens of milliwatts rather than microwatts.)

Rather than dotting the vertical line projected by each laser, you could make it short, and instead make the field of view of each photodiode dotted, using faceted mirrors or a faceted lens.

Switching between illumination directions

Instead of illuminating the scene from a single spinning mirror or other scanning device, illuminated alternatingly by light sources that reflect onto slightly different parts of the scene, as above, you could illuminate it alternatingly by scanning light sources at different locations. Instead of merely photography at a higher vertical resolution, this provides near-simultaneous photography from several different points of view. If the light sources are all in a horizontal line, this effect should be fairly pure, but if they are in some other arrangement, the Y parallax will be out of sync, since the Y dimension comes entirely from the sensor array.

Time-domain sparkle sensors

However, for applications like those described in Starfield servo (p. 1709), the 16×16 matrix could be very useful — not for motion video made of frames, but for measuring with high precision and low latency the times at which each sparkle begins to impinge on each camera pixel. This should provide nanosecond-level-precise times when the movement being tracked crossed one or another threshold, and thus allows the measurement of smooth movements with high spatial precision, despite the small number of pixels.

And at these speeds, even fairly quick movements will be smooth: if you are detecting the crossing of a 1-µm-wide threshold with a time-domain resolution of 2 ns, your spatial precision doesn't start to suffer until the motion is faster than 1 µm/2 ns, which is 500 m/s.

The timing resolution is high enough that you may need to compensate for the light travel time to the camera; 2 ns is 600 mm in air or vacuum.

Balanced flip-flops

Since we're talking about such small, high-frequency signals (-20 to -40 dBm at 500 MHz, so, femtojoule scale, on the order of tens of thousands of electrons, or less at low light levels) it might be desirable to rig up some kind of robust amplification physically on the focal plane, like the humans' retinas do. One possible way to do this is with the goofy differential-amplifier scheme DRAM uses (see Snap logic (p. 2580)): an RS latch with a short in the middle, biasing it permanently to its metastable point. When the short is removed (it's really a transistor!), the latch can settle to either the R or S state, and even a small amount of charge on its R and S inputs can determine which way it goes. It's a sort of clocked latching differential amplifier.

In DRAM that charge comes from a just-discharged capacitor that held a bit, but in this case it would come from the light current of a reverse-biased photodiode — from the delta in voltage from the time that both photodiodes' capacitance had been initially charged.

This would allow you to amplify the *difference* between adjacent photodiodes, rather than a single photodiode signal, and generate a binary output from it. By using the history of past outputs, we can adjust the bias in the original photodiode charge levels to cancel out any DC bias and give us a sigma-delta bitstream of the high-pass-filtered difference signal between the two photodiodes, using a mechanism analogous to neural habituation. This leaves you with a bitstream with no trace remaining of the absolute levels of light or variations in gains and offsets among sensor pixels, only detected edge movements over time. The humans seem to do okay with not much more than this.

(Such a circuit might be useful for applications other than fast photodiode amplification, too.)

In particular, two such photodiode pairs that overlap by one photodiode can distinguish the direction of movement of a shadow boundary if it's slow enough. Something like this is the principle of operation of the coded-tape and coded-wheel shaft encoders commonly used in laser and inkjet printers.

A phase-change soldering iron

Kragen Javier Sitaker, 2019-05-08 (updated 2019-05-09) (14 minutes)

I was thinking about soldering irons, temperature controlled high-end soldering irons and primitive ones consisting of a chunk of metal heated in a propane torch, and phase-change materials, and it occurred to me that with a phase-change material, you could get very tight temperature control of the primitive kind of soldering iron heated in a propane torch — perhaps very useful for Ghettobotics: making robots out of trash (p. 2747).

Soldering

Electronics soldering requires heating the junction to the melting point of the solder — 183° for 63–37 tin–lead solder, according to Filling hollow FDM things with other materials (p. 2119) and Wikipedia's soldering article. To achieve this, the soldering iron has to be hotter than 183°, because if the iron is at 183°, it would take infinite time for the joint to reach 183°, even in a perfectly insulated vacuum; in a situation where you're losing heat to radiation and air, it will never reach it. So the iron needs to be hotter than the temperature needed at the junction.

But the junction can't get too far above the melting temperature, in order to reduce damage to the electronic components. Traditional through-hole leaded packages were only connected to the solder joint with a thin copper wire, but surface-mount components are often entirely leadless, and so experience much faster heat flow from the joint. So it's important for the iron not to be *too* hot.

Wikipedia's reflow soldering article tells me that normal reflow temperatures are 20°–40° above the solder's "liquidus" (the high end of the melting temperature range).

Thermostat-controlled soldering irons are now becoming standard — because the necessary electronics are now much cheaper than the rest of the iron, because of the trickier nature of surface-mount soldering, and because the higher temperatures required for lead-free solder leave less room for error. The other advantage they have, aside from not overheating, is that their tips don't cool down when you touch them to a joint; the iron kicks up the current to compensate for the heat loss, which is an enormous help when you're trying to desolder a power transistor from a big ground pour.

Eutectic tin–silver–copper solder melts at 217° and thus requires higher soldering temperatures. Other lead-free solders are in the 211°–227° range, including tin–copper, tin–silver, tin–silver–copper–zinc, and tin–silver–copper–manganese.

A can of phase-change alloy as a heat reservoir

Phase-change materials serve as reservoirs of heat over the relatively narrow temperature range of their phase change — in the case of melting, the range between the solidus and liquidus.

For a eutectic, the liquidus and solidus are equal. By adding more

of one or the other metal to the eutectic, the liquidus is increased while the solidus remains unchanged; in between, the equilibrium state is a slush with crystals enriched in the excess ingredient mixed with a liquid eutectic. So, for example, 70–30 tin–lead solder has the same 183° solidus as the eutectic, but its liquidus is 193°, and 40–60 tin–lead solder (60% lead) has an even higher liquidus of 247°, which is actually higher than the liquidus of pure tin at 231.93°.

Suppose you have 10 mℓ of 40–60 tin–lead sealed in a container, perhaps one made of 400-μm-thick copper flash-plated with nickel and then plated with, say, 10 μm of iron, the way soldering-iron tips are made. If you heat the container to 247°, the contents will be entirely liquid; if you allow it to cool uniformly to 183°, the contents will have entirely solidified. For its density, let's say 9 g/cc, since molten lead is 10.7 g/cc, room-temperature lead is 11.3 g/cc, and molten tin is 7.0 g/cc, so this is about 90 g of molten metal, which will yield up its heat of fusion as it solidifies; I don't know what the eutectic's is, but lead's is 4.77 kJ/mol (= 23.0 J/g) and tin's is 7.03 kJ/mol (= 59.2 J/g), so let's suppose the mix is somewhere around 20 J/g; that gives us 1800 J of heat released through this transition. (Plus the small amount of sensible heat from the 60° temperature change, about 0.2 J/g/K (lead being 0.129 and tin being 0.227), adding another 18 J.)

A typical non-temperature-controlled hand soldering iron is 15–30 W, although soldering guns are commonly 150 W. 1800 J at 150 W is 12 seconds of soldering; at 30 W it's 60 seconds of soldering.

So you could heat up such a reservoir (with fire or whatever) and then solder with it for a few seconds to minutes while it stays hot enough to melt tin–lead solder — up to a total mass of solder similar to the 45 g it contains — or a shorter time while it remains hot enough to melt lead-free solder.

Since solidified solder is a much poorer conductor of heat than copper (401 W/m/K for copper, vs. 35.3 W/m/K for lead, 66.8 W/m/K for tin, so solder is probably somewhere in that neighborhood), some copper bars inside the can might be useful in conducting heat from its interior to its surface. In the other direction, some fiberglass or porous ceramic around the can might be useful in preventing heat loss through other than the tip.

How big a reservoir can you reasonably hold?

I have one of those goofy multicolored ballpoint pens, with eight sliders near the back end to select the color. It's comfortable to use, but it's toward the chunky end of what's comfortable; it's about 17 mm in diameter and 130 mm long, and the tip curves down to a cone of about 60° included angle; so its total volume is about 30 milliliters.

Electric soldering irons are normally held much further from the tip, which I assume is because the old thermostat-less type only had its temperature limited by losing heat to the air; if they had only a little area exposed, then they could only use a very small amount of power, and consequently would heat up slowly and require very low duty cycles. But this would seem to be unnecessary with any kind of

thermal regulation. Certainly it is possible to insulate the iron sufficiently that you can grasp it quite near the tip, and this would be advantageous. So this pen is probably a reasonable way to estimate the comfortable volume that can be used for a phase-change soldering iron.

However, if my estimate of solder's density above is in the ballpark, a reservoir of 30 mℓ would weigh some 270 g — in folk units, nearly a pound. Finely manipulating such a heavy reservoir would probably tire the hand before long (I did a brief test with a half-full 600mℓ plastic coke bottle, and found fatigue but no diminution of dexterity), so most likely the reservoir-based iron should be smaller than this.

Phase-change alloy choice

If you only wanted to solder traditional tin–lead solder, maybe instead of a 40–60 tin–lead phase-change reservoir which needs to be heated up to 247° to be fully melted, you should use 70–30 tin–lead, which is fully melted at 193°. This gives you a much more precise temperature, dramatically reducing the maximum temperature the delicate electronic components can reach — but the temperature is a bit low, meaning that heat flow will be slow, and this can actually increase the risk to the components by giving them too much time to heat up.

Better choices for tin–lead soldering might include Sn 89%, Zn 8%, Bi 3% (191°–198°), which has the advantage of being entirely non-precious-metal; Pb 60%, In 40% (195°–225°); the tin–zinc eutectic Sn 91%, Zn 9% (199°); and the near-eutectic ternary alloy Sn 86.9%, In 10%, Ag 3.1% (204°–205°), which is 87% non-precious-metal. (Indium and silver are about the same price.) For lead-free soldering, pure tin (232°, as I said above) or the tin–silver eutectic (3.5% silver, 221°) might be the best phase-change material.

Hot-oil soldering for larger reservoirs and higher powers

As described in Hot oil cutter (p. 3287), you can heat a thin pipe to a consistent high temperature by pumping hot oil through it; as described in Coolants (p. 3235), sunflower oil, glycerin, and mineral oil are all liquid and fairly stable at the temperatures under discussion as well as at room temperature. So you could perhaps maintain a large "solder pot" partly molten, with a thick coolant pipe serpentining through it to carry off the heat of fusion, connected to a thinner coolant pipe to heat the iron tip. However, this is probably more elaborate than a thermostatically-controlled electric tip would be, so probably isn't justified.

Thermal conductivity; a steel can is fine

I suggested above using a thin can of copper to hold the phase-change alloy, but that's probably unnecessary; a thick can of steel would surely work just as well, and would be cheaper, stronger, stiffer, and not at risk of dissolving in the phase-change medium. As mentioned above, copper's thermal conductivity is 401 W/m/K, so sending 150 W through a 400-µm wall with a 20° temperature difference would require a 3.8-millimeter-diameter circle of wall

with an area of 7.5 mm²; this is about the diameter of a soldering tip, so you could reasonably just expose a conical tip of the can as the soldering tip. That's the only part of the can that would need to be copper, though.

A more sensible approach, though, is to use a separate conical solid-copper tip to conduct the heat, which communicates with the can through a much larger contact area, at which point the can itself can be steel — despite its lower thermal conductivity (80.4 W/m/K for iron), the can is no longer contributing the majority of the thermal resistance. This also makes it practical to use the plated copper-bar or plated copper-sheet conductors mentioned earlier to conduct heat out of the center of the can.

Copper bars? Nah, maybe heat pipes?

Earlier I talked about using copper bars to conduct the heat from the midst of the solidifying reservoir to the tip where it is used, because of copper's five-times-higher thermal conductivity. Thinking about conducting heat lengthwise through a long cylinder, if the copper is to conduct more heat than the rest of the reservoir contents — much less *far* more heat — it needs to have at least a fifth of the cross-sectional area. That suggests that, for example, if a cylindrical reservoir is to have a diameter of 15 mm, the copper bar must have a diameter of 6.7 mm. That's not enough to make the idea impractical, but it's a fucking hell of a lot of copper.

Consider, though, the total power we can get. Suppose my reservoir is 100 mm long and 17 mm in diameter, a bit smaller than the multicolored pen mentioned earlier. If nearly all of it is filled with a massive copper bar, the most heat we can get from the middle of it to the end at a ΔT of 20 K is 401 (W/m/K) · 20 K · 2π(8½ mm)² / (50 mm) = 72 W. This is barely adequate, and becomes less so once more realistic amounts of copper are considered.

Materials are known with higher heat conductivity than copper. They are silver, diamond, carbon nanotubes, and graphene. At present none of these is a practicable alternative.

A possible alternative is the "heat pipe", called by Wollaston, its inventor, the "cryophorus". This is an elongated, evacuated chamber, with a little liquid coolant in equilibrium with its vapor, in modern realizations with a wick to carry the liquid throughout the system. When one end of the chamber is cooler than the other, the vapor condenses at that end, lowering the pressure until the liquid vaporizes equally fast at the other; with the wick, this is an endless cycle. Because the vapor carrying the enthalpy of vaporization from one end to the other moves bodily through space, it can travel considerably faster than heat diffusing through a body — the heat transfer power is almost independent of the distance the heat must be transferred.

Most often, heat pipes are used near room temperature and employ water as the coolant; in theory, this works from water's triple point at 0.01° up to its critical point at about 374°, but as I understand it, water is normally only used up to about 200°, perhaps to avoid dangerously high pressures.

Heat pipes don't suffer from the drawbacks of the hot-oil approach mentioned earlier, in that they don't need any pumping and don't contain any moving parts.

Alternatively, perhaps a much shorter, more bulbous heat reservoir

could enable mere copper to deliver the heat adequately.

An affine-arithmetic database index for rapid historical securities formula queries

Kragen Javier Sitaker, 2019-09-15 (15 minutes)

I started writing a README.md for a project called "affinebase" in 2017, but then never wrote any code for it; this note outlines what I had in mind to implement.

Suppose you want a database of financial tick data that can efficiently evaluate queries for things like "when the price of SPY was at least 1% higher than its 15-minute moving average but lower than its 4-hour moving average", or "when the price of GOOG.A was more than 26 times the price of GOOG.B".

Conventional database indices provide very little help with such queries, but an organization based on affine arithmetic occurs to me as an efficient structure for such things.

Query evaluation with interval-annotated trees over sequences (p. 1423) considers associating an interval-arithmetic interval with substrings of a sequence of records as a form of index; this note considers moving from interval arithmetic to affine arithmetic.

Affine arithmetic

Affine arithmetic is a system of "self-validating arithmetic" similar to interval arithmetic, but supporting linear cancellation of approximation errors.

In affine arithmetic, instead of evaluating expressions to numbers under some assignment of numbers to their free variables, we evaluate them to *affine forms* under some assignment of affine forms to their free variables; these affine forms take the form $k + \Sigma i a_i \varepsilon_i$ and are stored as a vector $[k, a_0, a_1, \ldots a_n]$. The ε_i are gremlin variables that are free to introduce error into your results by taking any value within some fixed range, usually $[-1, 1]$. (The standard term for "gremlin variable" is "error symbol".) Whenever you execute an arithmetic operation that may introduce rounding error, you introduce a new ε_i to account for that rounding error, with an a_i sized appropriately for the computed size of the rounding error.

In its most basic form, this is a somewhat less conservative form of interval arithmetic; in ordinary interval arithmetic, the expression $x - x$ evaluates to some interval around zero whose error is twice the size of the error of x, but in affine arithmetic the errors cancel exactly and you are left with exactly 0, as the SF intended. In general, affine arithmetic can precisely cancel the linearly-varying parts of numerical errors, but nonlinearly-varying parts will be incompletely canceled, so it still provides error bounds that are wider than the real error can be.

The part where this gets interesting is when you assign non-negligible a_i to the free variables. Suppose you want to plot the surface $x^2 + xy + 2$, for example. With affine arithmetic, you can directly evaluate it over a region such as $x \in [-1, 3]$, $y \in [2, 4]$, by assigning $x = 1 + 2\varepsilon_0$, $y = 3 + 1\varepsilon_1$. Depending on the particular evaluation approach, the result will depend not only on ε_0 and ε_1, but

also two to four more ε variables representing the rounding error from the additions and the nonlinearity of the multiplications. If we ignore the rounding errors, this works out to $8 + 10\varepsilon_0 + 1\varepsilon_1 + 2\varepsilon_2 + 2\varepsilon_3$.

For use as self-validating arithmetic, which is to say saving you the trouble of calculating static bounds on your algorithm's approximation errors, you probably want to run each calculation more than once with different floating-point rounding modes by calling the C99 function `fesetround` or something similar: 0 is round-toward-0 and 1 is the default round-to-nearest, but the relevant ones are 2 for toward-positive-infinity and 3 for toward-negative-infinity; with GCC I think you also need to compile with `-frounding-math`. However, in this note, I'm focusing on the non-self-validating-arithmetic uses of affine arithmetic.

Now, the simplest reading of this result $8 + 10\varepsilon_0 + 1\varepsilon_1 + 2\varepsilon_2 + 2\varepsilon_3$ is that if x and y are inside the specified ranges, then the surface will be between the heights of $8 - 10 - 1 - 2 - 2 = -7$ and $8 + 10 + 1 + 2 + 2 = +23$, and this is true. In fact the surface actually does reach +23 at (3, 4), but its lowest point in this range is at (-1, 4), where it reaches -1, so the -7 is a bit conservative. This is in fact precisely the same result that ordinary interval arithmetic would have given us on the factored form $(x + y)x + 2$, but affine arithmetic gave it to us without doing the factoring step.

However, a *much more interesting* reading of this result is to re-express it in terms of x and y. $5x = 5 + 10\varepsilon_0$, so it's $3 + 5x + 1\varepsilon_1 + 2\varepsilon_2 + 2\varepsilon_3$, which is $0 + 5x + y + 2\varepsilon_2 + 2\varepsilon_3$, which is to say, $0 + 5x + y \pm 4$. This gives us *much tighter* bounds on the result: instead of ±15 we have ±4. (They are still conservative bounds, because the function never actually gets below $5x + y - 2¼$, which it reaches at (½, 4).)

So, a very interesting thing we can do here is to start with a large interval of our independent variables and recursively subdivide it to get a piecewise-linear approximation of our function of choice. We can choose whether to subdivide the interval based on criteria such as: the remaining error; for plotting, the geometric angle, in radians, between adjoining line segments; or simply whether it's possible for any point within the interval to satisfy an equation or an inequality — like the inequalities in the example queries at the beginning of this note.

As noted in Affine arithmetic has quadratic convergence when interval arithmetic has linear convergence (p. 1029) and Affine arithmetic optimization (p. 2801), the affine-arithmetic approximation has a higher order of convergence than the interval-arithmetic approximation — as the size of the interval decreases, the error of any regular function diminishes quadratically in the size of the interval with affine arithmetic, but only linearly with interval arithmetic.

In this connection it's worth mentioning "reduced interval arithmetic" in which we restrain the proliferation of the ε_is by introducing an ε_ω not subject to linear cancellation; its coefficient represents the errors proceeding from things like small rounding errors that we don't bother to track separately. This way we can still get the tasty quadratic convergence and even the self-validating property without paying the high cost of an ever-growing flock of ε_i variables on every operation.

Existing work

The above is not original to me; there are at least three papers

describing it, none of which I have managed to finish reading.

These papers are especially relevant to Reduced affine arithmetic raytracer (p. 2007), which is why I was reading them.

Jorge Eliécer FLÓREZ DÍAZ wrote his 2008 dissertation, "Improvements in the Ray Tracing of Implicit Surfaces based on Interval Arithmetic", on using this approach to accelerate the ray-tracing of animated scenes, but using a modal "completion" of ordinary interval arithmetic ("modal interval arithmetic") rather than affine arithmetic. I read someone else's dissertation in French on doing something similar with affine arithmetic, but I can't remember who it was or what it was called.

Knoll, Hijazi, Kensler, Schott, Hansen, and Hagen wrote a paper "Fast Ray Tracing of Arbitrary Implicit Surfaces with Interval and Affine Arithmetic" in 2008 describing how to use this approach to accelerate raytracing, including in GPU shaders; they trace the approach back to Toth in 1985 and also cite, among many others, a 2006 paper by Flórez Díaz.

Gamito and Maddock

There's also a paper on the subject by Gamito and Maddock from 2004 or 2005, "Ray Casting Implicit Fractal Surfaces with Reduced Affine Arithmetic"; I think this may be the paper that introduced reduced affine arithmetic.

I think it has a couple of errors in it. On p. 6 equation (13), computing the reduced affine arithmetic product of two variables $\hat{w} = \hat{u}\hat{v}$ represented as three-tuples (center, parametric coefficient, error bound) says $w_2 = |u_0v_2 + v_0u_2| + (|u_1| + |u_2|)\cdot(|v_1| + |v_2|)$, but this can incorrectly cancel the error bound v_2 of $\hat{v}$ against the error bound u_2 of $\hat{u}$ if their signs happen to be opposite, which would be pure happenstance; that first term should be $|u_0v_2| + |v_0u_2|$, not $|u_0v_2 + v_0u_2|$. (This is assuming that it's possible for the error-bound's sign to be negative, which would arise from a direct application of the affine operations in equation (7) on p. 5.)

On p. 5 I think equation (8) gives an avoidably pessimistic bound for the extra error coefficient of a product w_k. It says $w_k = \Sigma_i|u_i| \cdot \Sigma_i|v_i|$, which is safe but unduly pessimistic in the case where the two i variables coincide. $\hat{u} = u_0 + \Sigma_i u_i e_i$ for i > 0 (Gamito and Maddock use e_i rather than the ε_i used above), and similarly for v, and if we take $e_0 = 1$ this simplifies to $\hat{u} = \Sigma_i u_i e_i$. Then $\hat{w} = \Sigma_i\Sigma_j u_i e_i v_j e_j$. So the case $i = j > 0$ corresponds to a term in the fully expanded sum $u_iv_ie_i^2$, and the implicit presumption of that sum is that $e_i^2 \in [-1, 1]$.

This is not *incorrect*, but a tighter and also correct bound is that $e_i^2 \in [0, 1]$; if you take this into account, you need to add $\frac{1}{2}u_iv_i$ to the constant term w_0, so rather than being $w_0 = u_0v_0$, it's $w_0 = u_0v_0 + \frac{1}{2}\Sigma_i u_iv_i$ for $i > 0$; this halved sum is also what you would subtract from w_k. I think. I haven't really tried it, so I might be overlooking an absolute value or something.

Similarly, the "interval optimisation" algorithm they give in §4.3 and figure 2 on pp. 6–7 is not *wrong* but it is *suboptimal* — they had the brilliant idea of using the affine form to tighten the interval where they're trying to find the root, which is the whole thing that Fast mathematical optimization with affine arithmetic (p. 3163) is about, but then they wastefully divide the interval in half even if the affine-arithmetic-based tightening was very successful, guaranteeing

an additional time through the loop and perhaps even an additional branch to recurse down.

Also they misspelled "Lipschitz" as "Lipchitz".

A univariate affine-arithmetic database

So, if we have an affine form that summarizes a time-varying quantity, such as a stock price, in the form $k + a_0t + a_1\varepsilon_1$, for some interval, where ε_1 is a bound on the error of the linear approximation over that interval, then we can efficiently compute some bounds on the kinds of expressions in the introduction, and efficiently reject huge swaths of history at once as not meeting our query condition, and efficiently accept other huge swaths of history as always meeting it. For intervals where the condition may possibly be met, we can recursively subdivide them into smaller intervals with tighter error bounds.

But where do we get these affine forms? They already exist in the technical analysis of securities prices, where they go by the name of "channels" — a "channel" is a linear approximation of a securities price over some period of time within some error bounds. Although there is no guarantee of this, it is typically very efficient to compute the best channel for a given time period by computing the convex hull of the prices over that time period, which takes linear time, and then considering the slopes of the line segments of that convex hull; the best channel slope will be one of these, and it suffices to consider the points on the convex hull. In theory there could be a linearly large number of line segments on both the upper and lower convex hull, but in practice the number is much smaller.

You can subdivide history at arbitrary points and compute the best channel for those arbitrary intervals, but you can get much tighter channel bounds if you instead look for "natural" points to make the divisions. The points on the convex hull are promising candidates for "natural" division points, since the largest local extrema of oscillation from the trend line will necessarily be part of the convex hull, but I think there's a linear-time algorithm to find the "most natural" division point.

If you use FP-persistent stack structures to build the convex hull using the convex-hull algorithm mentioned in Some notes on morphology, including improvements on Urbach and Wilkinson's erosion/dilation algorithm (p. 216), you compute the convex hull not only of the whole interval but also every prefix of the interval in a single linear-time, linear-space pass. Doing this once in each direction allows you to evaluate every possible division point within the interval without redundantly recomputing those convex hulls.

In this way you can build a tree over time that permits rapid branch-and-bound evaluation of ad-hoc historical queries on arbitrary computable inequalities.

A multivariate affine-arithmetic database using PCA

Simply approximating security prices or other time series as linear functions of time plus guaranteed error bounds does allow you to compute things like ratios and differences between them efficiently with guaranteed error bounds. However, it's very common — not to

say nearly universal — for securities prices to have correlations, negative or positive, that go beyond a simple linear trend over some time period, and if you can take these correlations into account, you may be able to get much tighter error bounds.

One possible way to do this is to run a principal components analysis over historical prices, and then store the time series of several principal components in your database alongside the actual securities prices. Then you can summarize each interval in the tree of a security as a linear function not merely of time but also of these principal components. This should permit much tighter bounds on the results of the arbitrary expressions over long time intervals, thus permitting much faster branch-and-bound evaluations.

Non-market applications

This technique, of course, is applicable to any time-series quantitative data, not just securities prices — market prices of commodities, temperatures and other climate data, system administration metrics such as network traffic and error rates, telemetry data from satellites and space probes, audio signals, image data (with two "time" dimensions), and so on.

Topics

When should you give up waiting for the bus and just walk?

Kragen Javier Sitaker, 2019-04-24 (5 minutes)

Suppose you're waiting for the bus on a Sunday. You know that the bus goes where you want to go, and it will get you there in five minutes. But you may not be sure when or how often the bus runs on Sundays. You can walk where you want to go, but it will take you 50 minutes. At some point, if the bus hasn't come yet, you'll give up and start walking. You would like to arrive as soon as possible. How long is it optimal to wait before you start walking?

(To simplify the problem I'm ignoring many complexities of the real-world situation; for example, you might get lost walking, or fall off a bridge and die; or, if the bus comes while you're walking, you might be able to run back to the bus stop, or to the next bus stop; or the bus might catch on fire while you're on it, or take a detour that takes you further from your desired destination; you might be hallucinating the destination, or waiting at the wrong bus stop, or indeed be an Alzheimer's patient in a nursing home whose belief in both the bus and the destination is a demented delusion; you may be dreaming, and thus able to cause the bus to arrive whenever you want; and so on.)

This problem depends on two parameters: one is your prior probability distribution of bus arrival times, and the other is your utility function over destination arrival time distributions. There are some simple cases that are easy to solve. For example, if your probability distribution is just a Dirac delta at some time t_0, which is to say that you know for certain when the bus will arrive, then you should wait if $t_0 < 45$ minutes, walk immediately if $t_0 > 45$ minutes, and do as you like if $t_0 = 45$ minutes. If you absolutely need to arrive within 51 minutes, perhaps for a court date to appeal your upcoming execution, you should walk if there is any possibility of the bus taking longer than 45 minutes to arrive. (Of course, in reality, there is always some possibility of that.)

One solution which is robust (that is to say, it's not optimal, but the optimal solution can only beat it by some reasonably small margin) over wide ranges of these parameters is to wait 45 minutes. This bounds your destination arrival time to 95 minutes, which is less than a factor of 2 worse than the best result you can guarantee (if you just start walking immediately), and it has a "regret property" that is also bounded to a factor of less than 2: if you arrive at 95 minutes, the soonest you could have arrived if you'd waited longer would have been 50 minutes, which is better by less than a factor of 2. I want to make some kind of argument based on Lipschitz constants of utility functions here, but I'm not certain how to formulate it yet.

This problem is closely analogous to a wide range of planning problems in domains with large variance.

For example, suppose you want to write a video-codec subroutine for 60-frame-per-second video, and you are trying to choose whether to write it in C or Python. You know that you can write it in C, and if you write it in C, it will be plenty fast, but writing things in C takes

longer — say, 500 minutes. You know you can write it in Python in about 50 minutes, but you don't know if it will be too slow to use. (If it ever takes more than 16.7 milliseconds to run, it will make the video playback skip frames.) How long should you fiddle around with trying to optimize the Python version to be fast enough before you throw it away and write the C version?

In an analogous way, if you only have 500 minutes to solve the problem, you should just "walk", writing the C version to begin with. But if you can afford to take a bit longer — say, 600 minutes — you should try writing the Python version and see if you can get it to run fast enough. Maybe you'll finish the task in 50 or 100 or 150 minutes instead of 500 minutes. But by trying that option, you're taking the risk that the overall task might extend to 550 or 600 or 650 minutes, if the Python approach doesn't work out.

This simplified model highlights one reason that it is so costly to maximize the predictability of processes for, among other things, writing software. The fastest and highest-quality process is only very rarely the most predictable one.

Schedule estimation errors are widely observed to be lognormally distributed rather than normally distributed. This is not the only reason, but it is a significant one.

Topics

Backwards cockcroft walton

Kragen Javier Sitaker, 2019-12-01 (2 minutes)

I was thinking about capacitive-dropper power supplies, which limit the current from the 120V ac or 240V ac powerline with capacitive reactance (see Capacitive droppers and transformerless power supplies (p. 887) for more.). These can only supply a very small current without using very beefy capacitors and being quite hazardous. And it has to drop a lot of voltage through those capacitors before it reaches the load, if the load is something like a 5V or 3.3V electronic device.

In Can you bitbang wireless communication between AVRs? How about AM-radio energy harvesting? (p. 2509) I concluded that a Cockcroft–Walton generator could be used as a sort of variable-ratio rectifying autotransformer, stepping up the output dc voltage from a fixed ac input level to a variable level determined by the load voltage. But if you try to use it to get a ratio of less than 1, it won't work; in the limit of low output impedance, you just get the input ac voltage at the output plus a dc offset that just keeps it from going negative.

Is there a Cockcroft–Walton-like circuit that works for stepping voltages *down*? Because then you could use a capacitive dropper to reduce the input voltage to, say, 48 V, limited to 30 mA, "galvanically isolated" from the input powerline by the capacitors, and then use the Notlaw–Tforckcoc circuit to step that down to something like 5 V at 280 mA, enough for a standard USB1 charger.

The way the Cockcroft–Walton circuit works, from a certain point of view, is that the diodes in its string are in parallel across the ac input (since the capacitors act somewhat like wires at ac, albeit wires with some reactance), but in series across the dc output. In this case what we want is the opposite: for the diodes to be effectively in series across the ac input while being in parallel across the dc output.

It isn't yet obvious to me how to do this (without active control circuitry, which can of course do this by switching capacitors around using MOSFETs), but I suspect there might be a way.

Profile-guided parser optimization should enable parsing of gigabytes per second

Kragen Javier Sitaker, 2019-05-23 (8 minutes)

It should be possible to make parsing nearly always as fast as KMP string search, or even faster, without even resorting to SIMD.

parselov

As mentioned in Parallel DFA execution (p. 2337):

> Bjoern Hoehrmann has been working on an algorithm called "parselov" which compiles a context-free grammar to a finite-state automaton that approximates the CFG using a limited-depth parse stack (one stack item, I think).

The idea, as I understand it, is that you can parse a deterministic CFG with a deterministic pushdown automaton ("DPDA"), which can be analyzed as a finite state machine augmented with an unlimited-depth stack. It follows that you can parse a limited-stack-depth approximation of a context-free grammar with a finite state machine, since there are a finite number of stack states with N items or less. (Evidence from human errors in speaking natural languages, and from the verisimilitude of natural language generated by LSTMs and similar neural networks, suggests that in fact this is what we do most of the time.)

The potentially exponentially large number of stack states suggests that enumerating them for any reasonable depth might be infeasible, but typically the stack states are strongly dependent on one another; in most languages, for example, you can't be parsing a formal parameter list unless you're just inside a function declaration, and you can't be parsing a string unless you're just inside an expression. So the base of the exponential might be surprisingly low.

But what happens if your pushdown automaton wants to push an (N+1)th item on the stack? Of course, you could decide to abort, and if your stack depth was deep enough, that might be fine. But, as an alternative, you could shift the N-1 items on the stack over by one and enter an "overdepth" state. Then, when popping, you can deterministically reduce the number of stack items in your finite state while keeping the overdepth flag, until you reach some low water mark of such stack items; then you add nondeterministic transitions to unshift each of the possible next stack items, and nondeterministically clear the overdepth flag or not.

If the distance between the low water mark and N, the high water mark, is large enough, then only a tiny fraction of the tokens or characters input will result in a nondeterministic transition.

(The low-water mark could be as low as 0, but in that case, the state you could have to shift back in could be any arbitrary state. If it's at least 1, you have some context that reduces the number of possible transitions.)

By itself, this gives you a nondeterministic finite state automaton which functions as a sort of amnesiac pushdown automaton, accepting a regular language that is a strict superset of your original context-free

language. But, when implementing this, you can add an extra "spill stack" in memory, which precisely tracks the items shifted out of the finite stack window. Then, when doing an unshifting transition, you can pop the spill stack to see exactly which state to transition to.

Thus you have transformed a DPDA into another equivalent DPDA with many more states and much less frequent pushes and pops — most of the time it is just a DFA which occasionally pushes things, but occasionally it pops and consults the popped value, as well as the input, to determine its next transition. The transformation is parameterized by two numbers, the low-water mark and N, the high-water mark. If they are both 0, it's the identity transformation on DPDAs; if they are both 1, as I understand it, it's parselov.

(A precisely analogous transformation can transform a nondeterministic PDA into another, similarly more efficient, nondeterministic PDA.)

But we have more degrees of freedom available for optimization than that; we could vary those numbers depending on the stack situation. In particular, we would like to avoid stack activity in situations that occur frequently, but we don't care about avoiding stack activity in situations that occur rarely; instead we would like to avoid state proliferation.

But grammars don't carry any information about the relative frequency of different situations.

Profile-guided optimization

PGO is a technique used to enable modern AOT compilers to compete with JIT compilers. You compile your program with profiling turned on, run it for a while, and then compile it a second time using the profiling information to guide the optimization, so that it optimizes things that are important instead of things that aren't.

In this particular case, the only thing you would need to produce from "profiling" is the sequence of inputs and state and stack changes in your DPDA as it parses some sentences. Then, given a candidate set of sets-of-top-few-stack-items to assign to finite states to avoid pushes and pops, and some kind of description of the low-water-mark policy, it is straightforward to compute the number of pushes and pops that remain, and which states they are from; a greedy optimization process should do a reasonable and perhaps optimal job of choosing where to merge states and where to split them.

However, this PGO should enable us to not just equal lex's performance, but exceed it substantially, because, on modern processors, the cost of indirecting through a jump table is greater than the cost of a comparison tree in nearly all cases — but the comparison tree's performance can vary substantially depending on how it's laid out. So, by taking advantage of statistics about which characters are encountered in which states in practice, we should be able to parse context-free grammars at gigabytes per second on modern CPUs.

Eliminating caching of parse results

If that works out, it should have substantial implications for the architecture of software, because a substantial fraction of modern software is dedicated to caching the results of parsing. Python's .pyc bytecode files, the Emacs-Lisp .elc they aped, Java .class files, minified JS, the browser DOM, and all kinds of CSV storage things exist

mostly to avoid slowly reparsing things that have already been parsed. I'm typing this in Emacs, which has all kinds of stupid hacks to avoid reparsing the buffer for syntax highlighting until there's some idle time.

If you can parse at gigabytes per second, then in many cases it isn't useful to store those parse results. If Emacs reparses the buffer from the beginning after every keystroke for syntax-highlighting, that will only begin to impede its responsiveness once the buffer is several megabytes in size; if it checkpoints the parse state every megabyte, there is no danger. Similarly, you could run your database queries directly on the CSV rather than importing it into the database. (None of these examples are pure, though: indexing a column of ten million numbers so you can join it with another table would still take an appreciable fraction of a second, even if your CSV parsing were instant, and both Java and Elisp do substantial optimization before writing their bytecode. But maybe they shouldn't.)

And storing the parse results *is* potentially harmful, since in the absence of a general computation-result-caching system like A minimal dependency processing system (p. 911), Fault-tolerant in-memory cluster computations using containers; or, SPARK, simplified and made flexible (p. 870), or Kogluktualuk: an operating system based on caching coarse-grained deterministic computations (p. 257), or at least the kind of reliable filesystem change detection discussed in Immutability-based filesystems: interfaces, problems, and benefits (p. 1672), there's a constant risk of that preparsed data being outdated with respect to its original source.

Foil origami robots

Kragen Javier Sitaker, 2019-06-13 (updated 2019-06-14) (10 minutes)

Doing the crude experiments documented in Single-point incremental forming of aluminum foil (p. 769), I was surprised to learn how thin aluminum foil is — in the neighborhood of 10 μm, though heavy-duty foil is 25 μm. I had thought it was considerably thicker because of its strength and tendency to retain creases.

So it occurred to me that maybe cut, laminated, and creased aluminum foil, or for that matter steel foil, was a potentially useful material for self-replicating machinery, along the lines of cardboard furniture. The fact that aluminum foil is so thin means that you can increase its rigidity immensely by forming it into relatively small parts, which would then have the stiffness to easily bend the still-flat foil.

Stiffening by forming

Consider, for example, forming a corrugated sheet from aluminum foil similar to the corrugated iron sheets commonly used for the roofing of military bases and other slums. If you make it 10 mm thick, then you have about ¼ of the foil resisting tension on the outside of the bend with a lever arm of 5 mm, ¼ of it resisting compression on the inside in the same way, and the other ½ resisting tension and compression with an average lever arm of 2½ mm; the average lever arm is then 3¾ mm, while in the untouched sheet, the average lever arm might be 2½ μm. So the corrugated sheet is on the order of 1500 times stiffer. It's fucking magic.

(There's an additional work-hardening factor if you're working with ordinary aluminum foil from the grocery stre, which is annealed, rather than whatever comes out of your aluminum-foil-making machine on the moon or whatever.)

That also works for increasing flexural strength (in the sense of the bending force on a member needed to provoke plastic deformation, not the stricter sense of the tensile stress in the fibers of the material needed to provoke plastic deformation) and resistance to buckling, but there's no such magic for increasing tensile strength — although perhaps you could use the folded aluminum as a mold to be filled with some other material.

Origami

There's a bunch of work in computational origami for things like unfolding satellite space shades, which unfortunately I don't know anything about. Robert Lang is the big name in computational origami, and satellite space shades are folded with the Miura fold. My level of origami is basically that I can fold an origami crane, so I did that using this aluminum foil. It wrinkled considerably more than paper does, but it also creases better. To get the square to fold it from, I cut along the edge using my zirconia knife, a process which required only the tip of the blade, the last 30 μm or so — so presumably you could do the same thing with a 30-μm-long blade, which wouldn't require very much sharpened zirconia or alumina or similar material.

(At some point I had dropped the knife on its tip and chipped it, so

last week I bought a 750-grit diamond hone and sharpened the tip on it with some dish detergent.)

There's a "Handbook of Compliant Mechanisms" from 2013 out of the BYU flexures research group, published by Wiley; nearly half of it is a rather poor-quality "library of compliant mechanisms", much of which consists of things that can be cut out of a sheet but then flex into a three-dimensional shape (to which they have given the name "lamina emergent mechanisms"). The book doesn't mention origami at all, and much of the book focuses on techniques that are difficult or impossible to apply to origami. To me it seems clear that origami is an important technique for flexure fabrication, and it turns out that Magleby and Howell, two of the editors of the "Handbook", published a couple of papers on this, even before the Handbook came out. So I'm not sure why they didn't include anything about this in the book.

Some traditional origami forms, like the flapping-wing bird and the jumping frog, are designed as flexures; these are called "action origami" or sometimes "kinetic origami" (a term due to Magleby and/or his coauthors in a 2011 paper). Papers typically analyze these as rigid flat panels connected by flexible hinges at the folds, a model which seems unmotivated by physical considerations — in paper typically the folds are slightly less rigid than the panels in the "hinge" direction, but in aluminum foil, they are typically slightly more rigid.

Many of the annoying features of aluminum, such as its high cost, large springback, abrasive nature, and tendency to accumulate internal stresses during heating that produce delayed distortions, are less important in this situation.

Because the aluminum is about ten times thinner than paper, but only 2.7 g/cc (according to Compressed sensing microscope (p. 306)), this aluminum is about a third as heavy as paper, square millimeter for square millimeter. Consequently the crane is much lighter than a paper crane of the same size would be, rather astoundingly light. Unfortunately, it isn't very sturdy; I can plastically deform it by blowing on it. Work-hardened (unannealed) foil or a more reinforced design might help with this.

Foil properties, and comparison to paper

The foil is really amazingly flexible for its strength. According to the Wikipedia tensile-strength article, annealed aluminum has a yield strength in the neighborhod of 15–20 MPa, a Young's modulus of 70 GPa, and an ultimate strength ("engineering", I suppose, calculated according to the original material thickness) of 40–50 MPa, from which we can deduce that its plastic strain is about 0.2%–0.3%, while its yield strain is about 0.6%–0.7% (engineering, I suppose). So plastically creasing the foil involves bending it at a radius such that the inner surface is 0.2%–0.3% shorter than the centerline, and the outer surface is 0.2%–0.3% longer, so a bend radius of 1.7 to 2.5 mm.

The same article, though, points out that aluminum alloys are immensely stronger: 414 MPa yield and 483 MPa ultimate for 2014-T6 and 248 MPa ultimate for 6063-T6 (a tempered grade of a general-purpose "wrought" alloy), though their elastic modulus is about the same. The very common 6061-T6 is 275 MPa yield and 310 MPa ultimate, with 69 GPa Young's modulus, roughly the same. These alloys are precipitation-hardened; annealed 6061 ("6061-O")

has only about 55 MPa of yield strength and only about 125 MPa of ultimate tensile strength, but elongation of 25%–30%, so it might make sense to perform the origami on the annealed material and then heat-treat the finished product to precipitation-harden it, gaining an additional factor of 5 in resistance to deformation.

How does it compare to paper? According to UHMWPE clothes could be lightweight and sturdy (p. 3071), the tensile strength of cellulose is in the neighborhood of 40 MPa, but when paper tears, it commonly tears because the different cellulose fibers have come apart, not because all the fibers are failing at the crack, as when you cut it with scissors; the tear tends to rotate into an orientation near parallel to the surface as it propagates in order to break even less fibers, even though this spreads the failure over a larger surface. This is also why cotton paper like that used in dollar bills is harder to tear. Unfortunately, this leaves me little wiser!

Cellulose at room temperature is normally thought of as a brittle material, one which fails without an intermediate plastic-deformation stage, and indeed when you tear paper there isn't a noticeable stretched-paper area at the tip of the tear, nor does the edge formed by the tear crinkle in paper the way it does in aluminum foil. But this would predict that creasing paper should be impossible — like polyester napkins, the paper should just elastically return to its original form unless fibers were actually broken. Fibers *are* actually broken, as evidenced by the tendency of a tear to follow even a simple paper crease, but by itself that doesn't explain the tendency of paper to elastically return to the creased orientation — it would only explain its tendency to be more flexible at the crease.

At first, I thought we couldn't explain paper's tendency to hold creases through some kind of non-cellulose interaction, because cellophane holds creases too, and I thought cellophane was pure cellulose; but it turns out that cellophane also contains glycerin as a plasticizer. Presumably this very plasticity is what allows it to hold creases.

This suggests that paper holds creases by altering the interactions of cellulose fibers. On the inner radius of the crease, there is presumably some thickness of the paper that is crushed into rubble, around which is wrapped a series of layers of cellulose fibers loosely stuck together, either by other materials present in the paper or by interactions among fibers that touch one another. The fibers in these layers slide past one another and dig into inner layers during the creasing process, and perhaps in the outermost layers are broken by the tension. This leaves the natural length of the layers altered, causing the paper to elastically maintain the crease. This hypothesis is Original Research™ and therefore may be entirely wrong, but it gives me a reasonable alternative to supposing that the cellulose is deforming plastically.

A sentence-granularity hypertext editor

Kragen Javier Sitaker, 2018-04-27 (4 minutes)

I've been thinking about doing storage and communication in terms of small, atomic "grains", in the range of 64–2048 bytes. In particular I was thinking it would be interesting to structure a hypertext system in terms of such grains, such that you have a few grains on the screen at a time. Grains can include "implicit links" to other grains, and when you change focus to a new grain, the system tries to change the layout so the implicitly-linked grains are also on the screen, maybe hiding grains that have been less recently used in order to make room.

On a cellphone screen you have room for somewhere around 2048–4096 characters of text at a time comfortably, and that text may be referring to equations, graphs, drawings, schematics, computational models, or other parts of the text. If we display 8–16 grains at a time, and each grain has implicit links to the things it refers to (as well as the previous and next grains in the text), we should be able to always have all the referents of the focused grain displayed all the time, as long as that grain doesn't have more than 7–15 referents, plus a maximum amount of context. A simple LRU policy should be adequate to choose which grains to collapse (or scroll off the top, or whatever) to make room.

This suggests somewhere on the order of 128 to 512 displayable characters per textual grain, about a sentence, or a few tens of thousands of pixels (which, for raster graphics, is one impedance mismatch between this UI thing and the packet IPC systems I'd been thinking of).

What would an editor for this structure look like? If you have a petabyte of mostly-ASCII text in your hypertext, broken down into 128-character grains, that's 2^{33} grains, so an unambiguous grain number for each (mutable) grain would require almost exactly 10 decimal digits: "3804448033". Using letters shortens the identifiers to 7–8 characters, or with alternating numbers and letters (as in Augment, sort of) 8–9. A 512-byte grain would have room for about 64 grain identifiers in links, so a full B-tree would be about 5 or 6 layers deep.

You could use this structure directly for your editor's data structures; ideally you'd have keys to merge two consecutive grains and break the current grain at a point (into two grains linked with implicit prev and next links), and maybe some kind of UI affordance to encourage you to press the split key once a grain got uncomfortably large. You really only need to keep in memory the grains that are currently on the screen; you can flush the updated grains out to a transaction log (or sandpile?) as they are evicted. For many purposes, a search function that only finds strings within a single grain would be adequate, as searches for strings that cross sentences are rare, and could perhaps be accommodated with some kind of graph search.

In addition to implicit links, of course, you'd want explicit links

which only activate when clicked on.

A particularly useful kind of enhancement for such a system would be the ability to pass parameters to grains which they use to run some kind of code to render a template for display — potentially the identifiers of other grains. In this way, for example, you could instantiate a pipe flow formula in a hypertext with the particular parameters of a pipe you were considering.

Academic lineage

Kragen Javier Sitaker, 2016-10-30 (updated 2019-11-24) (15 minutes)

I spent some time tracing academic lineages, helped by the Mathematics Genealogy Project. It traces 132,301 mathematicians [2019-09-05 update: now 246,469], most of whom are still alive, back to a 13th-century astronomer named Shams ad-Din al-Bukhari or Shams al-Dīn al-Bukhārī, who enabled Gregory Chionades to obtain Greek translations of the astronomical handbooks in circulation in the Islamic world.

Mathematical lineages

From al-Bukhārī to Gauss

One path through 22 generations is as follows:

- Shams ad-Din al-Bukhārī
- Gregory Chioniadis
- Manuel Bryennios (aka Μανουήλ Βρυέννιος, Constantinople)
- Theodore Metochites (aka Θεόδωρος Μετοχίτης, 1315, Constantinople)
- Gregory Palamas (aka Γρηγόριος Παλαμάς, born in Constantinople and archbishop of Thessaloniki)
- Nilos Kabasilas (aka Νεῖλος Καβάσιλας, 1363)
- Demetrios Kydones (aka Δημήτριος Κυδώνης, Thessalonica, three-term Mesazon of Byzantium; 6 generations from al-Bukhārī)
- Georgios Plethon Gemistos, (1380; the MGP gives "Nómoi" as his "dissertation") usually called Gemistus Pletho and sometimes called *The Last of the Hellenes*
- Basilios Bessarion (1436; 8 generations from al-Bukhārī)
- Johannes Argyropoulos (Padova, 1444), who also taught Leonardo da Vinci
- Johannes "Kapnion" or "Capnion" Reuchlin (Basel, 1477), a Catholic who campaigned against the burning of the Jewish books
- Philipp Melanchthon (Heidelberg, 1511), the Lutheran theologian who wrote the *Augsburg Confession*
- Johannes Caselius (Halle-Wittenberg, 1560; Leipzig, 1566)
- Georg Calixt (Helmstedt, 1607)
- Johann Andreas Quenstedt (Helmstedt, 1643, De Transsvbstantiatione Contra Pontificios Exercitatio)
- Michael Walther, Jr (Halle-Wittenberg, 1661, Manichaeismi recensio historica; Disputatio theologica inauguralis de Paulina Petri increpatione)
- Johann Pasch (Halle-Wittenberg, 1683, Conjunctiones in genere dissertatione astronomico-theorica)
- Johann Andreas Planer (Halle-Wittenberg, 1686, Gynaeceum Doctum, sive Dissertatio Historico-literaria)
- Christian August Hausen (Halle-Wittenberg, 1713, De corpore scissuris figurisque non cruetando ductu)
- Abraham Gotthelf Kästner (Leipzig, 1739, Theoria radicum in aequationibus)
- Johann Friedrich Pfaff (Göttingen, 1786, Commentatio de ortibus et

occasibus siderum apud auctores classicos commemoratis; 21 generations from al-Bukhārī)
• Carl Friedrich Gauß (Helmstedt, 1799, Demonstratio nova theorematis omnem functionem algebraicam rationalem integram unius variabilis in factores reales primi vel secundi gradus resolvi posse)

Euler's lineage

There's also a path to Euler that diverges in the 14th century via Erasmus from Kydones:

• Kydones (6 generations from al-Bukhārī)
• Manuel Chrysoloras
• Guarino da Verona (1408)
• Vittorino da Feltre (Padova, 1416);
• Theodoros Gazes (Mantova and Constantinople, 1433);
• Rudolf Agricola (Ferrara, 1478);
• Alexander Hegius (1474);
• Desiderius Erasmus (Montaigu, 1497/1506; Turin, 1506; 13 generations from al-Bukhārī);
• Wolfgang Fabricius Capito (Freiburg im Breisgau, 1515);
• Simon Sulzer (Strasbourg, 1531);
• Johann Jacob Grynaeus (Basel, 1559);
• Sebastian Beck (Basel, 1610, Illustre Axioma, Ivstvs Avtem Fide Sva Vivet);
• Theodor Zwinger, Jr. (Basel, 1630, De Illustri Sententia Apostolica Hebr. c. 13. V. 8);
• Peter Werenfels (Basel, 1649, Diatribe In Psalmum S. S. Psalterii Primum. De Vnica Et Vera Hominis Felicitate);
• Jacob Bernoulli (Basel, 1676, Primi et Secundi Adami Collatio);
• Johann Bernoulli (Basel, 1690, Dissertatio de effervescentia et fermentatione; Basel, 1694, Dissertatio Inauguralis Physico-Anatomica de Motu Musculorum);
• Leonhard Euler (Basel, 1726, Dissertatio physica de sono; 21 generations from al-Bukhārī).

Nearly all modern mathematicians can trace their lineage to both Gauss and (weakly) Euler, and indeed a quarter of them can be traced back to Felix Klein, who can be traced back to both Euler (weakly) and Gauss.

Tarski descends from Kant and Huygens

For personal reasons, I'm particularly interested in Tarski's lineage, which does trace back to al-Bukhārī, but not via Gauss or Euler; it is a very distinguished line that runs as follows:

• Erasmus, as above for Euler (13 generations from al-Bukhārī);
• Jakob Milich (Freiburg im Breisgau, 1520, later Wien, 1524);
• Erasmus Reinhold (Halle-Wittenberg, 1535);
• Valentine Naibod (Halle-Wittenberg and Erfurt);
• Rudolph (Snel van Royen) Snellius (Heidelberg and Köln, 1572);
• Willebrord (Snel van Royen) Snellius (Leiden, 1607);
• Jacobus Golius (Leiden, 1621), advisor of Descartes;
• Frans van Schooten, Jr. (Leiden, 1635), also student of Mersenne, Descartes's correspondent;

• Christiaan Huygens (Leiden, 1647);
• Gottfried Wilhelm Leibniz (Leipzig, 1666, Disputatio arithmetica de complexionibus), from whom most living mathematicians descend via his other student Nicolas Malebranche; 22 generations from al-Bukhārī via this path, but see below for a shorter path;
• Christian M. von Wolff (Leipzig, 1703, Philosophia practica universalis, methodo mathematica conscripta);
• Martin Knutzen (Königsberg, 1732);
• Immanuel Kant (Königsberg, 1770, Meditationum quarundam de igne succincta delineatio; Principiorum primorum cognitionis metaphysicae nova dilucidatio; 25 generations from al-Bukhārī);
• Karl Reinhold (Jena, 1787, Briefe über die Kantische Philosophie);
• Friedrich Adolf Trendelenburg (Berlin, 1826, Platonis de ideis et numeris doctrina ex Aristotele illustrata);
• Franz Clemens Brentano (Tübingen, 1862, Von der mannigfachen Bedeutung des Seienden nach Aristoteles);
• Kazimierz Twardowski (Wien, 1891/1892, Idee und Perzeption ("Idea and Perception")—An Epistemological Investigation of Descartes) who also advised Banach;
• Stanislaw Lesniewski (Lwów, 1912, A Contribution To Analysis Of Existential Propositions);
• Alfred Tarski (Warsaw, 1924, O wyrazie pierwotnym logistyki).

This puts Tarski only 31 generations from al-Bukhārī via Kant.

Tarski and Leibniz from Pacioli and Bessarion via Copernicus

I've also found some other paths from Tarski back to al-Bukhārī, but most of the others aren't nearly as spectacular. There's an interesting side path, though:

• Bessarion, as in Gauß's genealogy (8 generations from al-Bukhārī);
• Johannes Müller Regiomontanus (Leipzig and Wien, 1457);
• Domenico Maria Novara da Ferrara (Firenze, 1483) who also studied under Pacioli;
• Nicolaus (Mikołaj Kopernik) Copernicus (Padova and Ferrara, 1499);
• Georg Joachim von Leuchen Rheticus (Halle-Wittenberg, 1535);
• Moritz Valentin Steinmetz (Leipzig, 1567, De Peste Capita Disputationis Ordinariae);
• Christoph Meurer (Leipzig, 1582, De Iride seu Arcu coelesti);
• Philipp Müller (Leipzig, 1604);
• Erhard Weigel (Leipzig, 1650, De ascensionibus et descensionibus astronomicis dissertatio);
• Leibniz (17 generations from al-Bukhārī).

This reduces Tarski to 26 generations from al-Bukhārī.

Sierpiński

Wacław Sierpiński is a particularly interesting node in the graph. He doesn't descend from Gauss or, except via Lagrange, from Euler; but he has a significant number of descendants today (about as many as Euler, discounting Lagrange), and a very distinguished line of descent indeed, one which traces back to Gauss's advisor Pfaff and to d'Alembert. The Pfaff line:

• Pfaff (21 generation from al-Bukhārī);
• Abraham Gotthelf Kästner (Leipzig, 1739, Theoria radicum in aequationibus)
• Georg Christoph Lichtenberg (Göttingen, 1765), with 70,574 descendants;
• Johann Martin Christian Bartels (Jena, 1799, Elementa calculi variationum), who also studied under Kästner and Pfaff;
• Nikolai Ivanovich Lobachevsky (Kazan), Bartels's only known student;
• Nikolai Dmitrievich Brashman (Kazan, also Moscow, 1834);
• Pafnuty Lvovich Chebyshev (St. Petersburg, 1849, On integration by means of logarithms);
• Andrei Andreyevich Markov (St. Petersburg, 1884, On certain applications of continued fractions);
• Georgy Fedoseevich Voronoy (St. Petersburg, 1896, On a generalization of the algorithm of continued fractions (Ob odnom obobshchenii algorifma nepreryvnykh drobei));
• Sierpiński (Jagiellonian University, 1906; 30 generations from al-Bukhārī).

This includes Lobachevsky, who with Riemann revolutionized geometry; Chebyshev, the crippled Tatar who revolutionized probability and polynomial function approximation and who taught Lyapunov; Markov, who created our modern theory of discrete dynamic processes; and Voronoy, the sickly Ukrainian whose "Voronoi diagram" underlies an enormous number of modern geometrical algorithms, and who brought the world-shaking St. Petersburg tradition to Poland.

This gives a path from al-Bukhārī to Sierpiński over 30 generations.

But Voronoy was not Sierpiński's only advisor, and Sierpiński's other lineage is no less distinguished for originating *sui generis* in France and Italy without a known earlier academic line of descent:

• Jean le Rond d'Alembert (Collège Mazarin of the University of Paris, 1735, no known advisor);
• Pierre-Simon Laplace (Caen, 1769, Recherches sur le calcul integral aux differences infiniment petites et aux differences finies);
• Siméon Denis Poisson (École Polytechnique, 1800), who also studied under Lagrange;
• Michel Chasles (École Polytechnique, 1814);
• Gaston Darboux (École Normale Supérieure Paris, 1866);
• Charles Emile Picard (École Normale Supérieure Paris, 1877, Applications des complexes lineaires a l'etude des surfaces et des courbes gauches);
• Stanislav Daremba (Sorbonne, 1889, Sur un probleme concernant l'etat calorifique d'un corps solide homogene indefini), who also studied under Darboux;
• Sierpiński.

We are some 34 generations from al-Bukhārī today

Consider a relatively arbitrary modern scholar, chosen not because she is world-famous but just because I've met her here at the University of Buenos Aires, Sandra Martínez, who descends from both Hilbert and Sierpiński, and is thus 34 generations from

al-Bukhārī:

• Sierpiński, with 5329 descendants (Jagiellonian; 34 generations from al-Bukhārī);
• Stefan Mazurkiewicz (Lwów, same as Lesniewski above);
• Aleksander Michał Rajchman (Warsaw, 1921) (also a student of Hugo Dyonizy Steinhaus; see below);
• Antoni Zygmund (Warsaw, 1923; also directly a student of Mazurkiewicz);
• Eugene Barry Fabes (Chicago, 1965);
• Julio Esteban Bouillet, with 19 descendants (U Minn, 1972);
• Noemí Irene Wolanski (UBA, 1983);
• Sandra Rita Martínez (UBA, 2007).

Rajchman is the link to Hilbert, and thence to Klein and thus Gauß and Euler:

• Gauß (22 generations from al-Bukhārī);
• Christian Ludwig Gerling (Göttingen, 1812);
• Julius Plücker (Marburg, 1823);
• Klein (Bonn, 1868; 25 generations from al-Bukhārī);
• Carl Louis Ferdinand Lindemann (Erlangen–Nürnberg 1873);
• Hilbert, with 2606 descendants (Königsberg, 1885; 27 generations from al-Bukhārī);
• Hugo Dyonizy Steinhaus (Göttingen, 1911; 28 generations from al-Bukhārī).

This, plus the six generations above from Steinhaus, puts Martínez at 34 generations from al-Bukhārī.

The rather weak path from Euler to Klein:

• Euler;
• Lagrange (no degree from Euler, and Euler didn't teach him in person, but in their correspondence they invented the variational calculus, and then Euler got him his position directing mathematics at the Prussian Academy of Sciences and at Frederick's court; he actually studied at Turin);
• Fourier;
• Dirichlet (Bonn, 1827; also studied under Poisson);
• Rudolf Otto Sigismund Lipschitz, the Lipschitz continuity guy; 61,331 descendants (Berlin, 1853);
• Klein (Lipschitz's only known student).

Unfortunatly, Euler was less prolific at training students than he was at engendering children or writing papers; if we discount Lagrange, Euler has only 5835 descendants, mostly in the Netherlands, many alive today.

Scholarchs of Plato's Academy

In ancient times, we can trace the sequence of scholarchs of Plato's Academy for some 300 years, who presumably each were in some sense the academic advisor of their successor:

• Socrates, in some sense, who died in 399 BCE
• Plato (from circa 387 BCE until his death in 348 or 347 BCE)
• Speusippus (347–339 BCE)
• Xenocrates (339–314 BCE)

• Polemo (314–269 BCE)
• Crates (circa 269–266 BCE)
• Arciselaus (circa 266–241 BCE)
• Lacydes of Cyrene (241–215 BCE)
• Evander and Telecles, jointly (215–circa 165 BCE)
• Hegesinus (circa 160 BCE)
• Carneades (circa 155 BCE)
• Clitomachus (129–circa 110 BCE)
• Philo of Larissa (circa 110–84 BCE)

At this point, the Academy was destroyed by Sulla during his siege of Athens, and Antiochus of Ascalon began teaching Stoicism; Cicero studied under him in 79 and 78 BCE and diffused Greek philosophy to the Romans.

This gives us two pieces of the chain connecting us over 2400-odd years to Socrates: one about 280 or 290 years long at the beginning, and another about 800 years long at the end. There's a 1320-year-long gap in the middle which runs through the Macedonian, Western Roman, Byzantine, and Muslim empires, which I don't know much about.

Presumably Archimedes of Syracuse (circa 287–212 BCE: "δῶς μοι πᾶ στῶ καὶ τὰν γᾶν κινάσω", "Transire suum pectus mundoque potiri") was aware of the Academy at Athens; I don't know if he was taught by anyone from the Academy, but he may have studied at Alexandria with Eratosthenes, the third Chief Librarian, shortly after Euclid wrote there.

Going back further, Imhotep ("He who comes in peace"), who designed Djoser's Step Pyramid 2000 years before (circa 2650–2600 BCE), presumably had teachers and students, but they are lost to history; the scribe Ahmes, who wrote the Rhind Papyrus around 1650 BCE, is similarly mysterious. Socrates might have been a follower of Pythagoras (circa 570–495 BCE) who was likely taught mathematics through a line related to that of Ahmes; he is reputed to have traveled to Egypt (and Babylonia, and Chaldea, and maybe India) seeking knowledge.

The Buddhist lineage of dharma transmission

There's another similar academic lineage tradition: the transmission of the Buddha Dharma from one teacher to the next, which connects us personally with Siddhartha Gautama through an unbroken line of Buddhist monks. For example, Stephanie can traced Shunryu Suzuki's dharma transmission lineage back to Bodhidharma, who brought Buddhism form India to China, as follows:

• Bodaidaruma (Bodhidharma, d. 532)
• Taiso Eka (Dazu Huike / Ta-tsu Hui-k'o, 487-593)
• Kanchi Sosan (Jianzhi Sengcan / Chien-chih Seng-ts'an, d. 606)
• Daii Doshin (Dayi Daoxin / Ta-i Tao-hsin, 580-651)
• Daiman Konin (Daman Hongren / Ta-man Hung-jen, 601-74)
• Daikan Eno (Dajian Huineng / Ta-chien Hui-neng, 638-713)
• Seigen Gyoshi (Qingyuan Xingsi / Ch'ing-yuan Hsing-ssu, 660-740)
• Sekito Kisen (Shitou Xiquian / Shih-t'ou Hsi-ch'ien, 700-90)

• Yakusan Igen (Yaoshan Weiyan / Yao-shan Wei-yen, 751–834)
• Ungan Donjo (Yunyan Tansheng / Yun-yen T'an-sheng, 780–841)
• Tozan Ryokai (Dongshan Liangjie / Tung-shan Liang-chieh, 807–69)
• Ungo Doyo (Yunju Daoying / Yun-chu Tao-ying, d. 902)
• Doan Dohi (Tongan Daopi / T'ung-an Tao-p'i, ???)
• Doan Kanshi (Tongan Guanzhi / T'ung-an Kuan-chih, ???)
• Ryozan Enkan (Liangshan Yuanguan / Liang-shan Yuan-kuan, ???)
• Taiyo Kyogen (Dayang Qingxuan / Ta-yang Ching-hsuan, d. 1027)
• Toshi Gisei (Touzi Yiqing / T'ou-tzu I'ch'ing, 1032–83)
• Fuyo Dokai (Furong Daokai / Fu-jung Tao-k'ai, 1043–1118)
• Tanka Shijun (Danxia Zichun / Tan-hsia Tzu-ch'un, d. 1119)
• Choro Seiryo (Zhenxie Qingliao / Chen-hsieh Ch'ing-liao, 1089–1151)
• Tendo Sokaku (Tiantong Zongjue / T'ien-t'ung Tsung-chueh, ???)
• Setcho Chikan (Xuedou Zhijian / Hsueh-tou Chih-chien, 1105–92)

• Tendo Nyojo (Tiantong Rujing / T'ien-t'ung Ju-ching, 1163–1228)
• Eihei Dogen (1200–1253)
• Koun Ejo (1198–1280)
• Tettsu Gikai (1219–1309)
• Keizan Jokin (1264–1325)
• Gasan Joseki (1276–1366)
• Taigen Soshin (d. 1371)
• Baizan Monpon (d. 1417)
• Shingan Doku
• Senso Esai (d. 1475)
• Iyoku Choyu
• Mugai Keigon
• Nenshitsu Yokaku
• Sesso Hoseki
• Taiei Zesho
• Nampo Gentaku
• Zoden Yoko
• Ten'yu Soen
• Ken'an Junsa
• Chokoku Koen
• Senshu Donko
• Fuden Gentotsu
• Daishun Kan'yu
• Tenrin Kanshu
• Sessan Tetsuzen
• Fuzan Shunki
• Jissan Mokuin
• Sengan Bonryo
• Daiki Kyokan
• Eno Gikan
• Shoun Hozui
• Shizan Tokuchu
• Nanso Shinshu
• Kankai Tokuan
• Kosen Baido
• Gyakushitsu Sojun (187?– 1891)

• Butsumon Sogaku (1858–1933)
• Gyokujun So-on (1877–1934)
• Shogaku Shunryu (Suzuki, 1904–1971)

Miscellaneous lineages

A third such academic lineage is the lineage of the rabbis.

Another is that descending from the Great Peacemaker of the Haudenosaunee, around 1200 CE, through Hiawatha, guardians of the Great Law of Peace, which was encoded on wampum belts and may have inspired the Western revival of democracy.

Topics

Dercuano rendering

Kragen Javier Sitaker, 2019-05-11 (updated 2019-05-12) (3 minutes)

As described in Dercuano drawings (p. 64), I want to add illustrations to Dercuano. Some of the cases where illustrations will help most are the shapes of three-dimensional objects, and it occurs to me that in many such cases it might be easier and quicker to specify the three-dimensional geometry of the objects than to sketch them by hand.

The trouble is that I want to make sort of casual sketches, and the semi-photographic quality of normal rendering makes conspicuous any insufficiency in the models being rendered; also, shiny eye-catching rendered graphics might be eye-catching enough to detract from the kind of thoughtful consideration I'd like the reader to be able to apply. So some kind of non-photorealistic rendering might work better.

In particular, I was thinking that maybe by using lines of varying width or varying darkness, I could get a kind of engraving effect, though maybe that's too skeuomorphic. To the extent that the lines run in straight lines (geodesics) along the surface of the 3-D model, they can additionally help by showing the curvature of the surface; to the extent that their orientations aren't determined by the view, the projection will tend to skew them in a way that shows the orientation of the surface even when it isn't flat.

It might be simplest, and perhaps adequate, just to render things in grayscale, though. That might be adequately calm.

Slow, perhaps periodic rotation or nutation might also help with showing 3-D structure; perhaps motion-blurring it would prevent the motion from being too distracting.

A separate question is how to carry out the construction of the 3-D model. Of course this can be almost arbitrarily easy or arbitrarily difficult, but the methods available to date leave a lot to be desired. Listing center-coordinates, radii, and colors of spheres is simple, but there's only so much you can build with spheres, and it's a time-consuming way to build it. CSG is intuitive, for what it can express, but algorithmically it can be very challenging, and it's worthless for modeling tree bark, filleted joints, or smooth curves, and again, it's (often) very time-consuming to use. Teddy 3D is intuitive but difficult to achieve precise results with. The constraint-solving pipeline approach used by FreeCAD, CATIA, and SolidWorks (modeled on the approach taken by Sutherland's SKETCHPAD) is clearly capable of constructing very complex shapes, but these programs' solvers not infrequently fail to converge, and when they almost fail to converge, are quite slow.

Another thing to keep in mind is the possibility of printing. Black and white polygons print very well on laser printers, as do solid lines and polygons of the printer's primaries if it's a color printer; color and grayscale regions require some kind of halftoning, which dramatically reduces the resolution.

Kernel code generation

Kragen Javier Sitaker, 2019-07-02 (6 minutes)

John Regehr just posted It's Time for a Modern Synthesis Kernel, and I wrote the following comment on the orange website.

This is a wonderful idea, and I hope many people start working on it right away.

Although Massalin has never published her code, according to my memory of her thesis, Synthesis's runtime code generation was *mostly* extremely simple, more like linking than what we think of as "code generation" — it copied a template method into the appropriate slot in the newly-generated quaject, then overwrote specific bytes in the generated code with pointers to the relevant callout (or, in some cases, the initial value of an instance variable for that quaject). Parts of the code that did not benefit from being specialized in this way were factored into ordinary functions the quaject method would just call.

This meant that only a small amount of code was generated for each quaject, and the runtime code generation was very nearly as fast as memcpy(), which meant that it was reasonable to use it on every quaject instantiation.

Massalin *also* talked about applying some optimizations to the generated code, such as the constant-folding and dead-code removal John mentions, but I have the intuition that only a minority of quaject instantiations involved such more aggressive optimizations. Since she never published Synthesis, it's impossible to know for sure. (I'm not questioning her integrity or claiming that the impressive benchmarks reported in her dissertation are faked; I'm saying that we unfortunately can't see the exact mixture of interesting things you need to do to get those kickass benchmarks; so, like an insecure Intel CPU, I'm reduced to speculation.)

Later implementations inspired by Massalin's approach included Engler's VCODE (which, to my knowledge, has also never been published; Engler's PLDI paper cites Massalin in the second sentence of the abstract), which was used to implement Engler's `C, and GNU Lightning (inspired by Engler's published papers *about* VCODE), used in a number of modern JIT compilers.

I suspect that, by contrast, John's idea of using LLVM is inevitably going to have much higher overhead — if only from the CPU cache devastation brought about by any LLVM invocation — so will only be a win for much-longer-lived objects, where the large instantiation overhead can be amortized over a much larger number of invocations. An intermediate approach like Engler's `C might be more broadly applicable.

John suggests this early on in his "for deployment" comment, but I think that it's probably necessary for prototyping too, since the objective of the whole exercise would be to get an order-of-magnitude speedup, and the objective of the prototype would be to find out if that's a plausible result. A prototype that makes all your programs run slower due to LLVM wouldn't provide any useful evidence about that.

I asked Perry what he thought about the above, and he replied with this gem:

So you're correct that the code generation was mostly "template instantiation". I think that was key to having calls like open() function in reasonable time. I also suspect LLVM is a blunt instrument for this work. That said, it would have been difficult for anyone but Massalin to work with the approach in Synthesis. It was very much the product of a person who was both intensely brilliant and completely comfortable with writing "weird code" in the instruction set they were working in.

So there's then the question of how one can take the ideas from Synthesis and make them a practical thing that ordinary programmers could build and contribute to. And that is almost certainly going to involve compiler tooling. As a prototype, making this work by using LLVM is probably a good approach. Ultimately, I think that one is going to have to do the magic at kernel build time and have something fairly lightweight happen at runtime. But to figure out what that is, one needs to play. And the easiest tools right now for playing involve LLVM. If, for example, you can use LLVM successfully to specialize a write call's instruction path down an order of magnitude or more, or to do similar things in the networking code, one can then ask how to do this better.

There are, of course, a number of interesting paths towards playing with this. I suspect that none of them end anywhere near where they start. But the only way to see what might be possible with much better tooling is to start, and you have to start somewhere.

BTW, I think the time is right, or even over-right, for this. Single processor core performance is stalled out, and while in 1992 one could just say "well, we'll have another factor of ten performance improvement in a few years, who needs the trouble", that's no longer the case. Note that this argument also applies, to a considerable extent, to other parts of the modern software ecosystem. When you can't just say "we could spend a couple of months optimizing this, but the next generation of processors will be out by then", things change.

Anyway, not sure if this answers your call for comments, but if you are interested in specific areas around this, I've no shortage of opinions. Many would say I have far too many opinions...

You can quote any subset or the entire thing. So long as you don't distort my intent I have no problem with people using my words that way.

What's wrong with ../../?

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

Relative links are great; they let you move your whole tree of HTML files from one place to another and still retain the internal link structure. However, they start to suffer when you have multiple levels of directory structure: is that `href="../../style.css"` or `href="../../../style.css"`? It's a bit confusing, and even if you don't get confused, you still have to modify links when you copy them from one file to another.

What would be more helpful would be the ability to say "up to a directory named foo". Suppose you have this setup:

```
kragen/
  index.html
  resume.html
  style/style.css
  images/
    kragenlogo.png
    headshot.jpg
  blog/
    1.html
    2.html
    archive/
      2008-03.html
```

Now, suppose there's some text in `2008-03.html` that was originally in `2.html` or one of its siblings. It would be nice if that text didn't have to be changed from `<a href="1.html">` to `<a href="../1.html">`. You can write `<a href="/kragen/blog/1.html">`, but in addition to being verbose, that makes it hard to use a tree of HTML that you've downloaded with `wget -r` or something similar.

Suppose you could instead write `<a href="$blog/1.html">`, meaning "go up until you find an ancestor directory named `blog`, then use its children". Now you can write things like `<img src="$kragen/headshot.jpg">` freely, and copy and paste them among all the files.

By itself, this would be a backwards-incompatible change to browsers and the URL spec, but it could degrade gracefully. You could program your web server to generate redirects for backwards-compatibility, while implementing the change in newer browsers. Compatibility problems would only arise if someone had a relative link to a directory whose name began with "$" whose name otherwise duplicated that of a directory higher up in the hierarchy.

The uses of introspection, reflection, and personal supercomputers in software testing

Kragen Javier Sitaker, 2019-02-04 (updated 2019-03-11) (12 minutes)

We can do a lot more automated testing now than we could before, but manual testing still requires the same amount of human effort. To some extent our new powers of automated testing are counterbalanced by our new ability to write inefficient software, but not in all cases.

When we have a program, we can run it many times on different inputs to see what it does. "Hypothesis" is David R. MacIver's Python system for doing this automatically ("generative testing" or "property-based testing"), and it has been remarkably effective in my experience in flushing out hidden bugs in programs — including, unfortunately, the Python interpreter!

The number of test cases we can run scales inversely with the amount of work done by each test. Consider this function:

```
void
yp_font_show(yp_font *font, char *text, ypic where)
{
  int x = 0, y = 0;
  for (int i = 0; text[i]; i++) {
    ypic g = yp_font_glyph(font, text[i]);
    if (x + g.size.x > where.size.x) {
      x = 0;
      y += font->max_height;
    }
    if (x + g.size.x > where.size.x) return; /* Glyph is too wide to fit */
    if (y > where.size.y) return;

    yp_copy(yp_sub(where, yp_p(x, y + font->max_height - g.size.y), g.size), g);
    x += g.size.x;
  }
}
```

In a benchmark, this function takes about 36 µs on my laptop to draw the text "hello, world" in a window in a large font, or 5.7 µs in a 12-pixel-tall font.

One core of my four-core laptop executes about 2.4 billion 64-bit instructions per second. A 33-MHz 80386 executed about 4.3 million 32-bit instructions per second; we can extrapolate that it might have run this function some 560 times slower, perhaps requiring 3.2 ms for the 12-pixel font instead of 5.7 µs. So the 386 could test this function (with similar inputs) 300 times per second, while my four-core laptop can test it 700'000 times per second.

Testing hardware: a 40-kW, 100-million-MIPS Pi Beowulf per

programmer?

Moreover, I can potentially take advantage of more than just my laptop for automated testing. A Raspberry Pi 2 is about 5000 MIPS and runs on about 2 to 2.3 watts. If I have a 1-kilowatt testing budget, I can run about 500 Pi 2s and get about 2.5 trillion instructions per second, testing this function roughly 700 million times per second.

(This works out to 400–460 pJ per instruction. The STM32L Cortex-M0 (see files Low-power microcontrollers for a low-power computer (p. 2602) and Notes on the STM32 microcontroller family (p. 3176)) uses about a third of that, but has less memory.)

Is a kilowatt a reasonable budget? Such a rig also costs about US$20k up front and has 500 gigabytes of RAM; at 67×56×11.5 mm each, it would occupy about 21 liters, a box 275 mm on a side, but probably a bit more space is needed for cooling fans and power supplies. A kilowatt costs about US$0.10 per hour, or US$900 per year, which is about a sixth of the depreciation, depending on how you calculate it. This suggests looking for ways to reduce the up-front cost per MIPS even if they increase power consumption.

If we figure that employing a programmer these days costs about US$300k per year (including overhead and benefits), the programmer dominates the expenses until the testing budget gets to 43 kilowatts per programmer, at which point we're spending US$600k per year and getting 30 billion tests of `yp_font_show` and 108 trillion instructions per second. This is more than a cubic meter of computer.

Manual vs. automatic testing cost comparison

By contrast, I might be able to write JUnit-style regression tests of this function at a rate of one per minute or so — which should be downgraded to one per ten minutes if we include the time to maintain those tests, and perhaps one per thirty minutes if we include the time I'm asleep or otherwise not working on the project.

So, to the extent that we can get any benefit at all out of running computer-generated tests, they have a multiplier of around 700 million · 1800 = 1.3 trillion over human-generated tests, or 30 billion · 1800 = 54 trillion with a 43-kilowatt system. Writing a test by hand costs about as much as running 54 trillion randomly-generated tests. In the days of the 386, this multiplier was about half a million, and now it's one to fifty trillion, or nearly a billion without extra hardware†. Each of your manual tests need to be worth more than a billion or a trillion automatic tests to be worthwhile. (This is not as hard to achieve as it sounds, particularly when we're considering tests number eleven trillion to twelve trillion for the same code; remember that a trillion is only a bit under 2^{40}.)

† If you're using Python, automated tests lose a factor of 100 or so because of the interpreter's poor performance.

Extending generative testing

Two obstacles to the usefulness of random testing are reduction and repeatability. The initial randomly-generated test case that reveals the bug may be fairly large and include any number of strange things not related to the failure, while manually-written test cases are simple by

design. And, once the failing test case has been found, it's important to be able to run it again in the future — otherwise it doesn't help you know whether you've fixed the bug (or avoided reintroducing it.) Hypothesis includes an automated test-case reduction which reduces the failing case to a (usually) fairly minimal case before reporting it, and a system for recording previously failed tests to run again — although I haven't tried checking them into Git, and I suspect there might be some impedance mismatches there.

Hypothesis has recently (I think around late 2017) acquired the ability to combine its generative testing approach with statement coverage testing, which is where you measure which lines of code were executed by your tests, so that you can work to focus new tests on lines that haven't been tested yet. In theory, this kind of testing could also give you a reasonable suspicion of which lines of code were responsible for a bug. And you could conceivably augment this with extended kinds of coverage such as loop coverage, multi-condition coverage, and mutation testing; these are just as expensive to apply now by hand as when Marick wrote his paper on it, if not more so, but three orders of magnitude cheaper to apply automatically — Marick was writing in 1991 or 1992, at a time when the 386 was current, though not cutting-edge.

Thus a moderate amount of introspection or reflection, like that needed for statement coverage testing, might enable large gains in test power.

Program search

Earlier I said, "Each of your manual tests need to be worth more than a billion or a trillion automatic tests to be worthwhile." Turning that on its head, what if you just write the tests and not the implementation? In a way, this is the approach behind deep learning: try to generate a program for a very restricted machine that passes some large set of tests.

You could imagine a generative testing system like Hypothesis that suggests code mutations that cause failing test cases to pass; this is a very small version of "what if you write the tests and not the implementation?". Once you have found a failing test case, you can try on the order of 50 million modified versions of the code per second. Perhaps you could expand this to a practical program search system by accelerating the process by writing some very verbose test cases that include some debug messages showing intermediate results while running the algorithm, so that the Kolmogorov complexity of each successive search objective is only 16–32 bits, making the search tractable.

The functional-programming equivalent might be to write test cases for subordinate functions that can be composed to do the desired computation.

Michał Zalewski's American Fuzzy Lop testing system, which provides random input data to programs to test them ("fuzzing"), uses Unix's fork() to virtually "take snapshots" of a process under test at different times during its execution; this allows it to execute many more test cases per second, because new test cases can start from the program state some tens of microseconds before the program exited, rather than from the beginning. Using this facility, he has demonstrated some very impressive results, including constructing a

legal JPEG file by fuzzing a JPEG decoder to find an input file it would accept.

Linux's implementation of snapshotting with fork() is unfortunately rather slow (though faster than other Unixes): some 130 µs on my laptop to fork() and wait() for a dietlibc-linked child process that merely invokes exit(), perhaps on another core. This compares to 0.4 µs for a minor page fault, 0.3 µs to call read(), and probably something like (guessing based on others' measurements) 5 µs to context-switch the core to another already-existing process and (guessing) 0.1–0.2 µs for a one-way IPC under seL4.

This suggests that, even using conventional protection mechanisms, it should be possible to take lazy process memory snapshots an order of magnitude faster than Linux does it, which in turn would make it practical to take them an order of magnitude more often — every 5 µs, for example, rather than every 50 µs. In cases where the the execution time from the last test case input to getting a test result — the feedback lag — is on the order of those 5 µs, this is an order-of-magnitude speedup, but its importance goes far beyond that, because the input search problem is exponential in the feedback lag. 5 µs is about 12000 instructions, which admits an insanely large number of possible executions to search through.

This suggests that unconventional protection mechanisms, such as Valgrind-like machine-code compilation and interpretation, might work better for program search; by recording every change to memory and registers, they can rewind the timeline to any arbitrary instruction execution, at a cost of optimistically 10× to more likely 100× execution time (and also some memory). In cases where the feedback lag can be reduced below, say, 120–1200 instructions, you can thus fail more tests per second with this approach than by using arm's-length mechanisms like virtual memory protection. With the Linux implementation, which costs on the order of 300'000 instructions, the crossover point is around 3000–30'000 instructions of feedback lag; for shorter feedback lags, the Valgrind and interpreter approaches will work better.

Abstract interpretation techniques can yield bigger speedups in some cases, like the miniKANREN system that is capable of finding a quine by searching through possible executions of an interpreter for one whose output is the same as its input.

Gradient descent beyond machine learning

Kragen Javier Sitaker, 2018-05-18 (2 minutes)

Gradient descent and friends are widely used in machine learning. The basic recipe is that you have some statistical model which contains some parameters, and you use gradient descent to set the parameters to, hopefully, minimize the prediction error.

This is an extremely useful approach, and you could argue that, even by itself, it's revolutionary. But gradient descent is useful for other things that don't fit into this model. Gradient descent is a general continuous optimization procedure; it can be used to approximate a local minimum of any differentiable function, and it scales well to large numbers of dimensions.

Let's unpack this a little bit. In the standard ML approach, you have a MODEL which, given PARAMETERS and INDEPENDENT VARIABLES, produces a PREDICTION of some DEPENDENT VARIABLES with some amount of ERROR. You use gradient descent, or some related algorithm, to try to set the PARAMETERS to minimize the ERROR. And you have to worry about whether you're overfitting, and so you use a training set and a test set to see if the model is starting to overfit your training data.

But gradient descent doesn't know anything about predictions or overfitting or the dependent and independent variables of your model. From gradient descent's point of view, the model and training set (including dependent and independent variables) are just part of a LOSS FUNCTION which, given INPUTS, produces an error or LOSS.

Gradient descent is a somewhat general procedure for finding the inputs that minimize such loss functions.

It turns out that there are a lot of other things in the world that can be represented in this way. There are a lot of things you might want to minimize that are not prediction errors.

You can't sort a file whose size is cubic in your RAM size in two passes, only quadratic

Kragen Javier Sitaker, 2015-05-28 (5 minutes)

This is a bad idea that has occurred to me before, and I want to write down why it's bad so that it can stop occurring to me.

The problem to solve

The problem to solve is to increase the capacity of two-pass external sorting, in which you ingest a large input file on one pass over the data, storing it on disk, and then emit it, sorted, during a second pass over the data, reading it from the disk. We're counting disk I/O here rather than, say, key comparisons, because the disk I/O is usually the slow part.

The main limitation of two-pass external sorting is that, in two passes, you can only sort files that are about twice the size of your RAM, times the size of your RAM, divided by your disk's bandwidth-latency product. So if your (spinning-rust) disk transfers data at 50 megabytes per second and has 9ms random-access latency, your bandwidth-latency product is 4.5 megabytes. If you have 4.5 gigabytes of RAM, then you can sort files up to about 2000 times the size of your RAM — 9 terabytes — in two passes. If you have 9 gigabytes of RAM, you can sort up to about 8000 times the size of your RAM — 72 terabytes — in two passes. So the critical size is quadratic in the size of your RAM, inversely proportional to the disk's access latency, and apparently perversely, inversely proportional to the disk's bandwidth.

(The apparent perversity here is only apparent; increasing the disk's bandwidth won't actually make two-pass external sorting slower. It just won't make it faster.)

We can model SSDs in this model as disks whose bandwidth-latency product is on the order of 1-4 kibibytes, which is five orders of magnitude better than spinning rust. Unfortunately, this does not increase the amount of data you can sort by five orders of magnitude, because your SSD probably isn't bigger than ten terabytes. It might make more sense to model the CPU-RAM-SSD system as "CPU and RAM" from the point of view of the disk, thus probably enabling you to sort files up to the size of your disk in two passes.

How two-pass sorting works

Simplest method: fill RAM with unsorted data, sort in RAM, write to a new temporary file on disk, repeat until input is consumed; now read these N sorted files and read them all concurrently, merging them together to produce the output.

Optimization: maintain in-RAM data in a bin-heap, and each time you write out a record, read in a new record to replace it, adding it to the bin-heap if possible. This doubles the size of your initial sorted files on average for randomly-ordered input data, and does much

better than that if the input is sorted or nearly so.

Backwards alternative: partition keyspace into N roughly-equal-weight disjoint partitions, and open N temporary output files. Deal input records into the appropriate file as they come in. Once input is exhausted, sort and output each of the N temporary files in order.

The efficiency limitation on the number of concurrently open files is that you need some buffer space in RAM for each open file in order to batch the I/O into operations big enough to use most of the disk's bandwidth. When the buffer space gets smaller than the bandwidth-latency product, the disk spends most of its time seeking.

If you do more passes, you can increase the sortable data size dramatically. Back in the magtape days, apparently many-pass sorts on three or more tape drives were common.

The bad idea

I keep thinking that there should be a way to make two-pass external sorting able to sort a data file *cubic* in the size of your RAM.

The basic idea is that you have N^2 temporary files: you write to N of them at a time during input ("column-wise"), and read from N of them at a time during output ("row-wise").

Why is this idea bad? Well, are these temp files going to be sorted or not? If they're not sorted, then you need to sort them before you can merge N of them together, which means you need to fit N of them into RAM at once during output if you're going to avoid making a third pass over the data. If they are sorted, then they have to get that way somehow, which means that you need to fit N of them into RAM at once during input.

So as far as I can tell, this approach just doesn't work, and there's no way to make it work.

Alien game challenge

Kragen Javier Sitaker, 2015-09-03 (6 minutes)

"8-bit" or "New Aesthetic" games like Minecraft, Bit Trip Runner, and arguably Dwarf Fortress are increasingly popular, perhaps reflecting a newfound appreciation for gameplay in place of high production values. To some extent this is also a way to disguise lack of production values: if you put crappy models on top of Unreal Engine, the environment they're in makes them look worse by implicitly comparing them to the ones in Counterstrike or Call of Duty [0], and indie devs can avoid suffering such comparisons in part by avoiding the engines that create production-values expectations they will inevitably fail to meet.

[0]: CoD is on Unreal Engine, right? Did I misspell that?

Occasionally there are games programming competitions that focus on some kind of artificial restriction like this, sometimes even using specific old platforms. The problem is that, for obvious reasons, these restrictions tend to resemble restrictions we have actually suffered in the past, so the aesthetic of the games tends to be somewhat predictable: square pixels, small color palettes, 2.5D, 7-segment displays, FM or square-wave or triangle-wave synthesis.

But what if, instead of creating video games that recall the age of Space Invaders, we tried to create video games that recalled the analogous stage of technological development on an alien planet, or perhaps an alternate-history Earth? We could have been laboring under different restrictions and produced different kinds of games.

A number of things have happened recently in games that suggest some possibilities. Flappy Bird could easily have been written in 1985 [1], but there were no similar games. 3-D wireframe games were feasible in 1985 (Maze War, the first first-person shooter, was from the 1970s, and the Star Wars game was a popular arcade game of the time) but they greatly benefited from vector displays, which went out of style at the time.

[1] I think James Hague pointed this out but I'm offline at the moment.

So, some example alternative histories:

- As I said, what if vector displays?
- What if hexagonal pixels had been the standard? They have more consistent spacing and thus reduce sampling error for the same number of pixels, which is why tabletop strategy games (arguably including Settlers) use hexagonal tiles.
- What if Tek-4014-style storage tubes had been the mainstream display technology? You can't erase part of the screen; you have to erase the whole screen.
- What if touchscreens? But we're already exploring that with game dynamics like Flappy Bird and Angry Birds.
- What if timesharing?
- Music synthesis with electronic difference engines, sort of like vector-display display lists, but for waveforms?

a. Music synthesis with circulating bit sequences in shift registers (like the Apple]['s NTSC colors) rather than analog waveforms?

• Vector displays with higher-order display lists? You could display quadratic splines as easily as points, but maybe only a small number of new ones per second.
• What if the CPU itself were fundamentally different in some way?
  a. If most of your memory were write-once read-many, so that every time you played a game, you irreversibly used up some of the memory?
  b. If most of your memory were fundamentally sequential-access, like bubble memory or magnetic tapes? (Arguably we're suffering that now with disks, and of course videodisc games of the 1980s explored some of this too.)
  c. If the CPU were a combinator-graph reduction machine like the SKIM rather than a RAM machine?
• Character-cell displays created an aesthetic that survives in Dwarf Fortress and Nethack, but also that influences any number of modern "8-bit" games, because they use fixed-width fonts. But to a great extent those displays were very culturally contingent, and while perhaps Greek and Latin alphabets are among the simplest systems to draw this way, it seems like it's probably a coincidence that the cultures that invented computers happened to use alphabets rather than other writing systems. So consider, what if your character display were for a language that was:
  a. Top-to-bottom?
  b. A syllable-block system like Korean hangul?
  c. One of those where accents are essential to understandability? Maybe, like APL, your display would need to support arbitrary overstrikes, or at least two or three overstruck characters. How could this reduce the size of the character set?
  d. Necessarily variable-width, or necessarily supported character overlaps? I don't know if Devanagari, for example, is actually this way, but I've never seen non-proportional Devanagari. Proportional font rendering isn't actually that much harder than fixed-width font rendering. Historically it came along with framebuffers, which certainly make it easier, but are framebuffers really necessary?
  e. Ideographic? Would you necessarily move to a small syllabary for computers, like 1980s Japanese PCs used katakana, or could you perhaps handle some kind of large ideographic character set in reasonably simple hardware?
• Hardware sprites and hardware scrolling were a big deal in 1980s games, since you didn't have time to redraw the entire screen each frame. Similarly, for fractals, hardware palette color-cycling was a big deal, a technique which also permits fade-to-black, flashing a certain color index, and so on, without having to redraw the entire screen; and a bit earlier, XORing objects into the framebuffer allowed you to move them around the screen without having to save the background they passed over in separate memory. But suppose the available display hardware had supported other interesting operations instead? Of course, there's an infinite variety of possible operations, most of which (like XOR) are mostly visually uninteresting. But there are a wide variety that seem like they would have been interesting but were never implemented in hardware:
  a. Displacement mapping, which is kind of a generalization of sprites: you have a number that you add to the pixel coordinates generated by the hardware counter to get the address in the

framebuffer (or tiles, or whatever) to draw the pixel.

Topics

2016 outlook for automated fabrication and 3-D printing

Kragen Javier Sitaker, 2016-08-11 (20 minutes)

I think other kinds of automated fabrication might serve as well as 3D printing or better for general-purpose home use.

There are several kinds of automated fabrication. CNC machining is pretty important. Lithography is pretty important; it's how both ICs and printed circuit boards are made, and in one or another form it's how almost all text and pictures get onto manufactured goods. Robot welding has been a major part of fabricating many kinds of metal goods since the 1980s. The first versions of CNC machining were cam-controlled, in the late 19th century; they were called "screw machines". After setup, you would feed them a piece of bar stock and they would conduct a programmable series of lathing operations on them, repeatedly, under the control of the cams, which is how screws have been made ever since then and why screws are cheap.

The promise of 3D printing was, when 3D Systems was founded in 1986, that product designers could rapidly produce prototypes to experiment with, even if the cost was far too high to compete with mass-produced products. My math teacher told the class about it in 1993; he'd seen a plastic apple produced by stereolithography.

In 2005, Adrian Bowyer founded RepRap as a project to make automated fabrication accessible to the masses. Its goal was to make "rapid-prototyping machines" so cheap that it's cheaper to make things with them than with injection molding, by making them self-replicate. But it failed at that goal.

Problems with RepRap-style 3-D printing

RepRap-style 3D printing — 3-axis gantry open-loop single-material FDM without a heated chamber — is really limited in what it can achieve for a variety of reasons.

Most of these are problems that would not be serious if the printer could self-replicate at a low cost, as was the original goal — it could print a new version of itself that solved the problem.

Imprecision

RepRap-style 3D printers typically have 100-micron errors even in the X and Y directions, and due to the nature of FDM, the Z-axis of each piece is quantized to typically between 250 and 500 microns, resulting in a stairstep appearance.

This doesn't sound like a lot, but it's common for any ordinary subtractive machining operation to be carried out to 20-micron or 10-micron precision, with 1-micron precision in areas that need it. An ordinary 600-dpi laser printer has 40-micron precision; an expensive 2400-dpi printer has 10-micron precision. 1-micron feedback sensors are easily available, but RepRap-style printers don't use them. Why? I think it's a design error, but I think the intention was to lower costs.

The big problem with imprecision is that it makes the properties of the material unpredictable, because you get unpredictable layer

adhesion. Poor layer adhesion gives you a tiny fraction of the potential tensile strength of your material in the Z direction.

Two of the main sources of poor layer adhesion are actually bed-leveling problems and filament diameter miscalibration.

Recent RepRap-family printers have ceded somewhat on the open-loop-control front to do automatic bed leveling by touching down on each corner of the bed before starting the print, then twiddling the Z axis dynamically as the extruder moves around in X and Y to compensate for bed tilt. This ensures that the first few layers deposited have a uniform thickness, greatly reducing layer adhesion problems. Without bed leveling (either manual, using screws, or automatic as described above) it's easy to have a bottom layer that's squished flat on one side of a piece and barely touching the bed on the other, with lots of roundness in the deposited filament.

Filament diameter miscalibration also affects layer thickness and dimensional precision; if the filament diameter is 10% smaller than expected (for example, 180 microns if your filament is 1.75 mm diameter, the most popular size), then the amount of plastic per linear millimeter is 21% smaller, and so the width of extruded traces will be 21% low, and you may get poor layer adhesion. Many commercial filaments have significant diameter variations even within a single spool, and they are rarely perfectly round, making precise measurement difficult.

Imprecision puts a severe limit on volumetric resolution. I'm particularly interested in volumetric resolution because, for mechanical computation, that's what counts — if a certain multiplier design requires 4 million voxels, then it will be 10.5 milliliters on a RepRap-style machine or 0.5 cubic millimeters (half a microliter) on a hypothetical 5-micron-resolution 3-D printer.

Material limitations

With FDM without a heated chamber, your materials are basically limited to PLA, ABS, and nylon, and filled or colored versions of these. (Except see below about PVA, elastomers, and PETG.)

These materials are not all bad. They come out of the machine sterilized, which is nice, and PLA and nylon are biocompatible; and the most interesting fillers I've seen are brass and fine sawdust, which give you the ability to produce objects that are mostly brass or wood. PLA is very dimensionally stable, ABS is very strong, and nylon is very tough and easily accepts very large deformations (30% elongation at break is typical).

But they do have many disadvantages.

PLA is weak and brittle.

But ABS and nylon offgas toxic fumes during printing, so you likely don't want to print in them indoors without a good ventilation system. ABS also leaches toxic styrene when in contact with acid, so you can't use it for food-contact applications. You can't use PLA for most food-contact applications, where you would expect it to shine due to its nontoxic nature; the problem is that it softens at a very low temperature, as low as 60°, even though you need at least 180° to extrude it.

PLA is hygroscopic and aquadegradable, so by leaving a PLA spool exposed to air, you can run into big problems printing after a few weeks or months. The water in the plastic can boil and make bubbles

as it goes through the nozzle, or it can just degrade the plastic, making it even weaker and more brittle than it already is.

ABS and nylon require high temperatures, like 210° and 240° respectively, which PLA can't withstand; this is a problem if you switch from printing in nylon to printing in PLA, because you have to print at nylon temperatures until all the nylon is out of the nozzle, because it's frozen solid at the usual PLA temperatures.

ABS, because of its larger thermal shrinkage and high stiffness, has a terrible tendency to curl as it cools without an enclosed build chamber; worse, this depends on the ambient temperature, which means your ABS printing may be going fine all day and then fail during the night. If it curls up off the bed, it can collide with the nozzle and be knocked entirely out of place, but even if that doesn't happen, you can get delaminations which totally vitiate the strength of your print.

PLA is vulnerable to glass-style fatigue; a piece of PLA held in a stressed position may crack through after weeks or months with no motion. Glass does this too, but mostly only if it's underwater. In both cases there seem to be critical stresses below which the fatigue cracks don't propagate. Probably whether this happens to a given specimen of PLA depends in part on the amorphousness (glassiness) of the PLA, which in turn depends on the composition and cooling rate.

I don't have any experience printing in nylon, but it's very soft, which limits its applications somewhat. And the higher temperature makes the hotend fail more often.

FDM prints unavoidably (?) come out with a stairstep surface because of Z-axis quantization. If they are ABS, they can be smoothed by brief exposure to acetone vapor; this is harder to achieve with PLA, because PLA is invulnerable to almost all organic solvents. People have had success using dichloromethane, which is outrageously toxic, and reportedly ethyl acetate, which is several times less toxic than table salt. But the ethyl-acetate-based nail polish remover I tried didn't do the job, it just swelled the plastic. Other people just recommend painting the piece.

Thermoplastic elastomers like "Filaflex", "Ninjaflex", and "Flexifil" are a promising new addition that I don't have any real knowledge of; they don't have the level of superelasticity that rubbers do. Ninjaflex is a thermoplastic polyurethane; I don't know what the others are made of. Supposedly Filaflex has 70% elongation at break, which is quite a bit more than nylon's 30%, and Ninjaflex 660%, but neither equals an ordinary rubber band, which can easily hit 1000%.

PETG filament, like Form Futura's HDglass, is another newish product that claims to let you use FDM to fabricate transparent objects. I don't have any experience with it. Being PETG, it ought to be food-safe, too.

Single-extruder limitations

Standard RepRap-style machines have a single extruder nozzle, fed by a single filament, in order to lower the cost and improve reliability. That means it can only print in a single material at a time, and changing between materials is far from instant. This creates a number of problems.

Most obviously, unless you paint the piece, it's a single solid color,

or it's the uncontrolled sequence of colors that the filament had — like when you knit with variegated yarn.

I think the single-material limitation is the main thing that prevents RepRap replication from really taking off. The single most failure-prone part of a RepRap-style printer is the hotend, and that's the part it can't print, because it's made of brass, Teflon, Kapton, and a cartridge resistance heating element, which don't melt at the temperatures it's exposed to.

(Somewhat less obviously, the hotend has a dimensional tolerance that's tighter than RepRaps are usually capable of achieving: the diameter of the nozzle aperture.)

Dual-extruder FDM printers are capable of doing several things that single-extruder models can't manage, aside from being theoretically better suited to self-replication. One is printing objects that have controllable visible patterns on their surfaces. Another advantage is the ability to print support material in a soluble form: polyvinyl alcohol (PVA), a nontoxic water-soluble plastic that melts at a conveniently low temperature, is a favorite choice. But ABS, which easily dissolves in acetone, is a reasonable alternative for supporting PLA, which is invulnerable to acetone.

Dissolvable support material is an enormous help in making preassembled mechanisms. The usual RepRap-style support material has to be cut away from the finished piece using a knife, which requires manual intervention, leaves crap on the surface, and is difficult to impossible inside enclosed spaces. Also, it's easy to cut your hands that way.

Here's an example of using a dual-extruder FDM machine for dissolvable PVA support material.

Finally, there are a lot of kinds of machinery that inherently require two or more different materials to be deposited in intimate contact. Circuitry requires both conductors and insulators; PLA filled with graphite, lead, or more expensively, brass, silver, or gold, is totally adequate as a conductor for many circuits, but you need insulators too. Electric motors could conceivably be 3-D printed, but as far as I can tell, practical motors need many thin layers of conductors, insulators, and high-magnetic-permeability materials. (Those are typically a poorly-conducting kind of steel, deposited in layers with insulating epoxy in between to reduce eddy-current losses.)

Many of the more interesting possible applications of 3D printers are in metamaterials; by careful design of a repeating 3-D structure, for example, you can combime two materials with different thermal coefficients of expansion to get a bulk "metamaterial" with a TCE that's orders of magnitude lower than either of the two "phases" or materials that compose it. That's super important for precision measurement, feedback, and control.

Self-replication problems

As I said above, the single-extruder RepRap design is one of the major obstacles to self-replication. You could imagine an alternative RepRap design that used two different materials for two different nozzles, plasticized using two separate mechanisms, such that either nozzle could print the other nozzle — for example, one material plasticized using heat, and the other plasticized with a solvent.

But multiple extruders is not the only possible solution.

You could also imagine a multi-step manufacturing process, where for example you first use FDM to fabricate a shape in PLA, then make a plaster cast around the PLA and use it to cast, for example, brass. You can find videos of people doing this on YouTube ("lost PLA process").

Or first you fabricate a shape in stainless-steel-filled PLA, and then you sinter it in an oven, or something. There are 3-D printing companies that do this with selective laser melting of stainless-filled thermoplastic.

Or you could use a material whose cradle-to-cradle life cycle includes more than two steps like PLA's melting and hardening. Plaster of Paris, for example, which you can deposit as a thixotropic liquid freshly mixed from powder and water, then allow it to harden. The full cradle-to-cradle process for plaster of Paris involves calcining the resulting hydrated gypsum at 150° to 180° and then grinding the resulting calcium sulfate hemihydrate to a fine powder. As long as the "nozzle" isn't doing the calcining, it won't have any trouble making an alternate nozzle. Which is a good thing, because once you let plaster harden in the nozzle, you'll need to replace it.

A fully autonomous self-replicating system will probably need to be able to make ceramics from clay and fire them, because essentially all industrial processes depend on ceramics. This might be a good place to start.

Open-loop stepper-motor actuation

RepRap-style printers use open-loop stepper-motor control. This results in three problems: imprecision, cost, and unreliability.

Open-loop stepper motors have poor precision (or, let's say, poor bandwidth) for reasons I don't fully understand. This is one of the sources of the problems in the "Imprecision" section above.

The beefy NEMA 23 or NEMA 17 stepper motors used in a RepRap are rare to find at salvage and quite expensive to buy new, because they're mostly used in industrial machinery, not consumer goods. Older 2-D printers used steppers, but much wimpier ones; newer ones use DC motors with closed-loop control.

The printer uses such large motors because the motors have to be strong enough to move the dynamic loads of the printer with basically no effort, because they cannot adjust the effort to the load without feedback. (A certain limited amount of feedback is provided by the variation in slip in the stepper.)

Finally, steppers add unreliability, because if the printer ever encounters resistance and misses a step, all subsequent movements will be offset by the missed step, resulting in a failed print, typically spaghetti.

That stupid gantry geometry

The gantry construction of RepRap-style printers amplifies the problem of imprecision.

Traditional CNC machine tools use a "gantry" geometry in which high-rigidity linear actuators at precisely aligned right angles determine the relative positioning of the workpiece and the cutting tool. With a gantry, you can make precisely parallel and right-angled cuts by hand, without doing a lot of numerical calculation. But gantries require immensely stiff beams and joints to achieve reasonable

precision, linear slides (which are difficult to make and even more difficult to make precise), and linear actuation, which typically adds backlash and therefore imprecision.

Fortunately, less stupid geometries are coming into fashion, including deltabots, parallel SCARA topologies, and polar robots.

Gantry construction synergistically causes problems with open-loop control, because the precision of open-loop control depends critically on rigidity, since the open-loop control can't correct for mechanical deformation any more than it can correct for missed steps.

My favorite robot geometry, the Stewart platform, has not become popular.

Emerging alternatives to RepRap-style 3-D printing

CNC laser cutters are actually far more accessible than 3D printers today, in the sense that there is likely a CNC laser cutter physically closer to you that you can use, and if you make something on it, it will cost you a lot less than doing the same thing on a 3D printer. It's just that it's limited to planar fabrication (as are CNC plasma torch tables, CNC waterjet cutters, and lithography per se.

Things like the Othermill at US$2200 are only a little more expensive than RepRap-descended 3D printers; the PocketNC FR4 is a fully-funded Kickstarter for a US$449 three-axis CNC milling machine, which is cheaper than many 3-D printers. The FR4 is milled from epoxy-glass-fiber composite circuit boards, which are very rigid, light, and cheap, compensating for its stupid gantry geometry (see below for the problems with gantries).

You can see that this FR4 is capable of reproducing its own circuit boards and the parts of its own structure, and has 5-micron precision in all three axes. That is about 20×20×50 = 20000 times better volumetric resolution than any open-loop-control FDM 3D printer.

Norbert Heinz built his 100-micron-resolution CNC machine entirely out of recycled junk, including closed-loop control of the underpowered DC motors he used. In that video you can see him using it to engrave glass with a diamond cutter, cut Styrofoam with a soldering iron, and mill gears from acrylic or aluminum, all of which are materials that are out of reach with FDM.

With FDM, you can't make anything transparent, anything as strong as glass or acrylic or aluminum, or anything as light as Styrofoam. And, at the 100µm precision achieved by both Norbert's junk heap and a thousand-dollar FDM 3-D printer using open-loop control, your gear surfaces suck, and you need a lot of extra clearance to print preassembled gear assemblies. (Although, of course, with CNC cutting, you can't print anything preassembled.)

Norbert's machine is 500×500×?? mm rather than the 200×200×150 of a typical RepRap-derived 3D printer, so it can make things that are about ten times as big.

Michal Zalewski has written is a superb introductory guide to CNC machining and resin casting. Remember what I said about a multi-step manufacturing process? His multi-step process is that he cuts a mold or a positive, casts a mold if necessary, and then casts the part. He gets 2-micron accuracy.

Topics

Error Reporting is Part of the Programmer's User Interface

Kragen Javier Sitaker, 2007 to 2009 (18 minutes)

(This is about the user interface provided to the application programmer, not the user interface the application programmer provides to the non-programmer.)

I have a quibble with the user interface design approach of web.py. Its user interface design slogan says:

"Think about the ideal way to write a web app. Write the code to make it happen."

And in a February 2006 post on the web.py mailing list:

The goal of web.py is to build the ideal way to make web apps. If reinventing old things with only small differences were necessary to achieve this goal, I would defend reinventing them. The difference between the ideal way and the almost-ideal way is, as Mark Twain suggested, the difference between the lighting [sic] and the lightning bug.

This is a very respectable user-interface-design philosophy: start from a conception of the user interface, and then proceed to write the code to make the user interface work. I totally agree with this point of view.

Unfortunately, the user interface for a library doesn't just include the code you have to write to use the library; it also includes implicit coupling created between parts of that code, and the error messages produced when your code is wrong. And web.py doesn't do very well on those latter items, because of hyper-optimizing the code you have to write --- to the point of being deceptive.

The fundamental merit that is somewhat lacking is that of explicitness; explicit is better than implicit, because explicitly stating the relationships in your program makes them both comprehensible to a reader and changeable by a maintainer. Implicit relationships are neither. Also, explicitly stating relationships allows errors in these relationships to be reported in the terms of the user's model (the green code) rather than the implementation model (the yellow code).

An Example of the Problem

I'm developing on top of web.py 0.3, which hasn't been released yet. Here I'm trying to reproduce an example from the docstring of `web.application.request`, but with `web.config.debug` turned on.

```
kragen@thrifty:~/devel/watchdog-git$ python
Python 2.4.4 (#2, Apr  5 2007, 20:11:18)
[GCC 4.1.2 20061115 (prerelease) (Debian 4.1.1-21)] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> import web
>>> web.config.debug = True
>>> urls = ("/hello", "hello")
>>> class hello:
...     def GET(self):
...         web.header('Content-Type', 'text/plain')
...         return "hello"
...
```

```
>>> app = web.application(urls, globals())
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "/home/kragen/devel/webpy.dev/web/application.py", line 62, in __init__
    module_name = modname(fvars)
  File "/home/kragen/devel/webpy.dev/web/application.py", line 54, in modname
    file, name = fvars['__file__'], fvars['__name__']
KeyError: '__file__'
>>>
```

This error leads me to wonder, "WTF?" This is not an error phrased in terms of anything I passed in to web.py. And it only occurs when `web.config.debug` is turned on.

It turns out that the problem is that, when `autoreload` is true, `web.application.__init__` tries to reload the module that contains the `urls` and `mapping` arguments I'm passing in, and it does so by assuming that the `mapping` is the `globals()` of some module loaded from a file and therefore will contains a `__file__` key that tells where to find that file.

Here's another test case that shows a related problem, this time in a file:

```
#!/usr/bin/python
import web

class hello:
    def GET(self):
        web.header('Content-Type', 'text/plain')
        return "hello"

def main():
    web.config.debug = True
    urls = ("/hello", "hello")
    app = web.application(urls, globals())
    app.request("/hello")

if __name__ == '__main__': main()
```

This gives the following error, which you'll note is several times longer than the program itself --- actually two errors:

```
Traceback (most recent call last):

  File "/home/kragen/devel/webpy.dev/web/template.py", line 621, in h_expr
    item = self.h(i[THING])
  File "/home/kragen/devel/webpy.dev/web/template.py", line 553, in h
    return getattr(self, 'h_' + item[WHAT])(item)
  File "/home/kragen/devel/webpy.dev/web/template.py", line 635, in h_test
    return e(ox) in e(oy)
  File "/home/kragen/devel/webpy.dev/web/template.py", line 553, in h
    return getattr(self, 'h_' + item[WHAT])(item)
  File "/home/kragen/devel/webpy.dev/web/template.py", line 621, in h_expr
    item = self.h(i[THING])
  File "/home/kragen/devel/webpy.dev/web/template.py", line 553, in h
    return getattr(self, 'h_' + item[WHAT])(item)
  File "/home/kragen/devel/webpy.dev/web/template.py", line 676, in h_var
    raise NameError, 'could not find %s (line %s)' % (repr(i[NAME]), i[LINENO])
NameError: could not find 'x' (line 178)
```

Again, I didn't pass in anything called "x"; I never asked web.py anything about "x"; and I didn't pass in any non-string things that could reasonably be used as dict keys. It turns out that in order to get the auto-reloading logic to work, web.py is rooting through the globals of the specified module in order to find the `mapping` argument I passed in, so that it can reload `mapping` from that module after it reloads the module.

This is an example of what is wrong with "magic". The error is rather confusing for the user to debug, at least if they're kind of dumb like me, because the web.py API being called makes all sorts of hidden assumptions about the arguments and the relationships between them. The API leads you to believe that it is called with some arbitrary mapping and a dictionary to look up keys from the mapping, but that's a lie. At least when you have `debug` turned on, it really needs a module and a global variable name in that module, in order to support auto-reloading. It's just sneaky about it, and produces incomprehensible error messages.

The solution, for what it's worth, is to instantiate the `web.application` with `autoreload` turned off:

```
app = web.application(urls, globals(), autoreload=False)
```

The Cost In The Yellow Code

It's not just that this magic makes it harder to write and debug applications on top of web.py. It also makes web.py itself harder to understand. Here's the code in `web.application.__init__` to do this magic:

```
        if autoreload:
            def modname(fvars):
                """find name of the module name from fvars."""
                file, name = fvars['__file__'], fvars['__name__']
                if name == '__main__':

                    # Since the __main__ module can't be reloaded, the module has
```

```
                # to be imported using its file name.
                name = os.path.splitext(os.path.basename(file))[0]
            return name

        mapping_name = utils.dictfind(fvars, mapping)
        module_name = modname(fvars)

        def reload_mapping():
            """loadhook to reload mapping and fvars."""
            mod = __import__(module_name)
            self.fvars = mod.__dict__
            self.mapping = getattr(mod, mapping_name)

        # to reload modified modules
        self.add_processor(loadhook(Reloader()))

        # to update mapping and fvars
        self.add_processor(loadhook(reload_mapping))
```

Here's what I think it would look like if you passed in `module_name` and `mapping_name` directly:

```
    if autoreload:
        def reload_mapping():
            """loadhook to reload mapping and fvars."""
            mod = __import__(module_name)
            self.fvars = mod.__dict__
            self.mapping = getattr(mod, mapping_name)

        # to reload modified modules
        self.add_processor(loadhook(Reloader()))

        # to update mapping and fvars
        self.add_processor(loadhook(reload_mapping))
```

Additionally there's copy-and-pasted code in `web.webpyfunc`. Here's what it looks like now:

```
if not hasattr(inp, '__call__'):
    if autoreload:
        def modname():
            """find name of the module name from fvars."""
            file, name = fvars['__file__'], fvars['__name__']
            if name == '__main__':

                # Since the __main__ module can't be reloaded, the module has
o
o
                # to be imported using its file name.
                name = os.path.splitext(os.path.basename(file))[0]
            return name

        mod = __import__(modname(), None, None, [""])
        #@@probably should replace this with some inspect magic
        name = utils.dictfind(fvars, inp)
        func = lambda: handle(getattr(mod, name), mod)
```

```
        else:
            func = lambda: handle(inp, fvars)
    else:
        func = inp
```

I don't completely understand this, but I think that with a more honest interface, all that code would look more like this:

```
func = lambda: handle(getattr(__import__(modname, None, None, [""]), name),
                      inp)
```

This would enable the removal of `web.utils.dictfind`:

```
def dictfind(dictionary, element):
    """
    Returns a key whose value in `dictionary` is `element`
    or, if none exists, None.

        >>> d = {1:2, 3:4}
        >>> dictfind(d, 4)
        3
        >>> dictfind(d, 5)
    """
    for (key, value) in dictionary.iteritems():
        if element is value:
            return key
```

That's about 30-50 lines of code to implement this single misfeature, which could be removed with a simple interface change.

The (Lack of) Benefit in the Green Code

But how much does all that extra complexity above shorten the code you have to write to use the library? (I've argued above that it actually makes the application code harder to write, although shorter, because it renders important dependencies invisible.)

If the interface were changed as I suggest, the cost to user code would be that instead of writing this:

```
app = web.application(urls, globals())
```

You would write this:

```
import mywebapp
app = web.appreloader(mywebapp, 'urls')
```

Or, if you standardized on the name `'urls'` (which is what most web.py apps call the mapping) it would just be:

```
import mywebapp
app = web.appreloader(mywebapp)
```

But I think that, in this case, explicit is better than implicit.

Global Variables: Another Example

I originally ran into the above problem not because I was manually

setting `web.config.debug` to `True` in Python's REPL, but rather because I was writing post-hoc unit tests for a web app that did (http://watchdog.net/). That app set `web.config.debug` to `True` when it was imported. This violates the normal Python principle that you should be able to import a module without fear, but there doesn't seem to be another solution with web.py. In order to work around some of the bad effects of storing state in global variables, web.py uses `ThreadedDict`s so that HTTP requests in different threads don't interfere with each other.

Reporting Problems in the Terms of the User's Model

Above I said that being explicit instead of implicit makes it possible to "report problems in the terms of the user's model". Here's an example of what that means, from another context, where the user is the programmer in a language, not the caller of a library. Here's a small Python program that forgets to check its inputs:

```
kragen@thrifty:~/devel$ cat > len.py
import sys
print len(sys.argv[1])    # print length of first command-line argument
kragen@thrifty:~/devel$ python len.py  # note: no command-line arguments
Traceback (most recent call last):
  File "len.py", line 2, in ?
    print len(sys.argv[1])
IndexError: list index out of range
```

That's pretty straightforward. It shows you the broken line of code and tells you that what it's doing is trying to index into a list (`sys.argv`), but the supplied list index is off the end of that list. Both the list and the index are objects in the world of the Python programmer, the user of Python; they appear in the program.

How about in C?

In C, we don't have lists; instead we have mostly machine words with associated types. Any connection between the starting address of an array and the number of items in the array is necessarily implicit. (There are things like `valgrind` that can sometimes tell you if you violate array bounds, but the ANSI standard requires the compiler to allow some kinds of pointer arithmetic outside of array bounds.) Consequently the C runtime can't report such an error in the terms of the source C program (that is, the terms of the user of the C compiler); it has to report it in terms of the implementation of C.

So here's the same program in C:

```
kragen@thrifty:~/devel$ cat > len.c
#include <string.h>
#include <stdio.h>

int main(int argc, char **argv) {
  printf("%d\n", strlen(argv[1]));
  return 0;
}
kragen@thrifty:~/devel$ gcc -Wall len.c -o len
kragen@thrifty:~/devel$ ./len
```

```
Segmentation fault
```

That's not a very helpful error message, but we can do better.

```
kragen@thrifty:~/devel$ gcc -Wall -g -O0 len.c -o len
kragen@thrifty:~/devel$ ./len
Segmentation fault
kragen@thrifty:~/devel$ gdb len

5     printf("%d\n", strlen(argv[1]));
```

So now we know what line the error happened at (although this is not always possible in C) but it still isn't telling us that it was a pointer arithmetic error. To find that, we have to descend to the implementation level, which happens to be x86 assembly. Here's `main`:

```
(gdb) disassemble
Dump of assembler code for function main:
0x08048354 <main+0>:    lea    0x4(%esp),%ecx
0x08048358 <main+4>:    and    $0xfffffff0,%esp
0x0804835b <main+7>:    pushl  0xfffffffc(%ecx)
0x0804835e <main+10>:   push   %ebp
0x0804835f <main+11>:   mov    %esp,%ebp
0x08048361 <main+13>:   push   %edi
0x08048362 <main+14>:   push   %ecx
0x08048363 <main+15>:   sub    $0x10,%esp
0x08048366 <main+18>:   mov    0x4(%ecx),%eax
0x08048369 <main+21>:   add    $0x4,%eax
0x0804836c <main+24>:   mov    (%eax),%eax
0x0804836e <main+26>:   mov    $0xffffffff,%ecx
0x08048373 <main+31>:   mov    %eax,0xfffffff4(%ebp)
0x08048376 <main+34>:   mov    $0x0,%al

0x08048379 <main+37>:   mov    0xfffffff4(%ebp),%edi
0x0804837c <main+40>:   repnz scas %es:(%edi),%al
0x0804837e <main+42>:   mov    %ecx,%eax
0x08048380 <main+44>:   not    %eax
0x08048382 <main+46>:   dec    %eax
0x08048383 <main+47>:   mov    %eax,0x4(%esp)
```

```
0x08048387 <main+51>:   movl   $0x80484b8,(%esp)
0x0804838e <main+58>:   call   0x8048290 <printf@plt>
0x08048393 <main+63>:   mov    $0x0,%eax
0x08048398 <main+68>:   add    $0x10,%esp
0x0804839b <main+71>:   pop    %ecx
0x0804839c <main+72>:   pop    %edi
0x0804839d <main+73>:   pop    %ebp
0x0804839e <main+74>:   lea    0xfffffffc(%ecx),%esp
0x080483a1 <main+77>:   ret
End of assembler dump.
```

OK, but where are we?

```
(gdb) x/i $pc
0x804837c <main+40>:    repnz scas %es:(%edi),%al
```

`repnz scas` is what `gcc` compiles `strlen` to, so the problem is the argument of `strlen`. It reads from where `%edi` points. So `%edi` must be pointing somewhere bogus.

```
(gdb) x/a $edi
0x0:    Cannot access memory at address 0x0
```

Aha, `%edi` is a null pointer. So we probably passed a null pointer to `strlen`. Where did that come from?

```
(gdb) x/a argv
Cannot access memory at address 0x3
(gdb) p argv
Cannot access memory at address 0x3
(gdb) info locals
No locals.
(gdb) info args
argc = Cannot access memory at address 0xffffffff
```

Looks like our `argv` got horked. Oh well, too bad. We know the problem is that `argv[1]` was null.

```
(gdb) q
The program is running.  Exit anyway? (y or n) y
```

There is a striking family resemblance between the debugger session above and the process required to comprehend the web.py error:

```
TypeError: getattr(): attribute name must be string
```

It took me something like half an hour to figure out what was going on there. Probably if I were smart, it would have been more like five minutes, but in either case, the entire class of such hard-to-diagnose errors could be avoided by interface design that's explicit enough to report errors in the terms of the user's model.

References

In Economizing can be Penny-Wise and Pound-Foolish, Reginald

Braithwaite describes how you can divide code into "red code", which you don't understand, "yellow code" which you understand but which belongs to the solution domain rather than the problem domain, and "green code" which is purely problem-domain code.

Explicit is better than implicit is one of the design principles of Python. It's not an absolute law, but a design heuristic, helpful for the reasons explained here. You can read a little bit of Paul Prescod trying to explain it to Paul Graham at http://people.csail.mit.edu/gregs/ll1-discuss-archive-html/msg01587.oohtml.

IMGUI programming compared to Tcl/Tk

Kragen Javier Sitaker, 2018-12-24 (updated 2018-12-31) (8 minutes)

I wrote this example Tk program last night as an example showing how easy Tk makes GUI development:

```
scale .a -variable x -orient horizontal
entry .b -textvariable x
label .c
pack .a .b .c -side top
proc updatec {a b c} {global x; .c configure -text [expr 1.0 / $x]}
trace add variable x write updatec
```

(This leaves out the long and winding incremental road to getting it to work, which is a strong point of Tcl: it's interactive, everything is a string, and everything gives you helpful error messages. Just that the language semantics is a shambles.)

I think you could quite reasonably do this same application with an IMGUI framework in C, and maybe it would even be less code, because you don't have separate component states.

Something like this, maybe:

```
static int x;
ig_scale(ig_int_model(&x)); ig_horizontal();
ig_entry(ig_int_text_model(&x));
float r = 1.0 / x;
ig_label(ig_float_text_model(&r));
```

And yeah, it's actually about 25% less code than the Tk version.

The idea for the layout is that the framework does a pass over the UI definition function before the drawing pass to find out what sizes everything is requesting and how they're connected together. (It also does a pass over the UI definition function for each event, using the layout from the previous frame.) Then it computes the new layout and does a final pass to paint everything.

Tk lets you pack things on all four sides of your window, which allows you to avoid introducing frames in many cases. I don't think that's necessary here; you just need horizontal boxes and vertical boxes, for which you need to be able to `ig_hbox()` or `ig_vbox()` to start a new nested box, or `ig_end()` to end one of them. Additionally we can provide a default tabular setup, where adjacent sibling hboxes or vboxes have their inner items aligned by default — you can add an extra level of nesting to avoid this if necessary.

The `ig_*_model` functions wrap a raw pointer to the relevant type in a model struct that is passed by value to the widget function in question; presumably it contains a getter, a setter, and a userdata, although you could imagine that for strings it might have slicing functions or something.

Things like layout options can be provided with things like the `ig_horizontal()` call above; at runtime it will error if the current object doesn't have an orientation (like scales and scrollbars do).

The full set of configuration options for a Tk scale widget is as follows:

activeBackground background bigIncrement borderWidth command cursor digits font foreground from highlightBackground highlightColor highlightThickness label length orient relief repeatDelay repeatInterval resolution showValue sliderLength sliderRelief state takeFocus tickInterval to troughColor variable width

You could imagine providing these with named member initializers in a struct, but that requires an extra line of code to declare the struct and doesn't work well for options like `scale -to`, whose default is 100 but for which 0 is a valid value. So probably supplying them with functions (some of which perhaps take struct or multiple arguments) is better.

However, if those functions are to come after the widget name, as they should, then the actual layout or painting must happen after the widget function itself returns — it must be deferred. That also means that these option functions can't change the function's return value, which is relevant for, e.g., tab property pages or menu items, which really benefit from being able to return a boolean.

How Dear ImGui does it

For that matter, buttons also benefit from being able to return a boolean:

```
if (ImGui::Button("Button"))
    clicked++;
```

Dear ImGui has a `SameLine()` function which lays out the following text (or presumably other widget) on the same line, rather than a separate line, as per default. A possible hbox-oriented alternative would be a `ig_endl()` function which ends the current hbox and starts a new one. This is still more modeful, but it avoids having multiple mechanisms for the same purpose, and it avoids needing 5 `SameLine` calls to get 6 things into an hbox.

(Dear ImGui also has a horizontal mode.)

This treenode thing is a thing I really like about Dear ImGui:

```
if (ImGui::CollapsingHeader("Configuration")) {
    if (ImGui::TreeNode("Configuration##2")) {

        ImGui::CheckboxFlags("io.ConfigFlags: NavEnableKeyboard", (unsigned int *o
o)&io.ConfigFlags, ImGuiConfigFlags_NavEnableKeyboard);
```

Radio buttons share a model and specify a value:

```
static int e = 0;
ImGui::RadioButton("radio a", &e, 0); ImGui::SameLine();
ImGui::RadioButton("radio b", &e, 1); ImGui::SameLine();
ImGui::RadioButton("radio c", &e, 2);
```

Dear ImGui requires a PushID/PopID call in loops:

```
for (int i = 0; i < 7; i++)
{
    ImGui::PushID(i);
```

```
            …
            ImGui::PopID();
        }
```

It identifies clickable widgets with an "ID stack", which I guess is sort of like a pathname; windows and tree nodes push onto the ID stack. Within a window it normally uses the button (or whatever) label and hashes it, so there are hacks you have to use if you want to animate the label or whatever; the `"Configuration##2"` in the example above is one such hack — the 2 isn't displayed, but forms part of the ID. As a result, you need to call `TreePop` to end a treenode.

Within the implementation of treenodes, to find out if the treenode is open, TreeNodeBehaviorIsOpen fetches from `window->DC.StateStorage`:

```
    is_open = storage->GetInt(id, (flags & ImGuiTreeNodeFlags_DefaultOpen) ? 1 : 0) != 0;

    …

    if (toggled)
    {
        is_open = !is_open;
        window->DC.StateStorage->SetInt(id, is_open);
    }
```

StateStorage is a per-window sorted ImVector of key-value pairs, where the values are unions. It's amusing to me that the id is hashed with a CRC32 of the string, but then they don't bother to use a hash table to store it, instead resorting to binary search; but they expect to do insertions, as opposed to updates, quite rarely. Still, you'd think that would favor cuckoo hash tables rather than binary search.

The ID construct results in weird things where clicking on one button will activate another one, and so forth. Presumably it could result in a case where this happened even if the buttons had different IDs just because of a hash collision.

A convenient thing about Dear ImGui is that most (all?) of the widgets take printf format strings and varargs.

Dear Imgui labels everything with its ID string by default, since for usability you probably want to know what you're setting anyway.

Perhaps the other thing to beat in this space is REBOL's Visual Interface Dialect: http://rebol.com/docs/view-guide.html. An example from https://en.wikipedia.org/wiki/Rebol:

```
view layout [text "Hello world!" button "Quit" [quit]]
```

Or in REBOL R3-GUI:

```
view [text "Hello world!" button "Quit" on-action [quit]]
```

Examples from http://rebol.com/docs/easy-vid.html:

```
style yell tt 220 bold underline yellow font-size 16
yell "Hello"
```

```
yell "This is big old text."
yell "Goodbye"

vtext bold "Wild Thing" effect [gradient 200.0.0 0.0.200]
```

Here %. is the current directory:

```
vh2 "File List:"
text-list data read %.
button "Great!"
```

Here a "pair" specifies geometry:

```
button 200 "Big Button"
button 200x100 "Huge Button"
image %palms.jpg 50x50
image %palms.jpg 150x50
```

A file filtered to purple provides the backdrop for a button, behind the "Button" text:

```
button "Button" %palms.jpg purple
```

This action assigns `value` to a refinement of another widget and then invokes `show` on the widget:

```
slider 200x16 [p1/data: value show p1]
p1: progress
```

At least in R3-GUI, the layout is tabular: http://www.rebol.com/r3/docs/gui/panels.html explains that this has four columns:

```
view [
    panel 4 [
        button "First"
        button "Second"
        button "Third"
        button "Fourth"
        button "Fifth"
        button "Sixth"
    ]
]
```

Parallel DFA execution

Kragen Javier Sitaker, 2017-04-18 (9 minutes)

I was reading Raph Levien's notes on "rope science" in his "xi" editor. He's talking a lot about monoid cached trees for applications like maximum line width computation, height computation, parenthesis matching, detection, and word wrapping; the objectives are to enable these computations to be done in parallel (across multiple cores), incrementally, and lazily.

It occurs to me that most of these are kind of special cases of a generalized DFA monoid, and using the standard parallel prefix-sum algorithm on the DFA monoid might provide a more convenient way to express these computations.

Consider this simple example of a comment-tagging NFA, in Perl regexp syntax extended with `@x` to tag the just-matched character with `x`, using `N` for non-comment and `C` for comment:

```
([^#]@N|#@C([^\n]@C)*(\Z|\n@N))*
```

This works out to a fully deterministic regexp, in the sense that you never have more than one state live after a given character. If we unpack it from the regexp syntax into traditional programming outline syntax, it looks like this:

```
repeat:                 # 1
    either:
        match [^#]
        tag N
    or:
        match "#"
        tag C
        repeat:         # 2
            match [^\n]
            tag C
        either:
            match EOF
        or:
            match "\n"
            tag N
```

Despite being 15 lines of code, and not counting the final state, this FSM only has two states, marked above with the comments "# 1" and "# 2". The state diagram looks like this (pipe to `dot -Tx11` from the graphviz package to see):

```
digraph nc {
    rankdir=LR;
    LR_1 [ shape=circle, label="1" ]; LR_2 [ shape=circle, label="2" ];
    EOF [ shape=doublecircle, label="" ];

    LR_1 -> LR_1 [ label="[^#]\nN" ];   LR_1 -> LR_2 [ label="#\nC" ];
    LR_2 -> LR_2 [ label="[^\\n]\nC" ]; LR_2 -> LR_1 [ label="\\n\nN" ];
    { LR_1 LR_2 } -> EOF [ label="EOF" ];
```

```
}
```

XXX why is state 2's EOF transition sort of explicit while state 1's isn't?

Now, obviously, you can run this on a text sequentially, starting from a known initial state, tagging each of the characters with either N or C as you go. At any given point in the text, your state is either 1 or 2.

However, you can *also* run it from an *unknown* initial state. In this case, your state at any given point in the text is a *function* from the initial state to the current state. Initially this function is { 1: 1, 2: 2 }. And as you go, you tag each character, not with N or C, but with a *function* from the initial state to the tag. For example, if the first character is "q", then you tag it with { 1: "N", 2: "C" }, and your state doesn't change. But if then you match a "#", your state function changes to { 1: 2, 2: 2 }, which is to say, always 2, and you tag it with { 1: "C", 2: "C" }, which is to say, always "C".

If you run this algorithm over a block of data taken from the middle of a long file, you will end up with some final state function at the end of the block of data. For this DFA, it will be either { 1: 1, 2: 2 }, { 1: 2, 2: 2 }, or { 1: 1, 2: 1 }.

(If you do this with an NFA instead of a DFA, your result will be a binary relation rather than a function.)

If you break the file up into many blocks and run it in parallel over each block, you will compute such a function for each block. By composing these functions, you can compute such a function for longer runs of the file. For example, if block 39 comes out to { 1: 1, 2: 2 } and block 40 comes out to { 1: 2, 2: 2 }, then the concatenation of blocks 39 and 40 comes out to { 1: 1, 2: 2 }.

If you compose these blocks into a balanced binary tree, you can then compute the function for the whole file by propagating these functions up the tree; functions are, of course, a monoid under composition. Also, though, this allows you to take a known initial state and then efficiently propagate it back *down* the tree, left to right, to every character in the file.

This is the standard parallel prefix sum algorithm, applied to DFA execution.

If you were doing a similar kind of tagging in an NFA, you would probably want to only apply the tags that didn't belong to branches of the possibility tree that were ultimately discarded. This involves propagating information *backwards* as well in the down-the-tree stage. I think this simply involves rolling back the things that led to intermediate states that ultimately mapped to a null set of states.

You could think of this transformation of the DFA from a computation on states into a computation on functions from states to states as a kind of abstract interpretation with non-standard semantics of the DFA. You can do the same kind of abstract-interpretation trick with computational models more powerful than a DFA, although you lose the bounded-space guarantee the DFA gives you. For example, consider this parenthesis-counting automaton:

```
repeat:
    either:
        match "("
```

```
        n++
    or:
        match ")"
        n--
        either:
            n >= 0
        or:
            n < 0
            tag X
    or:
        match [^()]
```

It tags "X" whenever there's an unmatched ")". You can run it in the standard way with an initial concrete value of `n` such as 0, and it will tell you if there are mismatched parentheses in your text, its state at any given position being some concrete value of `n` such as 3. Or you can run it with an initial abstract value such as n_0, and its values at different positions will be further abstract values such as $n_0 + 3$ — or, you could say, $\lambda n_0.n_0 + 3$.

```
digraph pp {
    LR_1 [ shape=circle, label="" ];  EOF [ shape=doublecircle, label="" ];

    LR_1 -> LR_1 [ label="(\nn++" ];
    LR_1 -> LR_1 [ label=")\nn--\nn>=0" ];
    LR_1 -> LR_1 [ label=")\nn--\nn<0\nX" ];
    LR_1 -> LR_1 [ label="[^()]" ];
    LR_1 -> EOF [ label="EOF" ];
}
```

XXX graphviz is sucking at laying out those edges and labels

Although this automaton has an infinite set of possible states, as well as possible mappings from state at the beginning of a block and state at the end of a block, and representing one of them could in principle consume an arbitrarily large amount of space, you can apply exactly the same approach to composing those functions into a monoid tree. And, as it happens, these particular mappings have a relatively compact representation, all fitting the schema $\lambda n_0.n_0 + k$.

It seems to me that to make the abstract interpretation tractable, you need some kind of limitation on the power of the language — you don't want to have to solve the Halting Problem for one of the blocks. I suspect that it's probably sufficient to forbid loops that don't advance through any input, but I'm not sure.

The objective here is to have a scripting language in which you can conveniently express any of the monoid computations Raph talked about in "rope science", including word-wrap and the like, and that also provides some kind of evaluation efficiency guarantee. You'd like to be able to compute, for example, that if at character 512 the carriage position was between 110 and 170 pixels, then the word breaks thereafter will be at characters 547, 610, 665, ..., and that at character 1024 the carriage position will be 212; while if it was between 170 and 220, they will be at 542, 604, 665, ... and the carriage position at character 1024 will still be 212. And you'd like to be able to compute that automatically from a word-wrapping script

written in a backtracking language with numerical variables.

Parenthesis matching, however, is harder — the case where you want to not just count parentheses, but also blink the matching parenthesis. You need a stack, and the effect of running a paren-matching script over a section of the file will be to pop some set of parens from the stack (possibly requiring them to be of the right type) and push some others. Such functions can still be composed into a monoid tree, of course. (If you want the parenthesis locations to be integer offsets from the beginning of the file, maybe one state variable should be the current offset.)

Bjoern Hoehrmann has been working on an algorithm called "parselov" which compiles a context-free grammar to a finite-state automaton that approximates the CFG using a limited-depth parse stack (one stack item, I think).

Topics

Logarithmic maintainability and coupling

Kragen Javier Sitaker, 2015-11-23 (7 minutes)

In theory, with ideal design, the functionality of a piece of software grows exponentially with the amount of code in it: each new piece of code can take advantage of the entire existing set of capabilities, and so adding a line of code to a system adds capabilities proportional to those of the previous codebase.

In practice, this never happens. In a few hundred or a few thousand lines of code, we can write a hypertext system, or a ray tracer, or a full-text search engine, or a filesystem, or an operating-system kernel, or an interpreter or compiler for a high-level language, or a GUI, or a networking protocol, and so on. Naively extrapolating, we would expect that in a hundred thousand lines of code, you could go far beyond these capabilities, into things that seem like utterly alien technology — let alone what you could do in a million or ten million lines of code.

You could surely argue that this is somewhat ill-founded: it isn't clear how to reduce "amount of functionality" to a scalar quantity. But in fact, regardless of how you choose to define it, it's clear that this isn't happening: our existing computing systems routinely contain millions of lines of code, and rather than seeming like alien technology from the future, they often fail to work at all, and when they do, they often barely work.

Also in theory, the difficulty of writing a piece of software incrementally, piece by piece, should be proportional to the square of the amount of code in it, because the number of potential pairwise interactions between lines of code increases proportional to that square. This is often cited when hackers try to convince one another of the merits of simplicity.

In practice, however, the observed exponent seems to be around 1.05 per thousand lines of code: the basic COCOMO model estimates development effort at 2.4 person-months per KSLOC**1.05. So:

- a thousand-line project should take 2.4 person-months (410 lines of code per person-month), while
- a ten-thousand-line project should take 27 person-months (370 lines of code per person-month),
- a hundred-thousand-line project should take 302 person-months (330 lines of code per person-month),
- a million-line project should take 3400 person-months (290 lines of code per person-month),
- a ten-million-line project should take 38k person-months (260 lines of code per person-month), and
- a hundred-million-line project should take 430k person-months (230 lines of code per person-month).

These two departures from theory are connected! They have to do with the density of connectivity in the codebase. To escape the trap of quadratic complexity, only a tiny fraction of the possible

interactions in the codebase can exist — a line of code invoked by tens of thousands of callers probably cannot change its behavior, even for the better, without introducing bugs. By the same token, a subroutine cannot depend on too much about the behavior of too many other subroutines: it becomes too likely to break when one of the others changes.

So, just in order to be able to keep writing those 10 lines of code per day in that hundred-million-line project, you end up duplicating facilities that exist elsewhere, perhaps in a restricted or more efficient form. You may not even know they exist; certainly you can't depend on them to retain their existing behavior and performance, or not to have behavior or performance in corner cases that conflicts with your needs. Even if not, they may be in a language you can't invoke conveniently or contain subtle dependencies on control structure, runtime facilities, or resource usage that you can't afford and perhaps don't even know about.

And thus it is that the promise of exponential growth in software capability with growing effort is lost.

But what if we were to bite the bullet? What if we were willing to accept that adding a line of code to a hundred-thousand-line system was going to take 100 times as long as adding it to a ten-thousand-line system? If we could get back the exponential growth, would it be worth it?

In terms of flexibility for experimentation, *no*. If it takes you a month to write a piece of code that ends up being five lines, *and then you throw it away*, you surely would have been better served by writing that throwaway code in some other way. Even if it worked out to be 200 lines of code instead of five, that would have been a much better bargain.

But in terms of building the most powerful system, *yes*. If a thousand-line fully-coupled system takes you, say, 100 days and has functionality of, say, One OTCC†, then we can predict the following:

- a two-thousand-line system will take you 400 days and have a functionality of, say, two OTCCs;
- a five-thousand-line system will take you 2500 days (7 years) and have 16 OTCCs of functionality (at which point you're still behind where you would have been by just writing 25 single-OTCC systems);
- a ten-thousand-line system will take you 27 years and have 512 OTCCs of functionality, at which point you are beating where you would have been with 100 single-OTCC systems by a factor of five;
- a twenty-thousand-line system will take you 110 years and have 500k OTCCs of functionality, at which point you are beating where you would have been by writing 400 single-OTCC systems by a factor of 11;
- a fifty-thousand-line system will take you 680 years and have 560 tera-OTCCs of functionality, at which point you are beating where you would have been by writing 2500 single-OTCC systems by a factor of 200 billion. Yet you have been writing, on average, about a line of code per week.

† OTCC is a small C compiler written by Fabrice Bellard for the IOCCC, and it's an exemplar of powerful functionality condensed into a small package. In the

absence of any kind of reasonable unit for software power, it's my best approximation of the maximum amount you can get done in a thousand lines of code.

Even though I sort of pulled them out of my butt, these numbers are sort of discouraging, even though they suggest that we can do dramatically better at software development by improving reuse. The problem is that this level of reuse has such a high price tag that, under these assumptions, you don't start to break even for decades. It's hard to imagine that the correct numbers will make this look much better.

Cycle sort

Kragen Javier Sitaker, 2013-05-17 (1 minute)

Cycle sort is an $O(N^2)$ in-place sorting algorithm that only performs N writes to the original array in the worst case, handy if that array is stored somewhere very costly such as Flash. It's $O(N^2)$ because it eventually compares every element to every other element, twice, to find that element's position.

It seems to me that it's usually possible to do better, even under the constraint of only performing N writes. Of course, if you have an unlimited amount of RAM, you can just read the items into RAM, sort them, and write them back in order. That's why the "in-place" qualifier on cycle sort is important: it uses only O(1) space, while doing the RAM sort uses O(N) space.

What about the middle ground? What if you can afford O(log N) or O(sqrt(N)) memory? Is there a sorting algorithm that does better than the $2N^2$ comparisons of cycle sort, while maintaining the O(N) writes to the original array?

Topics

lattices, powersets, bitstrings, and efficient OLAP

Kragen Javier Sitaker, 2014-04-24 (17 minutes)

Some thoughts that occurred to me on the bus home about using bit-twiddling tricks to speed up lattice operations. The original genesis of the idea was the old idea that it's a shame that Unix doesn't have "sub-users" that have the same relationship to users that the users have to `root`, whose name is suggestive of the idea of a hierarchy of users, something that was never added to Unix. To implement such a thing, you'd ideally want to substitute a "user is equal to or has power over" check for the usual "user is equal to or is superuser" check, and you'd like it to be efficient enough that it doesn't slow down the operations it needs to guard.

As it happens, the uid of `root`, 0, has a special bitwise relationship to other user IDs: it is, in some sense, the AND of all the other possible user IDs. The AND of any uid with `root`'s uid will equal `root`'s uid. It's as if each 1 bit in your uid represented some restriction, and `root` is the uid with no restrictions. (And `nobody`, traditionally uid -1, is the uid with all possible restrictions, which is nicely symmetrical. Although in this case this would mean `nobody` was subject to the whims of any user at all, which might not actually be what you want, but whatever.)

So you'd substitute the check `(actor_uid & actee_uid) == actor_uid` for the check `!actor_uid || actor_uid == actee_uid`, which would be exactly as efficient; but you'd have to have some kind of magical way to assign uids to regular users so that you didn't accidentally end up with one regular user being superuser over another one, or over some sub-user of another one.

Is there such a magical way to assign uids? That's what this essay explores. I haven't found a universal solution, but I've found some solutions for some interesting cases.

This probably isn't actually practical for Unix kernel security policy, but it has other possible applications; for example, in databases, often the last step of query evaluation is to sift through a potentially large number of candidate records produced in some inconvenient order by index-traversal operations, filtering out the small number of records that actually match the query. In particular, in OLAP applications, there is often no index that can reduce the number of records adequately.

This technique is not related to bitmap indexing or compressed bitmap indexing.

Lattices and powersets

Any arbitrary finite lattice L is a sublattice of the powerset of some finite set S, with intersection and union of the powerset lattice being almost the meet and join operations (or vice versa, but I'll be using almost-intersection for meet and almost-union for join). The constructive proof is something like this: optionally, take the transitive reduction of L, removing the redundant edges; then take the remaining edges to be S. Represent each element E as the set of

edges through which E is reachable from the minimum, that is, the union of all paths from the minimum to E.

Clearly S might need to be about the size of L --- consider the worst-case scenario where your lattice is a totally ordered set. You'll need one new element of S for each element of L other than its minimum.

Are there cases where S needs to be larger than L? I'm not sure.

This construction is clearly not optimal, in the sense of finding a smallest possible S for any L; if you have, for example, a min, a max, and 6 incomparable items in between, you can represent represent these 6 items as {0, 2}, {0, 3}, {0, 4}, {1, 2}, {1, 3}, and {1, 4}, needing only 5 items in S rather than 6. In cases like this, the construction above gives O(N) elements, while O(log N) elements is possible, as I'll explain below.

I said "almost union" and "almost intersection". The meet and join operations are not quite intersection and union, because the intersection and union operations may produce a powerset element that doesn't correspond to an element of L; in this example, intersecting {0, 2} and {0, 3} gives you {0}, not {} as it should. I assert without even the handwaviest sketch of a proof that you can find a unique largest subset or smallest superset in any such case, or at least that you can choose your representation such that this is true, but I don't really care that much because mostly I'm interested in the poset operations rather than the lattice operations.

Bitstrings and powersets

The bitstrings of length N represent the powerset of a set of N items, with a 1 bit at position i representing that item i is present, 0 representing the empty set, bitwise complement representing set complement, bitwise AND representing intersection, and bitwise OR representing union.

The great advantage of bitstrings on computers is that you get a lot of parallelism for free; since bit-serial computers went out of style in the late 1950s (excepting the Clock of the Long Now) and until we move to FPGAs with arbitrary bit-length operands, normal computing hardware can take the AND, OR, or NOT of an entire word of bits as quickly as a single bit; depending on the hardware, this gives 8, 16, 32, 64, 128, or even 256-way parallelism, on top of whatever you get out of multicore, which has been exploited to good effect in bitwise DES key cracking programs, among others. (And constant-time AES-CTR implementations!)

But you still have the problem of encoding your desired lattice into bitstrings that encode the desired properties.

One-hot encoding

The simplest kind of lattice is one where all the elements, except the min and max, are incomparable; that is, the meet or join of any two elements that are not the min or max is the min or max. You can encode this as in the naïve version above: assign each of those elements a unique bit position that gets 1. For example, you can represent five such incomparable elements as 00001, 00010, 00100, 01000, and 10000. Electronics people call this "one-hot" encoding.

Note that this follows the usual lexical ordering of bits.

This is okay as far as it goes, but it's wasteful of space once you get

past five elements, because it takes linearly as many bits as you have elements. But for a logarithmic encoding, you can use the Cartesian product.

Cartesian product encoding

If you have a a bunch of such incomparable elements, then instead of using a single one-hot bitstring for all of them, you can chop the bitstring up into chunks, two to four bits per chunk, and use one-hot encoding independently in each chunk. With six bits, say, you have two three-bit chunks, or fields, each of which can one-hot encode three possibilities, so you have nine possibilities in all:

```
001001 001010 001100
010001 010010 010100
100001 100010 100100
```

instead of the six you'd get with straight one-hot encoding, or the eight you'd get with three two-bit fields, or one four-bit field and one two-bit field. It turns out that three bits per field is optimal in this sense, because log 3 / 3 > log 2 / 2, a little. This way you can get 2 * 3^10 = 118 098 unrelated elements, plus max and min, out of a 32-bit word, rather than 32. 118098 is bigger than 32.

In the limit as the number of bits gets big, this gives you log 3 / 3 bits-or-nats per bit, or 0.53 bits per bit; that is, 47% of the space is a tax imposed by the requirements of the representation. We'll see later that there's a more efficient alternative.

Cartesian hierarchies

But that's not all! If you fill one of those fields with all 0s or all 1s, you get an extra min or max element for just that one field. In particular, if you wanted to give Unix users the ability to create subusers, you could assign, say, the first 18 bits to the normal userid, while leaving the other 14 bits set to zero. This would give you 3^6 = 729 independent users, each of whom could create 2 * 3^4 = 162 sub-users.

In general, by setting all but the first N fields to all-zeroes, you get a sort of "Nth-level `root` user", who has authority over all the users whose uids start with its non-zero fields. In an OLAP context, this could correspond to the first N levels of a hierarchical dimension: for a datetime field, for example, perhaps the first 4 bits indicate a year, the next 4 a month, the next 10 a date within the month, the next 7 an hour, the next 12 a minute, and the next 12 a second, 49 bits in all.

Orthogonal dimensions

As the datetime example suggests, though, once you have separate fields, it makes sense to query on any subset of them: perhaps you're more interested in what happens at 8 AM each day, rather than 8 AM on a particular day. So the Cartesian-product approach gives you not just hierarchy but orthogonality.

Groups, in the Unix security context

In some cases, you could replace the notion of a "group" with a user that is subordinate to *multiple* users, so that any of those users can

write to its files (a common use of groups), but it can't affect any of those users. But making that work may require knowing about it ahead of time when you're assigning uids; unless you assign one bit position to each distinct user (quite doable these days, now that we usually have less than 64 people using a single computer) you wouldn't be able to construct groups containing arbitrary sets of people without changing their uids.

In particular, you could reasonably partition the uid space into one or more cross-cutting hierarchies of grouping, and each group (or intersection of groups) would have its own "administrator" with a bunch of zero bits, as well as its own "group" with the corresponding 1 bits.

Gray code

Consider, instead, the case of searching for other users of a smartphone app in geographical proximity to you. If you tile the geographical area in question with imaginary tiles, you mostly want to find people in the same tile as you; but if you're close to a tile boundary, you may also want to find people in up to three neighboring tiles. It would be nice to be able to do this query efficiently.

If you represent the tile coordinates in Gray code, then as you move along either axis, at most one bit changes as you cross a tile boundary. And you can calculate which one it is. If you simply take the AND of the coordinates of the up-to-four tiles in your neighborhood, you obtain a set of bits that you can then compare to others' candidate coordinates.

You can do Gray code in arbitrary bases, such as base 3.

A similar approach can be used to query for temporal proximity.

Binomial identifier assignment

As I mentioned earlier, assigning unrelated identifiers in 32 bits using cartesian product of one-hot fields only gets you 118098 unrelated identifiers. But you can get 16c32 = 601 080 390 unrelated identifiers by taking all the 32-bit values that have 16 1 bits and 16 0 bits: a binomial coefficient. If you use this approach to assign unrelated uids, you can use 12 bits to get 924 unrelated uids, rather than needing 18 bits to get 729 of them.

The binomial approach thus has a dramatically lower tax than the one-hot and Cartesian approaches (it costs you 36% of your effective bits at 4 bits, 23% at 8, 18% at 12, 15% at 16, 11% at 24, 9% at 32, 6.5% at 48, and 5.3% at 64), but at the cost of eliminating orthogonality and hierarchy. It seems like the tax may asymptote to zero with large numbers of bits, but I'm not sure. It definitely gets below 0.3% at 1928 bits, but that's already big enough to be sort of irrelevant.

It's already more efficient at 4 bits; you can represent 6 incomparable elements in 4 bits as 0011, 0101, 0110, 1001, 1010, and 1100, rather than the 5 needed for a Cartesian product of one-hot encodings.

All-or-nothing edge families

The efficient encoding schemes mentioned above take advantage of a particular property of families of edges in the transitive-reduced

lattice to encode them more efficiently: that for any element of the lattice, within some subset of the edges, either none, exactly one, or all of the edges are on a path between that element and the infimum. That is, those edges are mutually exclusive --- within a certain sublattice, except for its supremum; and each is paired with another edge whose representation would be redundant. This is what allows us to safely use such schemes.

This suggests an approach for finding more efficient representations of arbitrary lattices: begin with the basic construction, then look for families of edges with this property. Will it work? Is it optimal? I don't know.

Hashing

In database-query cases, it may be adequate to reject *most* of the candidate records from the index operations, rather than *all* of them. In this case, you may be able to hash a larger identifier space into a smaller one, which you then represent with approaches such as the one-hot, cartesian-product, and binomial approaches mentioned earlier.

There's a curious relationship here between binomial assignment, bloom filters, and approximate homomorphic processing, that I haven't fully explored. For example, if many-bit binomial names are uncorrelated, the AND or OR of two or three of these names is likely to have several bits still, respectively, set or cleared; and so you should be able to use that combined value as a first-pass to sift for candidate matches. The expected number of candidate matches is probably dominated by the improbable case that the names cancel badly, in which case you get an exponential number of false positives.

Query criticism

You could argue that this technique is not appropriate for query processing because it inflates the size of your index data: simple bitfields give you 1 bit per bit, while this gives you 0.53 bits (with Cartesian product of one-hot encodings) or between 0.64 and 0.95 bits per bit (with binomial assignment), all in order to allow any item to potentially represent, in effect, a simultaneous bitmask and value: a combination of a selection of a set of fields, with required values for those fields.

But in the context of querying a database, the records, and especially the records' index entries, do not need to waste space (whether it's 47% of your space, 36%, or only 5%) on something that is only useful in a query term. It would make more sense, instead of testing `(a & b) == a`, to test `(am & b) == ar`, with a separate bitmask and expected result.

This approach makes more sense in applications where the objects you're comparing really are the same kind of object, like when you have two Unix processes one of which wants to `ptrace` the other.

CAMs

Content-addressable memories, which are mostly used in routers' routing tables and virtual memory translation lookaside buffers, include the `(a & b) == c` query operation as its fundamental operation, returning all the `b` that satisfy it.

NTRU

Could this be useful for implementing NTRU? I have no idea because I don't know how NTRU works.

Hall-effect Wheatstone bridges for impractical steampunk electronic logic gates

Kragen Javier Sitaker, 2019-04-24 (2 minutes)

Some years ago I thought I had found a way to build electrical logic gates through magnetoresistance using 19th-century materials science. The phenomenon in question is the altered resistance of ferromagnetic materials when magnetized, by about 5% depending on the orientation of the field, as demonstrated by Kelvin in 1856. I concluded that, by using a Wheatstone bridge, you could get large amplification and inversion from this effect. What I didn't realize at the time was that, as my calculations later showed, the extremely high self-inductance of the ferromagnetic conductors would limit it to sub-hertz speeds.

A Hall-effect alternative might solve the problem. The Hall effect, demonstrated by Edwin Hall in 1879 in gold leaf, produces a few millivolts of voltage from one side to the other of a conducting ribbon with a magnetic field at right angles to it. The voltage is proportional to the current through the ribbon and the magnetic field and inversely proportional to the thickness of the ribbon and the charge carrier density.

The energy of whatever current is driven by the Hall-effect voltage, importantly, does not come from the applied magnetic field; it comes from the sensing current, which does not diminish that field. In theory, this means that you could use that voltage to drive another coil controlling another set of Hall-effect ribbons. In the absence of better means of amplification, you could drive the sensing current through many parallel layers of gold leaf with insulators between them from many isolated voltage sources, such as separate windings of a transformer, and put their Hall voltages in series, thus controlling an arbitrarily large amount of energy with an arbitrarily small magnetic field. This series Hall voltage could then drive a load whose resistance was not too high compared to the (ordinary, not Hall) resistance of the sensing ribbons. (Although, wait, aren't those sensing ribbons in series? Is that in fact a limit on the amplification you can achieve without superconducting ribbons?)

Such a device could, in theory, operate even at high frequencies. In practice, though, I think it might require an unreasonably large amount of apparatus for even a single logic gate.

Induction kiln

Kragen Javier Sitaker, 2019-06-02 (19 minutes)

I'm thinking that, with modern electronics, the most expedient way to heat up a small pottery kiln to a controllable temperature might be induction heating of iron inside the kiln, using coils outside the kiln driven by a simple 300W ultrasonic inverter; this avoids the need for any exotic materials or components.

The basic design

A small cylindrical space is the kiln proper, as in An electric furnace the size of a sake cup (p. 666), perhaps 150 mm across and 100 mm tall; it is enclosed by insulating refractory material. This is divided into a bottom plate with a raised rim and a sort of inverted bucket that fits on top of it; lining the upper part of the bucket is a steel or cast-iron pipe (## in the cutaway diagram below) heated by coils of copper wire (oo in the diagram) wound around the *outside* of the refractory.

```
 ----------------------------------------
 |                                      |
 |     ____________________________     |
 |_  ##                            ##  _|
oo|  ##                            ##  |oo
oo|  ##                            ##  |oo
oo|  ##                            ##  |oo
 |   ##                            ##   |
 |    |                            |    |
 |    |                            |    |
 |    |                            |    |
 |_   |                            |   _|
   \  |                            |  /
    \_|                            |_/

 --                                    --
 | \                                  / |
 |  \________________________________/  |
 |                                      |
 |______________________________________|
```

With this arrangement, when the contents overheat and melt into the bottom of the kiln, they destroy only the bottom plate, which is the easiest part to replace; and, of the electrical components, only the inexpensive steel pipe is exposed to the high temperatures inside the kiln. The copper windings, in particular, are insulated from the pipe by a significant thickness of refractory material.

The raised border around the edge of the plate also serves to lengthen and crookedify the air path between the inside and the outside of the kiln, thus reducing thermal leakage, though probably at the cost of increasing wear when you open and close it.

The power delivered to the pipe can be on the order of 100 to 500 watts, and there isn't any particular advantage (and maybe a bit of

disadvantage) to its tendency to deposit primarily in the outer diameter of the pipe, due to the skin effect, so we can use frequencies as low as is convenient.

(As explained below in "materials and thermodynamics", the walls and floor probably need to be proportionally thicker than is shown here.)

Temperature feedback

We can use the type-K thermocouples used for safety cutoffs for gas ovens and pilot lights; these are available at any hardware store and cost about US$3. To avoid creating a low-thermal-resistance path through the kiln wall, the lead can be passed through the wall in a spiral path from the inside to the outside. Accurately measuring the 50-millivolt DC signal from the thermocouple is somewhat challenging, as explored in Inductor thermocouple sensing (p. 2037), but also a well-understood electronics problem with off-the-shelf designs to solve it. We might have to turn the induction heater off when we're taking temperature measurements.

Materials and thermodynamics

As described in An electric furnace the size of a sake cup (p. 666), refractory firebrick has thermal conductance in the range 0.2–0.5 W/m/K. We can use ghetto firebrick made by mixing used yerba mate with a ball-clay-based clay body; as noted in file `ceramics-notes`, my previous experiments firing it at 1020° burned out all the yerba cleanly (making a terrible stench) and left solid ceramic results at ratios of 1:1, 3:2, 1:2, 1:3, 1:4, 1:6, and 1:8 in favor of the yerba; but the 1:6 and 1:8 results were noticeably friable and porous, so 1:2 (probably about 0.8 g/cc) or 1:3 (probably about 0.6 g/cc) is probably a safe bet. These probably conduct about 0.3 W/m/K.

The surface area of the inner cylinder described above is 100 mm · 2 π 75 mm + 2 π (75 mm)² = 0.082 m², so it will lose 100 W at ΔT = 1000 K if the 0.3 W/m/K refractory averages 246 mm thick; this suggests that 300 W and 82 mm thick is a reasonable goal. You probably want to be able to burst above 300 W in order to hit temperatures at or above 1020 K in a reasonable time.

This gives an outer diameter of 314 mm and an outer height of 264 mm, for a total outer volume of 20.4 liters, 1.8 of which are taken up by the inner chamber; this leaves 18.6 liters of refractory material, about 11.2 kg of fired clay (and 13 kg of used yerba or coffee grounds or sawdust or whatever) if we assume 0.6 g/cc.

It's probably worthwhile to put 5 mm or so of solid clay on the top of the plate to make it resist impacts and abrasion a little better.

Although you would clearly get better results if you fired the kiln in a larger kiln before using it, I think it will probably be usable even if you don't do this — the steel pipe will reach a high enough temperature to burn out the yerba in its near vicinity, which will provide enough insulation to allow it to start heating up the inner chamber and burn out the yerba there. The ball clay I was using really needs to be sintered at 1020° to reach full strength, but full strength may not be necessary for this application. The yerba should eventually burn to charcoal at even 250° or 300°, which is probably adequate insulation.

It would be nice to prevent the yerba from stinking before the

thing is dry, and maybe a small amount of copper sulfate or something would work as a biocide for this. This depends in part on how tolerant the neighbors are, though.

Nickel-plating the steel pipe might extend its life — steel doesn't melt until at least 1130° and usually 1300° or more, and pure iron won't melt until 1492° (and the mild steel we can most easily get will be close to that), but iron or steel in direct contact with air oxidizes rapidly above 200° or so. Nickel-plating isn't totally trivial (nickel salts are fairly toxic) but can be done successfully with nothing more than salt, vinegar, and electricity.

Induction heating

Rudnev et al.'s *Handbook of Induction Heating, 2nd Ed.* explains that it's possible to heat pretty much any metal (and also graphite) by induction heating, but there are significant differences; in particular, ferromagnetic metals have a much thinner skin depth δ in which the heat is deposited than non-ferromagnetic metals. For good heat transfer, the metal must be thick enough to be "electromagnetically thick" (p. 65), at least six times the skin depth δ.

This is substantially complicated when you are heating steel, because its skin depth increases by about a factor of 15 when it passes its Curie point (p. 64), which is around 720–770°, and also because the skin depth in ferromagnetic materials depends on the the magnetic permeability of the material, which is not constant but varies with the magnetic field intensity — perhaps $300\mu_0$ at room temperature and low fields, it may drop to $150\mu_0$ at room temperature and 20% of the saturation field intensity (Fig. 3.10, p. 60).

Now, in theory, we might not have to worry about this, because we don't really care where the heat gets deposited inside the kiln; it will eventually conduct to where it's needed. But at 60 Hz the skin depth in SAE 1040 steel is already 2.5 mm at low field intensity (Table 3.5 on p. 64). Six times that (to be "electromagnetically thick" and absorb nearly all the field) would be 15 mm, and 15 times *that* (when we pass 700°) would be 225 mm. Since I think it's going to be hard to find or work with steel pipes that are more than 5 mm thick, it's probably worthwhile to use a higher frequency; if we want a skin depth of a 90th of 5 mm, we need 100 kHz (0.06 mm in SAE 1040 at 10 A/mm and 21°, according to the same table).

(However, the penetration depth scales as the square root of the frequency, and the power delivered scales as a negative exponential of the number of skin depths, so even two or three skin depths would already be pretty good, so lower frequencies might be adequate. Probably not powerline 50 Hz, though.)

On p. 97 et seq. we have expressions for the electrical efficiency η_{el} and related quantities. It points out that you have losses from the resistance of the coil itself and losses from heating up nearby random metal objects, and it gives this approximate formula for heating a solid cylinder in an electromagnetically long solenoid coil made from electromagnetically thick copper tubing:

$$\eta_{el} = 1/(1 + (D'_1/D'_2)\sqrt{(\rho_1/(\mu_r\rho_2))})$$

Here D'_1 and D'_2 are the inside diameter of the coil and the outside diameter of the cylinder, offset by their respective skin thicknesses, and ρ_1 and ρ_2 are their respective resistivities.

Now, the pipe isn't a solid cylinder, and the coil here isn't electromagnetically long or electromagnetically thick, but let's assume that the situation is close enough. We have the major disadvantage of having 82 mm of refractory between the coil and the pipe, so $D'_1/D'_2 \approx 2.1$, which would give us $\eta_{el} \approx 0.3$ absent other considerations; but our resistivity ratio ρ_1/ρ_2 is about $0.017\mu\Omega m/0.16\mu\Omega m \approx 0.1$ (Table 3.1, p. 54), and, at least at first, the μ_r of the steel pipe ≈ 300, so our $\sqrt{(\rho_1/(\mu_r\rho_2))} \approx \sqrt{(0.1/300)} = \sqrt{.00033} = 0.018$, so $\eta_{el} \approx 1/(1 + 2.1 \cdot 0.018) \approx 96\%$, though it might decline to 83% as the steel heats up and stops being ferromagnetic. On the other hand, the hotter steel will be even more resistive, so the situation might improve.

An interesting thing about this equation is that it doesn't include any explicit dependence on the number of turns or the current, except indirectly through the lower μ_r that comes with a higher field. I don't yet understand what the implications of more or less turns are, except that more turns means more inductance and thus more impedance — easier to drive at low frequencies, harder to drive at high frequencies.

Electronics

Suppose we decide on 20 kHz and 50 V as being relatively friendly numbers. To get 300 W out of 50 V we need 6 A, and thus about 8 Ω of impedance; with a 50% duty cycle we'd need 4 Ω. A MOSFET like the IRF540N (see My attempt to learn about jellybean electronic components (p. 1974)) should work well for this if we have a source for the 50 V, but it can handle 33 amps; maybe a more interesting approach is to drive the low-impedance induction coil through a step-up transformer, perhaps stepping up voltage 4:1 from 12 V to 48 V and stepping current down from 24 A to 6 A. Perhaps even a higher induction coil voltage could work.

Okay, but what does that imply about our coil? Presumably we want its inductance to be high enough that, if the pipe weren't conductive (maybe we replace it with laminated steel that blocks the eddy currents), it has a much higher impedance than 4 Ω at 20 kHz, maybe 40 Ω, and we want its dc *resistance* to be much lower than 4 Ω, maybe 0.2 Ω. AWG20 wire can reasonably carry 5 A and is 0.812 mm in diameter and 33 mΩ/m, so you could reasonably use 6 m of it to get 0.2 Ω, which would be just about 6 turns around the outside of the kiln; this would make it a sort of 6× stepdown transformer to the steel pipe, so you'd see 36× the resistance of the (skin depth of the) steel at the induction-coil terminals.

I'm going to hazard a guess, though, that even with 6000 mA going through it at 20 kHz, six turns of AWG20 wire isn't going to be able to induce detectable heating in a 5-mm-thick steel pipe, especially once it passes its Curie temperature. Let's suppose we're starting up and so our skin depth in the steel is 0.14 mm, and take that as a reasonable approximation of how much steel is actually on our one-turn transformer secondary dissipating the eddy currents (to avoid having to do the integral). So we have a strip of steel 140 μm thick, maybe 50 mm wide (half the height of the inner chamber), and 470 mm in circumference, with steel's resistivity of 0.16 μΩm. This comes out to 10.7 milliohms, so with only a 36× boost from the 6:1 turns ratio, we're still at only 0.39 Ω. So if we want to use only 50 volts ac on the inductor to heat up the steel, we are going to need

more turns.

Not as many more turns as you'd think, though — only about 19 turns, 18.7 m of wire, for which we need less than 20 mΩ/m to hit 0.2 Ω, thus AWG17 or bigger. But that's for heating up the cold steel. Once it warms up and the skin depth increases 15×, we'll need more turns to hit the same resistance — though at 700° carbon steel's resistivity has climbed from 0.16 μΩm to about 1.1 μΩm, so only 2½× more turns. These extra turns would be detrimental at lower temperatures if we're using a constant-voltage power supply, since the higher impedance means lower current and thus lower power, but maybe it's best to optimize for low power at low temperatures, where heat leakage is low, and high power at high temperature, so 40 or 60 turns might be worthwhile. 60 turns is 59 m of wire, so to keep the resistance below 0.2 Ω, we need 3.4 mΩ/m, so AWG10 (2.6-mm diameter) or less.

(Alternatively you could complicate things and use two separate coils or a variable frequency.)

So at startup we have 10.7 mΩ in the skin layer of the steel, which looks like a 39 Ω resistance in the 60 turns of the winding at ac, although their dc resistance is 0.2 Ω. We're putting 50 volts across it, although it's really only 25 volts rms (a square wave has the same p-t-p and rms), so we drive 640 mA rms through the winding, producing 16 W, 99.5% of which gets dissipated in the steel inside the kiln. So maybe 60 turns is going a bit overboard with favoring the higher temperatures, or maybe I calculated something wrong; the power is low by a factor of 20.

Let's try 30 turns: now we see 9.6 Ω in the winding at ac, so we drive 2.6 A rms through the winding — 65 W, which is probably reasonable. If the skin depth increases so that we're using all 5 mm of thickness of the steel, its resistance would drop to 0.3 mΩ, except that the compensating resistivity increase gets us to 2 mΩ or so, which looks like 1.8 Ω in the winding at ac, thus 28 A rms (!!) and 1400 W (!!!) of which 10% is dissipated in the winding itself if it's still 0.2 Ω (!!!!).

(Hmm, I think I'm still calculating something wrong, because the eddy-current EMF should be 30·50 V = 1500 V both when it's cold and when it's hot, so V^2/R should only increase by a factor of 5.3, not 22.)

So we probably need to take some kind of measure against that. Just using thinner steel might help some, but increasing the frequency is another possibility. Also, you could adjust the duty cycle.

The leakage inductance of the coil presumably also imposes significant high-frequency reactance, which will limit the current you can push into it.

(Because of skin effect, it might be necessary to use thinner wire, perhaps two or more parallel windings.)

(15× may be understating it — this skin depth is atypically shallow because we're using an atypically weak field and thus have atypically high permeability, so we will have an atypically extreme increase in skin depth when we smash into Curie.)

Scaling laws

What scaling laws govern the dimensions of such a kiln?

Well, at a fixed inner volume, the necessary wall thickness is

inversely proportional to the power. So if we could increase the power from 300 W to 600 W, we could use 41 mm of refractory instead of 82 mm of refractory, reducing the weight of the thing by more than half and its volume by a third. Voltages and currents would increase. Lower powers would require using proportionally thicker walls (and, perhaps, proportionally smaller inner chambers) which would eventually make the pipe too short to pick up much current.

The inner volume is proportional to the cube of the characteristic dimension, and the leakage surface area to its square. So, for example, a 10% increase in width, height, and depth would increase leakage surface by 21% and volume by 33%. Maintaining the same power would thus require increasing the wall thickness by that same 21%, which very quickly gets us to absurd dimensions. It might be more reasonable to increase the wall thickness proportionally (by 10%) and the power proportionally (by 10%) as well.

Electrical efficiency η_{el} stays the same as long as the wall thickness and inner diameter increase proportionally. Using the proportionally thicker metal we could accommodate more easily in a larger chamber would permit proportionally lower frequencies due to proportionally thicker skin depths.

So a small prototype, like the sake-cup-sized thing suggested in An electric furnace the size of a sake cup (p. 666), might be a good thing to start with.

Flying spot reilluminatable stage

Kragen Javier Sitaker, 2017-05-15 (1 minute)

One of the key cost drivers in television filming today is the single-camera technique, in which each scene is filmed several times with a single camera in different camera angles, in order to get the lighting optimal.

You can use a flying-spot camera to do much of this in a single shot using multiple photosensors, each one corresponding to a different virtual light source, all filmed from the point of view of the flying-spot illumination source. This allows you to make a weighted sum of the signals from the various light sensors after the fact in order to compute a version of the scene with the proper "lighting".

This doesn't allow you to change camera angles (without multiple flying-spot sources and the attendant difficulties with higher-speed signals), but in many cases all that is needed is to crop a higher-resolution shot down to the area of interest.

The standard approach since the 1950s to making flying-spot stages livable for the actors is to illuminate them during the vertical blanking interval with a strobe light.

Barcode receipts

Kragen Javier Sitaker, 2007 to 2009 (6 minutes)

So it's kind of a pain to track my supermarket purchases, in part because the receipt isn't really machine-readable. The store often has all the data in machine-readable form in their cash register; could they give it to me in machine-readable form?

It's Technically Feasible, Inexpensively

The bare minimum information for the receipt would be a little bit of header information (store location, date and time, currency of transaction), and for each item on the receipt, a UPC code, a quantity, and a price. UPC codes seem to be 13 digits (abbreviatable to 8), quantities are usually either three digits (of weight) or one (of units), and prices are usually two to four digits, including price. You could prefix prices and quantities with a length digit or terminated them with a non-digit code (say, if you're using BCD). (Say you bought 2.30 kilograms of avocados for $12.40; the quantity-and-price field would then read 323041240, and the UPC number would have to indicate that the unit of measure was 10 grams). In this scheme, quantity 1 would be represented as "11"; you could special-case that as "0".

So the typical item would have five digits of price and quantity data, for a total of 18 self-delimiting decimal digits. In BCD that would be 72 bits, or 9 bytes. The per-receipt header might be 30 bytes. So a 30-item receipt might be 300 bytes. (In binary instead of BCD, you would need about 60 bits per item, but that's probably not worth the extra complexity.)

PDF-417 stacked barcodes hold up to 1108 bytes of binary data per symbol; DataMatrix/Semacode holds up to 1556 bytes per symbol; QR Code holds up to 2953 bytes per symbol (at 177x177 pixels, which is about one-third redundancy). So 300 bytes is small enough that you could print a small barcode directly on the receipt, probably even with old dot-matrix receipt printers, given appropriate driver software.

Minimally, with 1-bit pixels, you'd need 2400 pixels to represent 300 bytes, which is about 50x50 pixels. In traditional 5x9 dot-matrix fonts, that's less than 54 characters. I don't know if existing barcodes are sufficiently robust against the kinds of errors dot-matrix printers add (round dots, row-to-row misregistration) but there's plenty of headroom here for error correction. I vaguely seem to remember one of the matrix barcode systems recommending printing each pixel of the barcode symbol with at least 4x4 of the underlying pixels, so with that and the redundancy, you might need 16 * 4/3 * 300 * 8 = 51200 dot-matrix dots, 226 pixels square, or 1137 5x9 character cells. By my count, my latest dot-matrix receipt is 34 characters wide, so that would be 33 lines. On the face of it that sounds like an impracticably large amount to add to a 30-item receipt, but I've seen much worse, so it might already be reasonable. But you could presumably design a "barcode" whose overhead was close to a factor of 1.33 instead of a factor of 21, and then you'd be down to 72 characters instead of 1137, which obviously adds only a trivial amount of cost to the receipt.

So you could use a less obtuse data format, too, instead of the horrible all-decimal format suggested above, where "323041240" means "2.30kg $12.40".

How Could It Be Bootstrapped?

It may seem a little impractical to expect supermarkets and the like to upgrade their cash-register systems for the convenience of customers who want to itemize all their grocery purchases, which is something hardly any of them do. But here's a slightly plausible deployment path.

A few people, some of the time, have to itemize all their purchases and turn in receipts: businessmen, academics, and NGO workers on travel on expense accounts, mostly. They already do this even though it's a pain, and a lot of them do it when they're on travel without their secretaries. A lot of them would be delighted to avoid the hassle.

So if a major retailer of some expense-account-able commodity announced this kind of barcoded-receipt program and shipped free software to import your receipts into a few of the most popular ways of tracking expense accounts, it would attract these travelers. Maybe Ruth's Chris, or Avis, or Hyatt, or toward the lower end of the market, maybe T.G.I.Friday's, Chili's, Days Inn, and the like.

It would have to offer some substantial advantage over monthly credit-card bills to get adopted, since that's what a lot of these folks use now. I have a couple of ideas: - It costs the receipt issuer much less to print a barcoded receipt than to process a credit-card transaction, so small-transaction merchants who aren't willing to accept credit cards could therefore become expense-account options. - Issuing a company credit card to someone puts the company at some financial risk, and perhaps for this reason, academics on travel and workers for small NGOs rarely use company credit cards. Accepting barcoded receipt entries does not entail any extra risk to the company. - Credit-card bills lose any convenience advantage when only part of a purchase is expensable.

Similarly, self-employed USians who deduct business expenses on their federal tax returns are obligated to itemize those business expenses: travel expenses, raw materials, equipment, and the like. This suggests a broader group of retailers: Home Depot, OfficeMax, CompUSA, Best Buy, Kinko's, Ace Hardware, FedEx, Ikea, the Gap, Borders.

Once the receipt-importing software was out there, other companies could compete for these customers by barcoding their receipts too, if the software to do so is relatively easily available.

The path from Hyatt to Carrefour is pretty dubious, though. So is there anyone already in a position of routinely itemizing their supermarket purchases? Maybe servants who go grocery shopping for their masters?

Thanks

To Beatrice, for very helpful discussions on the subject.

Caching screen contents

Kragen Javier Sitaker, 2017-06-14 (2 minutes)

Suppose I have a 1920×1080 screen that doesn't always update, and I'd like to cache tiles of it. I could do it with quadtrees (11 levels down to the pixel level, or 7 levels down to the traditional 16×16 tile size) or I could do it by simply dividing the screen into a flat grid of tiles — tiles of 64×64 pixels, say, dividing the screen into a 30×17 grid.

Then, to redraw the screen in a kind of RESTful system, I could make 510 requests to a tile-rendering service, providing it with information about what was on the screen. For many uses, it would be okay for these requests to take too long for the screen to fully update in a single frame time. You could imagine a usable system, for example, where each 16.7ms frame only has time to refetch 50 of the tiles: 340μs to merely revalidate the cache of a tile.

(As a point of comparison, httpdito on my laptop takes about 50 μs per HTTP request, which would be not quite enough to redraw the screen.)

This would suck for watching a movie or mouse tracking, though, since you'd have randomly 0–100 ms of latency (0–6 frames) for screen updates, making your mouse pointer jitter all over the fucking place, making movies unwatchable, and making real-time games utterly unplayable. But if you have some kind of cache invalidation protocol that eagerly recalculates the tiles that have actually changed, you could reliably keep your latency to a fraction of a frame and track the mouse accurately.

Suppose we can improve somewhat on httpdito by using a binary protocol and not forking and accepting new connections and get down to 10 μs per request. (0MQ can normally handle messages in under 1 μs.)

Bitsliced operations with a hypercube of shuffle operations

Kragen Javier Sitaker, 2016-11-30 (2 minutes)

Doing bit-parallel operations with bit-parallel instructions on big bitvectors is a useful way to do computations with very high efficiency when you have enough independent computations. Bringing together bits from different bitplanes requires some kind of bit-shuffling or transposition operations, but the question remains which of the involute number of possible permutations should be provided. For example, if each of the 64 bits of a 64-bit output word can be a copy of any of the 64 bits of the input word, there are 64^{64} possible operations; specifying one of them would require 384 bits.

In essence this is a new face of the "topomania" problem faced in parallel computer design in the 1980s and early 1990s, with bit positions in all the register taking the role of processors. The typical early solution was a hypercube topology, in which, say, a 1024-processor CM-1 would have 10 communication links per processor.

This seems like a perfectly adequate solution to me. Given a 256-bit register, 16 bit-shuffling operations suffice to construct a useful hypercube:

```
rot(0) exchanges even and odd bits, taking ...ABCDEFGH to ...BADCFEHG
rot(1) exchanges even and odd bitpairs: ...ABCDEFGH → ...CDABGHEF
rot(2) exchanges even and odd nibbles: ...ABCDEFGH → ...EFGHABCD
rot(3) exchanges even and odd bytes;
rot(4) exchanges even and odd wydes;
rot(5) exchanges even and odd 32-bit words;
rot(6) exchanges even and odd 64-bit words;
rot(7) exchanges the two 128-bit halves of the register.
```

To these rot(n) operations we add copy(n) operations which discard half of the bits (say, the high half) instead of exchanging them:

```
copy(0): ...ABCDEFGH → ...BBDDFFHH
copy(1): ...ABCDEFGH → ...CDCDGHGH
copy(2): ...ABCDEFGH → ...EFGHEFGH
```

etc.

It's not very important, I think, which direction the copy operations copy; copy(n) ∘ rot(n) will copy in the other direction instead.

I think this provides adequate routing facilities for many aggregate computations. Together with an analogous set of instructions for filling registers with index bit patterns (…10101010, …11001100, …11110000, …) it should enable fairly general and efficient bit-sliced programming.

Gardening machines

Kragen Javier Sitaker, 2019-04-02 (updated 2019-04-24) (32 minutes)

Exponential rosemary accounting

I have a couple of small potted rosemary bushes on my balcony, with a third that I'm trying to coax to grow out some roots in a cup of water inside. All three of these grew from a cutting Beatrice's husband Santiago gave me when he and Beatrice moved to Holland late last year; I have perhaps quintupled his investment in me in five months, if we measure in rosemary biomass. If I can continue this rate of exponential growth for the rest of the year, by way of judicious propagation, in 7 more months I will have multiplied my current rosemary holdings by a factor of 10, a factor of 50 for the whole year, a 4900% internal rate of return on this project, a doubling time of about 66 days.

Of course, we don't usually account for agriculture this way. And I probably won't actually have 20 rosemary bushes in August, nor four rosemary bushes each five times the size of the ones I have. The exponential growth of the plants will eventually outstrip my balcony space, pots, and watering time; if I don't attend to them, they may die of dehydration, but also, they face other dangers which themselves grow exponentially: they may be choked out by faster-growing weeds, or they may suffer attacks by insects, fungus, or root nematodes. In any case, the last five months have been summer months, with temperatures around 25°, while the next few months will be winter months, with temperatures around 15°, so the Arrhenius law predicts that the plants will grow about half as fast. Ultimately, the limiting factor for my rosemary production will probably not be the capital equipment of rosemary plants, nor my labor or mineral resources, but the energy I have available: rosemary will not grow in the dark.

I also have an Aloe vera plant I found discarded in a gutter, which has rooted nicely after a few weeks of early failure, and another aloe that was a gift from my girlfriend Alejandra. In a third pot, I'm trying to root a leaf I accidentally knocked off the gutter plant. The aloe plants, too, are growing exponentially, though apparently at a slower rate.

Although these growth processes are exponential, they are also slow. Even on the rosemary plants, the difference from one day to the next is very hard to see; calculation suggests that it averages about 1%. Several days can go by without a noticeable change.

(Post scriptum: the above was written 2019-03-26. The cutting finally grew out roots (one root of 15mm and two roots of 5mm) on 2019-04-02, one week later. I'm not sure how long the whole rooting process took, since I'm not sure when I made the cutting, but it must have been a couple of weeks or so. As of 2019-04-05, the roots had increased to seven in number, including a tiny fork from one of the oldest ones, which itself had lengthened to some 40mm; this quantity of daily root growth is also on the order of 1% of the volume of the cutting per day, which is some 150 mm long. On 2019-04-07, the root tips had increased to, I think, 20 in number; on

2019-04-08 a root had sprouted from a node higher up the stem as well, though now I count only 15 tips.)

Ruderals

Rosemary and aloe are perennial plants adapted to somewhat harsh conditions: their ecological niche does not demand that they grow especially fast or reproduce abundantly, but rather that they successfully survive a variety of temporary adversities. Ruderal annual plants, on the other hand, survive by growing rapidly in soils that have been rendered temporarily plantless by plowing or some other catastrophe, ending their lives in a riotous explosion of sex called "going to seed"; the champion among cultivated ruderal annuals is corn ("maize"), which can grow several millimeters per day. Each corn plant — a corn kernel's way of making more corn kernels — normally produces several ears of corn, each bearing 200 to 400 kernels, in a single growing season, which normally only occurs once per year. But this means that a single kernel of corn can multiply into several thousand kernels within a year, not just the factor of 50 or so I'm estimating for the rosemary.

This means that corn's rate of capital growth is on the order of 100,000% per year.

Yogurt bacteria

I'm eating a small jar of yogurt I made the night before last. In the refrigerator right now I have another liter or so of it. The yogurt, like poop, consists mostly of dead bacteria, in this case mostly Streptococcus salivarius subspecies thermophilus and Lactobacillus delbrueckii subspecies bulgaricus, mixed with chemicals the bacteria couldn't digest, mainly a casein gel in this case (though the bacteria do digest some of the protein), and bacterial waste chemicals such as lactic acid and acetaldehyde. The jar contained perhaps 100 mℓ of yogurt, which was made from about 200 mℓ of milk through about 24 hours of fermentation after being seeded with about 1 mℓ of living yogurt culture. The bacteria are, say, about three cubic microns each, and occupy over 50% of the yogurt volume, so I just ate tens of trillions of bacteria which I produced overnight from only hundreds of billions of bacteria.

Probably, under better-controlled conditions, I could have gotten the yogurt to finish in under 8 hours; most of the jars were already relatively thick after 12 hours, though some had not fermented at all — perhaps I had inoculated them with the starter culture when they were still too hot, so I added more starter culture to them at this point. The 24-hour timescale suggests an average rate of bacterial reproduction of, conservatively, about 20% per hour, which amounts to doubling every three or four hours.

(More aggressive bacterial cultures like Escherichia coli can reproduce much faster, doubling every half-hour or so under ideal conditions, around 37° with all the nutrients it needs.)

Doubling every four hours would give you 2191.4 doublings per year, which works out to a multiplication by about 4.8×10^{651}. But only about 1×10^{98} of these yogurt bacteria would fit into the observable universe. So if these yogurt bacteria were to double 325 times, which would take less than two months at four hours per doubling, they would fill the observable universe, out to the farthest

galaxies and quasars. After about the first month, the yogurt sphere would have to be expanding outward faster than the speed of light, which is probably impossible. Even if you could find a way to defeat relativity, where would you get the milk?

Flour beetles

Some time ago I was the proud owner of a number of confused flour beetles. Confused flour beetles are marvelous little self-reproducing automata, about three millimeters long, which can acquire sufficient water by metabolizing the dry flour they eat to survive and reproduce, although if the flour is very dry, they reproduce more slowly. They can also survive a thousand grays of radioactivity (in about 10% of cases) and thus probably more than a thousand sieverts, more than cockroaches can. Five grays will usually kill a person; radiation therapy usually kills tumors with 20–80 grays. Confused flour beetles are commonly raised for use as laboratory animals, particularly in studies of genetics.

I didn't measure the rate of growth of my capital holdings of confused flour beetles, but Wikipedia's marvelous "Home Stored Product Entomology" article tells me that a female flour beetle can lay 300–400 eggs over a 5–8 month lifetime. So a mating pair of beetles can produce, conservatively, 150 mating pairs of beetles in 8 months, which amounts to a doubling time of 34 days, once exponential growth kicks in after an initial linear ramp-up period, and a multiplication factor of some 1800 per year, a return on investment of 180,000% per annum — nothing like the universe-consuming rate of growth of yogurt, but comparable to that of corn.

Rather than submitting my fortune to appraisal by counting my flour beetles, I took them, the grain they were eating, and the basket they were eating it in, and threw them all together into a dumpster, in hopes that they would cease their self-reproducing in my house. Thus I preserved my holdings of flour, beans, and other grains. This is because I could not program the beetles; they came preprogrammed from an optimization process which did not, for instance, offer me a quiescent mode in which a stock of flour beetles I already judged as more than sufficient would cease to increase, nor a practical way to employ the beetles to construct mosaics, murals, or sculptures directed by an STL file.

So far this measure has apparently been successful, though I live in fear of the beetles' return. Every new bag of flour I get spends some time in my freezer to kill any insects inside.

Mere capitalism

Capitalism, of course, is based on the exponential growth of productively employed capital. Wikipedia clarifies the terminology thus:

> In economics, "capital", "capital goods", or "real capital" refers to already-produced durable goods used in production of goods and services. The capital goods are not significantly consumed, though they may depreciate in the production process. "Capital" is distinct from "land" in that capital must itself be produced by human labor before it can be a factor of production. At any moment in time, total physical capital may be referred to as the "capital stock", a usage different from the same term applied to a business entity. In a fundamental sense, capital consists of any produced thing that can enhance a person's power to perform economically useful work — a stone or an arrow is capital for a caveman who can

use it as a hunting instrument, and roads are capital for inhabitants of a city. Capital is an input in the production function. Homes and personal autos are not capital but are instead durable goods because they are not used in a production effort.

The name "capital" refers originally to the heads of herds of livestock, which feature this same exponential growth through biological processes, except when limited by available feed. But, compared to an internal rate of return of 4900% or $4.8\% \times 10^{653}$, the traditional rates of return on capital investments, about 3%–10% per annum, seem fairly pitiful. The outrageous rates of exponential capital growth we see in gardening or herding invariably slam quickly into other resource limits: the sunshine on my balcony, for example, or the milk I have on hand to grow yogurt in, or the difficulty in controlling exponential-growth processes to produce the desired outcomes.

One of the rosemary plants, for example, has a blade of ruderal grass coming up in its pot. Grass is a relative of corn (more properly, corn is a sort of ruderal grass) and it grows much faster than the rosemary does. If I don't want a pot full of grass shading the rosemary, sooner or later I need to pluck out the weed. And this same rosemary plant had a close call with death when I was still rooting the cutting it in water: fungus started to grow on its bark, and if the process had continued, might have started to digest the living plant. I lowered the water level in its jar so that its bark could dry out, and the fungus disappeared and hasn't returned. This latest batch of yogurt all turned out without problems, but the previous batch had a couple of jars that grew some fungus after the bacteria, causing an off flavor.

Historically, the main determinant of power in agricultural and pastoral societies — those whose most important means of production grows by these insane exponential biological growth rates, rather than being human-designed machinery — has been control over land, particularly arable land. Landowners had power, and nobles and gentry were distinguished by their land holdings, not their wisdom, learning, machinery, or industry, nor even martial virtues like their honor and bravery, and certainly not by the amount of grain stored in their granaries. This was the rule in Europe from the time of the late Roman Republic, when Senators derived their income from the latifundia they owned, and of course in every feudal society too.

Consider, also, for example, Imperial China's 士 "shi"; until the Warring States Period they were noble-born charioteers. The 秦 "Qin" dynasty and its successor 汉 "Han", 隋 "Sui", 唐 "Tang", and 宋 "Song" dynasties needed to reduce the power held by the feudal nobility, for which purpose they established an empire-wide civil-service bureaucracy, redefined the 士 "shi" class to include it, and staffed it increasingly with commoner scholar-bureaucrats they hired according to their performance on 科举 standardized tests. But these scholar-bureaucrats also became agrarian landlords, and were generally landed gentry even before sitting for the examination.

Thus, even though Ricardo and Smith's classical economics was born at the moment and center of England's transition from such a feudal society to the new capitalist society, they do not consider plants or plant seeds to be capital, precisely because they multiply too rapidly for their scarcity to be a major limiting reagent in the production function in an economy with functioning agriculture. Only in

extreme cases, like when the Lykov family's millet crop was killed by a late frost, leaving them hungry until seven forgotten seeds sprouted the following year, or in Israel's destruction of generations-old olive trees in the Palestinian occupied territories, are we forced to confront the crucial nature of self-replicating automata to the economic production process. Under normal circumstances, they are either nonexistent or superabundant, and in either case their stock is not a relevant variable.

So, what will happen to human society when we develop programmable self-replicating robots that can work from inorganic feedstock? No longer will we measure the assets of a company by its stock of capital goods — indeed, apart from a few exceptions like railroads, it's been quite passé for a company's book value to be based on tangible assets like railroad cars since at least the 1980s, much less its market cap. Nobody would think to argue that Microsoft has a competitive advantage against software startup firms because Microsoft owns a lot of computers to produce software with, while the startups would have to buy them, though it seems reasonable to think that Ford, GM, and Chrysler had an edge over late-20th-century startup car firms because the Big Three already owned factories. (Tesla is the first successful automobile startup in the US in decades, although China's success at bringing new brands to market since 2005 suggests that US industrial policy has as much to do with the late-20th-century oligopoly in the US automotive market as raw economic factors did.)

But what happens when we can grow factories like rosemary plants, or even yogurt? How do we think about the effects on human society and future economic prospects?

Perhaps as we learn to garden programmable machines we will find ourselves thinking more in biological terms than in mechanical terms. We'll be constantly watching out for something or other going wrong, hoping to notice problems that could grow exponentially and stop them while they're small. We'll accept some degree of parasitism and predation on our production as the cost of having a system that works at all. We'll try to manipulate conditions to disfavor the growth of the elements we don't want, even at the cost of those we do — as I let the roots of my rosemary dry out a bit to get rid of the fungus on its bark. To a great extent, these sound like the skills of a turn-of-the-millennium business manager, drawing on the best of 20th-century management practice and Taoist practice.

Stability, size, durability, and repairs

Industrial-age machinery is prized in part by its stability, size, and durability; and it is repaired. But self-reproducing machinery need not work this way, and its logic will invert industrial-age logic in interesting ways.

Stability

A lathe which, left idle overnight, can no longer cut in the morning is hardly a lathe at all. Great efforts go into ensuring that form materials are dimensionally stable so that changes in humidity will not drive them out of tolerance. It is common for a machine left unused for decades to remain usable, perhaps with a few minor repairs.

But many bacteria will die if left without food for a few hours.

Suppose some strain can reproduce itself by a factor of a thousand in ten hours. A left-behind cell that lacked resources to reproduce itself during that time can only, at best, result in a single cell at the end of it. Even if it happens to fall back into the nutrient broth, its descendants will be outnumbered a thousandfold by those who multiplied the whole time. So, many such bacteria spend no resources on surviving lean times.

Similarly, a self-reproducing machine that requires continuous homeostatic control to remain viable, and "dies" irreversibly if that control fails for a significant length of time, may be a perfectly reasonable replicator. So stability is not necessary to self-replication if homeostasis can replace it.

Size

Machine size was the distinguishing feature of the mass-production era. A steam shovel that carried 100 tonnes per shovel-load would move rock 10 times as fast as a shovel that only carried 10 tonnes, and might require only 5 times as much material, and the same number of fabrication and assembly operations, though each handling pieces 5 times as big. Moreover, a 20-tonne rock could be moved by the 100-tonne shovel without being broken first. A bigger lathe could make bigger parts, and due to its greater rigidity and power, it could make the same parts faster and to tighter tolerances. So, bigger machines made more efficient use of material, tooling, and labor, and could do things smaller machines could not.

But replicators need not follow this logic. There is every reason to believe that a one-kilogram object can be built as easily by a thousand tiny replicators each processing a gram of material, followed by a final assembly, as by processing the kilogram in one operation with a large replicator. Indeed, it seems likely that the smaller replicators will work faster, working as they do in parallel. So the size pressure on replicators may indeed be opposite: toward the smallest practical dimension, to maximize flexibility.

Biological life certainly has followed this design. Despite the existence of large single-celled creatures like foraminifera and slime molds, and the occasional large cell like the squid's neuron with its giant axon, the typical size of a eukaryotic replicator — a cell — is close to a nanogram in complex organisms. You could argue that, for example, a human neuron is not a replicator because most of them die without ever producing a new neuron, and they are rather specialized to their climate-controlled environment; on the other hand, nearly all human neurons are produced by the replication through mitosis of a neuron, and they can be coaxed to grow and even replicate in vitro.

This composition from such a large number of quasi-independent replicators certainly has major disadvantages, including cancer, but it seems to have sufficient compensatory advantages that the cells of multicelled creatures are hardly ever big enough to see without a microscope. So we should expect artificial replicators to find significant advantages in smallness, as well.

Durability

Conventional machinery is considered better when it is durable. A lathe whose chuck or gears or ways wear out after a few hours of use is a very poor lathe. Often we go to great effort to improve the

durability of our machinery so that it can continue operating reliably for long periods of time, including measures such as jewel bearings in wristwatches, hardened steel gears, hardened steel calipers, all manner of bearings, and many others. One of the great benefits of vacuum tubes over relays in the history of computing was that they lasted for many more operations than relays did.

This industrial-age logic has come under assault by disposable products over the last few decades, with some degree of rationality: if money you invest has a 10% rate of return on investment, you can quite reasonably use a 9.1% discount rate to devalue the future use-value of your machinery. To be more concrete, suppose you spend US$1000 (of resources, energy, and labor) to build a machine that will last for 20 years. At the end of these 20 years, you will need to spend another US$1000 (inflation-adjusted, of course) to replace it. To be prepared for that eventuality, you can invest US$149 today into something productive, which will have grown to that US$1000 in 20 years. So if you had the option to extend the machine's life to 40 years by building it in a more expensive way that cost US$1200, it would be a poor economic choice. Indeed, by investing US$175 today, you can obtain enough investment income to replace the machine every 20 years for eternity; even increasing its lifetime to millennia for the extra US$200 cannot compete.

But replicators, as described above, have a rate of return many orders of magnitude greater than that of industrial-age capital. Their dynamics have a phase transition when they last long enough, on average, to produce more than one offspring: at 0.99 offspring before death, their population would gradually exponentially decrease, while at 1.01 offspring before death, it would gradually increase.

But suppose you have an autotrophic clanking replicator that can self-replicate in a week, and which lasts only three weeks before irreversibly failing. For the first week, you have one replicator; in the second week, you have it and the one it produced during the first week, each producing a child replicator. In the third week, you have four replicators, each producing a twin, but at the end of this week, your original replicator dies, so you have seven replicators in the fourth week; they produce seven new replicators, but the two oldest die, so you have 12; and so the process continues, with 20, 33, 54, and so on, with an exponential growth rate of $\varphi \approx 1.618$, the golden ratio, per week.

This means that, once you have reached an adequate population of replicators, you can use $\varphi - 1 \approx 61.8\%$ of the total to produce non-replicator products, while the remaining 38% are occupied with replacing the dying replicators. This 38% is the "overhead cost" of this limited durability; if some redesign would extend the replicator's lifespan to dozens or hundreds of offspring, it would increase the end-product productivity of the replicator "biomass" only by eliminating up to that 38%, working out to a 61.8% improvement.

The same logic applies regardless of the generation time: if your replicator needs an hour to self-replicate and dies after three hours, you still have a growth rate of 61.8% per generation. Three hours is a very poor lifetime for conventional industrial machinery; industrial products that are consumed this quickly, such as arc-welding electrodes and TIG-welding cups, are categorized as "consumables" rather than machinery.

Steel cutting as an example

As a specific example, suppose one of the cycles in our clanking replicator's fabrication process graph cuts steel.

The standard industrial process for this nowadays cuts the steel ceramic inserts made of tungsten carbide cemented with cobalt, pressed to shape in molds.

The previous standard industrial process for this, still in use in places, used a special "high-speed" steel alloy, sufficiently harder at high temperatures than ordinary steel to cut it rapidly and last a long time, cut to shape by abrasive grinding with a grinding wheel. The grinding wheel was made of, for example, crystals aluminum oxide or silicon carbide cemented with, for example, magnesium oxychloride, cast into the shape of a grinding wheel, and then trimmed to an accurately circular shape using star wheels, made of hardened steel. (Older grinding wheels might have been cut from stone.)

The process before that used cutting tools made from high-carbon steel, annealed and cut to shape using either steel tools or a grinding wheel, and then heat-treated to harden them.

The ancient process used cutting tools made from wrought iron, hot-forged, then cut to final shape using either hardened steel tools or a grinding wheel, and then case-hardened to harden them.

But abrasive cutting with, for example, a grinding wheel or abrasive sawblade, works fine for cutting steel. It's often used for cleaning up after welds, where it easily copes with oxide deposits, and it's often used as the most expedient alternative at construction sites. It's also used, in the form of "surface grinding", to cut surfaces more accurate than those that can be cut with steel tools, due to lower temperatures and deflection forces. The litany of other steel-cutting tools described above is purely a result of optimizing the cutting process; a high-speed steel or especially ceramic tool can cut much deeper into the workpiece with each cut than the microscopic spark removed by a grain of abrasive, and it also lasts much longer. Even the use of super-hard abrasives like silicon carbide and aluminum oxide is an optimization to cut faster and wear slower.

A clanking replicator might quite reasonably use only abrasive cutting or only case-hardening, thus dramatically shortening the time per generation by reducing the number of processes in the cycle; and, in the abrasive case, it might quite reasonably use only low-grade abrasives barely hard enough to cut the steel, such as quartz, soda-lime glass, feldspar (orthoclase feldspar being the defining mineral of Mohs hardness 6) or even apatite (Mohs hardness 5). Glass is especially promising here because of its isotropy, low-temperature thermoplasticity, and lack of need of time for crystallization.

This example also illustrates why small size could be a big advantage: the diffusion process of case-hardening, the crystallization processes of the crystalline abrasives, and the heating and cooling processes of a mass of glass all take time proportional to the characteristic dimension of the thing. So a replicator of one centimeter in diameter could reproduce its steel-cutting tools, all other things being equal, in one hundredth the time of a replicator of one meter in diameter.

Repairs

When my bicycle malfunctions, I debug it; I compare my mental

model of the ideal bicycle to the actual observed bicycle to discover where the reality departs from the ideal, meanwhile updating my conception of the ideal in accordance with the things I learn from the observed bicycle, and modifying the observed bicycle with wrenches to sharpen my observations. Once I have found the root cause of the problem — a spalled bearing ball, for example — I repair the bicycle, reconstructing the deviant parts in accordance with the ideal, perhaps an ideal I have improvised in the moment rather than my original conception. For example, when the derailleur bent irreparably, I removed it and shortened the chain, converting it into a fixed-gear bicycle for the time being.

In this way, my behavior provides the bicycle with the homeostatic processes it needs to continue working, which it is too simple to provide for itself.

When my rosemary malfunctions, I usually do not repair it; usually the malfunctioning part dies on its own, but sometimes I prune it. Self-replication takes care of replacing the damaged rosemary more easily than figuring out that, for example, some xylem channels are blocked in this branch due to excessive bark growth on the inside of a tight bend compressing the inner bark, and carrying out microsurgery to widen the xylem channels. The same kind of process usually handles malfunctions in my own body, and it will apply to autotrophic mechanical replicators as well: it will commonly be more practical to recycle broken replicators than to repair them.

However, this is not the case for "malfunctions" that happen so frequently that they would reduce machine fertility below the replacement rate; those must be repaired by either internal or external homeostatic processes, such as a dude with a wrench. In the initial stages of replicator bootstrapping, we can expect to have to repair many faults manually at first, until we have improved the replicators to intervention-free replacement-level fertility.

Also, malfunctions that affect the overall system of replicators, rather than an individual replicator, require a different approach. If the rosemary comes under attack from caterpillars, pruning it may not be adequate — the caterpillars will just eat the healthy part I didn't prune. Malfunctions that are themselves replicators, such as viruses, parasites, and cancer, may be able to outrun mere apoptosis-based approaches. Debugging such system problems promises to remain as challenging as in gardening, and presumably the future of humanity will be decided in this way, as different people or groups struggle for the power to program replicator populations.

Rhythm codes

Kragen Javier Sitaker, 2015-09-03 (4 minutes)

Suppose your codeword is a common-time measure; the symbols available for use within it are a quarter-note, two eighth notes, and a rest; you're using two pitches simultaneously, separated by a perfect fifth; the first beat, for timing, cannot be two rests or two eighth notes, nor can the second beat be two rests; and if only one of the pitches appears in the measure, it must be the low one (since without hearing the other one, it's hard to guess whether it's meant to be the low one or the high one). How many possible codewords do you have?

Well, a normal beat (the third or fourth) has 9 possibilities available. The first beat can be 7 of those 9 possibilities, and the second can be 8 of them. That gives us $7 \cdot 8 \cdot 9 \cdot 9 = 4536$ possibilities, but of these, a few have only rests at the lower pitch: $2 \cdot 2 \cdot 3 \cdot 3 = 36$. So the total number of these very simple biphonic melodies is 4500, so each one can encode just over 12 bits, which is roughly a single English word, depending on how sophisticated a model you use to measure the entropy.

I chose a perfect fifth because, although the two pitches are assonant, their harmonics will be largely distinct, potentially enabling decoding even if large swaths of the spectrum are lost. The fundamentals of the two of them are the second and third harmonic of a fundamental an octave below the lower pitch, and so the divisible-by-three harmonics of the low note will be the even harmonics of the high note. This means that half of the harmonics of the high note will not be found in the low note's harmonics, and two thirds of the low note's harmonics will not be found in the harmonics of the high note.

If, for example, we choose 220Hz (A, I don't know, is that A below middle C?) for the low note, then 330Hz (E?) will be the high note. The 220Hz note has about 68 harmonics in the easily-human-audible range, of which 46 are not among the harmonics of E; and E has 46 harmonics in the easily-human-audible range, of which 23 are not among the harmonics of A. You should be able to distinguish between these notes by finding the 9.09ms-lag autocorrelation peak and comparing it to the 4.55ms-lag one and the 3.03ms-lag one (they should be higher if there is a note there and lower if there isn't?), and that should work even if big parts of the spectrum (including the fundamentals) are strongly suppressed. And you should be able to find the note onset by differentiating these autocorrelations over time.

If you play the melody at 180bpm, which is pretty durn fast for music, you will get through one measure every 1333ms, for a total of 9 bits per second. This is slower than people talk, so people might be able to learn it. Your eighth notes will run for 167ms each, which is about 37 cycles of A's fundamental, which is plenty.

A 30ms window is 1323 samples at 44.1kHz, and brute-forcing its ACF is thus about 0.9 million multiplications, which seems like a lot. A 1024-sample Fourier transform should be something like 0.02 million, and you can derive the ACF by DFT | take magnitude |

DFT. But if you're only looking to compare autocorrelation at three particular lags, you can do that much more simply, with only three multiply-accumulates per sample and without explicit windowing.

(A thought here for pitch tracking: if you're trying to track a changing pitch using autocorrelation, maybe you could hill-climbingly adjust a pair of lags bracketing the true frequency, like nostrils, and get by with only two multiply-accumulates per sample? That's maybe cheaper even than the Goertzel algorithm or a software PLL, although it does require a multiply.)

Balcony battery

Kragen Javier Sitaker, 2019-02-11 (updated 2019-12-06) (6 minutes)

It's summer in Buenos Aires, and of course that means we have regular power outages, during which not even the electric fans work. I now have an apartment with a two-meter balcony; I could definitely put a bench on it. And the bench could have marine deep-cycle batteries in it. To be comfortable to sit on, it should have 500 mm from the floor to the seat height; it could be, say, 1750 mm long; and it could probably productively be 500 mm wide, too. (I could add backrests if that's too wide for comfortable sitting, but I think it may actually be a bit scanty.)

A properly designed bench could conceal a lead-acid battery bank within it, and its placement on the balcony could provide it with good ventilation to prevent hydrogen buildup, as well as safe drainage in the case of a containment failure. If we have 50 mm on each face of the cuboid devoted to supports and the like, we still have 400 mm × 400 mm × 1650 mm. A 1650 mm × 400 mm bottom area is ⅔m². A typical car battery (BCI group 58, 58R, or 59) might be 255 mm × 183 mm × 177 mm high, occupying a base area of 0.0467 m², 14 times smaller. In practice I think you'd have to line the batteries up inside a bench of this size in two rows of 6 batteries, with their long axis parallel to the bench's, so you'd only get 12 of them in there.

Let's be more specific, though: there is a large D-BAT DB180N 12V deep-cycle nautical battery which claims 12 V, 235 mm × 235 mm × 520 mm, and 180 amp-hours (7.8 MJ), for sale for AR$6500 (US$176). If you made the bench just a little wider, you could fit seven of these motherfuckers (US$1232, 54 MJ at US$23/MJ) in there: 520 mm × 1645 mm long.

Or, take a more typical car battery like a Bosch S4 55 D. It sells for AR$2799 (US$76) and is 12 V, 170 mm × 170 mm × 240 mm, and 65 amp-hours (2.8 MJ). If you put the batteries at right angles to the bench, you could get 18 of them (US$1368, 50.4 MJ at US$27/MJ) into a 480 mm × 1530 mm floor area. You'd probably be better off with a deep-cycle type and with fewer electrical connections to go wrong, but at least this shows that the pricing and energy density on the other battery are not too far off.

Amazon has a 35-amp-hour (1.51 MJ) deep cycle battery for US$110 (US$73/MJ) which is 127 mm × 167 mm × 196 mm and weighs, in archaic units, "25 pounds", which means 11.3 kg. This works out to an energy density (probably fairly invariant for lead-acid batteries) of 133 kJ/kg, so a 50-MJ setup like those described above should weigh about 370 kg.

So with 50 megajoules in your pocket, so to speak, how long could you run things?

This laptop is using 9 watts. It would drain the battery pack in 1500 hours. It would drain a single 2.8 MJ car battery in 86 hours. That's a pretty long power outage.

There are little 3-watt USB fans, but a strong electric fan might be 75 watts. It would drain the large battery pack in 185 hours (almost 8 days) or a single 2.8 MJ car battery in 10 hours.

If you were willing to limit your total power drain to, say, 250

watts, you could hook up the batteries internally with fuse wire to get some added safety against electrical faults. If you put the seven deep-cycle batteries in series to get 84 volts, 250 watts would be just over three amps; you could use four-amp or five-amp fuse wire, which would be about AWG28 (0.32 mm) for iron wire, AWG24 (0.51 mm) for tin wire, AWG33 (0.180 mm; hard to find!) for aluminum wire (also hard to find), or AWG35 (0.142 mm) for copper wire.

For the limited but extremely important use of cooling things to 0° or above, a potentially better approach is to bank cool in the form of ice rather than batteries. 370 kg of batteries holds 50 MJ of energy, which can remove about 100 MJ of heat from your house. By contrast, 370 kg of ice with its enthalpy of fusion of 333 kJ/kg can remove about 123 MJ. Moreover, water costs several orders of magnitude less than batteries do, kilogram for kilogram; it's just a matter of the refrigerative apparatus to freeze it with and then, possibly, some kind of automated ice-cube handling apparatus to allow you to handle large quantities of ice without running delicate pipes through all of it. But the crossover in cost probably isn't until a GJ or so.

(With 2 kW of sun streaming in through the window, 100 MJ is only 14 hours of cooling; surviving a week-long heat wave would require several times that.)

Lithium-ion batteries

BloombergNEF reports:

Shanghai and London, December 3, 2019 – Battery prices, which were above $1,100 per kilowatt-hour in 2010, have fallen 87% in real terms to $156/kWh in 2019. By 2023, average prices will be close to $100/kWh, according to the latest forecast from research company BloombergNEF (BNEF).

If we remove the Sumerian units, that works out to US$305/MJ in 2010, US$43.3/MJ in 2019, and US$27.8/MJ in 2023. Why are these prices so much higher than the prices I observe *in the retail market* here in Argentina in 2019? Because Bloomberg is specifically talking about battery packs for electric vehicles, although they don't mention this until later in the article, and lead-acid batteries are far too heavy for any but short-range or aquatic electric vehicles.

But it's very interesting that BNEF is predicting that lithium-ion batteries will get into the lead-acid price range.

Usability of scientific calculators

Kragen Javier Sitaker, 2016-09-29 (19 minutes)

I just bought a scientific calculator (for US$27) with the purpose of cannibalizing its solar cell (it can also run off a button cell) and maybe display and keyboard. But I got distracted with its user interface, which is kind of amazing given the constraints it's under.

First, I want to be clear that the calculator is unfortunately rather limited in its power, and there are a lot of things that are clumsy about its user interface. And I've crashed into quite a number of usability problems. Despite all this, it does achieve many amazing things.

This is a Cifra SC-9100 sold by Unitronic SA here in Argentina, but likely they didn't design the hardware or write the software, both of which are probably from a white-label company in China, where the calculator is made. In part I base this inference on the fact that the error messages are in English.

It has a large 5×4 keypad for the most basic functionality (arithmetic, entering numbers, clearing), a 6×4 area above it with two keys missing for most of the functions, and four navigational/shift and four directional keys, for a total of 50 keys.

This calculator is not comparable to the TI-83 or HP-48 lines of graphing calculators with computer algebra systems onboard. But then, they can't run off a tiny solar cell, either. Evidence suggests that it has on the order of 2K of memory.

Feature list

To some extent this calculator seems to have been designed to fill out a feature checklist, because many of the features don't work together properly.

- 79-step infix algebraic expression evaluation with 9 variables with letter names.
- Interactive editing of expressions before evaluating them on a 12-character alphanumeric line with 5×6 pixels per glyph.
- When you have a syntax error, you can jump the cursor to it.
- Stored history of the last few (6–8 usually) calculations and results.
- A direction pad on the keyboard, which makes the history editing pretty easy.
- Decimal floating-point, d°m's", complex, and rational numeric types.
- The usual complement of standard numerical functions: square root, cube root, square, cube, exponent, nth root, log, 10^n, ln, e^n, sin, cos, tan, $\sin^{-1}$, $\cos^{-1}$, $\tan^{-1}$, sinh, cosh, tanh, $\sinh^{-1}$, $\cosh^{-1}$, $\tanh^{-1}$, nPr, nCr, +, -, ×, ÷, factorial, reciprocal, polar to rectangular, and rectangular to polar.
- Newton's-method-based solver for (single) arbitrary general equations; you can supply values for some of the variables and ask it to solve for another one, although this may not always converge.
- Special solvers for quadratic and cubic equations in one variable and for systems of linear equations in 3 or 4 unknowns.
- A sort of forms-based user interface for the solvers where you can

navigate around the fields.
• Display modes including fixed-point, scientific notation, engineering notation, which can be selected after the fact and then used to review previous results.
• A very easy but limited programming facility reminiscent of BASIC without control structures.
• Twenty predetermined unit conversions and their inverses, including things like horsepower, acres, mmHg (but not psi!), and parsecs (but not lightyears).
• 40 physical constants, including things like the Stefan-Boltzmann constant and the permittivity of free space.
• Hexadecimal, octal, and binary bases and bitwise operations.
• Statistics: mean, standard deviation, and regressions (linear, logarithmic, exponential, power, inverse (reciprocal), and quadratic).
• Numerical integration using Simpson's rule; approximation of numerical differentiation using finite differencing.
• Matrices, but only up to 3×3.

Limited BASIC-like programming facility

Here's a version of Minsky's circle program in a 3-place fixed-point display mode.

I type 1 SHIFT STO X to set X to 1; this results in the display

```
1→X
    1.000
```

Then 0 SHIFT STO Y:

```
0→Y
    0.000
```

Now I enter the program:

```
X=X-.1Y:Y=Y+.1X:X²+Y²
```

And I press the = key (the other = key) repeatedly to single-step the program as an endless loop:

```
X=X-.1Y
    1.000
Y=Y+.1X
    0.100
X²+Y²
    1.010
X=X-.1Y
    0.990
Y=Y+.1X
    0.199
X²+Y²
    1.020
X=X-.1Y
    0.970
Y=Y+.1X
    0.296
X²+Y²
```

```
    1.029
X=X-.1Y
    0.940
Y=Y+.1X
    0.390
X²+Y²
    1.037
```

Continuing in this vein, after 11 more iterations (33 presses of the = key) we get to X = 0.020, Y = 1.001, X^2+Y^2 = 1.002. (The third expression is just a kind of a sanity check.)

To me, this is an incredible kind of immediacy: in 8 keystrokes I can set up the initial state of the program, in 33 more keystrokes I can implement Minsky's circle algorithm with a debugging statement, and then I can immediately start single-stepping it. A further additional keystroke — the left or right direction on the direction pad — takes me back into editing the program.

You can similarly easily program it to, for example, tabulate the values of a function:

```
0→X
X(1-X):X=X+.1
```

This gives us the sequence 0.000, 0.090, 0.160, 0.210, 0.240, 0.250, 0.240, 0.210, 0.160, 0.090, 0.000 (-0.110, ...) just as it should, with two keystrokes per output number. Or, to tabulate the logit at intervals of 0.05:

```
.05→X
ln (X÷(1-X:X=X+.05
```

(Note the unterminated parentheses before the :. Also note that `ln` was one keystroke.) In 27 keystrokes, plus two per answer, this gives -2.944, -2.197, -1.735, -1.386, -1.099, -0.847, -0.619, -0.405, -0.201, 0, and so on, with two keystrokes per output number. This agrees with the results of `scipy.special.logit(numpy.linspace(0.05, 0.95, 19))`.

Excel's user interface is probably the most optimized for doing such iterative numerical calculations in the history of the universe. Doing the same version of Minsky's algorithm in Gnumeric, which uses Excel's user interface, is `1 TAB 0 ↵ =↑-.1*↦ TAB =↑+.1*↓↤ TAB =↤ SHIFT ^ 2 + ↤ SHIFT ^ 2 ↵ ↑ SHIFT ↤ ^C↓↤ SHIFT PgDn ^V`, which is 45 keystrokes as I count it — almost 50% more! (And that's not even charging extra for the fact that my netbook doesn't have a keypad, so even some basic arithmetic operators need shift.)

Of course, Gnumeric (or Excel) doesn't require three more keystrokes to get each new answer, doesn't forget the previous results, can automatically recalculate, can graph, and so on. And in my Gnumeric instance, that `SHIFT PgDn ^V` at the end pasted 16 iterations, which would be 48 keystrokes on the calculator.

But I feel that these issues of the accessibility, manipulability, and inspectability of the state machine's execution history are nearly orthogonal to the issues of specifying the state machine's transition function. Yes, the two sets of functionality do compete for the same keyboard keys. But specifying the same state machine took 33

keystrokes on 50 keys on the calculator (about 186 bits), and about 45 keystrokes on 82 keys on my netbook (about 286 bits).

The good news kind of ends here, though. As far as I can tell, there are no conditionals, no way to loop without manually single-stepping, no way to assign to multiple variables in a step, no way to store a vector in a variable, no way to (programmatically) access previous values of a variable, and no way to loop implicitly rather than explicitly. Worse, your program is lost if you press ↑ or ↓ on the direction pad (although you can access single steps of it, the colon-separated form is gone, and you have no copy and paste to reconstruct it with), if the calculator automatically powers off from inactivity, or if you start entering another expression.

It has a random number generator, but with only three digits, and I haven't found a way yet to round or truncate to an integer in a formula. (There is a Rnd key for rounding, but what it does is round the currently displayed result to the displayed precision, so to a first approximation it appears to do nothing. You can't use it in a formula.) The closest I've come up with is $2\sqrt{(2\sqrt{(2\sqrt{(2\sqrt{(\text{Ran\#}-.5)^2}-.5)^2}-.5)^2}-.5)^2}$; my theory was that this would eliminate one bit of precision each time. However, iterating the formula $2\sqrt{(\text{Ans}-.5)^2}$ (here Ans being the result of the previous formula) starting from .555 gives me the orbit .11, .78, .56, .12, .76, .52, .04, .92, .84, .68, .36, .28, .44, .12; so it's definitely lost some information, including after the first three iterations, but then it enters a period-10 orbit, so it doesn't keep losing information. .133 enters a different orbit.

The above does illustrate that you can use the command-line history facility to supply different inputs to an iterative algorithm over time.

So this level of programmability of this calculator is inspiring, but ultimately very limiting.

Newton's-method-based solver

In a way this is the most amazing part to me, because it's close to a general interactive constraint system. If I enter

```
Y=X^6-2X+1 [SHIFT] [SOLVE]
```

(which is a bit harder than it sounds because the "=" and each of the occurrences of a variable requires pressing the [ALPHA] key first) it drops me into a "form" (one line displayed at a time!) where I can supply values for Y and X. Immediately it asks me:

```
Y?
    28.000
```

If I answer by typing 2π=, it calculates that result, invisibly stores it in Y, and continues:

```
X?
     5.000
```

I can scroll up and down between the two lines of the form with the direction pad, but if I respond to the X? with a second use of

[SHIFT] [SOLVE], the display goes blank for about 6 seconds and I get the result:

```
X=
    1.418
```

(I happen to have the display mode set to 3-place fixed-point, which isn't quite enough for displaying the solutions of sixth-order equations.)

If instead I supply the value for X, move back up to Y, and press [SHIFT] [SOLVE], it calculates Y rather more quickly.

This isn't quite modeless — I can supply the value for Y by an algebraic expression, but not by specifying a different equation to solve, and I can't apply the solver to systems of equations with a : separating them (that gives a syntax error).

A related but sort of redundant facility is its CALC key; given an algebraic expression like

```
√(X²+Y²)
```

pressing CALC will query you to update X and Y in the same way (but mysteriously without the ability to scroll to the other fields), then display the result of evaluating the expression.

Cubic solver

To solve $x^3 - 4x^2 - 5x + 2 = 0$, I have a couple of different options; I can try the Newton solver, or I can use its cubic solver. The cubic solver is like this:

```
(MODE MODE MODE 3)
 Unknowns?   →
    2   3
(→)
↤Degree?
    2   3
(3)
 a?
(1=)
 b?
(-4=)
 c?
(-5=)
 d?
(2=)
```

(half-second delay)

```
X₁=          ↓
 4.93163002
X₂=          ↕
 0.323190091
X₃=          ↑
-1.254820111
```

These answers were quickly obtained, and they are correct as far as

they are displayed, although at first I mistakenly thought they weren't.

Obtaining a result using the general solver turned out to be a little trickier; I entered this expression:

```
0=X³-4X²-5X+2
```

and used SHIFT SOLVE twice, with X initially at 0. This ran about as fast and got the .323 solution. X initially at 2 also yields the same solution; with X initially at 3, I instead get the -1.25 solution. To try to find the third solution if we didn't already know it, we could try dividing out the other solutions; by using the left-arrow on the solution we can get back to edit the equation into

```
0=(X³-4X²-5X+2)÷(X-.323190091)÷(X+1.254820111)
```

With this version — which unfortunately I couldn't copy and paste the numbers into — I still get a solution at "-1.254820111" if X starts there, but now if X starts at 0, I get the 4.93 solution.

This is considerably more effort, but it's applicable to equations of any degree. It's not guaranteed to work, due to roundoff error, but it will often work.

It turns out that the 0= I'd stuck in there at the beginning isn't necessary. This works too:

```
X^6-2X+1-2π [SHIFT] [SOLVE]
```

From some starting point, it comes up with the answer X=-1.193859 or so. Given instead (X^6-2X+1-2π)÷(X+1.1939) and a start of X=-1, in about three seconds, it comes up with another solution at X=1.417685166. If we divide that factor out too, it comes back with an error message, "Can't solve", after about 45 seconds or a minute; and indeed (upon graphing the equation elsewhere) those seem to be the only two real roots of this polynomial. (In a sense it should be obvious that there are only two real roots from its form.)

Numerical integration and differentiation

To calculate $\int\sqrt{(1-x^2)}dx$ from -1 to 1 with 512 partitions using Simpson's rule, I type

```
∫√(1-X²),-1,1,9=
```

and wait about 13 seconds. It yields 1.5707, which is accurate almost as far as it goes, but that isn't very far. (The exact answer is $\pi/2$, close to 1.570796.) If instead of 9 I specify 7 (for $2^7 = 128$ partitions rather than 512) it runs in about three seconds and produces 1.57 as the result.

This manages to be simultaneously counterintuitive (I never would have guessed either the comma, the logarithmic notation for the number of partitions, or the limit of 512 partitions), opaque (it's no easier to write than to read), and impressive (that the calculator can do this at all).

As a crude approximation, this speed suggests that it's running a few hundred floating-point operations per second.

Numerical differentiation is faster, of course. It uses a finite

difference, because apparently the numbskulls who implemented the calculator's software haven't heard of automatic differentiation yet. To tabulate the derivative of the logit, for example:

```
.05→Y
d/dx(ln (X÷(1-X,Y,1e-9:Y=Y+.05
```

This gives 21.052, 11.111, 7.844, 6.250, 5.333, 4.762(166667), 4.395, 4.167, 4.041, 4.001, 4.040, and so on. These are accurate to nearly four places, which is fairly underwhelming given that I specified using $\Delta x=10^{-9}$. The extra digits on the 4.762 number suggest that it's not actually bothering to calculate the intermediate results to more than about five places.

Base-N and logical operations

In base-N mode, the trigonometric keys become hexadecimal digits, and the reciprocal key opens a menu of bitwise operations. This allows you to explore mappings like `Ans and(Ans-1)` or `Ans xor(Ans-1)`, which last generates a Sierpinski triangle in binary, one row at a time, if you seed it with a power of 2. Unfortunately in this mode you apparently cannot assign to variables, not even X, Y, and M.

However, I did manage to get it to tabulate reflected-binary Gray code values using two keystrokes each. First I set M to 0 using `RCL M SHIFT M-`, and then I entered and ran the program `1M+:Mxor(M÷2`, getting the hexadecimal sequence 1, 3, 2, 6, 7, 5, 4, C, D, F, E, A, B, 9, 8, 18, 19, 1B, 1A, 1E, 1F, 1D, 1C, 14, 15, 17, 16, 12, 13, 11, 10, 30, ... sequence A003188. (The program also works in decimal mode in base-N.)

Modefulness

This calculator suffers terribly from modefulness. You can't take absolute values except in complex-number mode; you can't use trigonometric functions in base-N mode (although you can use arithmetic) because the keys are remapped to hex digits. You can't use square-root in base-N mode for no apparent reason; the key just doesn't do anything. You can't numerically integrate in complex mode. You can't assign to variables in base-N mode or complex mode. And so on.

Worse, in some cases the meaning of programs is dependent on the mode. In base-N mode, any numeric constant in your program will vary depending on base — and most give a syntax error in base 2. Worse, this happens when you merely try to scroll back in history to the formula.

Usability lessons

Except for when asked to do significant amounts of computation or when dealing with a key that maps to nothing, the calculator is always instantly responsive. Its silent keyboard, despite presumably being rubber carbon-bottomed domes under hard keys, works reliably. These are big pluses.

Bigger still is the immediacy of most operations. Doing base conversion with a single keypress in base-N mode is really nice. This doesn't excuse the absence of features like variable assignment in base-N.

The form-based UI for off-the-shelf models (e.g. cubic equations)

really eases using them, but makes composing them difficult to impossible.

Writing the transition function of a numerical finite state machine as a series of colon-separated assignments works surprisingly, even amazingly, well. Being able to nest assignments and to compute and display two or three results per keystroke (rather than just one) would help. Being able to run the iteration out of user control (with conditional and iteration operations) would make an even bigger difference. The single-step-and-see-labeled-result one-keystroke flow is magical, though.

After my initial astonishing experiences with the device, I was starting to become attached to it and doubt my tentative plans to rebrain it with a low-power high-performance microcontroller; my further investigation, however, shows that it's actually kind of an unusable piece of shit. Current mass-market low-power ARM microcontrollers like Atmel's picoPower line run at 12 milliwatts at 48 million 32-bit instructions per second, which is 250 pJ/insn; my best estimate is that in full sun this calculator's solar cell can produce 29 milliwatts.

TI's current Nspire line of graphing calculators run on 150MHz ARM microcontrollers with 64MB of RAM. But they don't run off a solar cell.

I can't find the information on the ARM picoPower microcontrollers I was thinking of.

Topics

A two-operand calculator supporting programming by demonstration

Kragen Javier Sitaker, 2018-12-11 (22 minutes)

Historical programmable calculators have mostly either used BASIC-style infix expressions and jumps, or FORTH-style stack operations. When I'm programming, I find FORTH code more bug-prone than register-to-register code. Could you design a usable programmable calculator using a non-stack-machine machine code? I think so, and in fact, I think you could make it more usable than traditional calculators by taking advantage of programming by demonstration.

Or, to put it another way, how easy could you make programming in raw machine code, so that you don't wish for an assembler?

Physical description

In front of you is a box with an unusual keyboard and two knobs, one above the other, each with a 16-digit numeric LCD display next to it. Each knob has 16 positions around it labeled with the letters J through Y. A third knob with a third display is located below the keypad; it also turns indefinitely in either direction, with a larger number of detents. The top knob and display are labeled Γ; the bottom knob and display are labeled Δ. Turning a knob to one of its 16 positions selects the number displayed on its display; there are 16 different such numbers. Both knobs access the same set of numbers; when they are turned to the same position, they display the same number.

There is also a peripherals box connected to it with a cable which will be described later.

The keypad looks like this:

0↓ 1↓ 2↓ 3↓ ± B C
7 8 9 + ~ > ←
4 5 6 - ^ : ↓
1 2 3 × & ; ⇐
0 @ ! /% | { }

XXX missing: ››, ‹‹, some way to swap stacks

Calculation

The numeric keys enter a number into the upper display, Γ. If a number was there previously, it is replaced, unless the last thing you did was also a numeric or backspace key, in which case it is appended to the number there. The backspace key (⇐) removes the last digit from the number. If you turn the Γ knob away from that position, the displayed number will change, but when you turn it back to that position, the number you entered is still there. If the Δ knob is in the same position, the same number shows on both displays, and they update together.

This is because the machine contains 16 registers, named P, Q, R, S, T, U, V, W, X, Y, J, K, L, M, N, and O, and the knobs select which of the registers is displayed on each display at each moment.

The arithmetic keys +-× alter the number on the Δ display by respectively adding to it, subtracting from it, or multiplying by it the number on the Γ display. The Γ number remains unchanged, unless both knobs are in the same position, in which case it shows the same number as Δ.

The arithmetic key /% alters Δ by dividing it by Γ, leaving the quotient in Δ, but does not leave Γ unchanged; rather, it leaves the remainder in Γ. The quotient is rounded toward zero, and the remainder is consequently sometimes negative.

XXX maybe use 32.32 fixed-point? × differs only by a right shift but /% differs radically.

The ± key changes the sign of the number in Γ.

So far, this allows simple use of the machine as an integer (XXX?) calculator. You select some register with both Γ and Δ, type a starting number into it, and then select a different register with Γ and type more numbers into it and apply operations to update your Δ accumulator.

The keys ^~&| are similar to the arithmetic keys, but perform bitwise operations on the numbers: XOR, NOT, AND, and OR, respectively. ~ applies only to Γ, not to Δ, on the theory that much of the time that you invert the bits in a number, it's because you're about to use it to clear some bits in something else. You can pull out either knob to set the corresponding display to hexadecimal, or push it back in to go to decimal.

Memory

The @ and ! keys use Γ as an address into a larger "main memory" of 65536 numbers; @ reads main memory at the address Γ and copies it into Δ, while ! copies Δ to main memory at the address Γ. The display below the keypad displays one of the numbers in this memory, and the knob moves backwards and forwards in this memory. It has a narrow stem in the middle to allow spinning it quickly, and this implements something like mouse acceleration so that you can scroll rapidly through memory. Main memory is nonvolatile, retaining its contents even when the device is unplugged.

Programmability

The other keys are somewhat more difficult to explain, because they pertain to the device's programmability.

Defining subroutines

Whenever you are typing, the program counter displayed in the display below the keypad advances, recording your instructions in the memory so that you can replay them later; numeric entry is not recorded until it is complete, so backspace does not create a program instructions, nor does typing a number followed by : or a few other things. The : key marks a label, which can be used as the beginning of a subroutine or loop. This is implemented by storing the current program counter at address Γ and magically restoring Γ to its previous value. The ; key marks a return address; it has no effect on the Γ and Δ registers, so its only immediate effect is to store an instruction in memory.

This means that you can define a subroutine by doing a calculation, typing ;, then using the third knob below the keypad to

scroll back in memory to the beginning of the calculation, entering a subroutine number, and pressing :. Or you can enter the subroutine number and :, then do the calculation. This third knob's somewhat larger display shows a main memory address and its contents in two formats: as a decimal number and in a strange alphabetic hexadecimal format, the same one used to label the register knobs.

Only numbers in [0, 511] are valid labels due to the instruction encoding.

There is the potential to accidentally overwrite things by recording an interactive computation in this way, so you may want to use the third knob to jump backwards from time to time when you aren't recording things on purpose.

Interactive mode and execution mode

Once a subroutine is defined, you can invoke it with the ↓ key, which calls the subroutine whose label number is displayed in Γ by pushing the program counter on a stack and fetching from memory at the number displayed in Γ into the program counter. An extra bit in the program counter tracks whether the machine is in interactive mode or execution mode, so upon returning from the subroutine from an interactive call, the machine reverts to interactive use. The B , and C keys interact with this bit: B in execution mode sets the machine to interactive mode (pausing whatever program is running) and C sets it to execution mode, resuming the paused subroutine. B in interactive mode is used for single-stepping; in most cases, it simply interactively executes the instruction at the program counter without leaving interactive mode, but if that instruction is a ↓ or ;, its effect is slightly modified — the interactive bit remains set after the context switch, so you can single-step through the subroutine as well. (Or you can continue until its exit with C.)

This fact of having an interactive bit saved on the stack with the return address allows you a lot of debugging flexibility. You can interrupt the program at any point with B to see what it's doing, then C to continue, even if you're nested inside some other similar debugging session higher up the stack. You can update the contents of the registers by typing numbers followed by B to step to the next instruction.

XXX exactly when entered numbers get stored into the instruction stream needs some clarification. What if you turn the Γ knob to modify multiple registers before typing B?

Shortcut keys

The 0↓, 1↓, 2↓, and 3↓ keys are shortcut keys to call the subroutines whose addresses are stored at addresses 0, 1, 2, and 3. This allows you to implement simple applications just by vectoring those functions to subroutines of your choice and, perhaps, placing stickers on the keys.

Local variables

Registers P through W are saved and restored on the stack in memory along with the program counter by the ↓ call and ; return instructions, making them local variables in each subroutine. However, because they are copied to the stack during the call instruction, their value in the caller is available in the callee; so you can use them to pass parameters, and the callee's changes to those

parameters will be automatically discarded upon return. So if the callee wants to return values to the caller, it should put them into one of the other registers, such as X and Y.

Conditionals

The { key adds a conditional jump instruction to the program and stores the address of that jump instruction on a special small stack not stored in main memory; the } key then backpatches that conditional jump to point to the current program counter. The conditional jump jumps if Δ is zero. In order to preserve the programming-by-demonstration feel of the machine, all 16 data registers are also stored on that stack and restored when you type }.

The > key sets Δ to 0 if it was negative. This means that the sequence ->{…} executes the … only if Δ was greater than Γ originally.

Unconditional jumps and loops

The ← key fetches an address from the address Γ points to and adds a jump to that address to the current program. This is basically intended for loops: you type, say, 8: at the beginning of the loop, and then 8← at the end of the loop; but it can also be used for subroutine tail calls. I'm not sure what it should do in interactive mode.

Generally you will want to use { and } inside the loop in order to make it not infinite. In particular, {;} conditionally terminates the subroutine the loop is within.

Wide program counter

Because memory words are fairly large (64 bits?) several instructions can normally fit into one; the opcode field is 4 bits and the source and destination register fields are 4 bits each, for a slightly awkward total of 12 bits. This makes the program counter three bits wider than the usual 16-bit memory addresses, plus the interactive bit, which allows single-stepping at sub-instruction-word granularity, as well as returns, calls, and jumps into the middle of instruction words.

Interrupts

No.

Peripherals

In addition to the three numeric displays already mentioned, there are some other peripherals on the calculator, mostly in the peripherals box.

When the value of the last register, register O, changes, there is an audible click whose volume increases with the magnitude of the change. This is because register 15 is connected to a digital-to-analog converter which is connected to a speaker.

The peripherals box has eight smoothly turning dials on it. The current positions of these dials are mapped into main memory at positions 0x7f00 (WOPP) through 0x7f08 (WOPX).

The current time is always available in memory at address 0x7f09 (WOPY).

There is a 320×240 touchscreen LCD display on the peripheral box with 16-bit color and an integrated framebuffer. The current touches are available in addresses 0x7f10 (WOQP) through 0x7f14

(WOQT); each one contains X and Y coordinates and an active bit to indicate whether it's active or not. Its current vertical scan position is in 0x7f15 (WOQU). By placing 80 64-bit words in the addresses starting at 0x7f20 (WORP) and writing a scan line number to 0x7f70 (WOWP), you can update a scan line on the display.

There is a switch on the peripherals box attached to an LED that illuminates a sign saying "RECORDING" and a microphone. When the switch is turned on, the LED flashes, and the current microphone sound pressure level is available at 0x7f30 (WOSP).

When in execution mode rather than interactive mode, the current 34-bit state of the keyboard (except for the B key, which returns to interactive mode) is available at 0x7f40 (WOTP).

Machine code encoding

This is especially important on this machine because if you're writing the machine code without an assembler, you're probably also reading it without a disassembler, and indeed the third knob and display are designed for this.

Each instruction except for immediate constants is 12 bits, 3 nibbles. A memory word is 64 bits, 16 nibbles; this allows space for five instructions in 60 bits, plus an extra one-nibble tag field which is used for literals. Normally it is 1111 (f/O) but when it is 0000 (0/P) the word is a literal word with 56 bits of immediate data, here nibbles labeled nd through n0.

nibble f e d c b a 9 8 7 6 5 4 3 2 1 0
normal 1111 op0 A0 B0 op1 A1 B1 op2 A2 B2 op3 A3 B3 op4 A4 B4
literal 0000 reg nd nc nb na n9 n8 n7 n6 n5 n4 n3 n2 n1 n0

The fields labeled An and Bn vary in interpretation according to the instruction format; for two-operand instructions, they are generally the source and destination registers; for one-operand instructions, An specifies the instruction and Bn specifies the operand register; and for zero-operand instructions, all three fields specify the instruction.

Two-operand instructions

Optimizing for 12 bits and hexadecimal legibility, the two-operand opcode format is as follows:

opcode Γ Δ
xxxx xxxx xxxx

The Γ source and Δ dest fields each identify one of the 16 registers (with the low 4 bits of the register's letter), and the opcode fields identify one of the two-operand operations:

conventional hex 0 1 2 3 4 5 6 7 8 9 a b c d e f
operation + - × /% { ^ & | ! @ one-operand (see below) (control flow) (see below)
ASCII alphahex P Q R S T U V W X Y J K L M N O

This means, for example, that the three-nibble sequence PTJ means "J = T + J".

For most of these operations, as explained earlier in the section about the user interface, the source operand Γ is left unchanged and

the destination operand Δ gets the result. There are two exceptions: /%, which like the /% key, leaves the remainder from the division in the source operand; and {.

{ tests the source operand Γ to see if it's 0, and if so, executes a forward jump. The destination operand field Δ is not treated as a register reference at all. Rather, its value from 0 to 15 indicates a number of instruction *words* to skip over, starting from the instruction word following the word containing the { instruction. That means that when the Δ field is 0, the conditional jump goes to the beginning of the next instruction word, skipping up to four instructions; when the Δ field is 1, the conditional jump goes to the beginning of the instruction word after that, skipping 5, 6, 7, 8, or 9 operations (or possibly only 1 to 5 if the next instruction word was a literal word); and so on up to 15, which skips 15 entire instruction words, plus the remainder of the word containing {. If the register indicated by Γ was nonzero, however, instruction continues as if nothing had happened.

This means that the } key may need to insert nop operations to fill out the current instruction word, so that it has a word-aligned address to backpatch the { instruction with. This is an annoying amount of complexity to attach to a key, but the alternative would be to only enable { to skip over up to 16 *instructions*, rather than up to 84, which would be a painfully anemic conditional. (But hey, HP calculators' conditional only skipped a single instruction.) Still, the complexity involved here is small compared to the complexity of division or procedure calls.

One-operand instructions

There's a different format for one-operand operations:

opcode xop reg
1011 (b/K) xxxx xxxx

The one-operand operations are encoded with the following xop values:

conventional hex 0 1 2 3 4 5 6 7 8 9 a b c d e f
operation 0 1 2 ~ ± > ;/nop -2 -1
ASCII alphahex P Q R S T U V W X Y J K L M N O

The operations named with numbers set the register to that constant.

Zero-operand instructions

; and nop need no operands, so we distinguish between them by the register field: 0 for nop, 1 for ;.

Instructions taking labels

Looking at what's left of the keyboard, : just defines a label; it doesn't add anything to the instruction stream. B break, C continue, and ⇐ backspace similarly are purely interactive operations. However, both ← and ↓ require a label number, which is not actually taken from Γ (that's just the interactive user interface!) but encoded in the instruction. These are encoded with a 9-bit label number field:

opcode label (meaning)
110 x xxxx xxxx ←, goto
111 x xxxx xxxx ↓, call

Literals (immediate data)

As mentioned above, literals larger than ±2 are encoded using an entire instruction word by putting tag 0000 in the first nibble of an instruction word, followed by a destination register and 56 bits of literal data. The literal data is sign-extended to put it into the specified register. In particular, this means that a memory word containing a positive number less than 2^{56} can be interpreted as an instruction to load that number into register 0 (P), which is a technique that you can use to improve the legibility of your program.

Examples

So an instruction word written in alphahex as O PTJ PUT KTU KWP consists of two addition instructions (J += T; T += U), a negation instruction (U = -U), and a nop.

XXX reshuffle opcodes for ASCIIhex legibility. P for + is good, maybe M or L for -, T or M for ×, O or Q or R for /%, N for ~, X for ^, S for !, L for @, which leaves the less important & and | to get less desirable letters. But we need groups of two letters for ← and ↓, chosen from PQ, RS, TU, VW, XY, JK, LM, or NO. JK suggests "jump" and TU suggests "to" (maybe shuffle × off to M), but nothing in particular suggests "call" or "invoke".

XXX maybe use BCD?

XXX maybe merge &, ^, and ~ into a NAND operation, given their relative rarity? Maybe add a MOV operation?

Thanks

This document draws on discussions with Sean Palmer and John Cowan.

Image approximation

Kragen Javier Sitaker, 2019-05-14 (10 minutes)

I've mentioned the problem of image approximation in a few different notes — Ideas to ship in 2014 (p. 1409), Simplifying computing systems by having fewer kinds of graphics (p. 1110), and Ideas to pursue (p. 1084). Basically the idea is a specific application of mathematical optimization algorithms: making something look, visually, like some reference image. But it turns out to be an interestingly fertile family of applications.

There's now a Twitter bot called something like "Minimal Pictures" which illustrates the idea; it applies some single graphical primitive (Bézier curves, translucent rectangles, or translucent triangles, for example) a few hundred times to get an image that looks similar to a reference image, but not so similar that you can't see how it's done. And in 2016 I wrote a hill-climbing optimizer to approximate a given image with opaque irregular pentagons, with stunning, but very slow, results.

So here is an attempt to outline the space a bit.

Design spaces

A design space is a set of variables the optimization algorithm can tweak to satisfy its objective of making the right image. This can be pretty much anything. Interesting design spaces include polygons (translucent or opaque); polylines; Bézier curves; points; DCT coefficients in a JPEG; images constrained in some way, such as sparsity, to be convolved with the known, estimated, or optimized OTF of some optical system; widths and/or slight displacements of a given set of lines, as in engraving or font hinting; toolpaths, or more generally robot movement plans; arrangements of a given set of pieces (overlappable or not, scalable or not, but generally rotatable); heightfields, 3-dimensional meshes, or other three-dimensional models such as collections of spheres; parameters controlling a model like a face puppet; or colors of pixels chosen from a small set, as on an inkjet printer.

Similarity metrics

The simplest similarity metric to optimize is probably just the sum of squared pixel differences, but this leaves a lot to be desired. A very simple alternative is blurring the images a bit first, but there are many other possibilities. Transforming the images into Fourier or Gabor space and then weighting the different spatial frequencies according to perceptual salience might be an improvement. A perhaps more interesting possibility is using the first few layers of a neural network trained for image classification or in a GAN; this would presumably put extra weight on things that are important to "real images" in some sense, and might do a reasonable job of simulating the first few layers of human visual perception, too.

In some cases, perhaps something like Canny edge detection would be a useful step in the similarity function, if the visual similarity you're going for isn't purely literal.

Other objective function components

The objective function you optimize might not be purely similarity; it might also include some kind of "cost model" for the design space. For example, if you're planning a toolpath, you might want to prefer faster toolpaths; if you're trying to approximate an image by deriving a sparse set of stars or other bright points that have somehow gotten convolved with a known or unknown OTF, you might want to prefer sparser sets; you might prefer heightfields that are mostly smooth rather than containing thousands of sharp spikes; for artistic purposes, you might want to minimize the number of graphical primitives used, just to keep the approximation from being too perfect; and so on.

Simulation

In many of these cases, you won't know how well you've actually approximated the image until you set some kind of physical machinery in motion. A robot wielding a pen, a hot wire, a FDM nozzle, or a milling cutter can produce somewhat unpredictable results. Also, it's slow. A potentially worse problem is that its results aren't differentiable — you can evaluate your objective function over them, but you may not be able to determine the gradient of the objective function with respect to your design variables.

So in many cases you'll want to do some kind of simulation, even if in the end what you're optimizing is a physical process. A numerical simulation, even of things like robots cutting things, can support automatic differentiation with respect to your design space, which enables the use of non-gradient-free optimization algorithms.

Optimization algorithms

There's been an enormous amount of work on variations of gradient descent in the last few years, largely with an eye to accelerating learning of parameters for deep neural networks, and there are also a substantial number of older variants. This includes Nesterov accelerated gradient, AdaBoost, AdaGrad, Adam, and so on.

Gradient-based algorithms have an enormous advantage in high-dimensional design spaces; they tend to slow down linearly with dimensionality, while gradient-free optimization algorithms commonly slow down exponentially with dimensionality.

However, other metaheuristics other than gradient descent are applicable; for example, Nelder–Mead optimization, genetic algorithms, and simulated annealing.

In some cases, the most appropriate optimization algorithm may actually be something like a particle filter.

Purposes

This family of techniques can be applied to many problems.

The minimal-picture bot mentioned above has output that looks cool.

Non-photorealistic rendering is a useful approach for avoiding the plasticky hard look of a lot of 3-D rendering. Image approximation is a general approach to NPR — you ask for an approximation of a conventional near-photorealistic rendering, using a design space that

only allows pencil drawing, for example, or pastel chalk painting, and perhaps using a similarity measure that privileges whatever you think is most important to preserve, such as edge orientations.

In the opposite direction, a possible way for someone to specify a 3-D model that can later be used for photorealistic rendering, virtual puppeteering, or 3-D printing is to sketch it in a non-photorealistic way, maybe from a few different points of view, then optimize in an appropriate design space of 3-D models, using photorealistic rendering to generate the image to be compared to the sketch, and some kind of similarity metric that emphasizes the features that are likely to survive.

Autotracing, vectorizing raster images, can be framed as an image approximation problem: you want to approximate the raster image as closely as possible with a polyine with a very limited number of control points. Carrying this further, you could optimize a representation of a printed book that consisted of one or more fonts and a vector of (pageno, x, y, codepoint) tuples, subject to appropriate penalties for wiggly lines of text and fonts with too many glyphs, in order to simultaneously OCR the text and digitize the font used. This is presumably not too far from what current bilevel image compression does.

Star tracking for spacecraft orientation control can be viewed as an effort to approximate a series of images by estimating the camera's OTF, the attitude of the spacecraft, and the contents of the galaxy (although we already have a pretty good prior on that). Sun glare and Earth glare need to either be taken into account or somehow ignored by the similarity metric.

Grid fitting and hinting of fonts can be viewed as an image approximation problem. The difficulty with just doing nearest-neighbor things is that you can end up with uneven spacing, uneven widths, etc., which are more perceptually salient than what you got right. Optimizing the rasterized glyphs according to a perceptual model, for example in Gabor space, should solve this problem.

Dithering is the problem of approximating an image using only a few colors, and existing dithering algorithms face unappealing tradeoffs between edge sharpness and color precision. By optimizing the similarity between the dithered image (which, note, is not a continuous domain) and the original image as measured by a perceptual model, you should be able to get substantially better results, privileging edges where those are more perceptually salient, and color precision where that is, for example where there are no edges. Dithering algorithms could even take into account LCD subpixels if it's just a matter of tweaking the similarity function.

Lossy compression is, generally, the problem of approximating an image using some kind of sparse representation, and is of immense importance right now. Again, optimizing the similarity between the original and decompressed images according to a perceptual model might give improved results.

Resampling of images to different sizes could also be viewed as a process of image approximation, using a larger image to approximate a smaller one, or vice versa. This requires a similarity metric that penalizes you if sharp edges get blurry when the image is enlarged.

Structure-from-motion (SfM) and structure-from-shading can be

formulated as image approximation problems; you want to approximate an image or series of images with a colored point cloud and a camera trajectory, or possibly some other kind of 3-D model like a heightfield. In some cases lighting may be changing. By using a sufficiently fancy renderer, specular reflections and refraction can provide information about 3-D structure.

Statically bounding runtime

Kragen Javier Sitaker, 2016-07-19 (4 minutes)

I want to implement preemptive multithreading inexpensively at the level of a language compiler with a hard upper bound on response times, without depending on interrupts. This means that the compiled program has to yield control to a scheduler every so often, and we need to statically guarantee that it never goes for a long time without yielding; but, while the scheduler check is relatively inexpensive, it isn't free — maybe 100 or 1000 CPU cycles. (For example, if the scheduler calls select() to see if there are I/O events that need to be handled, that's about 3000 cycles.) So we'd like to use static analysis to avoid inserting it in too many places if we can.

Let's suppose our program is built from the following grammar:

```
function ::= name expr
expr ::= instruction | call | seq | forloop | whileloop | conditional
call ::= "call" name
seq ::= expr ";" expr
forloop ::= "for" var const expr
whileloop :;= "while" expr expr
conditional :;= expr "if" expr "else" expr
```

This version has a statically computable control-flow graph and therefore doesn't accommodate function pointers; you could treat them as CLOS-style generic functions and treat them as conditionals on a type test.

I'm glossing over parameter passing and local variable allocation for the time being; you can consider them to be implemented by some unspecified instructions.

It seems clear how to compute a conservative approximation of run-time-before-yield. whileloops can run forever, as can recursive functions; either of these need to have a yield inserted into them. Then, the run-time-before-yield of a call expression is the run-time-before-yield of the function it calls, plus a tiny amount; each instruction presumably has a known worst-case run-time-before-yield; a seq expression's worst-case run-time-before-yield is the sum of those of its children; a forloop's is N times that of its body expression, where N is the constant; and a conditional is the maximum of its two branches plus its condition.

It may be necessary to separately compute a worst-case run-time *before* yielding and a worst-case run-time *after* yielding for each syntax tree node.

Note that the above remains safe even in the presence of early-exit instructions from either loops or entire functions: those might shorten the run-time, but they can't lengthen it.

Inserting yields optimally is almost certainly an NP-hard problem.

Ideally if you have a recursive loop of functions, you would only insert a yield into the prologue of one of the functions rather than all of them.

You can generally do a better approximation. Most while loops are not intended to run forever; by supplying a "loop variant", an

integral nonnegative quantity that strictly decreases every iteration, you can guarantee that the loop terminates and even provide an upper bound on its iteration count. But that level of detail probably isn't necessary for inserting yields, and it probably requires extra work from the programmer.

This kind of analysis also works, with some tweaks, for bounding stack depths and total heap allocation size, either to optimize the number of checks down toward some limit or to provide strong static bounds on resource usage, statically guaranteeing resource adequacy. (Heap allocation can be twice as fast if it doesn't have to check the allocation pointer against the end of the arena, and implementations of threading and call/cc that use segmented stacks also normally have to bounds-check the stack poitner on every function call.)

The book written in itself

Kragen Javier Sitaker, 2016-06-12 (updated 2016-06-14) (18 minutes)

Darius Bacon has suggested writing a software system that is a "book written in itself": a book-length hypermedia literate program which is fully self-sustaining, all the way down to hardware, and accessible to any interested reader.

"Self-sustaining" means that the book contains full compilable source code for itself, for a compiler with which it can be compiled, and for a computer on which to run it.

Comparison to other related projects

In a way, this is a project analogous to Knuth's magnum opus, The Art of Computer Programming, in that it has to cover a very broad spectrum of computer applications — minimally: hardware design, compilers, filesystems, operating systems (also known as kernels), garbage collection, dynamic dispatch, windowing systems, font design, and typographical layout; but possibly also including text editors, video and audio codecs, data compression, database query evaluation, HTML parsing, constraint systems, type inference, theorem proving, SAT solving, cryptography, full-text indexing, games, numerical methods, SPICE-like electrical simulation, CNC fabrication, and OCR (to be able to scan its own text).

Other similar projects are the "NAND to Tetris" book, formally known as *The Elements of Computing Systems*; and Charles Petzold's *Code*; the Thwaites Toaster Project; the Dave Gingery "Build a Machine Shop from Scratch" series; the Primitive Technology series on YouTube; the 1978 port of Smalltalk-76 to the portable 8086-based NoteTaker computer, known as Smalltalk-78, which weighed in at 200 kilobytes; Project Oberon; Plan 9; the VPRI STEPS program to rebuild a full personal computing environment in twenty thousand lines of code; and the biological cell.

Differences from TAOCP

The project has two enormous differences from TAOCP and some smaller differences.

First, it's much less ambitious in scope — TAOCP seeks to provide an overview of all known solutions to a problem, telling the story of their historical development and mathematically analyzing the limitations and advantages of each solution; the Book-In-Itself need ony provide one solution. For example, TAOCP's volume 3 is "Sorting and Searching", which covers nothing more than sorting and various kinds of table lookup (in trees and hash tables) for 800 pages. The Book-In-Itself might include a single kind of hash table, or it might need three or four different kinds of hash tables for bootstrapping or efficiency reasons. It probably needs sorting; a single implementation of Heapsort is likely adequate. In any case, it's unlikely to spend more than three pages on sorting and searching.

So this reduces the project scope by a factor of 300.

Second, it's much more ambitious in scope — TAOCP's scope is limited to software, and even more so, to generally applicable algorithms. You aren't going to find a filesystem implementation, a

gate-level CPU design, or a text layout engine in TAOCP; although its author found it necessary to design his own font design system, his own fonts, and his own text layout system for TAOCP, those are described in other books.

This probably increases the project scope by a factor of 10. This multiplies out to about 30× reduction. Since TAOCP has taken 50 years so far and may be done in another ten or so, this suggests that the Book-In-Itself should take about two years of work.

Smaller differences are that the Book-In-Itself is almost certain to be written by lower-quality authors; it's likely to be a team effort, rather than an individual effort; and, simply in order to be feasible, it's likely to suffer from Dirac-like levels of terseness.

Differences from "NAND to Tetris"

The NAND to Tetris book (*The Elements of Computing Systems: Building a Modern Computer from First Principles*, 320 pages, 2005, Nisan and Schocken) describes a computer system, starting from NAND gates and D flip-flops, moving up through sequential logic, the design of a Harvard CPU called "Hack", assembly language, bytecode interpretation, a simple recursive-descent compiler for a "high-level" language called "Jack", an "operating system", and some video games.

This is thrilling, and additionally the authors have separately published a series of exercises and computer software to guide readers through the implementation of the entire system themselves, rather than simply providing them with working code.

Unfortunately, some aspects of the system are sort of fake, and some others are overcomplicated:

• the "operating system" is just a set of device drivers and doesn't provide multitasking or a filesystem;
• the "high-level" language Jack doesn't provide garbage collection, function pointers, or even dynamic dispatch, and its compiler emits bytecode for a stack machine implemented in software rather than machine code;
• the hardware definition language seems to have been designed by software people so soft they don't know what dynamic RAM is, don't know the difference between a chip and a printed circuit board, and have never seen a RISC instruction set;
• the hardware doesn't have virtual memory, interrupts, any I/O devices other than a screen and keyboard, or any way to modify its program memory;
• the tokenizer and parser output XML;
• although they have infix expression parsing, it doesn't handle operator precedence;
• there is this entire unnecessary bytecode virtual machine;
• the absence of a filesystem prevents you from running the compiler under the "operating system";
• the whole system is so slow that students are never expected to run the whole thing at once, always using a provided efficient implementation (written in Java) of the layer below the one they're working at. Their Pong game is 400 lines of code and compiles to twenty thousand lines of assembly.
• although this is subjective, all in all, the book has a somewhat leaden

and uninspired feel; even the authors describe Jack as "clunky". After each chapter, one is left with the sad feeling that the functionality of the system at that point is surprisingly weak, given its complexity, and the forlorn hope that it will get better in the next chapter.

By contrast, the Book-In-Itself will not rely on separately provided software; it will use more tasteful design choices to get surprisingly powerful functionality instead of surprisingly weak functionality; and it will be efficient enough to run its entire software stack unmodified on a CPU emulated in software on a modern CPU.

One gets the idea, for example, that Jack's syntax is "clunky" in part by the authors not wanting to introduce backtracking, perhaps because they don't know about it, although they published their book three years after Bryan Ford's thesis came out.

Differences from Petzold's *Code*

Where NAND to Tetris is somewhat too theoretical, idealized, and plodding, Petzold's *Code* (1999) goes into nitty-gritty detail, but doesn't teach you enough to build a working system. It's considerably more hardware-focused than NAND to Tetris, which is sort of unfortunate, since Petzold's hardware knowledge is a bit weak.

On page 304, for example, you have the pinout of the 2102 one-kibibit MOS SRAM chip, state of the art in the 1970s. At times Petzold seems to be trapped in the 1970s, too; he claims that TTL is faster than MOS, which stopped being true about 15 years before he published this book.

But the book includes a lot of detail that's hard to find coverage of elsewhere outside of much more specialized books, including things like DIP switches, ripple-carry adder circuits made of relays, Samuel F.B. Morse's hobby of making daguerreotypes, the PARC visit inspiring Macintosh, bit-shift operators in C, the atomic number of lithium, the PostScript format, Java bytecode, how the resistance of tungsten varies with temperature, CP/M filesystem and memory layout, the dynamic range of the CD-DA PCM format, tri-state MOS outputs, GNU and Linux, circuit diagrams of master-slave edge-triggered D flip-flops, the Sieve of Eratosthenes, redundancy in the design of UPC codes (and their detailed decoding algorithm), the vector graphics display screens at SAGE, the Memex, the ALGOL committees, binary-coded decimal, IBM extended ASCII code pages, telegraph relays, the RTF format, Siskel and Ebert movie ratings, LZW compression in the GIF format, the number of electrons in a coulomb, Sutherland's Sketchpad, the process by which Louis Braille went blind, the number of fingers usually possessed by cartoon characters, the comedic etymology of "WYSIWYG", the number of pins on the 8087, the IEEE-754 floating point format, DX-encoding on 35-mm film canisters, Grace Hopper's career trajectory, the frequencies used by 300-baud FSK modems, the pricing of 10-gauge hookup wire at Radio Shack, George Boole's ancestry, ANSI cursor-addressing escape sequences, the 8080 instruction set and assembly syntax, Longfellow's poem about Paul Revere, Morse code, Radio Shack relay part numbers, NTSC sync pulse voltage levels, logographic "contractions" in Braille, the rise of the IDE starting from Turbo Pascal, Altair BASIC, the hardware floating-point encodings of the IBM 704, examples of Ohm's law, the failed GUI

VisiOn, MIDI sound cards and the structure of MIDI commands, transcendental function approximation using Taylor expansions, and so on.

In short, it goes into enough detail that you can actually learn things from it — it's not at the Wired-article level of pseudo-informative flimflam — but it's far from presenting a complete design for a working computer, much less a healthy software ecosystem.

The Book-In-Itself will have to omit most of the flashy, entertaining historical detail, but will include a complete system.

Differences from the Thwaites Toaster Project

Thomas Thwaites mined mica and metal ore from mines and plastic from garbage dumps; he made a wooden mold to shape the plastic; he smelted the metal; he refused to travel by air or use CNC mills. After nine months of work and US$1800 of expenses, he had an nearly functional toaster. Unfortunately, aside from looking terrible, it burned out after a few seconds of operation, because his metallurgy wasn't up to snuff when it came to making oxidation-resistant alloys.

Thwaites complicated his life significantly by deciding to use steel and plastic for his toaster. His choice of Constantan for the heating elements was probably unavoidable, but I suspect that making most of the toaster from copper would have worked significantly better. (To be fair, his mentor Professor Cilliers informed him of this at the beginning of the project. Steel and plastic were a hair-shirt for Thwaites.) He made his life harder still by insisting on using the obsolete bloomery process to smelt the iron, then lowering its carbon content by remelting it in his microwave.

The Book-In-Itself starts at a layer above where the Toaster Project ended: it presupposes the capacity to make complex physical artifacts, including megahertz-class logic circuits with tens of thousands, if not millions, of components. However, given that capacity, the Book-In-Itself is intended as a complete design that can execute *itself*, rather than just a story of a personal quest, perhaps a story that could inspire another person to undertake their own quest.

Moreover, a possible extension of the software core of the Book-In- Itself is an automated manufacturing module, capable of fabricating the hardware artifacts automatically, given suitable materials. This may or may not be included, depending on time and experiences. It would likely enable the Book-In-Itself to fabricate not only more instances of itself, but also to fabricate toasters — perhaps a *reductio ad absurdum* of Lincoln's axe-sharpening dictum.

Differences from the Dave Gingery series

Dave Gingery, and later his family, have published a series of books on how to build a metalworking shop from scrap materials, including techniques like hand scraping flat surfaces, sand casting of metals in a charcoal foundry, and lathe turning.

The books are unreadable without an existing background in the techniques they discuss; if you don't know the names of the parts of a lathe, you aren't going to get very far in understanding Gingery's explanation of how to build one.

Unlike most of the other similar projects, the results in the Gingery

books have been successfully replicated by several people, some of whom have documented their experiences on YouTube.

As with the Thwaites project, the Gingery series stops at a level of abstraction below where the Book-In-Itself begins, but Gingery succeeded in producing competent industrial machinery — not quite from scratch, as Thwaites aspired to, but from scrap materials. (Gingery had the advantage of being an experienced machinist rather than a 24-year-old second-year postgraduate design student.) But the relationship is rather similar: the Book-In-Itself cannot be built without the ability to construct complex artifacts, going even beyond what the Gingery books can produce, but perhaps it could include software modules for producing machine-shop equipment, given access to the right materials.

Differences from the Primitive Technology series

An anonymous or pseudonymous man in the rain forest in Australia is undertaking an even more ambitious project than Thwaites' Toaster: he is constructing a series of artifacts made entirely with materials and tools available in nature. The process is meticulously documented in a carefully edited YouTube video series and a blog. So far, he has created several stone axes, a stone adze, a ceramic-firing kiln, some ceramic pots, a ceramic tiled roof, two houses (one with a hypocaust), a woodshed, some wicker baskets, bow and push drills, a bow and arrow, charcoal, and a fenced sweet potato patch. He aspires to smelt iron. So far he has not mentioned any plans for electrical appliances.

This project consists of the levels of abstraction underpinning the Gingery project, and points out one of the reasons the Thwaites project was so difficult: Gingery used existing industrial materials and tools, while Thwaites attempted to abjure them. Within Gingery's constraints, a toaster would be entirely feasible — perhaps a project of a day or two, maybe a week, certainly not nine months. But once you're mixing your own Constantan, you're playing at a much higher level of difficulty.

However, the Primitive Technology series has a purity that parallels the purity of the Book-In-Itself: its author apparently begins with no tools, not so much as a steel pocketknife, and thus begins his project by banging rocks together to get split-cobble cutting edges. Similarly, the Book-In-Itself depends — in theory — on no hardware or software outside of the book itself; once you have the capability to make machines of almost any kind with tens or hundreds of thousands of parts, you need no further information-processing facilities to bring up a complete computing environment.

There's a crucial distinction here: the Book-In-Itself will be "self-sustaining", in the sense that it can easily replicate itself, and modified versions of itself, once it's running; but only optionally will it be "self-bootstrapping" in the way the Primitive Technology series is — that it's easy to get it running starting from a minimal basis. A self-sustaining system is written in itself; a self- bootstrapping system is written in something that already exists.

There are two basic approaches to adding bootstrapping to a self-sustaining system: you can write two versions of the bootstrapping core, one implemented in the system's own language and another written in some already-implemented language; or you

can write the bootstrapping core in the intersection between the language implemented by the system and a language implemented by something else, which may be a subset, a superset, or an extended subset of what the system implements. In either case, by positing different base layers to bootstrap from, you can get very different results

In the more fundamental layers explored by Gingery, Thwaites, and the Primitive Technology series, a self-sustaining system might consist of a lathe; a small blast furnace, like the kind used in China in late antiquity (around the Qin era); a charcoal-generating kiln employing metal cans; a woodland, harvested using steel axes; a smithy, with its hammer, tongs, anvil, and hearth; a concrete grindstone, mounted on bearings cut on the lathe; a ceramic-firing kiln for making refractory bricks; a cement kiln for making new grindstones; and mines for fire clay, quartz sand, iron ore, and limestone. But bootstrapping that system from stone, mud, and trees is likely to involve additional tools and materials, such as stone axes and perhaps facilities for smelting tin and copper to make bronze tools.

Cold plasma oxidation

Kragen Javier Sitaker, 2019-05-01 (updated 2019-08-21) (7 minutes)

You should be able to oxidize things that are difficult to oxidize using a rapidly cooled air plasma, and this should be feasible even without refractory electrodes and at atmospheric pressure.

The basic principle

If you convert a gas into a hot electric plasma between two electrodes, then cool the plasma rapidly to the gas's original temperature, the cooled plasma will still be different from the original gas in several ways: its molecule energies will still be far from the Maxwell–Boltzmann distribution, as it will still have a significant number of very hot molecules and free electrons (this is called an "anisothermal plasma"); many of the molecules will still be ionized; many of the non-ionized molecules will have excited electrons; and, if it's not a noble gas, many of the molecules will have been ripped apart, and some will have reformed in new conformations. In particular, if the source contained O_2, the resulting gas will also contain O and O_3, which are very strong oxidizers, and if it contained O_2 and N_2, it will also contain a variety of nitrogen oxides, some of which are also very strong oxidizers.

Wikipedia's nonthermal plasma article tells me that the oxygen atoms have a lifetime of about 14 μs.

Applications

Directing a stream of air, converted to this cool plasma, against a material that should have an excellent chance of oxidizing it further, if it's not already fully oxidized with oxygen or something stronger, without necessarily setting it on fire or even heating it much, and volatilizing some of the oxide, which could be useful for a variety of purposes:

- removing organic contaminants from oxide surfaces, such as calcite, clay, concrete, glass, sapphire, or viridian, including the glass, sapphire, and viridian passivating layers formed naturally on silicon, aluminum, chromium, and stainless steel surfaces in air;
- metal passivation, including selective thickening of passivation layers, including on iron;
- selective functionalization of organic surfaces;
- selective production of oxidation products on organic surfaces — in some cases, for example, this can be used to make a dark mark, making the device a printer;
- low-temperature cutting of materials whose oxides are volatile, including any organic material (other than teflon), graphite, diamond, zinc, and possibly even silicon carbide, molybdenum, iron, and steel (certainly at higher temperatures where the oxide will melt and can be blown off);
- acquiring trace amounts of volatilized oxides and nitrides for spectroscopic analysis;
- gasifying an oxidizable blowing agent from a matrix without heating it excessively, producing a foam, as in the traditional means of

producing firebrick by burning organic material out of the pores of a matrix;
• sterilizing drinking water or solid objects, especially solid objects that would be damaged by high temperatures, although maybe you should see if an ordinary ozone generator without plasma jets would be adequate (I see that this is currently under investigation for food processing);
• selective oxidative polymerization of, for example, linseed oil, tung oil, or stand oil, for example for 3-D printing, for 2-D printing with the polymer as a binder, or for depositing resists to guide later etching — and polymerizing almost any energetically favorable monomer should be possible at the right temperature, perhaps including polymerizing aqueous silicic acid into silica gel, as plasma polymerization is already used to form films of polystyrene, polyethylene, and poly(methyl methacrylate), among others, though normally from low-pressure gas-phase monomers;
• curing linseed-oil or stand-oil finishes very quickly;
• very rapid selective polymerization of cyanoacrylate by selectively adding hydroxyl radicals, although maybe ordinary water vapor is a better way to do this;
• oxidizing hazardous organic chemicals such as mustard gas, PCBs, benz(a)pyrene, and possibly-unknown mixtures into tamer and simpler oxides that can be more easily disposed of;
• cutting composites made of oxide grains cemented together with a carbon or organic binder.

Possible applications of non-air plasma ingredients include surface-nitriding metals and selectively "salt-glazing" silicate ceramics with a part-sodium plasma, or superpassivating surfaces that need to withstand exposure to strong oxidants by using a part-fluorine plasma. If the sodium source is chlorine-free (for example, NaOH or $NaNO_3$), the chlorine and HCl emissions that plague salt-glazing will not occur.

Directing the plasma

If the stream is sufficiently cool, its rate of erosion of already-oxidized materials such as teflon, soda-lime glass, iron oxides, quartz, viridian, sapphire, zircon, or zirconia should be relatively low, so it might be feasible to use a nozzle made from these materials to direct it onto the workpiece without eroding the nozzle too rapidly.

Cooling the plasma

Rapidly cooling of the plasma that has just passed through the arc can be effected by misting water into the plasma. The water will flash to steam, some of which will itself ionize and dissociate, contributing further reactive oxygen species to the mix.

Alternatively, you might be able to use corona discharge to ionize enough of the air to be useful, without ever heating it to arcing temperatures — maybe like a garden-variety ozone generator with more concentrated output and maybe gold-plated or carbon points for longer life.

Liquid electrodes

Optionally, the electrodes themselves can be covered with a

constantly replenished liquid electrolyte, such as water including a substantial mixture of NaOH or KOH, or molten $NaNO_3$ or KNO_3. This avoids the need for electrodes of refractory materials such a graphite, silicon carbide, tungsten, or hafnium. Some of the electrolyte will find its way into the arc, which may be preferable to the evaporation from solid refractory electrodes under some circumstances.

(Why don't potters just use chlorine-free sources for salt-glazing in a kiln? NaOH and $NaNO_3$ convert to NaO at high temperatures, which doesn't boil until 1950°, much higher than NaCl's 1413°, so a pottery kiln at 1100°–1200° has a hard time volatilizing the sodium from NaOH or $NaNO_3$ without an admixture of the lower-boiling NaCl, while the arc should have no trouble. However, they *do* use $NaCO_3$ and $NaHCO_3$ for "soda firing", sprayed into the kiln during firing, so I don't know.)

Hazardous emissions

However, if made from air, the cooled plasma inevitably contains sufficient ROSes and nitrogen oxides to be hazardous; the resulting gas needs to be thoroughly reduced unless you're doing this at a very small scale somewhere adequately ventilated. The standard approach to this problem is a platinum catalytic converter, but maybe bubbling the gas through consumable linseed oil or passing it over a consumable bed of sulfur, phosphorus, powdered lanthanoids, or really any easily oxidized chemical would be adequate.

What would a basic income guarantee for Argentina cost?

Kragen Javier Sitaker, 2014-04-24 (7 minutes)

What would a basic income guarantee for Argentina cost?

Last year I calculated that a person here could get adequate nutrition for some AR$3 per day, which is probably more like AR$5 now. Housing in the capital costs more; I'm paying AR$1500 per month for my one-bedroom apartment, but an apartment this size could host four people if they got along really well; living in it alone is a "luxury", which I put in quotes because I fucking hate living alone.

I did spend a week and a half late last year in an apartment here in the capital that was AR$300 per person, but the roof leaked badly enough that mushrooms were growing from the ceiling, there were crack dealers downstairs, and getting along with the other roommates and other people who had claims on the place proved impossible — not just for me, but for them as well.

On the other hand, just outside of the capital city, housing costs are a little lower. So the AR$400 or AR$500 per person suggested by the price of my apartment might actually be a little high. Let's say AR$300 per person, or AR$10 per day per person.

Beyond living space and food, what else do you need to survive? Utilities here are inexpensive; here's what I'm paying per month:

	AR$/month
building management services ("expensas")	200
electricity	17
ABL	27
telephone and internet	162
cellphone, approximately	50
gas	22
water	10
total	488

ABL is a set of city taxes known as "ABL" ("Impuesto Inmobiliario, Alumbrado Barrido, Limpieza, Mantenimiento, y Conservación de Sumideros"). The electricity and water bills come every two months, so the amount on the bill is twice what I've shown above; if someone pays $20 on their water bill, they're paying $10 per month.

The cellphone above is individual, but the other items would be shared with other people if I weren't living alone; they might be a little more expensive with more people (more gas for hot showers, say), but not much. Let's say a bit over 20% with two roommates, plus two more cellphones, rounding off at AR$700 per month, AR$233 per person per month.

In a city, transportation is a necessity rather than a luxury; typical is AR$1.70 for a bus ride twice a day per person, AR$102 per month. You may be able to get by with a bicycle, and a bicycle may actually work better at some times of day, but it's not an option for everyone

(like me, when my knee started to hurt a couple of years ago, although it's better now) and the bicycle is not without its own expenses; and transportation is more expensive for some people, particularly once you stray outside the capital; so I'm going to use AR$102 as my estimate of the basic cost of transportation.

That is, the basic expenses come to roughly this:

	AR$ per person per month
food	150
housing	300
utilities	233
transportation	102
total	785

There are people who live on less than AR$800 per month, but it's difficult and risky; there are always unplanned expenses. For example, I was very grateful to have AR$30 for antibiotics earlier this week when I came down with an unplanned kidney infection. A few weeks ago, I wouldn't have.

On the other hand, it seems like an AR$800/month/person basic income guarantee would be enough to nearly eliminate material insecurity. Right now that's about US$95, or US$150 at the official exchange rate. Per year, it would be about US$1800 per person, using the official rate. Argentina's per-capita GDP is about US$10600 nominal, so this is about 17% of GDP. Current population is about 41 million people, and the official government budget (not counting the difference between the official and unofficial exchange rates, which amounts to a heavy export tariff on legal exports) is about US$113 billion per year, US$2800 per person per year, or US$233 per person per month.

Providing a universal basic income, then, would cost about 64% of the current government budget, 17% of the total GDP. But it would subsume certain existing government programs --- for example, there's already a limited basic-income program called the *Asignación Universal por Hijo*, which only applies to minor children, only to 30% of them, and provides much less than the AR$800 I'm arguing is necessary.

I think the US$40B budget of ANSeS, the National Social Security Administration, is a good estimate of the size of the government programs that would be replaced; ANSeS's budget includes the AUH, the pensions of basically everybody (since the 2008 nationalization of the private pension funds), maternity leave, and so on. There might be some programs within the ambit of ANSeS that would not be replaced by a basic income, but there are also housing and healthcare subsidy programs which could possibly be replaced with a basic income which are not part of ANSeS.

So if we replaced an ANSeS-sized chunk of the budget with a basic-income program that paid US$1800 per person per year, and whose administrative costs were an additional 10%, we'd add only US$42 billion per year to the national budget — US$1010 per capita, a 37% increase from its current level:

	US$/year/person
basic income	1800

total expense of basic income guarantee program	1980
cost of ANSeS	-970
net tax increase from replacing ANSeS with BIG	1010
current total national government revenues	2700

On the other hand, this might be unrealistic; in particular, I think most pensioners need quite a bit more than AR$800 per month, something like twice that, and they're not as flexible as younger people — working for extra money, or moving in with roommates, is very difficult for many of them, and they have medical expenses younger people don't. So you might not be able to replace pensions entirely with a basic-income guarantee. You might need to allocate an extra AR$1000 per month to each of the 5 million retirees, an additional AR$5B or US$1B per month, US$12B/year; and there might be a need for other programs along these lines.

But it does seem like the magnitude of the expenditure would be manageable within the context of a modern society like Argentina, if nontrivial. Politically, however, it seems impossible at the moment, since even the modest AUH attracts heavy criticism, along the usual welfare-queen lines.

Friction-cutting plastic

Kragen Javier Sitaker, 2019-02-25 (8 minutes)

I just tried friction-cutting some PVC pipe with cotton string. A thicker braided string worked very reliably, but required a lot of work to melt the large amount of plastic, also leaving a rougher cut with bigger burrs. A thin twisted cotton string worked with a lot less effort, leaving a cleaner cut, but also broke several times.

I was thinking that you could probably do a kind of low-energy friction bandsaw/jigsaw for thermoplastics, as a kind of low-budget substitute for laser cutting and waterjet cutting, at least those that soften enough at a low enough temperature; cellulose string works up to about 200°, while steel wire should work well at higher temperatures. Nylon reputedly also works for PVC, since its softening temperature is so much higher than PVC's; cellulose reportedly works for nylon itself, while other sources claim cotton won't cut PVC. I think UHMWPE cord will not work at all, though I haven't tried it.

Ideally you'd have much, much less mass attached to the string than my hands and arms, so that when it encounters extra resistance it just stops instead of breaking the string, and then maybe backs off a bit to extricate the string from the melt before trying again.

In theory the energy for making such a cut is strictly proportional to the volume of the cut, so as the cut becomes thinner, the energy to make it decreases proportional to the width. However, the force available decreases proportional to the cross-sectional area of the cord, which (if it stays round rather than becoming a strip like an actual bandsaw or even jigsaw) is proportional to the *square* of the width; so applying the same amount of power per unit material requires increasing the speed in inverse proportion to the thread thickness.

I was thinking that for straight cuts, slots, and non-through cuts, you might be able to use a paper or card disc in a sort of angle-grinder configuration — clamped somewhat close to the edge between two thicker discs to provide it with a sufficiently stiff forward force, to keep the paper from buckling too much. In this case, at a high enough speed (for a small enough disc) the centrifugal force of the paper itself would provide most of the pressure against the material.

Plumbers say PVC is rated for up to 154° F continuous service, which works out to be almost 68° in modern units and softens at 250° F (121°), but doesn't melt until 360° F (182°); Wikipedia claims the Tg is 82° and the melting point can be as high as 260°. Probably somewhere in the middle is when it gets soft enough to be easily moved by the string.

The variability in PVC's heat-stability is partly because it needs heat stabilizers to work at all; otherwise it starts to release HCl at only 70°, according to Wikipedia.

According to the plumbers' discussion thread, its specific heat is 0.25 "Cal/°C/gm", which I think means a quarter of that of water, working out to 1.05 J/K/g in SI units, pretty close to the 0.9 kJ/kg/K in Wikipedia. I think we're talking about a ΔT of around 150 K, so around 150 J/g; due to PVC's density of about 1.4 g/cc, this is roughly 210 J/mℓ. The cotton string I was using might have been 0.8

mm wide, the pipe was about 1.5 mm thick and about 20 mm across, and it took me less than a minute to cut through it at about 1 m/s of string motion at close to its breaking tension, which is about 30 N — about 30 W and about 30 seconds, so about 900 J. The annulus of $\pi((10\text{ mm})^2 - (8.5\text{ mm})^2) \approx 90\text{ mm}^2$ had a volume of about 70 mm³ and thus weighed about 70 mg or 0.07 g. So the heat needed to soften it adequately should be about 15 J, about 60× smaller than what was being applied. (More experienced people report shorter times to cut even thicker pipe.)

Presumably the extra heat was lost to inconsistent pressure, conduction into the plastic with its ≈0.2 W/m/K conductivity (in part because the contact area was large — cutting worked much faster once I had gotten through the first wall), heating of the air, and heating of the string. So probably using much higher power would have been more efficient; perhaps instead of 1.7% efficient we could reach 5% or 10%.

To be concrete, maybe 10 m/s would have been a better speed for the 800-µm string, cutting through the pipe in more like 3 seconds, or maybe 1 second if the hoped-for efficiency advantages materialize; if we were using an 80-µm cellulose string, we might prefer to run it at 100 m/s and only about 2–3 N; this would theoretically melt the same amount of material per second, but in an 80-µm-wide path, so it would use 0.3 seconds or 0.1 seconds to cut through the same pipe. This works out to about "500–1500 inches per minute" in archaic units, which is a quite fast cutting speed for panel-cutting machines like laser cutters, CNC plasma torches, CNC oxy-acetylene torches, and waterjet cutters.

How much efficiency improvement could we expect from cutting faster? A W is a J/s, so we have 0.2 J/s/m/K of conductivity. Presumably if we put the heat in in one-tenth as many seconds, we'll have the heat spread out into the same set of nested cylinders it would have had if we had been cutting at the same speed in a material with one-tenth the thermal conductivity, 0.02 W/m/K. I don't know how to estimate how much this improves your efficiency.

Is it plausible to run an 80-µm cellulose thread at 100 m/s (220 mph in archaic units) and 2–3 N (7–11 ounces)? You could maybe use a 10-meter long loop of it at 10 Hz; it would be 50 mm³ and thus about 50 mg. 3 N could accelerate or decelerate it at 60000 m/s/s, so it could start or stop in 1.7 milliseconds at the edge of breaking. That sounds fast, but it's 85 mm of travel at that speed, which is how much stretch would need to happen.

So that might be too much, but a slightly less ambitious goal is probably feasible, though.

Doing this in Styrofoam or other foams might be even more interesting, since there's so much less mass, its thermal conductivity is so much lower, and the quality of a melted cut through Styrofoam is so much better than that of a cold cut, due to sealing off the cells.

You might think polyethylene would be much easier to cut this way, given its lower melting point, but in practice it's more difficult; I think this is because it's softer and has a higher specific heat (2.3 J/g/K, 2.5 times higher) and higher thermal conductivity (0.3–0.5 W/m/K rather than 0.2), but also because it lubricates much better, so much higher normal forces are needed to get the same frictional force. Presumably stepping up the power as outlined above

would be sufficient to solve the problem.

Methods of pumping ice-vest coolant silently

Kragen Javier Sitaker, 2019-09-28 (12 minutes)

I was thinking about Ice pants (p. 298) and related ice vest stuff on the bus the other day. One of the potential problems with the design is that it needs a pump; pumps are usually noisy and unreliable, in part because they contain a lot of moving parts. A pump that avoided these problems would be desirable for an everyday-wear ice vest, which after all only needs a small total flow rate. (To remove 200 watts of heat by warming water from 0° to 20°, you need about 2.4 milliliters per second: 200 W / (20 kcal/ℓ).)

Magnetohydrodynamic motors

Magnetohydrodynamic motors are pumps that solve these problems by passing a current through the liquid to be pumped at right angles to an applied magnetic field. The magnetic field produced by the current creates a pressure gradient in the fluid, which propels it silently through the passage. Jacque Fresco famously envisioned silent ships propelled by this means, although this might require unreasonably large fuel cells if you aren't going to generate the electricity with a noisy heat engine; perhaps some navy has tried this approach for silent nuclear submarine propulsion. In, I think, 2018, the YouTube channel Cody'sLab demonstrated the use of such a pump for pumping mercury between reaction vessels for the chloralkali process.

The electrolysis problem

However, electrolysis poses a potential difficulty for magnetohydrodynamic motors in water and other ionic conductors: the electrodes immersed in the liquid will tend to produce bubbles of oxygen and hydrogen. This problem can be reduced to some extent by periodically reversing the direction of the current (and of the applied magnetic field, so as to not reverse the flow direction) but not, I think, eliminated, in a classical MHD motor. In most circumstances, this is not a problem for MHD motors, though measures must be taken to prevent anodic dissolution, such as using carbon electrodes.

Perhaps the lore of electroplating has useful information here, because bubble buildup is a problem for electroplating — plating doesn't happen in regions of the cathode covered by bubbles. But anode bubbles are no problem for electroplating.

The buildup of explosive gases in the tubing of an ice vest could not only impede liquid flow but potentially even pose a hazard of rupture and fire.

Brine coolant

The coolant in the ice vest needs to have a melting point below that of pure water so that it can pass unimpeded through the ice pack without risk of freezing, and it needs to prevent bacterial and fungal growth inside the tubing, since those can also produce gases and

potentially corrode the tubing. One possible solution to this problem is to use water sufficiently salty that almost no life forms can survive in it, and this has the advantage of greatly increasing the water's conductivity. This probably requires keeping the water from contact with glass or metal to prevent heavy corrosion, though most common plastics would be fine.

Eddy-current-driven pumping

A possible electrolysis-free way to do a magnetohydrodynamic motor to pump an electrolyte is to use eddy (electrical) currents rather than linear (electrical) currents through the electrolyte, thus eliminating the need for electrode contact — in essence, a squirt coilgun rather than a squirt railgun. This is the same approach used in squirrel-cage AC motors, coilguns, and some magnetic-levitation systems. I think eddy currents should provoke no ionic concentration gradients at all.

One way to do this would be to wrap many coils around an electrolyte-filled tube and energize the coils in the same current direction in sequence, moving the magnetic field along the length of the tube. This will induce eddy currents inside the electrolyte around the axis of the tube opposing the direction of the coil current, thus producing an opposing magnetic field, growing with a time constant related to the inductance of the single "turn" around the axis and the resistance of the electrolyte; when the coil magnetic field moves to the next coil, the thus-magnetized electrolyte will be attracted to it, with its magnetic field potentially diminishing with the same time constant. Energizing the coil behind it with the opposing direction of current will also help.

The movement speed of the applied magnetic field needs to bear a certain relation to the movement speed of the liquid and the RL time constant of the induced eddy current. If the field moves too fast (e.g., 100 000 m/s), the eddy currents induced in the liquid will not have time to build up to a level where they can produce an appreciable magnetic force; indeed, the magnetic field will be confined to the skin of the electrolyte by the skin effect. (Am I misunderstanding this? Perhaps large eddy currents occur almost instantly and the magnetic field penetrates more deeply as they begin to die away?) On the other hand, if the field moves too slowly (e.g., 1 μm/s), the eddy currents will have decayed to very low levels before the applied magnetic field moves to the next coil. Somewhere in between is a sweet spot.

It may be more efficient to use a small tubes to get a more concentrated magnetic field or large tubes to get less viscous losses, to use concentric tubes separating liquid layers to force the eddy currents in the outer parts of the liquid to enclose a large area of magnetic flux, to use an annular tube with just an air space in the middle for the same reason, and perhaps even to replace that air space with something like ferrite — although perhaps that would result in increasing the force on the ferrite rather than the liquid.

A centrifugal magnetic stirrer

As an alternative to magnetohydrodynamic motors, you could drive a solid impeller.

Chemistry labs nowadays commonly use magnetic stirrers, often

built into hotplates. These apply a magnetic field rotating at a few Hz to the reaction vessel, typically an Erlenmeyer flask; a magnet moving freely at the bottom of the vessel is free to rotate to align itself with the rotating magnetic field. (The magnet must be encapsulated in something; I suspect teflon.) This usually produces a substantial amount of noise, but much less than a conventional motor driving a gearbox which turns an impeller on a bearing-mounted shaft that passes through a seal. And, although it has a moving part, that moving part has tolerances measured in centimeters, so wear is not much of a problem.

You could apply the same approach to the ice vest, applying a rotating magnetic field to rotate a solid impeller entirely contained inside the liquid chamber; the low speeds involved (< 60 rpm) suggest the use of a permanent-magnet-based impeller rather than something like a squirrel cage. To prevent the clattering noises common with chemistry-lab magnetic stirrers, the impeller could be circular, like a centrifugal blower, rather than oblong; a Tesla-turbine design might work. By giving it the same overall density as the liquid, balancing the extra density of the permanent magnets by including air bubbles, you could avoid stresses from impacts and changes in the direction of gravity.

The magnets themselves might be sufficient to prevent its axis of rotation from deviating too far from the axis of the pumping chamber without requiring a shaft, and to prevent it from translating axially until it hit a wall of the chamber; thus it could normally operate without any solid-to-solid contact and thus without any wear. Whether the magnetic fields were radial (as in a squirrel-cage motor or ordinary BLDC motor) or axial (as in a pancake motor), active position control may be necessary to prevent instability that would cause it to drift closer to some of the electromagnets until it hit a wall. Perhaps fluid-bearing effects could be adequate to prevent this.

In some sense the ideal would be to have the highest MMF density and thus flux density at the center of the pumping chamber rather than near its walls, so that the magnet or magnets in the impeller would tend to drift toward the center rather than toward the walls. Given that the coils applying the magnetic field are necessarily in the walls, I'm not sure if this is feasible, but it might be a good start to wrap the coils around the center of the chamber (e.g., in the xz plane and the yz plane, if the z-axis is the rotation axis and the origin is the center of the chamber — not parallel to those planes, actually in them) rather than around cores outside its walls.

The use of a solid impeller would obviate the necessity for using an electrolyte, allowing the use of less corrosive liquid coolants (see Coolants (p. 3235)) such as propylene glycol or a water–(propylene glycol) mixture. This in turn could perhaps enable the use of a bare metal impeller without excessive corrosion, though I would think that plastics such as PET would still be a better choice.

If the pumping chamber were spherical rather than cylindrical, the impeller could rotate freely in it when the pump was being rotated in space, thus avoiding collisions with the walls, even if the impeller itself were still cylindrical (though it could be spherical as well, like those spherical compasses people mounted on their car dashboards in the 1980s). The applied magnetic fields would eventually bring it back into alignment for proper pumping action.

Pump energy use

Another reason to want to use a tiny, low-power pump is to reduce the amount of heat added to the water from viscous friction. If you're using a 10-watt pump that's 50% efficient, it's adding 5 watts of energy to the water, and so the water will heat up at 5 watts. While this is small compared to the total cooling load of a one-person ice vest, it is not insignificant --- someone relaxing at 70 watts might find that the reduction in "battery life" from 5 hours 17 minutes to 4 hours 56 minutes (on 4 kg of ice) was a significant loss.

An even bigger issue, though, is the weight of the battery used to power the pump. 10 watts over 4 hours is 144 kJ, which is about 250 g of lithium-ion batteries. Reducing the pump power usage down below the one-watt level, if it's possible, would lighten the battery weight of the suit dramatically.

Pulsing

As described in Intermittent fluid flow for heat transport (p. 521), a pulsing flow is more effective than constant flow for this sort of thing, because it distributes the coolth more evenly. One way to achieve this is to use a pump with several times the needed flow rate, but only run it a small fraction of the time. This results in higher viscous losses (for a given tube diameter) but may be worth it.

String tuple encoding

Kragen Javier Sitaker, 2017-04-28 (2 minutes)

A number of algorithms and data structures depend on the lexicographical ordering of bytestrings; for example, tries, LevelDB, `LC_ALL=C /bin/sort`, the American Flag Sort, and suffix array construction algorithms. These are often asymptotically higher in performance than alternatives based entirely on item-to-item comparisons, and often have better constant factors as well. So it can be useful to find bytestring encodings of different abstract data types that preserves those data types' natural orderings.

There is existing work on this. Dean Landolt's `bytewise` is a library for encoding arbitary JS data structures as byte strings for just such purposes. UTF-8 is an algorithm for transforming a sequence of Unicode codepoints into a sequence of bytes or vice versa, and it preserves lexicographical ordering in precisely the way I'm talking about here.

This note, however, is about a specific subproblem: the problem of encoding a tuple of bytestrings as a bytestring while preserving lexicographical order. That is, if the alphabet of bytes is `Σ`, we want an injective mapping `Σ** → Σ*` that is a homomorphism when we consider the elements of `Σ**` and `Σ*` as elements of a totally ordered set whose order is defined lexicographically.

Bytestuffing

The approach taken by `bytewise` for arrays is to encode them as an array type byte 0xa0, then each item followed by a NUL byte 0x00, then a final terminating NUL byte 0x00. This is clearly correct if the encoded items in the array cannot contain NUL bytes, but of course they can if they themselves are arrays (or, as it happens, numbers, buffers, or some other types). So `bytewise` bytestuffs the item encodings as follows: an embedded 0x00 as 0x01 0x01 and an embedded 0x01 as 0x01 0x02, and symmetrically, but for other reasons, 0xff and 0xfe are bytestuffed to 0xfe 0xfe and 0xfe 0xfd. This correctly preserves the lexicographical ordering.

The example currently given in the README is that `new Buffer('ff00fe01', 'hex')` encodes as (hex) 60ff00fe01, `'foo'` encodes as (ASCII) 'pfoo', `['foo']` encodes as (C) `"\xa0pfoo\0\0"`, and `[ new Buffer('ff00fe01', 'hex') ]` encodes as (hex) a060fefe0101fefd01020000.

While this is correct, it has the disadvantage that, for a single level of bytestuffing, the worst-case encoded size is double the decoded size, and, as it happens, the encoding of a value needing bytestuffing will

Lab power supply

Kragen Javier Sitaker, 2017-02-21 (updated 2018-06-18) (17 minutes)

I just made a 0–11.5V adjustable power supply from an ATX power supply in the Ekospace hacklab. Soldered the green wire (what is this called?) to ground so the power supply turns on automatically and cannibalized a SATA power connector to hook up the +12V yellow wire and ground to an emitter follower built out of a TO-220 D13007K NPN power transistor someone salvaged from a motherboard, three 2.2kΩ resistors (half-watt I think), and a 10kΩ potentiometer.

This works for spinning up a tiny motor I found in the parts bin, but it's not very efficient, and it's likely to burn up the transistor at some point, because whatever voltage doesn't appear on the output is dissipated across the transistor. The TO-220 could theoretically dissipate 80W if it were like screwed to a heatsink or something, but it's not. It could maybe dissipate like 20W, which at 12V would be just 1.7 amps, although it can probably handle its rated 8 amps at its max voltage, if not the full 18 available from the power supply in question.

It has the additional disadvantages that there's no display for the voltage or current (you can set the voltage by hooking up a voltmeter to the output while turning the knob) and the output voltage will fluctuate with the input voltage from the ATX power supply, which can vary.

So, what would a better solution look like? You could build a buck converter based on the AVR ATMega328 used in the Arduino. It has an internal 1.1V voltage reference. You could use one of its six PWM outputs (with 8 bits of precision you get 31.25kHz; I think you can get 62.5kHz if you accept 7 bits of precision) to control the buck converter. A couple of external resistors could form a voltage divider to scale down the buck converter's output voltage to the 1.1V range, which feeds into the ATMega328's 10-bit ADC. A transistor, inductor, diode, and capacitor would complete the buck converter. An additional low-value sense resistor could measure current on a second ADC channel (there's one ADC but 6 or 8 pins that it can multiplex between). Then the AVR could produce output displaying the voltage and current either on six seven-segment displays (13 digital GPIO pins in the usual multiplexing arrangement) or through a speaker on a second PWM channel. A third ADC channel could be used to read a potentiometer to control the output voltage.

How big do these external components need to be, and how much precision do we need?

Supposing arbitrarily that I were to use a similar ATX power supply capable of 18A on its 12V output, which works out to 216W (a bit over a quarter horsepower), it would be nice to be able to carry that 216W most of the way down the range, say down to 2V — which would mean 108 fucking amperes. This is a somewhat unreasonable amount of amperage, as common power transistors are typically in like the 1 to 8 amp range. A popular power transistor with somewhat more oomph is the Siliconix SiS410DN, which costs 94¢ from Digi-Key and handles 35 amps; then there's the Nexperia

PSMN4R0-40YS from 2010, which costs 88¢ and handles 100 amps. But I'm probably not going to salvage those from discarded Argentine electronics.

I can buy similar power MOSFETs here in town at G.M. Electrónica or SyC Electrónica, though, even if they are somewhat inferior and more expensive. They only carry International Rectifier parts (or STMicroelectronics versions of them) in that range, though; they both have, for example, the IRF540. SyC's price for the ST version is 60¢.

So let's say I use one of those. It turns on at 4V, so I don't need a gate drive level shifter. The STMicroelectronics version SyC sells for 60¢ handles 22 amps, which is more than the ATX power supply can deliver anyway (though maybe a capacitor on the input of the buck converter could help with that). We only really need (or can display on a 3-digit LED) about 100mV precision, so 128 duty cycles is probably enough, so we can probably use the 62.5kHz speed. How much energy do we need to store in the inductor at 62.5kHz?

That's 16 microseconds per cycle. I'm a little unclear on exactly how the math of buck converters works out but I am pretty sure that it will not involve storing more than 16 microseconds' worth of power in the inductor, which would be three or four millijoules, and I'm pretty sure it's okay for the inductor current to fluctuate by 10% or so, maybe a lot more. So if $\frac{1}{2}LI^2 = 4$ mJ and $I = 18$ A, then $L = 2{\cdot}4\text{ mJ} / (18\text{ A})^2 = 25\mu\text{H}$, which I would have thought a fairly small inductor but is apparently around the 75th percentile of modern inductors. Combining that with the high current requirement leaves very few options in Digi-Key's catalog.

One such is the Würth 7443643300, which goes for US$8.50 — 33µH, 30A, 2.4mΩ, self-resonant at 7MHz, ferrite, 28.5mm × 19.5mm × 18.5 mm, ferrite, saturating at only 11.5A (which seems like it could be a problem in this application!). It seems to be five turns of flat 3.8mm × 0.8mm copper tape!

So it's feasible but maybe more study of buck converter math would help me more. PDM might also help by reducing the cycle time to submicrosecond levels; ST's IRF540 has a turn-on delay plus rise time of 105ns, which means we can't go deep submicrosecond without losing efficiency, though Infineon's part may be a bit faster.

Horowitz & Hill draw the buck converter with a Schottky diode, which makes a certain amount of sense — 18 amps at an 0.7-volt voltage drop would be about 13W dissipated in the diode, and indeed most popular large-current diodes on Digi-Key are Schottky, like the VB30100S-E3/8W, which is 100V, 30A, in a TO-263AB surface-mount package with a cathode-body connection; this has the ordinary 300mV Schottky silicon voltage drop at ordinary currents, but at 10A it's already up over 500mV, and at 18A it's almost 700mV. At its rated maximum 30A it's 910mV.

Horowitz & Hill also end up using a 150µH inductor for their first example (5V, 500mA, 50kHz). Is that less of a pain in the ass?

A 220µH 700mA ferrite inductor costs 32¢ at Digi-Key; a 150µH 1A ferrite inductor is 56¢. It has axial leads and is 6.4 mm in diameter and 14 mm long. A 150µH 2.2A ferrite inductor (saturating at 1.8A) costs US$1.03 and is 12mm × 12mm, and at this point we're starting to get into lower frequencies, higher costs, and shielded construction. At 4A and 150µH we're getting into US$2.37 25mm iron toroids with

thick copper wire around them, and the price trend is clear, although at this point still only linear with current — this one holds 1.2 millijoules, 500µJ/$, while the 2.2A one was only 350µJ/$. Above 8A, prices start to climb proportional to energy and we're getting into big wirewound powdered iron cores and then laminated silicon steel.

Someone tried making an Arduino-driven buck converter like what I'm suggesting and discovered that since the IRF540 is an N-channel FET it's a pain to switch the high side with it. Also apparently buck converters need to react quickly to inductor saturation to prevent explosions. Some Croats did it successfully. They did use a humongous wire-wound toroid.

Man, I've really gotten hung up on the inductor, haven't I? It's just that I'm worried that a giant piece of shit like that could really ruin what would otherwise be a tiny, cheap, ferocious power supply.

The freewheeling diode itself might function as an adequate current sensing "resistor"; as mentioned above, a Schottky diode varies over the 300–900mV range on its way up to 30 amps. This is pretty dependent on the temperature, but if you can somehow correct for that, you should be able to measure the current within about 3% over a 10mA to 10,000mA range, no problem. I think the inductor-driven current through the freewheeling diode may generate a negative voltage with respect to ground, though, which is inconvenient for measurement.

Alternatively, you could have like a 50mΩ sense resistor on the ground side; at 18A this would be 900mV, and each millivolt change (about one count on the ADC) would be 20 mA. This introduces a little instability into the voltage regulation, although for many loads you could compensate for that adequately in software.

Scanning six 7-segment displays should be fairly trivial if you have 13 available GPIOs after the buck regulator PWM output and two ADCs.

To run the AVR itself off the 12V supply, if you're not using an entire Arduino, you could just use a 7805 regulator. An ATMega328 supposedly uses 12mA at 8MHz active, so probably 30mA at 20MHz (though another part of the datasheet says 12mA at 20MHz). If it's using ¼W or ½W, it isn't going to burn up the 7805 to be wasting another ⅜W or ⅝W. Or maybe you could use a resistor and a 5V 1W zener (SyC has them in stock for 11¢, although I have no idea how to salvage them).

Cheaper AVRs might work. The ATTiny5 costs 35¢, runs at 12MHz, has a four-channel 8-bit ADC, and has four I/O pins. The cheapest AVR with 16 or more I/O pins is the 76¢ ATTiny40; it has 4KiB of flash, 256 bytes of RAM, runs up to 12MHz, and has 12 channels for its 10-bit DAC.

I think probably the very next step is to hook up an AVR display to the existing linear power supply to merely passively measure its voltage. This involves minimally an Arduino, three current-limiting resistors (220Ω or 470Ω, say), three seven-segment displays, 10 GPIO pins to run them, and a voltage divider to get the voltage input down below 1.1V.

As a sub-step before that, I should see if I can run this calculator LCD off my Arduino. For that I won't even need resistors. But maybe I can buy some transistors too.

So, I salvaged (is that the word?) a four-digit seven-segment green

LED clock display from a Philips clock radio. It's an LTC-637D1G, which turns out to be a Lite-On product from 2000; I already reverse-engineered its pinout before googling up the datasheet, which pretty much confirms what I'd already figured out — it's a supremely shitty pinout, with the dubious grace of having only two cathodes instead of the expected four, so I can get by with two resistors instead of four. It had the benefit of lighting up visibly when probed with the multimeter in the hacklab on the diode-test setting. LED voltage measurements on the variable-voltage power supply show that the LEDs start to become visible at about 4V on a 220Ω resistor, at which point they themselves are dropping about 2 volts, leaving 2V for the resistor, so the current is about 9mA. Turning the power supply up to 11.5V illuminates the LED more brightly but doesn't burn it out; at this point it has about 3V across it, which exceeds the 2.6V max from the datasheet, though I guess that was at 20mA, and this is more like 38mA, which also exceeds the 25mA continuous current max in the datasheet.

The datasheet says it can handle 100mA peak currents, but that's not safe if they're running straight off an AVR pin. The AVR as a whole is only rated for 200mA on its Vcc and ground pins, and only up to 40mA per channel. And if I use the 220Ω resistors I now have soldered to the common cathodes, the max I'll get at 3V (5V minus the LED's 2V or more drop) dropped across the resistor is 14mA. On the plus side that means I can run two diodes off one anode pin at the same time, so I can scan across the active anode pins, toggling the cathode pins between tri-stated and low according to whether that "pixel" is supposed to be on or off.

Since this is a 24-hour clock display, the first digit is missing the segment that isn't displayed in either the digit 1 or 2. So it's probably better to use just the last three digits. These have only 11 anode lines between them; if all 11 have active data on them, I can manage a 9.1% duty cycle. This works out to an average bright current of 1.3 mA, which I think will be barely visible at all. This could be improved slightly to like 1.8mA average, but getting it up to near the 10mA average suggested in the datasheet would require 11 high-side drivers for the LED anodes, like bipolar transistors or something, since that would require the full 100mA peak current specified — twice that if both cathodes are active. So for now I think I'll give it a pass.

So the AVR power supply voltmeter needs 11 anode pins, 2 cathode pins, and one analog input pin, which means it can fit into much smaller AVRs than the ATMega328. The ATTiny40 with its 18 GPIO lines and 4K of Flash, for example, should be fine. It costs 76¢ and is 3.1mm × 3.1mm in a VQFN. (The 328's smallest package is 5.1mm × 5.1mm.)

Refreshing at 1kHz (again, as suggested in the display datasheet) would require iterating at 11kHz. At the AVR's internal RC oscillator speed of 8MHz, this gives us 727 clock cycles per display update — far more than necessary to respond to the timer interrupt. At an Arduino's 16MHz speed, we have twice as many.

I cobbled together a voltage divider out of some carbon-composition resistors found lying around; it turns out they are 140kΩ and 4.2kΩ, so the voltage scaling factor will be 4.2/144.2 = .0291, so 12 volts would be measured as 350 millivolts. However, the AVR's 1.1V internal bandgap voltage reference is specified to be

between 1.0 and 1.2 V, so that might digitize as anywhere from 298 counts to 358, and the count will change at least every 40 millivolts, which is about the right accuracy for an 0.1-volt-resolution digital voltmeter.

A thing I largely neglected above: a bench power supply needs current limiting. A purely linear approach to this is to use an LM317 (1.5A max) with ADJ connected to the load and a sense resistor between it and OUT — the LM317 will let the full voltage through until 1.25V is dropped over the sense resistor. 2Ω limits you to 625 mA, for example.

You could reasonably run a sense resistor like this in series with the usual voltage divider, limiting a weighted sum of current and voltage rather than either one alone. Or maybe you could use a couple of diodes to limit them separately with a single LM317: either a large enough output voltage or a large enough output current would pull down the ADJ pin through diodes from the ADJ pin to the end of the sense resistor and the middle of the voltage divider. This also gives you an extra 0.7V or so, so the ADJ pin won't get to 1.25V below output until the point that's pulling it down is 1.95V below.

The LM317 has internal thermal overload protection, a plus, but it needs 2.5 mA of output current to stay in regulation. One big disadvantage it has for this purpose is that it's not LDO — it has a 2.5 V dropout, so it can't deliver more than 9.5 V off a 12V ATX supply. If you keep the output resistor to ground under 500Ω then it'll always have enough bias current.

Jello printing

Kragen Javier Sitaker, 2016-12-14 (8 minutes)

I think jello normally has about the refractive index of water, but it's possible to change it from about 1.3 to about 1.7 by adding sugar, or lower it as low as 0.7 by adding alcohol; both will diffuse through the jello once it is set. To avoid chromatic diffraction patterns, the difference in optical path length should be over 10λ, or about 7μm for red light. This in turn suggests that a variation in refractive index from 1.3 to 1.4 would require layers of some 70μm or more in thickness. But of course that is easy to achieve; what is difficult to achieve is layers of *less* than about 100μm.

The proposal, in short, is to deposit jello with a 3-D printer in thin layers with continuously variable sugar or alcohol content, in order to approximate a desired optical transformation function. Other food gels such as agar, carrageenan, or konjac are also likely to work well, and have the advantage of avoiding ethical issues with cruelty to animals. As the jello is deposited, it will cool and gel, slowing but not eliminating the diffusion of the dopants.

Discontinuities in refractive index that scatter light in conventional optical systems, producing stray light that limits optical system performance. Dopant diffusion eliminates these discontinuities, replacing them with gradients, permitting order-of-magnitude improvements in optical system complexity.

Active closed-loop control of refractive index of deposited material permits the use of very small differences in refractive index to improve control of optical phase delay. Given a layer thickness of 200μm, a minimally acceptable phase delay error of 100nm would seem to require .05% error in the refractive index of the deposited material, for example, controlling whether the refractive index is 1.4000 or 1.4007. This turns out to be feasible with closed-loop control, as follows.

According to the International Scale of Refractive Indices, water's refractive index at 40% sugar is 1.3997; at 41% it is 1.4016, a difference of 0.0019 units of IOR over 1%. Ordinary lab refractometers provide a readout to 5 digits of precision. So this level of control amounts to controlling the sugar content of water to a precision of about 0.3%, or 0.3°Bx, which I think is feasible. Indeed, it should be feasible to control it to within the precision of the refractometer, 0.0001 units. This corresponds to a phase error of some 20nm, which is acceptable for even the most demanding optics. Some refractometers have 5× smaller errors than this, which requires wavelength calibration of their light source and temperature compensation of the sample.

Such closed-loop process control using process refractometers has long been common practice in industries that process sugar solutions.

It isn't necessary to control the IOR of the finished product to this level of precision in an absolute sense, because what matters for refraction is the *gradient* of IOR; it's just necessary to avoid random errors between passes and layers. This is fortunate, because the refractive index of the sugar-water system varies with temperature by about 0.0001 per kelvin.

It should be possible to achieve fine control of sugar concentration

by mixing two or more homogeneous solutions in varying proportions; for example, a mixture of 36%-sugar jello A and 42%-sugar jello B that is 50-50 would be 39% sugar, while if it's 55-45, it would be 38.7% sugar. In this way a 5% error in the mixing process amounts to only an 0.3% error in the final concentration.

Some other related solute systems have nonmonotonic refractive-index curves; the ethanol-water system, for example, reaches its maximum refractive index of about 1.3658 at about 80% ethanol, thereafter declining to 1.361. In the neighborhood of this local maximum, fairly large changes in the concentration of ethanol are needed to obtain small changes in refractive index; for example, IOR is 1.3654 at 72% ethanol, but 1.3657 at 76% ethanol. This improves the control over IOR that can be achieved despite errors in mixing.

Ethanol has the major disadvantage that it is a very small molecule, so diffusion and consequent degradation of the instrument is likely to be very fast. Instead, larger molecules than sucrose would be advantageous in order to delay diffusion further.

A perfectly flat "Fresnel" lens of jello with a thickness of about 200μm should be achievable with this approach. A simple waveplate pattern would provide an aspheric focusing lens, for example, although at the cost of dispersion and some stray light from the boundaries between the rings. A thicker lens, probably thicker than normal glass lenses, could reduce the number of rings (perhaps to 1) and thus eliminate the stray light. It should be feasible to fabricate an entire compound microscope or telescope in a single solid block in this way.

To prevent decay of the product (before it is destroyed naturally by diffusion), some kind of antibacterial and antifungal agent should be included. Ethanol at levels above about 15% is one possibility; sodium chloride is another; acids such as acetic acid or citric acid are yet another. Finally, a sufficiently high level of sugar would also prevent decay, but that level might be high enough to prevent gel formation.

It's probably desirable to encapsulate the final result in some kind of airtight container (sandwiched between glass plates, filling a transparent polyvinylidene-chloride balloon, etc.) to prevent evaporation from converting the result to a xerogel, which would likely impair its optical properties. Alternatively, if the degradation is acceptable, xerogel conversion would protect against decay, dramatically slow solute diffusion after drying, and reduce layer thickness considerably, thus improving phase delay control.

Diffusion could also be controlled by chemically bonding the index-altering solutes to the solid matrix of the gel, perhaps by making the gel itself from a mixture of different substances with different refractive indices, or perhaps just using glucomannan or a similar dense gel former at different concentrations. (What's the name of that hydrophilic polymer they use for contact lenses and ceramic gelcasting?)

Correcting chromatic aberration probably requires multiple solutes that induce different dispersions, thus varying IOR independently at different wavelengths.

Avoiding air bubbles is of the highest importance. The simplest way to achieve this would be to do the entire printing process under vacuum, but unfortunately that is not an option with a water-based

gel at room temperature, because water boils rather violently at room temperature in vacuum. Alternatively perhaps the product could be degassed under vacuum before the gel forms, the way we do with polyester resin casting, if there aren't too many bubbles. It would be better to use a liquid (like, uh, polyester for resin casting) that has a relatively low vapor pressure and therefore can be printed under vacuum.

These gels are capable of substantial elastic deformation, often with strains exceeding 10%, which provides another axis of variation; they can be designed to provide an optical transformation which depends in a designed way on elastic deformation.

To research:

- phase-delay spatial light modulators
- konjac gelification
- diffusion
- total internal reflection
- that nontoxic hydrophilic polymer they use for contact lenses and ceramic gelcasting

Additive smoothing for Markov models

Kragen Javier Sitaker, 2007 to 2009 (updated 2019-05-19)
(11 minutes)

So when you estimate the probability of an event from a sample, you have to "smooth", which is to say that you have to increase your estimate of the probability a little bit so that it is never zero, since concluding that the probability of any event is zero based only on a sample is clearly wrong. The most common way is to add 1 to both the sample size and the number of observed events, and I think that this is in fact an unbiased estimator.

But if you have more information, maybe you can do better. In particular, I was thinking about estimating the statistical likelihood of a particular word being the next word in a sentence. This is useful, for example, for travesty generators like Mark V. Shaney.

Zeroth-Order Markov Models

You can use a "zeroth-order [Markov model][]", and just figure that the probability that the next word is, say, "figure" is the probability of "figure" being any particular word --- regardless of context. That is, it's the number of occurrences of "figure" in your training corpus (plus one), divided by the total number of words in your training corpus (plus one).

That gives you some information, for sure. But if you use that model to generate text, it doesn't look much like real text.

First-Order Markov Models

If you use a first-order Markov model, you use the previous word, say, "just". And you look for the number of occurrences of "just figure" in your corpus (plus one) and divide that by the number of occurrences of "just" (followed by any word) (plus one) in the training corpus. And you use that for your estimate.

Text generated from a first-order Markov model tends to look like relatively real text. If you don't smooth the probabilities, then you only ever get word pairs that occurred in the real text, so the text minimally conforms to a [regular-language][] approximation of the [grammar][] that generated your corpus, and if the model is [ergodic][], the frequencies of the words will additionally be about right. (See also the Jargon File entry on Dissociated Press.)

Second-Order Markov Models

You can use a second-order Markov model and look at the two words, say "and just", and then divide the number of occurrences of "and just figure" (plus one) by the number of occurrences of "and just *" (plus one) in the corpus. This generates even more realistic text, because although it's still using a regular-language approximation, the [DFA][] (a Markov model is a DFA augmented with transition probabilities) can now have N^2 states instead of N states, where N is the number of distinct words in the corpus. So it can be a better approximation.

However, now you run into a problem. The number of states in a second-order Markov model can be greater than the number of words in your text. For example, before I wrote this sentence, this note contained 475 words, of which 162 were unique. That means that a second-order Markov model built from its vocabulary would contain 26244 states, only 474 of which, at most, could contain any sample information!

So if you smooth in the way I suggested above, by adding one to the counts of both "and just figure" and "and just *", you probably wind up with a gross overestimate of the probability of "and just 26244" and a gross underestimate of the probability of "and just the", and so in fact the output can look less realistic than the output from a "zeroth-order Markov model". The usual way to deal with this in Dissociated Press is to not smooth at all; most of the transitions have zero probability. Unfortunately this often results in repeating long passages from the training corpus, especially once you go to third- and higher-order Markov models.

Essentially, such higher-order models are almost inevitably [overfitted][] --- they are so flexible that they end up learning the detailed structure of their training set, and if you try to compensate by smoothing, they don't learn anything.

How to Fix the Problem

However, it seems to me that you could do the smoothing in a more effective way, by using first-order and "zeroth-order" Markov models from the same training corpus to fill the gap.

Effectively, when you're spewing out randomly generated text, the smoothing amounts to adding one extra occurrence of, say, "and just". The standard way of smoothing amounts to assuming that all words that haven't been seen after "and just" are equally likely.

If instead you use your first-order Markov model to decide on that distribution --- in this case, the smoothed probability distribution of words following "just" --- you'll do much better.

And, of course, you can smooth the first-order Markov model using the observed word frequencies (the "zeroth-order model"), instead of assuming that all words in the vocabulary are equally likely.

When you're generating random text, there's no obvious way to smooth the zeroth-order Markov model; you can't straightforwardly generate an arbitrary word you've never seen before. But in some other applications of Markov models, such as data compression, OCR, speech recognition, and entropy estimation, you only have to deal with things that are actually found in the input text.

Note that in the case that the word pair in the current state does not occur in the training set, this reduces to a first-order Markov model. This suggests that it is the Right Thing.

Data Structures

If you want to implement this algorithm, you can use a [suffix array][] or [suffix tree][] on the training set. This allows you to efficiently answer questions like "how many times does 'model, and just' occur in the input, and what is the distribution of what occurs next?" without storing an excessive amount of data. Suffix trees take up an awful lot of space, but Udi Manber and XXX Myers

discovered a reasonably efficient algorithm for constructing suffix arrays in 1989–1991 (or was it Manber and Wu in the 1990s?), and it's used as the basis for the [Glimpse][] search engine. The suffix array merely needs space for one pointer per index point in the original text.

If you want to know what words occurred somewhere preceding a given word or phrase you really want a "prefix tree", which is a suffix tree built on a reversed version of the input corpus. ...

Other Applications

It occurred to me that if you wanted to know what words to boldface in an English text, you might have some success highlighting the lowest-probability words. This could also be useful in source code highlighting: figuring out which tokens are most informative and which are just noise.

References

Dissociated Press correctly describes Markov-chain random text generation, but incorrectly claims that Emacs's "dissociated press" is an example thereof. According to the Emacs manual:

> Dissociated Press produces results fairly like those of a Markov chain based on a frequency table constructed from the sample text. It is, however, an independent, ignoriginal invention. Dissociated Press techniquitously copies several consecutive characters from the sample between random choices, whereas a Markov chain would choose randomly for each word or character. This makes for more plausible sounding results, and runs faster.
>
> It is a mustatement that too much use of Dissociated Press can be a developediment to your real work, sometimes to the point of outragedy. And keep dissociwords out of your documentation, if you want it to be well userenced and properbose. Have fun. Your buggestions are welcome.

Penn Jillette wrote a lovely explanation of Markov-chain travesty generation in his article on Mark V. Shaney, "I Spent an Interesting Evening Recently with a Grain of Salt", published in PC Computing volume 4, number 7, July, 1991, p.282.

The idea of an index point is explained in Gonnet, Baeza-Yates, and Snider's 1991 paper, "Lexicographical Indices for Text: Inverted Indices vs. PAT trees". They had been working on putting the Oxford English Dictionary on CD-ROM, and so they'd done a bunch of work on full-text indexing. Gonnet was at ETH at the time, and Baeza-Yates was already at the Universidad de Chile. The paper is mostly devoted to advocacy of suffix arrays (called PAT arrays in the article) rather than inverted indices. They explain:

> An index point is the beginning of a word or a piece of text which is indexable. Usually such points are preceded by space...

I am a little bit puzzled about this paper; it says the PAT tree data structure "was originally described by Gonnet in the paper 'Unstructured Data Bases' [Gon83]". But the PAT tree is "a Patricia tree constructed over all the possible sistrings [suffixes] of a text," citing Donald R. Morrison's 1968 CACM paper on PATRICIA, which I believe describes constructing PATRICIA trees over all the possible suffixes of a text. But I don't have the paper handy to check.

Tim Bray, who also worked on the OED project, recently wrote a series of articles about the technical aspects of full-text indexing. He also worked for some years at a startup called Open Text whose main product used suffix arrays for its searching. His analysis of why suffix

arrays are not widely used today is very interesting.

PATRICIA has been explained in a lot of places, but unfortunately I don't know where to find the original paper online.

Overfitting is a problem with statistical models generally. Sometimes with neural networks and other machine-learning systems, it's called "overtraining".

Hey, maybe I should look at http://www.stat.cmu.edu/~cshalizi/754/.

Perry Lorier tells me that this is how the PPM* algorithm models; IIRC that's what's used in the champion PAQ family of compressors. I should look into it.

Rendering iterated function systems (IFSes) with interval arithmetic

Kragen Javier Sitaker, 2014-09-02 (6 minutes)

Not sure if this is a new IFS-rendering idea or not, but I was thinking about a recursive algorithm I'd written to render implicit functions using interval arithmetic, and it occurred to me that you can perhaps use it to do efficient escape-time IFS rendering.

Interval arithmetic computes with intervals of real numbers rather than pointwise real numbers; (-1, -½) / (-3, -2) evaluates to (⅙, ½), for example, because any number in the interval (-1, -½) divided by any number in the interval (-3, -2) will give a number in the interval (⅙, ½); and, if there's no further relationship between the numerator and the denominator, it can give *any* number in that interval.

This is a kind of very simple abstract interpretation; it gives you a conservative approximation of what values a function can range over, given a conservative approximation of its inputs. If you're, say, just looking for zeroes of the function, you can disregard whole swaths of its domain once you've computed that the function's range over that part of its domain is strictly positive, strictly negative, or (in the case of multi-interval arithmetic, which is useful for handling division by zero) a union of the two; this can give you asymptotic speedups.

My 2-D implicit rendering algorithm with interval arithmetic, inspired by my very limited understanding of Flórez Díaz's 2008 raytracing thesis, works as follows:

- evaluates the given function over X and Y intervals covering the entire canvas to be drawn;
- if the output interval it computed excludes zero, it is done;
- otherwise, if it is now evaluating deep-subpixel intervals, it simply draws white;
- otherwise, it divides the rectangle into thirds, and recurses on the thirds. (Halves or fourths or any other number works too, but is less efficient.)

So it occurred to me that you can compute a similar kind of approximation of an IFS's attractor by escape-time analysis. You can run an IFS either forward (toward the attractor) or backward (away from it). If you run it forward, regardless of which transform you choose, you will stay on the attractor if you're already there, and approximate the attractor more closely if you're not; while if you run it backward, even if you're in the attractor, most choices of transform will generally push you off of it, while there exists at least one choice (generally exactly one) that will keep you on the attractor. This means you have to *search* for the correct choice.

So I propose that you divide the canvas into a k-d tree, as in my implicit-function rendering algorithm, but one that remains stored, in which each node (bounding box, let's say, or just "box") is in one of three states:

• it's known to not overlap the attractor;
• it's known to be entirely inside the attractor, which I believe is only applicable if the attractor has Hausdorff dimension the same as the space we're working in;
• it's suspected to overlap the attractor.

We iteratively look for nodes in state 3 that are still big enough to be interesting for our purposes, and we transform them with all of the transforms at our disposal, both forward and reverse. If *any* forward transform leaves its image entirely inside a node in state 2, then this node also changes to state 2; if *all* reverse transforms leave its image entirely inside a node in state 1, then this node also changes to state 1.

This also suggests that we should link nodes in state 3 to the other state-3 nodes that we have discovered to be able to transform to and from them, so that we can propagate state changes properly when we change the state of a state-3 node.

Once this link structure has been discovered, though, we choose a state-3 node to divide into pieces, and transform it again. Presumably once the pieces are small enough, we will choose to stop subdividing, but smaller pieces might transform entirely within a state-1 or state-2 node.

But how do we get any state-1 or state-2 nodes to begin with? If we can compute a conservative bounding box for the attractor to start with, then boxes outside that bounding box will be in state 1, but state 2 is a little trickier. To find the fixed point of any of the transforms, we can solve some simultaneous linear equations, or just exponentiate the transform, since it's contractive. But that still just gives us a point (a unique point, by the Banach fixed-point theorem) rather than an interval that could actually contain another interval inside of it.

And indeed many IFSs will contain no such intervals that are entirely inside their attractors. Others, however, do; consider the 1-D IFS $f_1(x) = x/2$, $f_2(x) = (x+1)/2$, whose attractor solidly covers the space between 0 and 1; or the 2-D IFS

```
f1(x, y) = (x/2,     y/2)
f2(x, y) = ((x+1)/2, y/2)
f3(x, y) = (x/2,     (y+1)/2)
f4(x, y) = ((x+1)/2, (y+1)/2)
```

which I believe similarly solidly covers the square you would expect it to.

State 1 and state 3 are clearly enough to render a fractal, but if your particular IFS has state-2 regions in it, then it will be exponentially more efficient to be able to recognize them, since you'll be able to focus on the boundary of the set instead of deeply recursing on the whole thing. I just don't know how yet.

Anyway, so I think this algorithm, even without state 2, should scale with an exponent very nearly the Hausdorff dimension of the IFS you're looking at, multiplied by the number of IFS transforms.

Topics

High temperature semiconductors

Kragen Javier Sitaker, 2019-12-01 (2 minutes)

The distinction between insulators and semiconductors is temperature-dependent; an insulator becomes a semiconductor when the thermal energy of its electrons is enough to permit a significant number of its electrons to transition from its valence band to its conduction band, continuously replacing those that fall back down. Even if the bandgap doesn't decrease with temperature, as they generally do, this means that any insulating material will eventually become a semiconductor at a high enough temperature.

There is a lot of work on "wide-bandgap high-temperature semiconductors" like gallium nitride and silicon carbide with applications up to 300°. But I think we can think bigger: what about semiconductors at 900° or 1200°? The Stefan-Boltzmann law gives us power dissipation proportional to T^4; if at 100° we can dissipate 1 W/cm², then at 700° we should be able to dissipate 16 W/cm², and at 1200°, some 243 W/cm². This should permit substantially higher computational speeds, even despite other temperature-driven phenomena that will slow down computation.

What materials barely begin to conduct electricity at such temperatures? Quartz, of course, but perhaps also other refractory materials like lime, beryllia, thoria, urania, and magnesia. Other conduction phenomena also come into play at these temperatures, like zirconia's conduction by mobile oxygen ions.

Building devices that operate successfully at such temperatures will be challenging, among other things because they would probably be destroyed if ever allowed to cool to room temperature, and because the lifespans of structures even in fairly stable materials is human-scale at high temperatures. As discussed in Gardening machines (p. 2365), though, automated fabrication should reduce the importance of such durability considerations considerably.

Another difficulty is that you probably still benefit *something* to use as an insulator in your circuits, although room-temperature gallium arsenide integrated circuits seem to mostly do okay just using reverse-biased diode junctions.

Composing code gobbets with implicit dependencies

Kragen Javier Sitaker, 2018-04-27 (updated 2019-05-21) (3 minutes)

Suppose we have this scrap of code:

```
f = buxus.open(buxus_filename)
viewport = f.bbox()
canvas = buxcanvas.create(viewport)
```

There are lots of ways to read this gobbet of code, but one of them is as a rule which, given values for `buxus`, `buxus_filename`, and `buxcanvas`, can produce values for `f`, `viewport`, and `canvas`. Or possibly fail to.

Or consider these two lines of code separately:

```
interval_size_log = math.log(stop) - math.log(start)
```

That gives us a rule to compute `interval_size_log` given values for `stop`, `start`, and `math`.

```
n_divisions = int(math.ceil(interval_size_log / math.log(1 + spacing)))
```

That gives us a rule to compute `n_divisions` given values for `int`, `math`, `interval_size_log`, and `spacing`. This rule chains nicely with the previous one, which provides `interval_size_log`.

If you were going to apply this approach in a general way to large programs, you'd need some way to namespace these names, of course. And you need some kind of subroutine call mechanism.

In Python 3.3 and later, you can supply a custom mapping to `exec` that logs these accesses as they happen. So you can really write these just as little gobbets of Python code.

Here are some ideas for how such a soup of code gobbets could be useful:

• Conditional computation. Given the knowledge that `interval_size_log` depends on `stop`, `start`, and `math` (or, more pleasantly, `log`) you can efficiently compute all the `interval_size_log` values for a range of `stop` values, a range of `start` values, corresponding sets of `stop` and `start` values (depending, for example, on some index `i`), or independently varying sets of `stop` and `start` values.

This becomes more powerful if you add quantifiers and aggregation, although it is not clear to me how this should work.

• Incremental recomputation, although of course this requires you to make your changes to variables rather than down inside of data structures somewhere.
• Transactions. You can run an arbitrary piece of code that runs in an environment where the variables it reads and writes are monitored, and only commit its writes if none of the variables it read have been changed by a previously committed transaction.
• Inference systems.
• Hot code reloading.

• Lazy computation — although you do have to try to run each gobbet at least once to see what it might produce.
• Pattern matching. You can provide different possible ways to compute the same variable, given different possible inputs.

For many of these applications, you could have a subroutine call mechanism that works by putting some parameters into a new namespace and then trying to pull things out of it. For example:

```
isl = ns(start=1, stop=20).interval_size_log
```

Something like that might be the way to handle quantifiers and aggregation, too. Instead of saying, "What if start=1?" you're saying "What if start is any value in range(10)?" But then of course if you are going to get a scalar value out of it at the end you need to specify how you are going to aggregate the pointwise values.

Win32 startup

Kragen Javier Sitaker, 2007 to 2009 (2 minutes)

So how does a process get started in Win32?

I compiled a program `fract.exe` with a WinMain with MinGW. Callers:

```
_WinMain@16:
    _main:
        # (which seems to call _GetModuleHandleA and _GetCommandLineA etc.)
        ___mingw_CRTStartup:
            # (which seems to call _ExitProcess@4)
            _mainCRTStartup:
                # 0x401210, offset 0x0210
                no callers
            _WinMainCRTStartup:
                # 0x401230
                no callers
```

This made me suspect that those bottom two are the actual entry points, and that they have magic names looked for by the COFF loader or something. But those strings don't appear in the Wine source code, so that must not be it. But neither their addresses nor their offsets appear in the output of `objdump --full-contents` or `xxd` on the stripped binary.

The top few levels of the stack in a crash look like this:

```
  3 0x0040155a WinMain+0x9d(hInstance=0x400000, hPrevInstance=0x0, lpCmdLine=0x11o
o57f1, nCmdShow=0xa) [/home/kragen/devel/w32dry/fract.c:87] in fract (0x0069fe38)
  4 0x00401867 in fract (+0x1867) (0x0069feb8)

  5 0x004011d9 __mingw_CRTStartup+0xc9 [/home/ron/devel/debian/mingw32-runtime/mio
ongw32-runtime-3.9/build_dir/src/mingw-runtime-3.9/crt1.c:226] in fract (0x0069feeo
o8)
  6 0x00401223 in fract (+0x1223) (0x0069ff08)
  7 0x7b86eeab in kernel32 (+0x4eeab) (0x0069ffe8)
  8 0xb7e0b7a7 wine_switch_to_stack+0x17 in libwine.so.1 (0x00000000)
```

The address +0x1223 is right after the call from _mainCRTStartup to ___mingw_CRTStartup.

Looking in the WINE source, in kernel32/process.c I find "static void start_process", which has this code:

```
    LPTHREAD_START_ROUTINE entry;

    LdrInitializeThunk( 0, 0, 0, 0 );

    nt = RtlImageNtHeader( peb->ImageBaseAddress );
    entry = (LPTHREAD_START_ROUTINE)((char *)peb->ImageBaseAddress +
                                     nt->OptionalHeader.AddressOfEntryPoint);
```

AddressOfEntryPoint is in struct

_IMAGE_OPTIONAL_HEADER... but I can't find where it gets initialized for executables loaded from the filesystem.

HOWEVER! `winedump dump fract.exe` lists, among other things:

```
Optional Header (32bit)
  Magic                          0x10B         267
  linker version                 2.56
  size of code                   0x1000        4096
  size of initialized data       0x1a00        6656
  size of uninitialized data     0x200         512
  entrypoint RVA                 0x1210        4624
  base of code                   0x1000        4096
  base of data                   0x2000        8192
  image base                     0x400000      4194304
```

Which corresponds to most of this data from `xxd`:

```
0000090: 0000 0000 e000 0f03 0b01 0238 0010 0000  ...........8....
00000a0: 001a 0000 0002 0000 1012 0000 0010 0000  ................
```

Comparable counters

Kragen Javier Sitaker, 2018-08-16 (1 minute)

For generating PWM waveforms, it would be nice to have a state machine design that could expand to larger registers without increasing its depth. Synchronous ripple carry has O(N) depth, while lookahead carry has O(log N) depth, but designs with O(1) depth include ring counters, LFSRs, and Johnson counters. However, those three cases have disadvantages: ring counters require N bits to represent N states, while Johnson counters are almost as bad, requiring N/2. LFSRs are nearly optimal in flip-flop efficiency and can always work with depth of one or slightly more, but comparing LFSR states for beforeness is very difficult. In some cases it may be adequate to compare the LFSR state for equality.

Carry-save counters have depth of 1, but it is also not clear to me that they can be compared for greaterness with any reasonable degree of circuit depth. Also, they use twice as many bits as a regular binary counter, and while this isn't as bad as a Johnson counter, it's significantly bad.

The context of all of this is that it would be nice to have counters that we can clock very quickly.

The ultimate capacity of human memory if spaced-practice memorization works as advertised

Kragen Javier Sitaker, 2017-01-04 (updated 2017-01-08) (14 minutes)

Here I am going to consider learning with ulterior motives — the learning we do in order to become more human and more capable, the ostensible motive of an educational system, rather than the learning we do purely for pleasure. None of what follows applies to recreational learning, because it all considers time applied to studying as a cost, not a benefit.

The spaced-practice psychology literature find that generally the ideal spacing interval is 10% to 20% of the time you want to remember something — so, say, 15 years if you want to remember it for your entire life. You would think that this would imply you need exponentially increasing study intervals, since it would seem that your chances of remembering that $\int \cot x\,dx = \ln|\sin x| + C$ if you hear it once every 15 years are very poor indeed. So far, though, no convincing experimental evidence confirms this apparent common-sense conclusion; the studies that have been done did not find evidence that such "expanding-interval" spaced practice is superior.

However, it seems clear that the schooling system as it stands is at the opposite extreme. K-12 is 13 years of 36 weeks of 30 hours of torture, about 14000 hours of institutional child abuse in total. Abusive treatment aside, that's a massive cost: about 7 years of normal working hours or 2.4 years of waking hours. You would like such a massive cost to be well-spent, providing an equivalently massive benefit, for example of education. But, by concentrating them in 13 years, we guarantee that any learning point with a 15-year practice interval is presented at most only once; the possible degree of recall after a single presentation is very low even when testing is the next day, much less decades later.

So, in order to achieve any kind of reasonable level of recall at all, schools waste the students' time with massed practice, guaranteeing that nearly all of what is taught will be forgotten by adulthood. Worse, the waste of practice-massing in schools is fractal, happening at many levels:

- K-12 schooling is massed in 13 years rather than being spread throughout a person's entire life;
- taking courses on different topics each year guarantees the loss of most learning even before K-12 schooling ends;
- summer vacation guarantees the loss of nearly all new learning from the last months of the school year, and although this could be avoided by devoting those months exclusively to review of earlier material, this is not done;
- moving from unit to unit within each course, with little attention given to material from previous units, guarantees the loss of most learning from the course even before the end of the course;

• pre-scheduled large examinations incentivize students to "cram", massing their practice in the days immediately before the examination, in order to cheat the examination into indicating a level of mastery of the material that they do not in fact possess, or, more precisely, will lose within a week or two;
• and, although the evidence for this is less clear in psychological studies, hour-long classes are very likely to result in poorer retention from one day to the next than if they were split into two half-hour chunks at different times of day. Teachers assign homework to compensate somewhat for the loss of retention, but this worsens rather than improves the waste of time.

Psychological studies have shown 40% increases in learning throughput (that is, 70% as much study time to reach the same level of achievement) from adding a single level of distribution to practice sessions, which is something more than two standard deviations. If we could increase learning throughput by 40% six times in succession, the total increase would be 650%. A person whose life had not been wasted by any of these six levels of massing could — very speculatively! — perhaps learn seven times as much per hour of study, reaching apparently superhuman levels of intellectual achievement, at no increase in total study time.

However, this learning would be spread across a lifetime rather than concentrated in the 5–18 range. If we spread it across the 70-year-long 5–75 age range, it would be only 200 hours per year (33 minutes per day). If we were to accept the optimistic 650% improvement speculation above, this would be equivalent to some 1500 hours of regular K-12 schooling per year, only moderately better than the 1080 hours in the standard system. You would only start to see a really significant difference after age 18, when the students using a program rationally designed to optimize their learning, rather than subjugate them and provide fake "educational achievement" on tests, continued learning, and their knowledge and competence continued to grow, while the victims of industrial-age schooling instead began the inexorable intellectual decline that is such a universally-remarked- upon phenomenon today.

(These numbers change a bit if we include "higher education", which, for an undergraduate degree, is typically about 5 years of about 40 hours a week, 28 weeks a year, between lectures, labs, and homework, about 5600 more hours; most of the same criticisms can be applied to it, some *a fortiori*. This would bring us to almost 20000 lifetime hours of schooling, 280 hours a year if spread across 70 years.)

This even allocation of 200 hours per year represents a tradeoff, though, and probably not a good one. If you learn a skill at 10 years old and die at 75, you can use that skill to your advantage for 65 years. But if you learn it at 65 years old, you can only use it to your advantage for 10 years. This is the logic that underlies the traditional soul-destroying system of studying first, then working, and in itself it isn't flawed; it just doesn't take into account the psychological discoveries made since the 18th century. It's yet another form of the exploration-exploitation tradeoff, a general feature of bandit problems.

A better tradeoff would weight the expense of learning toward the beginning of life, while leaving the human more time to exploit their

skills toward the end of their life. The optimal curve depends on many factors, including your model of how skills improve life utility, how studying fatigues you, how risk-tolerant you are about dying early or late, the probability of dramatic human life extension, and so on, but a linear reduction from 400 hours per year at 5 years old down to 0 hours per year at 75 seems likely to capture the majority of the benefits from the optimal curve.

On this study schedule, you start by studying 66 minutes per day on your 5th birthday and taper down by about 56 seconds per year (154 milliseconds per day) until reaching 0 on your 75th birthday. On your 18th birthday, when you would normally graduate from high school, you are down to studying almost 54 minutes per day, and you've spent 4740 hours of study, about a third of what the victims of high school have. But, because they were in a system optimized to waste their time, you've learned more than twice as much.

How much is that? If we take the 1.8 minutes per "card" in Gwern's review of spaced repetition systems as a good approximation, it would be about 158 000 "cards", somewhat more than the users of these systems report having memorized, somewhat more than the number of words in the Oxford English Dictionary. Of course, most knowledge cannot be separated into isolated "facts" or "cards" in this way, but I suspect that improves the situation for our optimized learners — when you work on a real-world problem, you are inevitably practicing many procedural skills at once, while recalling a flash card only reminds you of a single fact.

This suggests that the speculation in my 2010 post, "could we learn a new foreign language every week?", might actually be plausible, as unlikely as it sounds. The 70-hour budget mentioned there works out to about 2 hours per year or about 2300 "cards", which is not far from the size of existing Anki decks designed to reach basic competency in a foreign language; that post estimates that you really need more like 8500 cards' worth, which would work out to 260 hours rather than 70.

Devoting an hour a day to a system like Anki, it's reasonable to add about 30 "cards" per day with an hour a day devoted to practicing them, so you can't compress those 8500 cards into less than about 280 days, and that only works if that's the only subject in which you're adding new "cards". While this takes into account that you're continuing to practice other things during that time, it seems likely that learning will be more efficient if you aren't adding material entirely from a single subject, spacing out the addition of similar things. I've found, for example, that memorizing the atomic weights in the periodic table, I frequently confuse elements that I add in the same day (especially if they're otherwise similar), and in my hanzi recall practice, I'm currently confusing the characters 是 and 在, even though they look nothing alike, just because they're the same kind of thing and I learned them at about the same time.

However, if you add those 8500 cards over the course of, say, four years, you could easily speak three foreign languages at a basic level by the time you're 18, at a total cost of about 1000 hours out of the 4700 total prescribed above.

(It seems likely, though not certain, that acquiring languages has a critical period in childhood and later becomes much more difficult or even impossible to do in the same way, so it might be better for small

children to spend more of their time on foreign-language learning and less on, say, math and history.)

At 8500 cards per language and 158 000 cards in all, you could expect to speak 19 languages with basic fluency in an average lifetime if you were to focus entirely on foreign-language learning, all in the same amount of time a normal person loses to K-12 education. This may not be the best use of your time, but it gives a very plausible example of the kind of superhuman intellectual achievements we could expect with an optimized learning system, even if all we optimize is the practice schedule. Note that this number is not computed from the speculative exponential computation of the waste of traditional K-12 education above, but from observed time per card in existing spaced-repetition systems and a speculative guess that you can achieve basic fluency (roughly equivalent to that of a six-year-old native speaker, who has some 6000 vocables) with 8500 cards per language.

As some kind of indication that such large improvements are possible, I'm currently studying the Hebrew aleph-bet using Anki since a week ago. Currently I'm at 80% correct on the review cards and have spent a total of 21 minutes on its 22 cards over those 7 days. I'd probably be doing better if I hadn't added half the cards all at once on Saturday, resulting in confusion between some letters like taf and tet; it will probably take me a total of more than 40 minutes to finish memorizing the whole thing. But how long do Israeli children or Hebrew students normally spend learning the alphabet? I think it's typically several hours.

Above I've talked about how you could spend the same 14 000 hours of K-12 education or 20 000 hours of an undergraduate degree in a much more efficient manner, learning several times as much, at the same cost in time and probably without even learning more slowly. However, in practice, the Jevons paradox will probably kick in. Just as improving the efficiency of steam-engines, allowing them to do more work on the same amount of coal, resulted in them being applied to new applications and increasing the total consumption of coal, it seems likely that if time spent learning things is dramatically more effective, people will consider it worthwhile to learn more things.

So, a typical optimized learner probably will not spend only an hour a day studying in this new, more efficient manner; they might be unable to resist spending two or three hours a day, even if the learning is not quite as efficient, learning perhaps 50% or 100% more. At this rate, an average learner might complete the equivalent of an undergraduate degree's 20 000 hours in 6000 hours, sometime around age 12. (XXX actually do the calculation!)

Simple dependencies in software

Kragen Javier Sitaker, 2014-06-05 (9 minutes)

Suppose we have a function to compute some value:

```
def f(a, b, c):
    if get(a, 3) > 5:
        return get(b)-get("x")
    else:
        return get(c)
```

Now, we run this function in an environment where we will record its return value where we will record its return value for the results of pending or future calls to `get()`. (So far I haven't specified how `f` gets associated with some value you can pass to `get`.) We also record its calls to `get` as resulting from this invocation of `f` and may even throw exceptions from some of the `get` calls, for example if their values are not known yet, exceptions which will be caught by the context that invoked `f`. Now we know which set of `get` invocations the current return value of a particular call to `f` depends upon: clearly `f(3, "/", "@")` invokes `get(3, 3)`, and if that returns 4, it will cause it toinvoke `get("@")`. Now we can infer that the return value of `f(3, "/", "@")` depends only on `get(3, 3)` returning 4 and on `get("@")` returning whatever it returned at the time; so it's valid to cache `f(3, "/", "@")` until one of those two values changes. In particular, we do not need to worry about `get("/")` or `get("x")`, since they weren't invoked. But if `get(3, 3)` changes its return value, then the cached value for `f(3, "/", "@")` is no longer valid, and when a new value for it is computed, it might have a different set of dependencies — it might depend on `get("@")`, for example.

This allows us to write code in a fairly imperative style and automatically transform it into a reactive dependency-driven computation.

Meteor's implementation

Meteor's `Deps` facility is probably the most popular implementation of this in practice today, although I first encountered a variant of it in the paper that popularized software transactional memory, Composable Memory Transactions, in 2005; and The Trellis is an older Python package that does the same thing. `Deps` has a few surprising design choices, which are interesting in that they represent the experience of Meteor's developers and users using it extensively in practice over the last two years, rather than merely in theory:

• Its implementation supports nesting;
• If an exception is thrown the first time a computation is invoked, it prevents the computation from ever being rerun in the future; there's also an explicit `computation.stop()` API to prevent this.
• Computations are rerun eagerly when their dependencies change, but only once the system is idle or someone calls `Deps.flush`, which you can't do from inside a Computation; this enables you to use them to e.g. update the DOM in the page rather than just producing a return

value, and the delay-until-idle makes them serializable so that one Computation doesn't see partial updates produced by another Computation not having finished;
• they additionally have an `onInvalidate` callback which is invoked immediately when their result is invalidated;
• Computations normally communicate with one another by writing to a shared global store (e.g. the database, which is replicated onto the MongoDB server) rather than by nested invocation, although nested invocation is also supported;
• dependency links have separate identity from the variables they track:

> The reason Dependencies do not store data themselves is that it can be useful to associate multiple Dependencies with the same piece of data. … A Dependency could represent whether the weather is sunny or not, or whether the temperature is above freezing. `Session.equals` is implemented this way for efficiency. When you call `Session.equals("weather", "sunny")`, the current computation is made to depend on an internal Dependency that does not change if the weather goes from, say, `"rainy"` to `"cloudy"`.

• Dependency links remove their dependent computations after invalidating them, trusting that they will re-add the dependency again if necessary.

I've been told by Meteor users that Meteor doesn't have transactions, but the Computation and Dependency objects described here are essentially the same ones that implement transactions in a software transactional memory system: a Computation is a transaction, and its Dependencies are the variables it reads. (It just doesn't support rollback, which would require at least logging the variables it writes in order to undo the effect.)

Continuously changing variables

Time changes continuously, so in the simplest possible system, any transaction that depends on the current time will be constantly invalidated, and thus constantly recomputed if you're using an eager re-evaluation strategy. But, as the `Session.equals` example above from Meteor shows, in some cases you can make the transaction's dependency considerably more specific. You could say `if time.between(nyc.hour(10,00), nyc.hour(10,05))":`, for example, so that your transaction would only be rerun upon crossing the 10:00 or 10:05 boundary.

This is difficult to generalize, but there are ad-hoc approaches that may work well in practice. For example, you could sample a variable periodically, and assume that it doesn't change at other times. Meteor in fact does this on the server to detect MongoDB changes that aren't intermediated by Meteor itself.

Dependencies with exceptions as a substitute for futures

Futures are a mechanism for writing code that computes with data that aren't known yet — actually, several similar mechanisms. The first was proposed by Baker and Hewitt in AIM-454 in 1977. They used "future" to refer to more or less what we know in Haskell as a "lazy value" — Baker and Hewitt were proposing that structuring the program's run-time state as a pure dependency graph, and then eagerly computing it in parallel while incrementally

garbage-collecting the parts of the dataflow graph that had been cut off by a conditional, would be a good way to write parallel programs to efficiently compute on massive multiprocessors. They turned out to be wrong about that, but nobody would actually build a massive multiprocessor until 1983, so we have to give them credit for trying. (Besides, it's not too far off from `make -j 16`, which is an effective way to program moderately massive multiprocessors, and Stu Feldman wrote the first, non-parallel, version of `make` only the year before.)

Basically their mechanism was that your computation would block when it attempted to apply a primitive operation such as arithmetic to a future, unblocking once the value was available.

Composable Memory Transactions proposes that transactions can "block" by, essentially, throwing an exception (called `retry` in the paper) which aborts the transaction, marking it to be retried when one of its dependencies changes. As long as the code inside the transaction really has no communications with the outside world that aren't intermediated by the transactional memory (a problem cited by Joe Duffy in 2010 as one of the killers of STM.NET), then the effect is very similar to the transaction magically not being able to execute at all until one of the dependencies that would guide it toward the fatal exception is modified. It's like the system knows that the transaction would fail, so it doesn't attempt it, and it magically knows what inputs the transaction takes. (Of course this won't work in systems like Meteor that don't support rollback.)

Consider this Python code to calculate how much a share of AT&T stock costs in pounds sterling:

```
def t_in_gbp():
    quotes_csv = "http://download.finance.yahoo.com/d/quotes.csv"
    data_url = lambda sym: quotes_csv + "?f=sl1d1t1c1ohgv&e=.csv&s=" + sym
    t_data   = www.get(data_url("T"),        max_age=minutes(5))
    gbp_data = www.get(data_url("GBPUSD=X"), max_age=minutes(5))
    price = lambda text: float(csv.reader(StringIO(text)).next()[1])
    return price(t_data) / price(gbp_data)
```

You could implement this using blocking HTTP client calls, storing the result in a cache, and then, to get concurrency, spawn off a separate thread for each such computation, sharing the result between threads. As an alternative to threads, though, you could run `t_in_gbp` in a transaction and have `www.get` try to fetch the data from the cache, initiating the fetch and aborting the transaction if the cached data is stale.

Sandwich theory

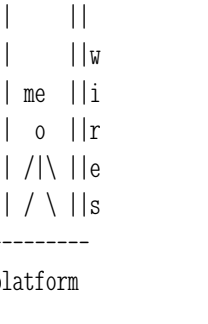
Kragen Javier Sitaker, 2019-08-05 (updated 2019-08-29) (31 minutes)

Sandwich theory is the theory of sandwich structures, which are a kind of anisotropic composite material consisting of two stiff "facesheets" bonded to a lightweight "core", like a two-dimensional version of a one-dimensional I-beam; corrugated cardboard and drywall are the most common examples. I started reading about this because of an interest in cardboard furniture (see Cardboard furniture (p. 742)) and recycled materials.

The basic theory

Basic strength-of-materials background

When built with materials that aren't full of cracks, structures stressed in tension are generally quite strong, and in a way that barely varies with size. Piano wire (aka music wire — a kind of steel used mostly for springs nowadays) has a yield stress of about 2.5 GPa, so a platform that can support my 110 kg can be supported by 0.43 mm² of piano wire, a wire 0.75 mm thick. I'd have to sit down on it very slowly to not break the wire on impact, and if you just connect the wire directly to the platform, it will be kind of tippy; but hanging by three or four such wires would be safe:



Scaling

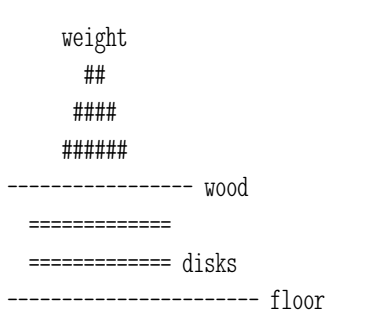
Moreover, this holds whether the wires are connected to the ceiling 2.6 meters above my floor or to the top of a 100-meter-tall building I'm swinging at the base of. 100 meters of four 0.43 mm² piano wires would only weigh 1.4 kg, which is not a significant addition to my weight; you have to get into kilometers of height before the weight of the wire is a significant fraction of what it can support.

As Descartes observed, if we scale up the whole situation instead of just the cable length, things get a little worse: a King-Kong-sized person ten times my height, width, and breadth would weigh a thousand times what I do, about 110 tonnes, while scaling up the cables from 0.75 mm to 7.5 mm in diameter only strengthens them to be able to support 11 tonnes. You'd need to increase them to 24 mm in diameter to support the Kragen Kong. Still, though, that's not such an extreme departure from uniform scaling.

Compressive strength

There's a compressive strength that works the same way; if I put a 10-cm-diameter disk of cardboard under a wooden board and start

piling weight onto the board, there's a certain amount of weight above which the cardboard will get crushed; let's say 300 kg, which is in the ballpark but not a measured figure. If you use several different disks of the same cardboard, they'll all crush at about the same weight, and moreover that weight doesn't change even if you stack two or three or ten of the disks up; the same 300 kg will suffice to crush the stack of ten disks as to crush a single disk. If you use a bigger disk, the weight needed to crush it will go up proportionally.



Buckling

But if you use smaller and smaller disks (and proportionally smaller weights, including the wood), or taller and taller stacks, something weird happens. Well, not weird if you have any experience with material objects, but different. Once the stack gets taller than a certain limit — say, around ten times its width, for cardboard — taller and taller stacks can support less and less weight. So I can stand on one 10-cm cardboard disk, and I can stand on a stack of ten of them, and I can probably stand on the column of 650 of them that it would take to reach 2.6 meters, but I definitely cannot stand on a column of 100 meters of them. In fact, I probably can't even build one. Adding more cardboard to the stack in this way *reduces* its compressive strength rather than leaving it unchanged.

I'm not talking about the top of the stack falling over sideways, which also gets harder to avoid when the stack is taller; the phenomenon I'm talking about happens even if you go into an elevator shaft and rest an elevator-shaft-sized wooden platform on top of the stack of smaller-than-shaft-size disks. I'm talking about *buckling* (*pandeo* in Spanish), where the *middle* of the stack bends outwards in some random direction and it stops being a linear stack. Buckling is governed not by the compressive strength of the column but by the *rigidity* of the column.

Euler worked out the basic math for this. For compressive forces below Euler's critical value, any small bend in the column, for example due to sound waves, gets straightened back out by the column's elasticity. But once the column is bearing a load over Euler's critical limit, such a small bend will get amplified by the compressive stress more and more. Euler's critical load is $\pi^2 EI/(KL)^2$, where E is the modulus of elasticity of the beam, I is the least planar area moment of inertia of the column's cross section ($\pi r^4/2$ for a solid circle), L is the length of the column, and K (the "column effective length factor") varies between ½ and 2; it's ½ in this case because the cardboard disks resting flat on the ground and the elevator-shaft platform are not free to rotate.

Sadly I don't have the faintest idea what the modulus of elasticity of corrugated cardboard in lateral compression is, but the things to

notice about this expression are:

• It's inverse-quadratic in L, so a column ten times as long can bear only one-hundredth the weight without buckling.
• It's directly proportional to the modulus of elasticity, so a beam that's made from a material that's one-third as stiff can only bear one-third the weight without buckling.
• It doesn't involve the *strength* of the cardboard *at all*; it only depends on its *stiffness*.
• Compressive and tensile strengths are proportional to the cross-sectional area, but Euler's critical buckling load is proportional to the area moment of inertia, *not* the cross-sectional area.

The consequences for designing large structures

Point #1 here means that, normally, large structures fail because of buckling before than they fail because of tensile or compressive failure, unless they're made of materials that are full of cracks. This means that if you can improve buckling behavior somehow, you can dramatically extend the size of structures you can construct.

These last three points are crucial to sandwich theory! By stiffening columns with high-stiffness facesheets, and increasing the moment of inertia by moving those facesheets further apart by inflating the core (even at the cost of some strength), we can make sandwich-structured composites that resist buckling enormously more effectively than their component materials.

There's also flexural stress. Sometimes large structures fail because of flexural failure — trees dropping branches or blowing over in a storm are examples. Moreover, flexural stress shares with buckling the property that you really need a great deal more material to resist the load than you would expect — a steel beam that can support my weight in flexion is generally going to need a great deal more than 0.43 mm² of cross section. I am going to mostly ignore flexural stress, except as it contributes to buckling, because ⓐ the same sandwich-panel construction that helps with buckling also helps with flexural stress, and ⓑ flexural loads for a given beam construction only fall inverse-proportional to the characteristic dimension of the structure, while buckling loads are inverse-proportional to its square, so for large enough structures buckling still dominates.

Cracks

The cheapest building materials — earth, brick, other fired-clay ceramics, concrete, mortar, glass, plaster of Paris, and often even stone — are all full of cracks. As long as they're in compression, this doesn't matter, but once they're in tension, the cracks form stress risers that weaken them enormously. This makes it difficult and dangerous to build large structures from them unless they're heavily reinforced with materials with good tensile strength. Adobe is made from earth reinforced with straw, plaster of Paris is commonly reinforced with horsehair, and concrete is commonly reinforced with steel rebar. Even so, larger buildings are invariably steel-framed rather than relying on the tensile strength of even reinforced masonry.

Basic sandwich-theory background

The moment of inertia around the x-axis, I_x, is $\iint y^2 dx dy$ where the area integrated over is that of the cross-section. For panels, that's the only one we care about, because the panel is much wider than it is thick, so if we take our x-axis parallel to its surface, the y-axis

moment of inertia is orders of magnitude too big to worry about.

This says that if we have some cross-sectional area of material, we can increase its moment of inertia proportionally, to an arbitrarily high level, by moving it further from the x-axis:

```
small moment  large moment
               *****

  *****
--*****--     --*****--
  *****

               *****
```

The trouble with this is that once we insert empty spaces in the middle, it stops being a solid object. We need to put enough stuff in the middle to keep the parts moving together; the stuff in the middle is pretty much only stressed in *shear*. Also, when the column is flexing, the facesheet on the inside of the bend is in compression merely from the flexing, and that compression can cause *it* to buckle.

If we only have one material to work with, we can improve the situation by moving almost all the material as far as possible from the x-axis in both directions, leaving the rest of the material as fine "webs" in between to resist the shear, and we have an I-beam, or rectangular tubing, or a channel, or a sort of sandwich panel:

```
  *****     *****     *****     **********************
    *       *   *     *         *   *   *   *   *   *
    *       *   *     *         *   *   *   *   *   *
----*---- --*---*-- --*------ --*---*---*---*---*---*--
    *       *   *     *         *   *   *   *   *   *
    *       *   *     *         *   *   *   *   *   *
  *****     *****     *****     **********************
```

(This kind of sandwich panel, a single plastic with square channels running through it, is in common use for translucent roofing for bus stops around here; it's called "twinwall plastic" when made from polycarbonate, and similar sandwich panels made from other plastics are called "corrugated plastic", "corriboard", or "coroplast".)

More generally, you can use a different kind of material in the middle, maybe one with not much strength of any kind, just enough to resist the shear stress. Incidentally, that shear stress is *also* inversely proportional to the distance between the facesheets, so if your panel is thick, you can get by with a very wimpy core material. You do still need enough tensile and compressive strength provided by the cross-sectional area of the facesheets *and* the core to withstand the tensile and compressive stresses on the panel from its edges, but in a large structure, that is a much easier problem than preventing buckling.

XXX understand the theory

An underappreciated aspect of sandwich panels is that they are not only stronger (in flexure and buckling) but also softer than the same materials would be if solid. This can increase their impact strength.

Common current sandwich-panel examples

Single-wall corrugated cardboard, as I said, is the most common kind of sandwich panel in daily life. It has a smooth "linerboard" paper on the "outside", according to Angela Ben-Eliezer, a corrugated paper layer of "flutes", and a second linerboard paper on the "inside" which is not smooth, all glued together, typically with sodium silicate. The linerboard layers play the role of facesheets, while the flutes play the role of the core — a highly anisotropic core, in this case.

The inner fluted layer is mostly air — typical corrugated cardboard is made from paper of about 90–130 g/m², which makes it about 150 μm thick, but has a 4-mm-thick fluted layer, so the fluted layer is about 96% air and 4% paper, and the cardboard as a whole is about 88% air and 12% paper. In fact, only part of the flutes — about half — is in the fluted layer itself. The other half is glued flat to one or the other linerboard, making it part of the facesheet.

Double-wall and triple-wall corrugated cardboard is a less common material, used for higher-strength applications. Triple-wall cardboard has three layers of flutes and four layers of linerboard, and the interesting thing here is that the inner layer of flutes is typically substantially thicker than the outer layers. That is, it's a sandwich panel whose facesheets are themselves sandwich panels! It's a recursive sandwich!

Drywall is a sandwich of gypsum (plaster of Paris) between two sheets of paper. Unlike the other examples, this isn't to help it bear buckling loads; it's to give it tensile strength (and thus flexural strength) so you can carry it around and drive screws through it, instead of shattering the way plaster on lath would do if you treated it that way.

Corrugated sheet steel is similar to corrugated cardboard, but just the flutes, without the linerboard; it's just a wavy sheet of steel. This is not the most efficient use of material, since the "core" consists of roughly as much steel as the "facesheets", but it's very cheap to make. Slightly more elaborate corrugated sheet metal, like that used for the walls of shipping containers or aluminum siding, uses sharp bends to increase the amount of material in the "facesheets" while still being inexpensive to fabricate by bending a single sheet.

Foamcore is a sandwich made of two sheets of paper with styrofoam in between, commonly used for architectural models and picture framing.

The Hexayurt is made from sandwich panels sold in the US and some other countries for house insulation; these are foamed polyisocyanurate with aluminum-flashing facesheets. Similar lightweight rigid sandwich panels made of various materials are common insulating materials; when the facesheets are some kind of structural board material like OSB or drywall, it's called a "structural insulated panel".

Current more exotic examples

Fiberglass fabric glued onto the surface of styrofoam is a common material for small airplanes, especially model airplanes.

RV enthusiasts have taken to fabricating furniture by cutting styrofoam to shape, fitting them together, and coating the surface with some kind of stiffener, such as fiberglass window screening material stuck to the foam with latex paint.

I'm seeing sandwich panels on some of the bus lines here in Buenos Aires; they seem to have polyethylene cores and melamine facesheets.

Cement board has been a common building material for decades; it's a sandwich with a cellulose-reinforced portland cement core and glass-fiber mesh facesheets. It's kind of like drywall, but a lot stiffer; it's useful as an underlayment to keep tile floors laid over wood from breaking when the wood flexes.

Common FDM 3-D printing slicers will, by default, fill the interior of the model (whatever its shape) with a honeycomb, thus making it a sort of three-dimensional quasi-sandwich-panel. This is mostly to cut down printing time, but it also helps to compensate for PLA's abysmal impact strength.

In aerospace, sandwiches with sheet-metal facesheets and metal honeycomb cores are common.

The Grenfell Tower fire in 2017, which killed 72 people, about a quarter of those present, was caused in large part by the use of Arconic Reynobond PE sandwich panels, with aluminum facesheets around a polyethylene core (not, I think, foam), which were covering an 150-mm-thick layer of polyisocyanurate foam under a ventilation space.

Candidates for upcycling garbage into sandwich panels

Very common materials: styrofoam, cardboard, boPET, TetraPak, beer cans, plywood, sheet metal

Styrofoam and cardboard are the two most obvious candidate core materials, but many others are possible. boPET, as in discarded chip bags and one of the layers in TetraPak drink boxes, is fairly stiff, and so boPET and TetraPak are abundant candidates for facesheet materials; cardboard is also a good candidate.

Thin aluminum sheet, as from drink cans, is considerably stronger and stiffer in tension than either of those; it might make a good facesheet. More broadly, sheet metal is often discarded, and it makes a fantastic facesheet material, as do plywood and OSB.

Drink cans have a particularly interesting property: they are mostly coated on the inside with a thin layer of very chemically inert plastic, usually a food-safe epoxy. It might be possible to use this coating as a ready-made glue (see below about the difficulties of glues) to stick the rolled-flat shreds of shredded cans together, like wood chipboard. Some combination of heat, pressure, and previous functionalization with cold plasma (see Cold plasma oxidation (p. 2406)) might do the trick. This should not require temperatures anywhere close to those necessary to melt the aluminum.

Expanded sheet metal — that stuff they use for security grilles and transparent nonskid steel stairs — is likely an *excellent* facesheet material, but it is only very stiff along one of its axes.

Fabric-backed vinyl is discarded in bulk when billboards are updated with new advertising, and it has its merits, but it is sufficiently useful that it already tends to get recycled.

Cloth and circuit-board facesheets

Woven cloth (from discarded clothes, mattresses, etc.) is another candidate facesheet ingredient — unbroken chains of fibers running in long straight lines along the surface will contribute more stiffness than the same fibers in a more disordered mass like that of paper. Knit cloth would contribute little stiffness by itself, but "nonwoven cloth" ought to be intermediate, like paper. Glass-fiber cloth or cloth woven from Kevlar, Nomex, or Spectra would be ideal, but are hard to find, except in the form of glass-fiber window screens. Some cloths are probably not suitable: nylon and silk are elastic enough that they probably wouldn't add enough stiffness.

(Aluminum or steel window screens would work too.)

Of course, these materials by themselves need some kind of glue to turn them into facesheets. (See below about glues.)

Discarded circuit boards are extremely stiff: they are made of glass-fiber cloth impregnated with a plastic such as phenolic resin. They are relatively abundant in the waste stream, and would be ideal.

Other core materials derivable from garbage

Since the core is ideally very thick, it can be made from a quite weak material, including plastic foams, especially microcellular foams. So foaming discarded thermoplastics, for example with nitrogen, is a potentially very interesting way to upcycle them.

Most organic matter can be reduced to some kind of charcoal by heating at high enough temperature without oxygen. Charcoal is very rigid — more so the purer it is — and lightweight, because it's basically a foam. It might make a very reasonable core material. It's usually full of cracks, so unless you crush it into a powder, its tensile strength is very low. One possible approach to that problem is to form the organic matter into a fine *open-cell* foam *before* carbonizing it, for example by baking it into bread, and then heating and cooling it very slowly. That might yield a carbon foam with reasonable tensile strength but I wouldn't bet on it.

Carbon black — charcoal formed as smoke rather than in solid form — is routinely used to add tensile strength to rubber, for example in car tires and shoe soles. It, too, can be produced from almost any organic matter.

Pretensioning facesheets

Facesheets are only strong when in tension; when in compression they rely on the core material to support them against buckling. If there's a way to pretension them somehow, this could increase the strength of the whole structure. One way would be to simply pull on the facesheets during the lamination process, so they are stretched while the bond is being formed. Alternatively, some plastics might enter into tension when heated, the way PET drink bottles and shrinkwrap do. Another alternative: in cloth aircraft construction, after construction, the cloth surface is impregnated with a substance called "dope", which shrinks as it cures, setting up tension in the cloth. Is there a "dope" that could be used to pretension sandwich panel facesheets in this way?

Alternatively, if the core material is a closed-cell foam, you might be able to pretension the facesheets this the other way around, by setting up compression in the foam. A couple of ways to do this: you could assemble the sandwich panel in a chamber under high pressure,

thus partly collapsing the cells of the foam; or you could arrange for air to diffuse through the foam into the cells after assembly, for example by baking the foam in a vacuum *before* assembly, long enough for a substantial fraction of the air to diffuse out.

Typically the blowing agents diffuse out of the foam after it is produced, and this is often considered problematic when it happens faster than air diffuses in — it means that the foam contracts shortly after fabrication, then later expands again after absorbing air — but it produces a critical period during which sandwich-panel fabrication would pretension the facesheets. So, perhaps the same phenomenon could be provoked intentionally, either by foaming the plastic with the usual blowing agents or by provoking a very volatile gas like hydrogen, helium, or methane to diffuse into the foam first. (A chamber full of methane is a lot easier to produce than a vacuum chamber, if perhaps more dangerous.)

Stiff facesheet materials (some weak)

Because the primary purpose of the facesheet is increasing *rigidity*, not strength, in order to resist buckling, it might make sense to use materials with high rigidity and low strength; glass, plaster, and cement come to mind.

Generally, filled plastic systems can get a lot of rigidity from the filler, so using a high-rigidity filler like rocks, sand, clay, cullet, grog, eggshells, carbon, or machining swarf might make sense. (The usefulness of such fillers isn't strictly limited to "plastics" as such; they are of course a key part of concrete, mortar, and fired-clay ceramics, in which cases they mostly contribute strength rather than rigidity.) Such fillers work better with large aspect ratios, so that the individual filler particles can more easily be much closer together than their large dimension, so that when the material as a whole is stressed in tension or compression, the binder between them is stressed in shear over a much larger cross-sectional area than that of each interacting filler particle. This way, most of the tensile deformation of the bulk material comes from stretching filler particles rather than stretching or shear-deforming the less-rigid binder.

A hexagonal, herringbone-brick, or jigsaw-puzzle pattern of facesheet tiles, with a little space between them, could provide rigidity without causing the facesheet to break when its elastic limit is exceeded.

These approaches aren't viable if ⓐ the core material is so weak that you're depending on the facesheet to provide tensile *strength* as well; or ⓑ the sandwich panel is sufficiently stressed in flexion, as opposed to buckling, to depend on the facesheet's strength as well as its rigidity.

Other facesheets

Masonite, medium-density fiberboard, wood, paper, PMMA, CDs, wet wipes, fabric-softener sheets, and many other things are also plausible facesheet materials.

Particle board is made from sawdust pressed into panels under pressure with a glue, typically melamine resin or phenolic resin. This approach, possibly with different glues (see below about glues), might be feasible for fabricating facesheet panels from a variety of waste-stream fiber sources: sawdust, wood shavings, coffee grounds,

yerba mate, grass clippings, hair clippings, machining swarf, dry leaves, chipped prunings, shredded paper, shredded cardboard, dehydrated sliced vegetables, fiberglass from demolition (at the risk of asbestos), shredded cloth, bagasse, straw, pencil shavings, peanut shells, sunflower-seed shells, wicker, or chicken feathers, for example. As mentioned above, adding some high-rigidity fillers like sand, clay, cullet, grog, or eggshells may improve the rigidity of the resulting material, just as it would a filled plastic system.

(Needless to say, such composite materials could be used for things other than sandwich panels, too, or even panels.)

Glues

How can you do the lamination, so the facesheets can't slide along the surface of the core?

You might be able to use just standard modern adhesives: epoxy, melamine, and phenolic resins. But these are entirely impractical to obtain from the waste stream, and there are cheaper alternatives.

Some materials can be bonded just with heat, and in some other cases you can use small amounts of thermoplastics to bond together layers of non-thermoplastic materials, like the EVA in a hot-glue gun. And, as mentioned above, latex paint works well enough under some circumstances, but it's difficult and somewhat dangerous to find discarded. Porous facesheet materials like cloth and window screen allow air access to the binder, which is essential for the curing of many binders.

In some cases the strength requirement for the adhesive may be low enough that even paraffin wax (or polyethylene or PET) could be used as a hot-melt adhesive, perhaps with a filler such as clay to stiffen it and add strength. Wet clay also makes an excellent weak adhesive which hardens and contracts on drying.

The five traditional adhesives are slaked lime, wheat paste, mucilage, hide glue, and birch tar, the first four of which can be made from garbage at varying levels of personal risk, or from very inexpensive non-garbage materials. They might work. Wheat paste and mucilage don't stick very well to nonpolar materials like common plastics, and slaked lime is caustic. Birch tar is probably not practical in the modern context. Most of these need some degree of care to keep them from rotting, blue vitriol being a traditional pH-neutral antifungal.

Blood is also sticky and dries hard, due to its albumin content, and there's a lot of animal blood in the waste stream, but for whatever reason it isn't widely used as an adhesive, perhaps due to excessive clotting.

"Pressure-sensitive" or "constant-tack" adhesives like those used in duct tape, packing tape, and postit notes are not really suitable for structural use, because, being viscous liquids, they will flow continuously if under strain. They can resist compression, but in shear or, especially, tension, they will gradually release their bond. In structural applications this is potentially disastrous: weeks, months, or years after initial construction of a structure, its sandwich panels could delaminate and fail, apparently spontaneously.

Asphalt or pitch, as used in roofing membranes, is on the edge here. It's a viscous liquid, but at room temperature its flow rates are low enough that it might be acceptable, if the panels won't be exposed to

heat.

Thin-enough porous facesheets could be simply painted with boiled linseed oil, but oxygen needs to be able to diffuse to the facesheet-core interface to be able to polymerize the oil there. More generally, it might be possible to polymerize such "drying oils" with oxidizing agents like sodium percarbonate or ozone. (Linoleum flooring is polymerized linseed oil with a filler painted onto a coarse cloth backing.)

Some kinds of core or facesheet materials could be welded with a small amount of solvent, such as acetone, MEK, or ethyl acetate. Doing this on styrofoam is tricky because the solvent tends to eat the cells it touches; perhaps a little vapor, rather than drops of liquid, would do the trick.

Such solvents can also be used to make glues from other waste plastics, such as PVC pipe or polystyrene foam, peanuts, or food containers.

A final, more exotic, glue is sodium silicate, which can be made in bulk very inexpensively, simply by boiling quartz in lye; this has the benefit of hardening on timescales measured in seconds when gassed with CO_2. As I mentioned above, this is commonly used to make corrugated cardboard; it also waterproofs concrete. (Potassium silicate is nearly equivalent.)

Glueless lamination

Since the objective of gluing the lamination interface is resisting shear, not tension, the facesheets could also be connected to the core by non-adhesive means, such as nails, tacks, staples, or sewing — a thread or wire passed repeatedly through holes in the sandwich panel to keep the facesheets from sliding relative to the core. These approaches are more practical with fairly rigid facesheets, since in between the mechanical attachment points, the facesheet on a side in compression must resist buckling on its own without any real support from the core.

Minimal transaction system

Kragen Javier Sitaker, 2017-09-21 (5 minutes)

A minimal transaction processing system

(See also A minimal dependency processing system (p. 911).)

The data store is a key-value store that supports set(k, v), get(k) -> v, and getNextAfter(k) -> (k, v) operations; keys and values are arbitrary bytestrings, and keys are ordered lexicographically.

You start with a transaction running as an isolated virtual machine. It has the above-mentioned data-store operations available, plus sbrk(n), commit() (which exits), fail(), and fork(), which commits the current transaction and creates two new coequal transactions with copies of the same memory, though one is running a different subroutine.

It starts by reading through a section of the key-value store (perhaps `"tx/" < k && k.startswith("tx/")`) where it expects to find source code for transactions to run. For each key of source code found, it fork()s a child transaction that reads that source code, compiles it into memory, and starts running it. When it finds no more source code, it invokes fail().

When a transaction invokes fail(), its writes do not become visible to other transactions, but the set of get() and getNextAfter() calls it made is remembered. If the data store changes in a way that would change what those calls saw, the transaction is retried. The system has the option to transparently checkpoint the transaction at any point and rerun it from there, rather than from the beginning — this is why fork() commits, because the child transactions are externally visible side effects.

These initially compiled transactions are mostly "servers". They look for messages in some section of the key-value store and, like the initial transaction, fail() if nothing is there. But if something is there, they spawn a child transaction to process it (and then fail if it's still there, to avoid repeatedly processing the same thing repeatedly.)

A transaction that has not yet committed will also be pre-emptively fail()ed by the system if it has previously read data that has now changed — when it attempts to commit(), if nothing else.

Initially I thought that after fork() the parent transaction should continue as before, but then I realized that it might fail, so either fork() needs to commit, or the child transaction needs to be nested, which would prevent writing servers. Then I resigned myself to the idea that, since the server must commit on every iteration, it wouldn't be automatically restarted if its source code changed.

Now, though, I realize that it is possible to have my cake and eat it too: ancestor transactions' read sets can be included in your read set, so if your source code changes, you can be instantly rolled back and recompiled, even though your committed ancestor transactions won't be rolled back. I think. I'm not sure how to make that work with message queues yet.

This form of IPC implicitly and modularly supports a wide variety of different communication patterns and both batch and interactive computing. If you want to wait for a message at either location a or

location b, you do this:

```
a = get("a");
b = get("b");
if (a == null && b == null) fail();
```

If you instead want to wait until both messages are present before proceeding, you do this:

```
a = get("a");
b = get("b");
if (a == null || b == null) fail();
```

If you want to get a message if one is present, but continue anyway if one is not, then you can handle nullness by a method other than failure:

```
c = get("key");
if (c != null) { /* handle keypress */ }
```

Because it doesn't support nested transactions, you can't directly turn blocking subroutines into nonblocking ones as with the orElse operator in the Composable Memory Transactions paper; if you want to be able to make a failure blocking or nonblocking, you should return that failure up the stack to the point where you actually want to make that decision. For example, the first example above might read as follows, assuming a context where a successful return value cannot be null:

```
a = get("a");
b = get("b");
if (a == null && b == null) return null;
```

You could spawn off a blocking subroutine into a child transaction that stores its result back to you somewhere that you're looking for it in a nonblocking fashion, but because fork() commits, this interferes with modularity.

This system is very simple, with only seven system calls (three of which take no parameters), full ACID transactions, and no explicit deadlock, although of course you can arrange communication patterns to provide deadlock. It should be possible to implement it extremely efficiently.

The definition of the store as a simple byte-blob key-value store is not essential to the system; it could have nearly any form whatsoever — relational, hierarchical, with private namespaces, graph-structured, message queues, tuple spaces, seekable files, a distributed transactional store, typed values, whatever. The byte-blob key-value store is just a minimal approach.

Rsync message base

Kragen Javier Sitaker, 2019-11-08 (updated 2019-11-30) (29 minutes)

I was discussing eventual content synchronization for disconnected operation through eventually-consistent data stores for computer-mediated communication systems with an entity known as The Doctor, and they suggested the use of the rsync algorithm and its variants, which I thought was really interesting.

As it turns out, the rsync delta-transfer algorithm offers an interestingly scalable approach to synchronizing eventually-consistent data stores like these, one that has not been exploited previously to my knowledge.

Broadcast and flooding

The basic problem to solve here is how to distribute each of a large number of messages originating from many different sources to each of a large number of subscribers. For example, you might want every reader of alt.tasteless to be able to see all of the recent postings from anyone to alt.tasteless, or everyone who joins #hottub to be able to see all the messages someone sends to #hottub after they join, or every host on your Ethernet to be able to see every ARP request any host broadcasts on that Ethernet. Moreover, rather than achieving this through a centralized bulletin board or a shared broadcast medium like thinnet, you want to achieve it via some potentially complex and changing topology of interconnected network nodes (originally, "gateways"; nowadays sometimes "routers").

(For the time being I will ignore the questions of multiple channels, unicast messages as well as broadcast, whether the subscribers and the publishers are the same set, whether there are some security requirements on their membership, and whether there's some kind of need for load-balancing or "sharding" for performance.)

The obvious thing to try is for each node to send each message it receives to all of the other nodes to which it is connected. So if you have the topology A -- B -- C -- D; B -- E, then if node A sends a message, it will arrive at node B, which will forward it to nodes C and E; node C will then forward it to node D; and we're done. This simple flooding approach has one main problem: first, any cycle in the connectivity graph will produce an infinite number of copies of every message.

I know of four approaches to solving this problem: TTLs and return-paths, the spanning-tree protocol, the Usenet message-id approach, and the per-publisher log approach used in Kafka. And I think the rsync approach might offer some interesting benefits.

TTLs and return-paths

The most basic approach to limiting broadcast message duplication by routing loops is a "time-to-live" field on each message sent across the network. This field is decremented at each router, and messages with TTL of 0 or less are discarded. So a message originally sent with a TTL of 5 is guaranteed to reach a distance of no more than 5 routers from the sender, and a message originally sent with a TTL of 10 is guaranteed to reach a distance of no more than 10 routers from the

sender.

This is a crude approach, but it does at least guarantee that the number of duplicates of each message is *finite*. Consider the topology A -- B -- C -- A. If A sends a message with a TTL of 30, they will initially give a copy to both B and C. One copy will travel clockwise around the loop 10 times, while the other will travel counterclockwise around the loop 10 times; each node will receive the message (and every other message) 20 times.

But the number can be exponentially large. Consider the "diamond graph" A -- B -- C -- A; B -- D -- A. Every time a message reaches B or A, two copies of it will be made; for a copy arriving at B from D, for instance, copies will be sent to C and A, and A will then send copies to C and D. So a message with a TTL of 5 sent from A will go through the following population stages:

- B 1; C 1; D 1.
- B 2; C 1; D 1.
- A 4 (2 from B, 1 from C, 1 from D); C 2 (from B); D 2 (from B).
- A 4 (2 from C, 2 from D); B 2 (from A); C 3 (from A); D 3 (from A).
- B 10 (4 from A, 3 from C, 3 from D); C 4 (2 from A, 2 from B); D 4 (2 from A, 2 from B).

And at that point it stops because the TTL was 5. But it should be clear that even this simple graph with four nodes can produce exponential growth of the message population to some exponential function of the TTL with the simple flooding algorithm, making the TTL approach of limited effectiveness. This means that, at best, the network will perform very poorly, and very likely will fail badly under load.

A slight refinement of this approach was used on Usenet (though not as the primary duplicate-suppression mechanism); each copy of a message carries a "return path" that describes the path it took to get to where it is, which could typically be used as an email routing path to send a reply to the poster. The obsolete SSRR option in IP and the obsolete multihop mail routing system in SMTP work the same way (@foo,@bar:baz@quux, I think was the SMTP notation). This can serve to suppress duplicates due to routing loops because if a message received at node X has node X in its return path, then it is obviously going nowhere useful and should be dropped. This successfully suppresses exponential message growth in simple networks like the diamond graph above, but not in larger networks. Consider, for example, A -- B -- C -- D -- E -- F; A -- C -- E; B -- D -- F. A message injected at A goes through the following stages of evolution:

- B!A, C!A
- B!C!A, C!B!A, D!B!A, D!C!A, E!C!A
- B!D!C!A, C!D!B!A, D!B!C!A, D!C!B!A, D!E!C!A, E!C!B!A, E!D!B!A, E!D!C!A, F!D!B!A, F!D!C!A, F!E!C!A
- B!D!E!C!A, C!E!D!B!A, D!E!C!B!A, D!F!E!C!A, E!C!D!B!A, E!D!B!C!A, E!D!C!B!A, E!F!D!B!A, E!F!D!C!A, F!D!B!C!A, F!D!C!B!A, F!D!E!C!A, F!E!C!B!A, F!E!D!B!A, F!E!D!C!A
- B!D!F!E!C!A, C!E!F!D!B!A, D!F!E!C!B!A, E!F!D!B!C!A, E!F!D!C!B!A, F!D!E!C!B!A, F!E!C!D!B!A, F!E!D!B!C!A, F!E!D!C!B!A

Then it ends, because every return-path contains all six nodes, so there is nowhere else for any message to go. It should be clear that, although the amount of traffic generated on the network by this single message is finite, it is already large and grows exponentially with the size of the network because the number of simple paths by which a message can reach each node grows exponentially with its distance from the message origin. Node F got 13 copies of the message.

The spanning-tree protocol

In order to achieve very high message rates without the above kinds of explosive message duplication, IRC and networks of Ethernet switches use essentially the simple flooding approach described above. To avoid the disaster of infinite message multiplication, they maintain a strict spanning tree among the nodes: only enough links are active to achieve full connectivity, deactivating any links that would create cycles.

The topology of the network is assumed to change on a much slower timescale than the transit time of individual messages. Any message that is transiting the network when the topology changes may be lost or duplicated, so reliability and semantic deduplication must be done by network endpoints; if a message's transit is slow enough to include many topology changes, it may be duplicated many times.

Moreover, for the topology to avoid containing many cycles all the time, the interval between topology changes must be large compared to the end-to-end *latency* of the network, because activating two new links on opposite sides of the network may form a cycle which requires the deactivation of some link once detected. If the latency is large, this situation will go undetected for a long period of time. However, the same large latency will also limit the number of messages thus duplicated.

This approach is not very suitable for networks like FidoNet and UUCP, which in their heyday had end-to-end latencies typically on the order of a week, organized around daily modem telephone calls, and each of whose links might or might not function on any given occasion. So Usenet used a different approach for duplicate suppression.

The Usenet message-ID approach

The Usenet approach is to identify each message with a "Message-ID" unique to that message, but much shorter than the entire message. Then, before transmitting the entire message from one node to another, the communicating nodes verify that the message isn't already present on the receiving node; the Usenet protocol NNTP has commands called IHAVE and SENDME for this purpose. `IHAVE foo` indicated the availability of the message with the message-ID `foo`; `SENDME foo` requested its transmission, if possible. In the Bitcoin protocol, the `inv` message lists data blocks, block headers, or mempool transactions, like a bulk IHAVE; and the `getdata` message plays the role of `SENDME`.

A serious weakness of the Usenet implementation was that the message-ID is chosen by the sender, typically a string something like "trn.20190822.1830.10831@canonical.org", incorporating the

hostname, the date and time, the software being used, the PID of the running process, and so on, in an effort to avoid accidental duplication. Nevertheless, bugs did sometimes result in unintentional duplication, and people sometimes engaged in intentional duplication to attempt censorship.

Git uses a similar approach, but uses the SHA-1 of the "objects" as the message-ID rather than a sender-computed string. It is conjectured to be computationally infeasible to produce a different object with the same SHA-1, even intentionally, much less accidentally.

I think FidoNet used this approach to propagate messages in its "echos", which were distributed message bases similar to Usenet newsgroups, but somewhat more primitive. The Doctor tells me that the message-IDs FidoNet could use to avoid unlimited duplication of messages were tuples of the form (network, zone, region, board, sub, message), where the (zone, region, board) was a hierarchically assigned numerical address space uniquely identifying the particular bulletin board on which the message originated, and "network" presumably distinguished FidoNet proper from other networks that might use the same protocols.

(However, I'm not as familiar with FidoNet's protocols as I am with the internet protocols, and so I might have gotten that wrong.)

A weakness with the message-ID approach is that it still scales only linearly with the number of messages. If you have a billion messages comprising ten terabytes, each with a 20-byte message-ID, then an IHAVE command for each message-ID will still cost 28 gigabytes of network bandwidth in every conversation, even if only one or two new messages are to be transmitted. There are protocols involving more round trips, such as ping-pong breadth-first trie traversal and some approaches using compressed Golomb sets or Bloom filters, that can reduce this cost by a significant factor, but still only a linear factor.

Evidently some way of naming large, coherent groups of messages is needed if we are to get the desired superlinear speedup.

The per-publisher log approach

Kafka is a distributed modern publish-subscribe system used in high-bandwidth data-center environments. The way it works is that each new message is apended to a log and assigned an ordinal sequence number in that log; subscribers send requests not for individual messages but for ranges of ordinal numbers in a given log. Each subscriber remembers the ordinal number of the last log message it has seen on a given log, and when it loses a connection and reconnects, it requests the next, say, 100 messages after that point. This frees the server from maintaining any persistent per-subscriber state, allowing it to scale both to large numbers of messages per second and large numbers of subscribers.

This protocol permits a subscriber to efficiently mirror the log, if it wishes. It can then provide the same subscriber interface to other subscribers, as long as only the origin server is assigning new ordinal numbers to new messages. In fact, it can update its mirror from other subscribers in the same way; it doesn't need to talk to the origin server directly. (Kafka itself doesn't take advantage of this possibility, as far as I know.)

I think this is the way Secure Scuttlebutt works, as well. Each participant in the chat has their own append-only log of messages that it has published, and upon conversing with a peer, it asks for updates to the logs that it is a subscriber to.

Van Jacobson's "Content-Centric Networking" project (a generalization of which is known as "Named Data Networking", or NDN) uses this approach to handle streams of data.

In CCN, routing is done by naming pieces of data, not network nodes. Each router remembers some set of interests associated with its network links and some set of messages; it exchanges interests and messages with its peers. When it sees a message whose identifier matches an interest it has pending, it forwards the message to the router from which it got the interest, and if it receives an interest that matches a message that it has stored, it replies to the interest with a copy of the message. In either of these cases, it forgets the interest, since it has been satisfied.

On the other hand, if it receives a new interest that it cannot satisfy, it remembers it and uses some algorithm to choose which network links to forward the interest on to, perhaps related to which network links it has received similar messages on before, or some kind of hierarchical network addressing scheme and dynamically updated routing table. The interest being forwarded through the network leaves a path of backpointers which give a route back to the original requester, without that requester needing any kind of network address.

In this way, messages are only forwarded to routers that have requested them, eliminating many opportunities for denial-of-service attacks, and one copy of a message going into a router can evantually result in many copies flowing out of it, as if the router were a caching HTTP proxy, eliminating many other opportunities for denial of service.

The obvious question is how to handle things like streaming voice and video in a system like this: interests in data that doesn't yet exist. The answer is simply that you assign sequence numbers to the frames of streaming data ("ElRubius/videostream/d8s0g03402e/frame/3302") and the subscribers send interests for some window of sequence numbers that have not yet been produced, but which will be delivered to them when they have. As long as the window is large enough to compensate for the latency of propagation of new interests, this will result in immediate and efficient streaming.

This works out to be precisely the same per-publisher log protocol used by Kafka for the analogous problem. And in some sense the `getblocks` message in the Bitcoin protocol does the same thing --- but the "publisher" is the Satoshi consensus of the participating nodes, so blocks might sometimes be superseded.

Cryptographic authentication of messages in the log is useful in some cases to prevent one publisher from interfering with another. In the message-ID IHAVE/SENDME protocol this could be done simply by using cryptographic hashes as message-IDs, as Git does, but in the log-appending protocol, some different approach is needed; for example, each new message in the log could be signed with a private key associated with that log. Such an approach will only be successful, however, if the routing nodes in the system are checking

the signatures, which is a potential scalability bottleneck.

How does Git's protocol actually work? Originally it used rsync, but not the rsync delta-transfer algorithm mentioned below. Now it has "the 'smart' protocol" (better documented in the official documentation and also the v2 protocol. I don't really understand how this works; it has `have` and `want` messages but I'm not clear on how many of them need to be sent but it sounds like it uses the DAG structure to avoid sending all of them.

This per-publisher-log protocol is only more efficient than the per-message ID IHAVE/SENDME protocol as long as the set of publishers remains small, which, admittedly, covers many important cases. But if each message has a new publisher, it reduces to the per-message-ID algorithm.

Approaches based on rsync's delta-transfer algorithm

Rsync contains a delta-transfer algorithm designed to save bandwidth over Australia's undersea cables. Transmitting data to or from Australia was very expensive, so if you had slightly different copies of a file on opposite sides of the Pacific, it was important to find the parts that were different and transmit only those. If you have both versions of the file on one side of the connection, you can use the standard longest-common-subsequence ("LCS") dynamic-programming algorithm to find the minimal edit sequence. But how do you efficiently compute a small edit sequence between two files, each of which is only available to one of the parties in the protocol?

The simplest approach is of course to divide the file into blocks of some fixed size and use the message-ID approach, using the SHA-256 or whatever of each block. This would work well for files that are modified by overwriting some part of the middle of the file; only the modified parts will have a different SHA-256, and so only those modified parts (plus the rest of the blocks containing them) will be transmitted.

But if you insert a byte at the beginning of the file, shifting the rest of the data in the file by one byte, none of your hashes will match, and so the entire file will be transmitted even though the edit distance was one byte.

The bupsplit algorithm used by Avery Pennarun's bup backup program, and also the basis of Jumprope, attempts to overcome this problem by breaking the file into blocks of variable sizes in a way that will usually be consistent after insertions and deletions, similar to the "fuzzy hashing" used in forensics. (See Immutability-based filesystems: interfaces, problems, and benefits (p. 1672) for some related notes.)

The rsync algorithm takes a different approach. One of the versions of the file is broken into fixed-size blocks in the usual way, typically using a block size of a few hundred bytes, and each block is hashed with two different algorithms: a weak linear rolling-checksum algorithm (in rsync, a modified version of Adler32) and a stronger hashing algorithm — originally rsync defaulted to MD4 for this, which was cryptographically very weak, and even nowadays uses MD5, which has also been broken. The resulting collection of

hashes (let's call it a "digest", since the rsync papers don't give it a name) is transmitted to the other participant, where the rolling checksum is computed over *every length-N substring* of the other version of the file; any matches found in the digest are checked with the strong checksum. This allows the relatively efficient and precise computation of the byte-ranges of either file that are present at any offset in the other, as long as the shared data is more than a block in length.

It is interesting to note, as Andrew Tridgell does in his dissertation, that in some cases the rsync algorithm finds smaller deltas than the LCS algorithm used by diff(1), because rsync can detect and take advantage of transpositions, while LCS cannot.

The rsync algorithm is used not only in rsync but also in zsync, rdiff, and some other software. zsync in particular allows a sender-server participant in the protocol to be nothing more than a dumb HTTP server capable of byte-range access; this is achieved by precomputing the digest and placing it in a "zsync file" on a web server that points to the real file. The zsync client, upon fetching the digest file, can run the rolling checksum over its local version, occasionally running the strong checksum, and compute the set of byte-ranges that it needs to fetch from the origin server to reconstruct the origin server's version of the file.

If you want to rsync a mebibyte of data using a block size of 4 kibibyte (Tridgell's dissertation discusses block-size tradeoffs in chapter 3, finding optimal block sizes in the range of 256 bytes to 8 kibibytes for a few datasets), the digest to be transmitted will be 5 kibibytes, 0.5% of the total.

Note, however, that this 0.5% doesn't decrease as the file size increases, unless you also increase the block size. If you were to digest 10 tebibytes using 4-KiB blocks and 20-byte digest entries, your digest would be 50 gibibytes.

As a simple intermediate step between the IHAVE/SENDME system and the log-appending system, you could imagine using some variant of the rsync protocol on a document containing the concatenation of all messages in some well-defined order. In effect, this assigns a message-ID to each entire block of messages, rather than each individual message.

A key difference from the usual use of rsync is that the receiver don't want to delete messages that the sender doesn't have from their own database; instead they want the union of all interesting messages.

For this to be efficient, you want the ordering chosen for the messages to make the likely updates somewhat local, in the sense that they leave large chunks of the file untouched. For example, you could order the messages in the file temporally, so that new messages are usually added near the end, or by a combination between temporal order and publisher ID, or a combination of temporal order and topic.

This approach also permits participants, in theory, to blacklist certain known blocks to save space — rather than storing a tebibyte of uninteresting data (last year's Wikipedia edits, say), they can just store its hashes and its sorting key range. However, if new data appears that belongs to that sorting key range, it would change the hashes, making the simple blacklist approach fragile.

A potentially more interesting approach is to store the ranges of sorting keys, or at least their longest common prefixes, in the digest along with the hashes, permitting participants to choose which subrange of the keyspace they bother to replicate.

Recursive rsync delta transfer

Suppose that instead of using a single block size, we use several different block sizes on the same file. For example, we compute digests for block sizes of 1 KiB, 1 MiB, 1 GiB, and 1 TiB. If our total dataset is 16 TiB, its 1-TiB-level digest might be 320 bytes (assuming, for now, no sorting keys — just treating the file as opaque); a peer who fetches that digest can efficiently discover whether it matches their local replica, or matches it except for a few bytes inserted at the beginning.

But suppose they find that the last TiB-sized block in the 1-TiB-level digest doesn't match any of the 17.59 trillion overlapping tebibyte-sized blocks in their own replica. Rather than sending a network request or a purchase order to have that tebibyte of data shipped to them, they can fetch the corresponding block of the 1-GiB-level index. The entire 1-GiB-level index has 16384 entries, but it's only interested in the last 1024 of them, totaling 20 KiB, to discover whether any of the gibibytes comprising that tebibyte are among the 17.59 trillion overlapping gibibytes in their existing dataset.

Perhaps all but one of those gibibytes is a known gibibyte; in this case it can recurse down to the mebibyte level, and then down to the kibibyte level.

In this way, if anywhere from 1 to 1024 bytes have been inserted or deleted in any single place in this 16-TiB dataset, our peer can discover them by transfering 320 + 20480 + 20480 + 20480 + 1024 = 62784 bytes. This is what rsync would report as a "speedup factor" of about 280 million, although it's still worse than the theoretical limit by a factor of between 61 and 62784. Note that this is amenable to zsync's digest-precomputation approach.

The overhead in the worst case is 20 parts in 1023, or 1.96%, the same as nonrecursive rsync. But there are important cases that should admit these higher efficiencies.

Storing the file in such a way that this can be done quickly, including a summary of the 70 trillion rolling hashes involved to avoid needing eight passes over the 16-tebibyte dataset, and the desire to keep a local "virtual copy" of the sending peer's dataset (to avoid re-transferring blocks the next time around whose only sin was that they lacked a message, rather than having new ones) seems like it might be a challenging problem both in terms of algorithms and in terms of systems design. However, I think it's in some sense straightforward; it doesn't require any novel inventions.

Recursive rsync delta transfer applied to message bases and similar CRDTs

Suppose we have a nearly-16-TiB data store and we append one message to it, a message of under 1024 bytes. This can be synchronized with the 62784 bytes mentioned above. Once we bump past the 16-TiB line things get even a bit better still: 340 + 20 + 20 + 20 + 1024 bytes, since all the recursion levels except the top one only

contain a single hash.

This is considerably better than the 50 gibibytes required for non-recursive rsync or the 28 gigabytes I suggested the IHAVE/SENDME approach would need for a similar-sized base of messages (although there I was postulating an average message size of 10 kilobytes). But it remains efficient if we have, say, a mebibyte of new messages to sync. If they're scattered in 1024 random places through the 16-tebibyte base, due to a poor choice of sorting keys, we need on the order of 63 mebibytes of bandwidth to sync them, a 63x multiplier, but several hundred times better than the other protocols. If, instead, they are gathered together more or less in one place, we need to transfer 320 + 20480 + 20480 + 20480 + 1048576 = 1110336 bytes, an overhead of about 6%.

Archival of hypertext with arbitrary interactive programs: a design outline

Kragen Javier Sitaker, 2018-11-09 (3 minutes)

The pages you look at are deterministically executed code drawn from a content-addressable store, using indirections through a namespace. (So far, this is very much like Git.)

Code execution, since it's deterministic, can have its outputs cached. Ultimately what you need to see is a pixel image, so that's the product of the final bit of code. But it's working from a variety of inputs, and intermediate steps in the process can be cached.

The interaction with a page is structured more or less as in Redux: a state is built up by applying a set of reducers to a sequence of user interface events, and what you see on the screen is a function of that state and stuff drawn from the content-addressable store. In this case, the user interface events are ultimately just keystrokes, mouse events, and touch events. But these are transformed into higher-level events such as scroll events, button clicks, and text changes, according to a sort of previous document state.

This approach allows a very small, stable computational core to be extended to arbitrary interactive documents.

Because the code's interaction with the files it draws upon (images, libraries, etc.) is indirected through a namespace, you can get new results from the same code by runnning it in a new namespace. This means that, for example, if you want to view an existing document with a new font, you can make a modified version of it with the new font in the relevant place in its namespace, where it used to find the old font.

The blobs in the content-addressable store are simply sequences of bytes. The code's access to items in its namespace is by way of memory-mapping, and it has the option to view those sequences of bytes in a variety of ways, including as arrays of integers. The code's output is, similarly, some set of blobs placed in a particular part of its namespace, found there when its transaction terminates successfully. This means that many jobs can be performed without undergoing the overhead of serializing and deserializing data structures.

Jobs cannot map new blobs into their namespace except by supplying their contents; thus they cannot access any data they are not initially granted access to, nor can they delegate such access to other jobs. This means that you can statically determine the entire transitive dependency set of not only a given job but also all jobs that could be launched from it via UI interaction. This makes it possible to securely archive the data necessary to run it, which means that you can run it without risk of a failure due to data not being available, and also means that you cannot

Dutch auction raffle

Kragen Javier Sitaker, 2018-06-05 (3 minutes)

A raffle, like a tournament or a dollar auction, is a system designed to sell things for more than they are worth, manipulating the buyers by setting their incremental incentives against them. But the raffle tickets must have some price set on them — if the number of tickets is fixed, then this price could be set too high (reducing the total price paid by selling too few tickets) or too low (reducing the total price paid by selling out at too low a price). Making the raffle open-ended does not eliminate this problem, although it does reduce it.

It occurred to me that a Dutch auction for the raffle tickets might be a useful variant — all of the tickets are sold at the lowest price that sells all of them. This provides an incentive to buyers to reveal their true value.

An open-ended alternative would sell a previously undetermined number of tickets at the price that generates the largest amount of revenue. For example, given bids for 10 tickets at $10, 20 tickets at $20, 20 tickets at $30, 10 tickets at $40, and 1 ticket at $60, you could sell 61 tickets at $10, 51 tickets at $20, 31 tickets at $30, 11 tickets at $40, or 1 ticket at $60, with revenues respectively of $610, $1020, $930, $440, and $60. So selling 51 tickets at $20 is the best option, leaving out those who would only have bid $10, giving all others equal winning chances of 1.96%.

I'm not sure what the incentive landscape looks like for buyers. Suppose the raffled good is worth $1000 to you, and there's a closed-end Dutch auction for 100 raffle tickets. If you're risk-neutral, you should be willing to buy all 100 at any price up to $10 each, but none at any higher price. If it's worth $1100 to another risk-neutral rational actor, they would bid $11 each for all 100; according to the rules of Dutch auctions, this results in them getting all 100 tickets at $10 and you getting nothing. So far so good, since you also paid nothing.

But, if you're truly risk-neutral, you should be just as happy to pay $500 for a 50% chance of acquiring it as to pay $1000 for a 100% chance, so all numbers of tickets are equally good to you, regardless of whether your true value is $1000 or $1100 or $2000 or what.

All of this seems okay so far, except that it doesn't have the intended perverse incentive of inducing buyers to pay more than they get in return, as I think raffles are observed to do in the real world.

We could attempt to explain this by supposing that some buyers are risk-positive, so that a 50% chance of acquiring a $1000 good is worth more than $500 to them. But there are a large variety of different ways that someone could be risk-positive.

Dercuano grinding

Kragen Javier Sitaker, 2019-10-01 (12 minutes)

Right now all the code blocks in Dercuano are rather plain: black on gray, with one typewriter typeface in one size; I think some syntax highlighting would make it both more *pleasant* to read and more *inviting*. The contrast between the colorful source listing I see as I'm editing notes in Emacs and the dull gray listing I see in the rendered HTML is depressing.

The standard way to syntax-highlight code for the WWW is to run something like Pygments or Emacs `htmlfontify-buffer` on the server side to generate a passel of HTML spans that refer to some stylesheet, but in part since Dercuano doesn't have a server side, that isn't really an option, for the same reason prerendering of PNGs is not an option (see Dercuano drawings (p. 64)) — the resulting files are huge.

So, how can I syntax-highlight code in Dercuano? Presumably I need to write something in JS that can be instructed to attempt to tokenize code blocks with the lexical syntax of various languages, perhaps even parsing them, and apply spans and styles to them based on the results.

Languages: mostly Python, SQL, and very minimalist languages

First I thought it would be good to take a sampling of the syntax-highlightable languages I'm using in Dercuano.

Phase relations (p. 2200): none
Harvesting energy with a clamp-on transformer (p. 1952): none
Query evaluation with interval-annotated trees over sequences (p. 1423): SQL, Python, SQL fragments
Cheap textures (p. 736): none
Tagged dataflow (p. 405): none
A bag of candidate techniques for sparse filter design (p. 3250): Python
Flexures (p. 2211): none
Notes on Raph Levien's "Io" Programming Language (p. 1740): Io, Scheme, possible extensions of Io
Microfinance (p. 2875): none
Binate and KANREN (p. 3189): Binate
Midpoint method texture mapping (p. 1837): none
Forth with named stacks (p. 2101): possible extensions of Forth
Things in Dercuano that would be big if true (p. 3136): none
Spiral chinese windlass (p. 2915): ASCII art diagrams
Wang tile font (p. 1463): none
Replacing fractional-reserve banking with a bond market disintermediated with a blockchain (p. 333): none

The main conclusion I can draw from this random sample of 16 notes is that there isn't much code in Dercuano (≈⅓), and what there is tends toward very minimalist programming languages (Scheme, Forth, Io, Binate) which in many cases don't even have existing implementations — and, also, Python and SQL. Languages I've recently used in other notes include SQL, Python, OCaml, Lisp

S-expressions, Lua, GNU MathProg, and Golang.

Syntactic categories and aesthetic treatment

Popular syntactic categories to highlight include, in more or less decreasing order of importance, keywords, function names, type names, string contents, numbers, comments, and punctuation.

Common practice is **to** emphasize **the** keywords, **but** that does **not** make any sense; **the** keywords are **the** lowest-information-density part **of the** program code, so that merely adds noise. A better approach might be to reduce the contrast of keywords, allowing the reader to focus on the informative part. Reducing font size (and increasing letter-spacing to compensate) might also help. Much the same can apply to punctuation, and while this is fairly unimportant for *comprehension* because it's already visually distinctive, it can be a major boon to *aesthetics*.

A recent post discussed on the orange website suggested coloring identifiers by a hash of their contents, so that `pcall` would look very different from `pcal1`, especially to non-colorblind people. If you also wanted to use color to distinguish function names, type names, and keywords, you'd need to slice up the color cube into distinct regions for each one with a demilitarized zone between them to permit reliable discrimination.

One possible significant exception to the dismissal of punctuation is that parenthesis-matching can improve the readability of Lisp code substantially. Traditionally it's done interactively (e.g., by bouncing on % in vi or using C-M-f and C-M-b in Emacs), but by assigning different colors and weights to different parenthesis levels, noninteractive parenthesis matching could be facilitated.

The available aesthetic attributes for syntax highlighting in modern CSS go far beyond what was traditionally available either in hot lead or in emulated VT340+ terminals. Even without using different typefaces, sizes, and letter-spacing, we can oblique, drop-shadow, change the background color, greatly vary the line width, underline (though be careful about underlining spaces), overline, strikethrough, compress the letterforms, and rotate the letterforms.

The vgrind program would call out definitions (for example, of functions and types) by putting the name of the defined entity in the right margin in a larger font, which was useful for paging through printed-out listings but probably isn't useful for a small snippet of code with commentary around it.

Where do I get the tokenizers or grammars?

It would be nice to avoid writing parsers for Python, SQL, OCaml, Scheme, MathProg, Golang, and Lua, especially fragment-tolerant and REPL-tolerant parsers, but there's probably no way to get around writing parsers for things like Binate, proposed extensions of Forth, proposed extensions of Io, and Io itself.

Pygments

Pygments comes with a fairly comprehensive set of lexers optimized for this task; `grep --color -nH -e ^class /usr/lib/python2.7/dist-packages/pygments/lexers/*.py` yields a bit over 400

matches. Most of these contain some imperative Python code, but Pygments has a pretty extensive set of regexp-based facilities:

```
class MoinWikiLexer(RegexLexer):
    """
    For MoinMoin (and Trac) Wiki markup.

    .. versionadded:: 0.7
    """

    name = 'MoinMoin/Trac Wiki markup'
    aliases = ['trac-wiki', 'moin']
    filenames = []
    mimetypes = ['text/x-trac-wiki']
    flags = re.MULTILINE | re.IGNORECASE

    tokens = {
        'root': [
            (r'^#.*$', Comment),
            (r'(!)(\S+)', bygroups(Keyword, Text)),  # Ignore-next
            # Titles
            (r'^(=+)([^=]+)(=+)(\s*#.+)?$',
             bygroups(Generic.Heading, using(this), Generic.Heading, String)),
            # Literal code blocks, with optional shebang

            (r'(\{\{\{)(\n#!.+)?', bygroups(Name.Builtin, Name.Namespace), 'codeb
lock'),
            (r'(\'\'\'?|\|\||`|__|~~|\^|,,|::)', Comment),  # Formatting
            # Lists
            (r'^( +)([.*-])( )', bygroups(Text, Name.Builtin, Text)),
            (r'^( +)([a-z]{1,5}\.)( )', bygroups(Text, Name.Builtin, Text)),
            # Other Formatting
            (r'\[\[\w+.*?\]\]', Keyword),  # Macro
            (r'(\[[^\s\]]+)(\s+[^\]]+?)?(\])',
             bygroups(Keyword, String, Keyword)),  # Link
            (r'^----+$', Keyword),  # Horizontal rules
            (r'[^\n\'\[{!_~^,|]+', Text),
            (r'\n', Text),
            (r'.', Text),
        ],
        'codeblock': [
            (r'\}\}\}', Name.Builtin, '#pop'),
            # these blocks are allowed to be nested in Trac, but not MoinMoin
            (r'\{\{\{', Text, '#push'),
            (r'[^{}]+', Comment.Preproc),  # slurp boring text
            (r'.', Comment.Preproc),  # allow loose { or }
        ],
    }
```

Even things like pygments.lexers.ml.OcamlLexer (90 lines of code) are written entirely in this declarative style without any executable code. As you can see above, Pygments apparently has a stack machine for nested multi-line string constructs such as Trac code blocks or OCaml comments.

One drawback of trying to use this stuff is that it relies pretty

heavily on Python's regexp syntax, which is mostly, but not completely, compatible with JS's.

Another is that syntax-highlighting purely through tokenization doesn't have much chance of, for example, consistently distinguishing user-defined types from user-defined functions.

Vim

Vim comes with some 586 syntax definition files; many of them are fairly minimal. They are written in Vimscript, which is imperative, but most of the commands consist of defining regular expressions — which I originally thought would be in Vim's regexp dialect with `\(\)` for grouping and whatnot, but which has apparently adopted many PCRE-like features — though the backwards-incompatible ones are turned on on a per-regexp basis by the sequence `\v`, which means "very magic". Here's Honza Pokorny's Dockerfile syntax file:

```
if exists("b:current_syntax")
    finish
endif

let b:current_syntax = "dockerfile"

syntax case ignore

syntax match dockerfileKeyword /\v^\s*(ONBUILD\s+)?(ADD|CMD|ENTRYPOINT|ENV|EXPOSE
|FROM|MAINTAINER|RUN|USER|VOLUME|WORKDIR|COPY)\s/

syntax region dockerfileString start=/\v"/ skip=/\v\\./ end=/\v"/

syntax match dockerfileComment "\v^\s*#.*$"

hi def link dockerfileString String
hi def link dockerfileKeyword Keyword
hi def link dockerfileComment Comment
```

Vim also does automatic indentation, which requires a little deeper understanding, but this is done entirely separately and with no dependence on the syntax highlighting.

Consequently, even in C, like Pygments, Vim doesn't manage to distinguish between types and functions.

Emacs

Emacs does successfully distinguish between types and functions, and it is configured in a similar way to how Vim is configured, but with Lisp lists instead of sequences of commands, and perhaps a few more levels of indirection. However, some of the Emacs syntax highlighting setup involves truly unbelievable amounts of hair.

Golang in Emacs

go-mode.el is relatively simple; one of the first things the `go-mode` function does is to set `font-lock-defaults` to a list containing the name of a function that returns a declarative configuration for syntax highlighting as a list:

```
(set (make-local-variable 'font-lock-defaults)
   '(go--build-font-lock-keywords))
```

This list is built up more or less as follows, though I've omitted most of the individual items:

```
(defun go--build-font-lock-keywords ()
  (append
   `(...)
   (if ...)
   `(...
     (,(concat (go--regexp-enclose-in-symbol "map")
               "\\[[^]]+\\]" go-type-name-regexp)
      1 font-lock-type-face) ;; map value type
     (,(concat (go--regexp-enclose-in-symbol "map")
               "\\[" go-type-name-regexp)
      1 font-lock-type-face) ;; map key type
     ...)))
```

The mysterious `go--regexp-enclose-in-symbol` function is defined as follows:

```
(defun go--regexp-enclose-in-symbol (s)
  "Enclose S as regexp symbol.
XEmacs does not support \\_<, GNU Emacs does.  In GNU Emacs we
make extensive use of \\_< to support unicode in identifiers.
Until we come up with a better solution for XEmacs, this solution
will break fontification in XEmacs for identifiers such as
\"typeμ\".  XEmacs will consider \"type\" a keyword, GNU Emacs
won't."
  (if (go--xemacs-p)
      (concat "\\<" s "\\>")
    (concat "\\_<" s "\\_>")))
```

The two particular items I called out earlier, which cause `foo` and `bar` in `map[foo]bar` to be highlighted as type names, come out as the following:

```
("\\_<map\\_>\\[[^]]+\\]\\(?:[*(]\\)*\\(\\(?:[[:word:][:multibyte:]]+\\.\\)?[[:wo
ord:][:multibyte:]]+\\)"
1 font-lock-type-face)

("\\_<map\\_>\\[\\(?:[*(]\\)*\\(\\(?:[[:word:][:multibyte:]]+\\.\\)?[[:word:][:mu
ltibyte:]]+\\)"
1 font-lock-type-face)
```

This says to highlight subexpression 1 in each of those regexps as `font-lock-type-face`, which begins at the first `\\(` that isn't followed by a `?:` — Emacs, too, has adopted some of Perl's regexp syntax, though not the good part of not having to double-backslash things or backslash your parens at all.

The whole syntax-highlighting list is about a page long, mostly regexps like that, but it also includes a call to `go--match-func`, which parses function parameter lists to look for type names. This involves

several pages of Elisp that does a lot of stuff like `(save-excursion (if (looking-at ...) (goto-char (match-end 0))))`, which is precisely the kind of thing I'd like to avoid, convenient though it sometimes is as a way to munge text.

C in Emacs

By contrast, C syntax highlighting (like various other features for C) is mostly handled by a heuristic, forgiving C parser consisting of over ten thousand lines of Elisp written over the last 35 years in cc-engine.el, which also handles Objective-C, C++ (including the Qt extensions), Awk, IDL, Java, and Pike. No test suite is evident. As to how it distinguishes type names from function names, I have no idea and I might not find out tonight even if I spent the rest of the night on it, but it does.

Writing them from scratch

An appealing alternative, and really the only alternative when it comes to programming language syntax variants that I'm exploring that nobody has ever implemented, is to write tokenizers and parsers from scratch. This is especially appealing if the parser can be used to actually interpret or compile the language as well as syntax-highlighting it, although of course if I'm just interested in the language's semantics and not its syntax I can quite reasonably just serialize to S-expressions, as in A formal language for defining implicitly parameterized functions (p. 144), or just RPN, like Python pickle. But if I want compatibility with existing code or existing implementations, parsing arbitrarily complicated languages may be useful.

For interpretation, though, handling incomplete or incorrect code isn't necessary, and sometimes for syntax highlighting it is, though less often than for text editing. One possibility for that kind of thing is to write a normal parser using some kind of parsing theory (such as an Earley or Packrat parser) and then mechanically transform it to produce possible parses of *substrings* of the original language. (This approach is also useful for parallelizing and incrementalizing parsing; see Parallel NFA evaluation (p. 2967) for details.)

Another possibility, maybe a more interesting one, is to train a recurrent ANN to classify syntactic elements instead.

User-per-group (UPG), umask, and “Permission denied” on shared Git repos via ssh

Kragen Javier Sitaker, 2007 to 2009 (4 minutes)

Maybe we're doing something wrong, because I can't find anybody writing on the web having trouble with git and umask, although it looks like the umask situation in Debian has been kind of a PITA for a while.

The Current State of the umask Problem

So I made the mistake of believing /etc/skel/.profile when it said:

```
# the default umask is set in /etc/profile
```

It turns out /etc/profile doesn't do squat when you do this:

$ ssh watchdog.notabug.com umask

because there's no login shell involved. It does read .bashrc, but having every subshell reset your umask would be annoying and maybe dangerous.

/etc/login.defs explains:

```
# UMASK usage [in /etc/login.defs] is discouraged because it
# catches only some classes of user entries to system, in fact
# only those made through login(1), while setting umask in shell
# rc file will catch also logins through su, cron, ssh etc.
#
# At the same time, using shell rc to set umask won't catch
# entries which use non-shell executables in place of login shell,
# like /usr/sbin/pppd for "ppp" user and alike.
#
# Therefore the use of pam_umask is recommended (Debian package
# libpam-umask) as the solution which catches all these cases on
# PAM-enabled systems.
#
# This avoids the confusion created by having the umask set in two
# different places -- in login.defs and shell rc files (i.e.
# /etc/profile).
#
# For discussion, see #314539 and #248150 as well as the thread
# starting at
# http://lists.debian.org/debian-devel/2005/06/msg01598.html
```

But for whatever reason, libpam-umask is not installed and used by default.

Consequently there are now a bunch of directories in /home/watchdog/code/.git that are writable only by "aaronsw", so I probably won't be able to push any more changes until we fix that.

Why This Problem Arose

Probably everybody knows, but just for the record.

Debian by default uses "UPG" or "User Per Group". This lets you leave your umask at 002 (or 007, or 000) all the time, and just use group ownership to distinguish private from shared files; private files belong to the group that contains only you.

http://www.redhat.com/docs/manuals/linux/RHL-8.0-Manual/ref-guide/s1-users-groups-private-groups.html

But not all people, or all software, have adapted to this new world, so sometimes people like to have other umasks. This causes the problem we're seeing here: accidentally creating directories other people can't write to in shared spaces.

Why We Should Care

If we can get the infrastructure into a smoothly working state, we don't have to struggle with it later on. The opportunity cost of time at the start of a project is high, so it's hard to justify spending time on stuff like this up front, but the psychological phenomenon of hyperbolic discounting exaggerates that opportunity cost. I think putting in an hour or so on this stuff now will save us two or three hours over the course of the next few weeks.

http://en.wikipedia.org/wiki/Hyperbolic_discounting

Probably all of us have been burned a few times by not keeping our infrastructure in adequate order, so I expect this should be an easy sell.

What We Should Do

First, aaronsw or root should fix the nonwritable directories:

$ chmod g+w $(find /home/watchdog/code/.git -perm -200 ! -perm -020 -print)

Then we should fix the umask. Two choices:

- use libpam-umask. I've tested this on my server and it works:
  kragen@courageous:~$ sudo apt-get install libpam-umask
  Put this line at the end of /etc/pam.d/common-session: session optional pam_umask.so umask=002
  Remove the "umask 002" line from /etc/profile.
- Put 'if ["$SHLVL" = 1] ; then umask 002; fi' into /etc/bash.bashrc. Putting this in .bashrc does seem to work (I'm testing it on another server where other people didn't like the libpam-umask approach), so putting it in /etc/bash.bashrc should work too, as long as everyone uses bash.

In what sense is e the optimal branching factor, and what does it mean for menu tree design?

Kragen Javier Sitaker, 2012-12-04 (3 minutes)

What's the sense in which e is the optimal branching factor? The number of nodes you have to traverse to reach one of N nodes with branching factor B is ceil(log N / log B), and if you're examining each of the B branches in the node to figure out which one to follow, you end up examining B ceil(log N / log B) branches. If we remove the discretization, we get log N (B / log B), and it turns out that B / log B has a minimum at B = e, so in practice the optimal branching factor is 3.

This still holds if you are only examining B/2 branches at each node. It's only if there's an additional cost to visiting a new node that the minimum cost moves to a larger branching factor.

To be a little more concrete, suppose you're trying to track down an incorrect result from the execution of a program that runs for a hundred billion instructions, or about a minute. If the program is built out of functions that call other functions and combine their results, and you can tell from looking at each result whether it's correct or not, maybe you can navigate to the result you want by expanding the execution history as an outline.

If each function calls three other functions, then within 24 clicks, you can make your way from the top-level result to the particular incorrect result; at each step, you have to examine on average 1.5 intermediate results, so you need to look at about 35 results.

If each function calls only two other functions, you have to look at about 37 results, which is slightly worse; and the same is true if each function calls four other functions. So the B/log B function is pretty flat over the region of 2–4. Then it starts to climb: at 5 callees, you need to examine 39 results; at 6, 42; and at 7, 46. At 15 callees, the number of results you have to examine to find your way to the bottom-level fault has doubled to 70.

However, the number of nodes you have to examine (and the number of clicks you have to make) at that point has shrunk from 24 to 9. So if the cost of visiting a node is significant (e.g. you need to reorient yourself in a new context, or clicking is slow) then the optimal number of callees for debugging might be higher than 3. Already at 9 you've cut in half the number of nodes visited (12 instead of 24) at only a 50% extra cost in number of branches examined. So if the cost to visit a node is comparable to the cost to examine a branch (the same order of magnitude) then the optimum is probably somewhere around 9, say, between 5 and 18. (At 18, you're examining 79 branches, but still visiting 9 nodes. So going from 9 to 18 saves you about 3 nodes, but costs you 27 branch examinations, which only makes sense if examining a node costs at least 9 branch examinations.)

Set hashing

Kragen Javier Sitaker, 2017-03-09 (9 minutes)

There is a constant-time way to hash the value of a mutable set container, which converts some algorithms from $O(N^2)$ to $O(N)$.

A mutable set container of T is an abstract data type whose value is, at any given time, some set of values of type T; typically these support constant-time member addition, member removal, membership testing, and iteration over the items contained.

Often these don't guarantee a particular iteration order because they are implemented, for example, using hash tables, which may shrink with some hysteresis to preserve the performance guarantee for iteration. The data structure Nayuki calls the Binary Array Set is a non-hash-table mutable set container structure which can be iterated much more efficiently in some arbitrary order.

I am trying to be careful in this essay to distinguish sets, which are immutable mathematical objects, from set containers, whose value at any given moment is a set, but which contain different sets at different times — the relationship is that a set is a possible state of a set container.

Hashing sets: a more efficient approach

In Python, *immutable* sets are hashable (if their items are), which is a frequently useful feature, but often inefficient — making an immutable set from what Python calls a mutable set (what I'm calling a mutable set container) involves iterating over all the items.

To make the values of a mutable set container efficiently hashable, XOR together the hash values of all of its items, then perform some one-to-one transformation that doesn't commute with XOR, such as adding or multiplying some large constant, or computing its SHA-256 or Blake2. This (except for the final transformation) can be done incrementally as items are added and removed, and it will always produce the same value for the same set of items, regardless of how the set was arrived at.

The final transformation here is to ensure that related sets such as {1, {2, 3}}, {1, 2, {3}}, and {{{1, 2, 3}}} all have different hash values, a feature which seems likely to be desirable in practice.

Doing it this way rather than the standard Python way will convert some $O(N^2)$ algorithms into $O(N)$ algorithms. If you add N items to a set container one at a time, each time testing a set of hashes to see if you may have seen the current state of the container before, this will take $\theta(N)$ time with this approach, but $\Theta(N^2)$ time with the Python approach.

16-bit example

As a 16-bit example, if your set is {4, 5, 8}, your hash function for integers is multiplying by 33947 mod 2^{16}, and your final transformation is adding the random number 48709 mod 2^{16}, then you compute $((4 \cdot 33947) \oplus (5 \cdot 33947) \oplus (8 \cdot 33947)) + 48709 \bmod 2^{16}$, so the set's hash value is 19970. If you store the quantity $((4 \cdot 33947) \oplus (5 \cdot 33947) \oplus (8 \cdot 33947)) \bmod 2^{16} = 36797$ in a variable in the mutable set container, and you add 10 to the set, you can

incrementally update it by XORing in $10 \cdot 33947 \bmod 2^{16} = 11790$ into it, getting 36797 as the new untransformed hash value; upon request, you can return it with 48709 added, giving 19970. If you then remove 4 from the container, you can XOR $4 \cdot 33947 \,\%\, 2^{16} = 4716$ into the variable, getting 40401, which you can verify is $((5 \cdot 33947) \oplus (8 \cdot 33947) \oplus (10 \cdot 33947)) \,\%\, 2^{16}$.

(The $\oplus$ character is standard math notation for the XOR operation.)

Minor variants

(Alternatively, you can sum the hash values of the items, then use a final transformation that doesn't commute with addition, such as bit rotation or XOR with a constant.)

If your item hash functions and final transformation are cryptographically secure hashes, then you would be justified in concluding that two states of the container are equal if their hashes are equal, without iterating over their items.

Possible uses for incrementally hashing sets

You might argue that it isn't very helpful for you to keep around a hash value for a no-longer-current state of a mutable set container — certainly it isn't useful as a way of finding the set container in a hash table, for example. And in the common case where you don't use a cryptographically secure hash, there's the chance of hash collisions.

However, there are uses for this.

One possible use for this technique is in incrementally optimizing NFA execution by partial compilation to DFAs (each DFA state corresponds to a set of NFA states), which can in the worst case produce a memory usage explosion — but if only state-sets that occur many times are compiled to DFA states, then the problem is much less severe. If you snapshot states that appear in a list (or Bloom filter) of previously seen hashes, then you can recognize them if they come around again.

Another possible use for this technique is in memoizing set arithmetic: if you have already computed the union, intersection, or set-subtraction of two sets, you may be able to avoid iterating over the set items to compute them again.

A third use is in implementing operations on finite binary relations represented as sets of pairs — operations which, in addition to the set-arithmetic operations mentioned above, might include composition, converse, transitive closure, and various kinds of products.

A fourth, very general, use is in combination with a transaction log. If you maintain a transaction log in a layer on top of a basic mutable set container that supports both insertion and deletion, listing the additions and deletions in the log, you can hash positions in the transaction log, and the state at each of these positions is retrievable in time bounded by the size of the transaction log. This means you can add N items to a set container one at a time, making a hash table of the N successive sets that are the states of the container, in $\Theta(N)$ time, and then retrieve any state from the table in $\Theta(N)$ time.

This kind of undo/redo journal approach is a very general and efficient approach for obtaining FP-persistent† semantics on top of

ephemeral data structures. If you bound the transaction log size, you can preserve constant-time guarantees for access, but then when the journal gets too large, you need to copy the whole data structure to a new one with a fresh journal.

In the scenario given, if the transaction log size is k, you can retrieve any state in at most k steps, but you need to copy the hash table (in the limit, of average size N/2) ⌊N/k⌋ times, requiring $N^2/2k$ work inserting and deleting. Depending on the relative frequency of probes and updates, and in particular the frequency of access to very old states, this approach can often save several orders of magnitude of performance — not an asymptotic improvement, to be sure, but good enough in many cases.

Note that the Binary Array Set structure mentioned above can be viewed as a special case of this approach, where the update log is sorted into increasingly larger arrays.

Other approaches to hashing states of mutable set containers efficiently

A different approach is to store the sets in a trie, or in a binary search tree with a convergent tree balancing algorithm, like the jumprope data structure used for sets of large strings — convergent in the sense that a tree containing the same set of items will always be balanced in the same way. This way, the hash can be computed on each treenode, which additionally enables hash-consing, especially useful for FP-persistent data structures.

A third approach is to compute a bloom filter of some fixed parameters (or with some fixed sets of parameters) for the items in the set, rather than XORing their raw hash values together; then you can hash the Bloom filter by, for example, adding its words together at hash time. The bloom filter may be only a few words long (say, 64 or 128 bits) and yet effective under many circumstances, but there are difficult tradeoffs around expected set size.

This approach has the additional benefit that you can directly compute bloom filters for unions and intersections, though not set subtractions, and the bloom filter may speed up membership tests. Bloom filters' Achilles heel is their lack of support for deletion.

† "Persistent" unfortunately has two conflicting meanings when it comes to data structures; functional programmers use it to mean that modifying the data structure does not make its previous states inaccessible. By "FP-persistent" I mean this meaning, not the more common meaning of "retrievable after rebooting your computer".

Trees as code

Kragen Javier Sitaker, 2016-05-10 (4 minutes)

A typical representation of a binary tree in memory might be something like this:

```
typedef struct node { char *key; struct node *left, *right; } node;
node qn = { "queer", NULL, NULL }
   , rn = { "rude", qn, NULL }
   , tn = { "the", NULL, NULL }
   , sn = { "sad", rn, tn }
;
```

This is, as it happens, a binary search tree: the key of a node is always greater than any of the nodes in its left subtree and less than any of the nodes in its right subtree. In this case we're using it to store a set of words.

You could write separate functions to do things like efficiently look up a word to see if it's in the tree, print out all the words in the tree, hash all the words in a lexical range of the tree into a hash table. Most of these functions, in C, will have this general form:

```
void process_tree(node *n, context *ctx) {
    if (!n) return;
    results r = process_node(n->key, ctx);
    if (left_wanted(r)) process_tree(n->left, ctx);
    if (right_wanted(r)) process_tree(n->right, ctx);
}
```

Different `process_tree` functions will have different `results`, `process_node` `left_wanted`, and `right_wanted`, in some cases trivial ones, but all of the functions I mentioned above can be written in this way.

An obvious thing to do then is to factor out the common `process_tree` logic into a function and pass in a `process_node` function to it with a defined interface; for example:

```
typedef struct { bool left, right; } wanted;
typedef struct { wanted (*f)(const char *, void *); void *ctx; } visitor;
void visit_tree(node *n, visitor v) {
    if (!n) return;
    wanted w = v.f(n->key, v.ctx);
    if (w.left) visit_tree(n->left, v);
    if (w.right) visit_tree(n->right, v);
}
```

This definitely works, and it's within a constant factor of optimal, but it is maybe a little bit inefficient. In particular, it spends a lot of its time passing null pointers to itself, copying the two-word visitor struct, and consulting booleans to figure out whether to recurse on a null pointer. Also, even though it will always visit the parts of the tree that it visits in the same order, it requires that order to be represented wastefully in memory with a bunch of pointers, and then it recovers that order from those pointers.

So I was thinking about immediate-mode GUIs ("IMGUI") and tree traversal, and it occurred to me that there's an interesting alternative in many cases.

Here's an alternative representation of the tree above that works with the same `visitor` type:

```
void sad_tree(visitor v) {
    wanted w = v.f("sad", v.ctx);
    if (w.left) {
        if (v.f("rude", v.ctx).left) v.f("queer", v.ctx);
    }
    if (w.right) v.f("the", v.ctx);
}
```

In a sense, this is just a partially-evaluated version of `visit_tree` for the above tree; it will perform the same sequence of calls to `v.f` with the same arguments, given the same return values. Since it can do all of the preorder visitor traversals described above, it is in some sense a fairly universal representation of the tree.

Probably you wouldn't really want to write `sad_tree` by hand, at least in this case. But it might make sense to compile it from some other representation, either with run-time code generation or from some kind of source code.

It might actually be worthwhile to write it by hand in some cases, because the visitor interface allows you to traverse kinds of trees other than trees entirely materialized in memory ahead of time.

Very composite numbers

Kragen Javier Sitaker, 2014-04-24 (4 minutes)

It's often more convenient in practice to use feet and yards than meters because you can divide them evenly into three, four, six, or nine equal units, with a convenient whole number of inches. For the same reason, the Babylonian sexagesimal system remains in use today for angles (360 degrees, each subdivided into 60 minutes of 60 seconds). In some sense, both 10 and 12 are composite numbers, but 12 seems much "more composite", and 60 is "more composite" still, much more so than 100.

What are the "most composite" numbers, the ones that can be evenly divided in the most different ways? Of course you can always get more factors if you go to a larger number, but some numbers have more factors than any number smaller than themselves; there's a definite sequence of these "most composite" numbers, and there aren't really very many of them. You might think that you'd just go with the products of the primes: 2, 2·3 = 6, 2·3·5 = 30, 2·3·5·7 = 210, and so on; but it turns out that 30 only has six proper divisors greater than 1 (2, 3, 5, 6, 10, and 15), but 24 beats it by having the same number of factors and being smaller. It substitutes a versatile, lightweight extra couple of 2s for 30's 5, thus getting the same number of factors sooner.

It turns out our old friends 12, 36, 60, and 360 are in this sequence, along with 4 and 6. However, 360·60 = 21600 is not, because once you get past 720, it behooves you to start throwing a 7 in there. The champion that beats poor old Babylonian 21600, with its mere 70 divisors, is 10080 ($2^5 \cdot 3^2 \cdot 5 \cdot 7$) with 70 divisors, or alternatively 20160 ($2^6 \cdot 3^2 \cdot 5 \cdot 7$) with a whopping 82 divisors! (I'm still leaving out 1 and the number itself, here.)

Here's what I've computed so far:

```
>>> nfactors = lambda n: len([x for x in range(2, n) if n % x == 0])
>>> i = 1
>>> best_nfactors = 0
>>> while True:
...  i += 1
...  n = nfactors(i)
...  if n > best_nfactors:
...   print i, n
...   best_nfactors = n
...
4 1
6 2
12 4
24 6
36 7
48 8
60 10
120 14
180 16
240 18
360 22
```

720 28
840 30
1260 34
1680 38
2520 46
5040 58
7560 62
10080 70
15120 78
20160 82
25200 88
27720 94
45360 98
50400 106
55440 118
83160 126
110880 142

Unsurprisingly, I'm not the first person to discover this; the standard term is "highly composite number", and it's sequence A002182 in OEIS.

If, on the other hand, you're looking for a base for a positional numbering system that will give you maximum divisibility, 30 beats 24, and 210 is better still. True enough, in base 24, an eighth is simply 0.3, while in base 30, it's 0.3,22,15, which is more awkward; but in base 30, a fifth is 0.6, while in base 24, it's an infinite sequence: 0.4,0,19,4,0,19,...! Infinite sequences are far more awkward to calculate with. Base 210 gives you perfect divisibility --- in a finite number of fractional positions, but maybe more than one --- for any number of portions up to 10, and any composite number up to 21, plus of course many other numbers.

A reactive crawler using Amygdala

Kragen Javier Sitaker, 2014-09-02 (updated 2014-09-19) (4 minutes)

This is a design for a reactive programming system optimized for web crawling, to be implemented in Java. We want it to be as simple as possible to write a web-crawling application that transmits updates when it has them — say, to an IRC channel, or a webhook.

Suppose we want to send the Bitstamp Bitcoin price, translated into Euros, to an IRC channel, but only when it changes by more than 0.5%, and without hitting any of the web servers more often than once every 20 minutes. We'd like to be able to write code like this:

```
import org.canonical.amygdala.UserAgent;
import org.canonical.amygdala.Page;
import org.canonical.amygdala.DBVar;
import org.canonical.amygdala.DB;

// ...

final DBVar dbVar = DB.var("Ⓑ in €");
start("compute Ⓑ in €", new Runnable() {
    public void run() {
        String ratesUrl =
            "http://www.x-rates.com/calculator/?from=EUR&to=USD&amount=1",
            bitstamp = "https://www.bitstamp.net/";
        // Incapsula lets Googlebot access pages without having to
        // execute JS.  Bitstamp uses Incapsula.
        UserAgent ua = UserAgent.create("Mozilla/5.0 (compatible; "
            + "Googlebot/2.1; +http://www.google.com/bot.html)");
        Page exchangeRates = ua.get(ratesUrl).maxAge(minutes(20)),
             bitstamp = ua.get(bitstamp).maxAge(minutes(20));
        // Extract floating-point numbers with regular expressions.
        Float bitcoinPrice =
                bitstamp.extFloat("class=\"last\">$([\\d.]+)<"),
            euroPrice =
                exchangeRates.extFloat("class=\"ccOutputRslt\">([\\d.]+)<"),
            bitcoinInEuros = bitcoinPrice / euroPrice;
        dbVar.setFloat(bitcoinInEuros);
    }
});

start("irc announcement", new Runnable() {
    public void run() {
        DBVar last = DB.var("last Ⓑ in €");
        float newVar = dbVar.get().float(),
        Float oldValue = last.get().floatOption();

        if (oldValue == null
          || Math.abs(oldValue - newValue) / newValue > 0.005) {
            ircChan.say("Ⓑ = €" + newValue);
            last.set(newValue);
        }
    }
```

```
});
```

and have it "just work", which in this case involves fetching the requested pages, reinvoking the runnable once it has them, and reinvoking it again every time it has new versions of those pages.

Amygdala needs to run the first runnable once simply in order to find out what URLs it will try to fetch — but since it hasn't fetched any pages yet, the first attempt to use regexps to extract floats from the not-yet-fetched pages will raise an exception. But the page fetches will have been initiated, and the runnable will be reinvoked once one or the other is available.

Invoking get() on a DBVar notes that DBVar as a read-dependency of the current task; invoking float() on the result will return the float stored there. There are three possibilities:

• Nothing is stored there yet. In this case, float() will silently abort the transaction, and it will be rerun when something is stored there. To avoid aborting the transaction in this case, you can use floatOption() instead.
• Something is stored there that isn't a float. In this case, float() will abort the transaction with an error (and it will be rerun when the value stored there changes).
• A float is stored there. In this case it will be returned.

So the first time the "irc announcement" runnable is invoked, it will fail the transaction because "Ⓑ in €" has no value yet; if and when a value is stored there, it will be rerun, and then it will also read, and write, "last Ⓑ in €".

I don't quite know what the right handling of the ircChan.say call is — it could either check to verify that speaking on the channel is possible (and abort the transaction if not), waiting to actually transmit until the transaction as a whole commits; or it could simply transmit from the middle of the transaction, with the unfortunate result that retrying the transaction could result in duplicate messages on the channel.

The maxAge ensures that we never fetch the pages more often than once every 20 minutes. But as long as the task is running, the fetcher will continue fetching those pages whenever they become stale.

This means Amygdala supports both "push" tasks, like those above, and "pull" tasks, which only run as long as something is listening to them. (Actually, I think that's not quite true; perhaps everything here can be "pull" from the IRC channel?)

mechanical computation: with Merkle gates, height fields, and thread

Kragen Javier Sitaker, 2010-06-28 (36 minutes)
(Originally published 2010-06-28.)

So one of the reasons I'm excited about automated fabrication (e.g. Fab@Home, tabletop CNC mills, RepRap, inkjet-printing of circuits, fused deposition modeling) is that I expect it will make it possible to build computers from raw materials with minimal capital. It will be some time before those computers are as cheap or as fast as mass-produced microcontrollers, so they will start out as curiosities. But how far away is the prospect of automatically building a working computer from raw materials with minimal capital? I think it's already possible.

This post considers three kinds of mechanical computers: one using Merkle's buckling logic, one using mechanical height fields, and one using pulling of threads.

Organic semiconductors, nonlinear acoustic devices, fluidic logic, or something more exotic, might turn out to be the form that computers made by 3-D printers eventually take; but I'm pretty sure Merkle's approach is workable. So I'm going to consider that first. And I want to describe some ideas of my own.

Unfortunately, I don't know shit about mechanical engineering. If any actual mechanical engineer is annoyed at my ignorant speculations when they read this, I'd be delighted to hear about all the things I'm getting wrong.

How many logic gates? Around 64000.

There have been a number of capable small CPUs over the years that contain on the order of 4000–8000 transistors, including the 6502 used in the Apple][, the NES, and the Atari 2600 (4000 transistors, 8-bit ALU), Chuck Moore's MuP21 (6000 transistors, 21-bit ALU, including video coprocessor), Voyager 2's RCA 1802 (5000 transistors), CP/M machines' 8085 (6500 transistors) (the 8080 was smaller but needed more support circuitry), the Apollo Guidance Computer (4100 3-input RTL NOR gates, which I think is about 8200 transistors) and so on. The IBM 1401 was supposedly more complex: http://ed-thelen.org/comp-hist/BRL64-i.html says a minimal 1401 system had 6213 diodes and 4315 transistors. It ran at 86 957 Hz. (How big was the PDP-7 Unics was written on?)

To run an interpreted programming language, you probably need at least 32000 bits of memory, and twice that is better.

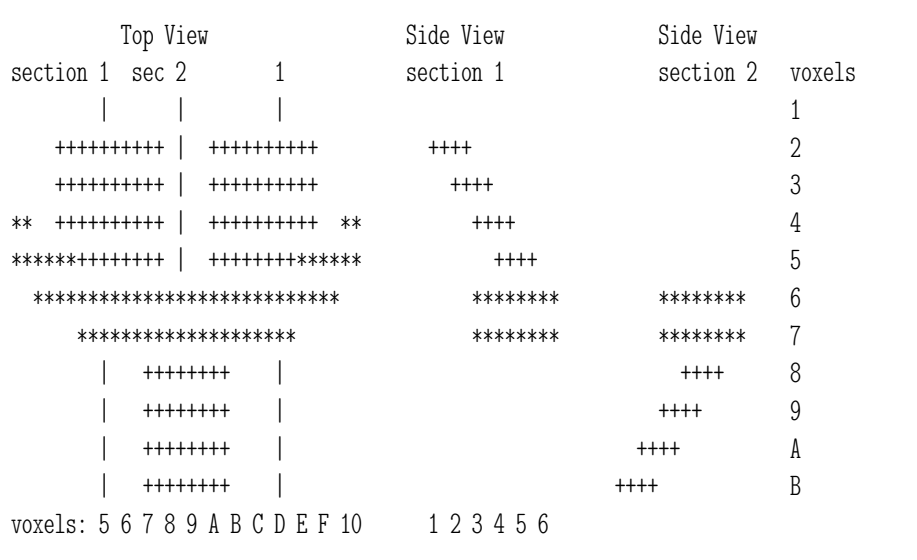
So 64000 "logic elements", each of which can be either a bit of memory or a gate, should more than suffice. 64000 is the cube of 40, so a 40x40x40 cube of logic elements would be sufficient if you didn't need any space for signal routing. In two-dimensional chips, I've heard it's typical to spend 90% of the area on routing; things are much closer together in three dimensions (64000 elements is about 250×250 in 2D, so that far-apart things in a device of that size need

more than six times as much wire to connect them), so 10x routing overhead is quite a pessimistic assumption for 3-D; but if we accept it, then we need an 86×86×86 cube.

It might be possible to reduce this substantially if the memory is some kind of bulk medium instead of one or more parts per bit. Historically-used bulk media have included mercury acoustic delay lines; magnetostrictive torsion acoustic delay lines in wire; magnetic films on tapes, drums, and discs; impressions in the surface of thixotropic substances such as wax or wet clay; ink or pencil lead on papyrus or paper; knots tied in khipu cords; and electric charges on the surface of cathode-ray tubes.

How many voxels per logic gate? Around 1200 for Merkle gates.

How big does each element need to be? Presumably if we're fabricating it with the CandyFab 2000, it needs to be pretty gigantic. (Sugar wouldn't bend enough, but maybe you could make it out of polyethylene pellets with the CandyFab.) But if you are depositing tiny beads of molten ABS plastic with 2-mil precision, you could make it a lot smaller. You could probably get a working Merkle buckling-spring cell in something like 16x6x12 voxels:



If that were really the size you needed, at 2 mils per voxel, it would be 32 × 12 × 24 mils, or about 0.8 mm × 0.3 mm × 0.6 mm, which altogether adds up to just over an eighth of a cubic millimeter --- 0.52 mm cubed.

You could probably do something a lot more ingenious and get an order of magnitude or two improvement.

Which means that the total 86×86×86 cube, 6 billion voxels, would be 45 mm on a side, if you have a 3-D printer that can construct a complex object with arbitrary 2-mil voxels.

One big advantage of the Merkle-gate design is that it doesn't require any contact between separate elements, sliding or otherwise, so surface finish may be less crucial than for some other kinds of machines.

Height-field computing: mechanical LUTs to reduce the number of elements

The elements in modern FPGAs ("field-programmable *gate* arrays") mostly consist of lookup tables ("LUTs") rather than actual gates in the array. The idea is that basically you use your N bits of input to index into a little EEPROM and get a bit of output, which allows you to emulate any possible combinational circuit, and then you have "routing resources" — basically crossbar multiplexers — to connect those outputs to the inputs of other cells.

For automated fabrication to help much with building mechanical computers, compared to just carving them out of wood or steel or whatever with non-automated machine tools, it's going to have to reduce the number of separate pieces that you have to assemble manually when you're done. Some kinds of 3-D printing can print already-assembled parts that mesh together nicely and aren't stuck together; others can't. Those that can't will probably require manual assembly for a while yet. (Although, hey, pick-and-place machines could be used for that, right?)

Height fields as a mechanical realization of LUTs

LUTs have a fairly straightforward low-parts-count mechanical realization. If you have a needle-like probe positioned over a solid height field, then when you lower the probe onto the height field, the height at which it stops will be an arbitrary function of its X and Y coordinates: the height of the surface at that point. This "lowering" step is similar to the step of squeezing the gate of a Merkle buckling-spring gate, or pushing a Drexlerian rod-logic rod to see where it stops.

If you encoded one bit in X and one bit in Y, you can get an arbitrary two-input boolean function in Z; but Z's range isn't limited to booleans. Likewise, you could encode multiple bits in each of X and Y; you're limited largely by the aspect ratio of holes you can carve into your height field. In fact, to compensate for minor errors in X and Y, there should be at least a dimple in the surface at the desired position.

But if you carry this out just like that, you may end up with tall, thin towers on your height field, which will be prone to bending or breaking. Instead, you could just drill a matrix of holes of different depths. How small could you make these holes?

Jewelers' twist drill bits, which cut cylindrical holes, normally come in sizes 1 through 80 in the US. According to Wikipedia, size 80 is 0.343 mm in diameter, or 0.0135", about a 74th of an inch. So you could probably drill a 32x32 matrix of these holes into a one-inch block of, say, aluminum, brass, or soapstone. Then you'd only need the positioning of the probe to be accurate to within about 0.007" to make sure that it went into a hole; if your machine drilling the depths, like certain inexpensive home knockoff CNC drill presses, were only accurate to 0.002", you could use a 3× mechanical advantage between the probe and whatever input it was driving so that you would need a 1" x 1" x 0.5" cube of metal for this 32x32 array of holes.

(It's probably best to translate the block itself in at least one of the three dimensions, rather than translating the probe in all three, in order to diminish the accumulated positional error.)

I'm not sure how many drill bits this procedure would use up, and how much it would cost. "The Real Cost of Runout" talks about

reducing the cost of drilling 3mm-diameter holes from 80 cents to 27 cents per hole by reducing runout on the drill press, or from 23 cents to 10 cents per hole when using high-speed steel instead of tungsten carbide — and these numbers are just for the cost of the drill bits! But 1024 holes at 10 cents per hole is still US$102.40. I hope smaller holes cost less?

Smaller drills exist; http://www.ukam.com/diamond_core_drills.html says they have diamond drills "from .001" to 48" (.0254mm to 1219mm) diameter." Being able to drill holes of .001" diameter would mean being able to drill a 32×32 array of holes in 0.064" × 0.064". On http://www.ukam.com/micro_core_drills.htm they actually only list drills down to 0.006", which they recommend using at 150 000 RPM, feed rate 0.010" per minute.

In some ways, this kind of drilling operation is less demanding than ordinary drilling operations: surface finish, hole straightness, and even hole positioning can tolerate quite a lot of slop. (If you countersink the holes, they can be off by quite a bit as long as it doesn't break the probe.) But microdrilling --- drilling holes of under 0.5mm --- apparently poses special problems in chip removal and cooling.

Other manufacturing processes might make more sense than drilling. For example, you could conceptually cut the chunk into 33 pieces along 32 lines of holes, cast the 33 pieces using lost-wax casting, and then clamp them together. Or you could make a mold with 1024 adjustable-height rods stuck in through holes in the cope, and cast in that. (Maybe in plastic.) Etc.

What a LUT is good for

So that's a LUT with 10 bits of input — one of 32 possible positions in two independent axes, positioning the needle probe over the array of holes — and 5 bits of output — one of 32 possible depths for the needle — realized in about a cubic inch. That's also about 5120 bits, or 640 8-bit bytes. That's enough to realize an arbitrary 32-state state machine with 5 bits of input at each step, or to perform 4-bit binary addition or subtraction with carry-in and carry-out and an extra input bit left over (say, to select between addition and subtraction), or to perform a selectable one of four arbitrary 5-bit combinational functions on two 4-bit inputs --- say, addition with carry out, AND, XOR, and something else.

If you split the same 1024 holes into two LUTs with ganged input — that is, two probes — then you get 9 bits of input and 10 bits of output. A 4x5-bit multiply needs only 9 bits of output. You could do a 4x4-bit multiply in half the area and half the depth.

All of these applications still work just as well if any or all of the quantities are encoded in some weird way such as a Gray code or an excess-N code.

At some point you have to encode the 32 slightly different linear displacements into five distinct bits. You can do this with a 32x5-hole LUT, with five probes sticking into it, and only two distinct hole depths.

Decoding five bits encoded in five separate displacements into 32 levels of displacement in a small number of moving parts is maybe more difficult.

The ZPU project on OpenCores is a 32-bit CPU; realized in a

Xilinx FPGA of LUTs, it uses "442 LUT @ 95 MHz after P&R w/32 bit datapath Xilinx XC3S400". I don't remember offhand how big the XC3S400 LUTs are, but they have only single-bit outputs.

Memory

A shaft that can slide freely is merely transmitting positional information from one place to another. A shaft that has a clamp closed on it can remember its position from before the clamp was closed until the clamp reopens. If the clamp and shaft surfaces are not flat, the shaft can be retained in any of its valid positions (reshaping the signal) with very little force and comparatively imprecise surfaces.

This allows you to store, say, 40 bits with nine moving parts: eight shafts (each encoding 5 bits) and one clamp for all of them.

Shift registers in LUTs

You can make an 8-bit shift register out of two $4\times4 \to 4$ bit LUTs and two 4-bit memory units (known as registers) if you are willing for it to always shift; each LUT given (a, b) computes (a << 1 & 15 | (b & 8)

3), which is written to its memory unit for the next cycle.

The communication from the low nibble LUT to the high nibble must be intermediated through the memory; this allows both LUTs to transition at the same time and means that the bit being shifted into the high nibble is the old MSB of the low nibble, not the new one. Using (b & 8) >> 3 means you don't need to decode the LUT output.

The contents of the LUT (two four-bit inputs producing one four-bit output) looks like this:

```
array([[ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15]])
```

Clearly you can reduce this to a $4\times1 \to 4$ bit LUT if you have a way to extract just one bit from the b input. For example, you could use a $4 \to 1$ bit LUT: 0000000011111111. You could perhaps integrate this into the memory from which it's being read, as an additional row of holes with a probe over it.

If you have a way to do that, you have space to include an opcode that tells the register what to do. For example, shift left, remain steady, shift right, or reset to 0. If you have a way to combine this opcode, the MSB of the less-significant nibble, and the LSB of the

more-significant nibble into a single 4-bit input `b = LSB | MSB << 1 | opcode << 2`, your table can look like this instead.

```
>>> def shift(a, b):
...     lsb, msb, opcode = b & 1, (b & 2) >> 1, b >> 2
...     shift_left, nop, shift_right, reset = range(4)
...     if opcode == shift_left:    return a << 1 & 15 | msb
...     elif opcode == nop:         return a
...     elif opcode == shift_right: return lsb << 3 | a >> 1
...     elif opcode == reset:       return 0
...
>>> Numeric.array([[shift(a, b) for a in range(16)] for b in range(16)])
array([[ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 0,  2,  4,  6,  8, 10, 12, 14,  0,  2,  4,  6,  8, 10, 12, 14],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 1,  3,  5,  7,  9, 11, 13, 15,  1,  3,  5,  7,  9, 11, 13, 15],
       [ 0,  1,  2,  3,  4,  5,  6,  7,  8,  9, 10, 11, 12, 13, 14, 15],
       [ 0,  1,  2,  3,  4,  5,  6,  7,  8,  9, 10, 11, 12, 13, 14, 15],
       [ 0,  1,  2,  3,  4,  5,  6,  7,  8,  9, 10, 11, 12, 13, 14, 15],
       [ 0,  1,  2,  3,  4,  5,  6,  7,  8,  9, 10, 11, 12, 13, 14, 15],
       [ 0,  0,  1,  1,  2,  2,  3,  3,  4,  4,  5,  5,  6,  6,  7,  7],
       [ 8,  8,  9,  9, 10, 10, 11, 11, 12, 12, 13, 13, 14, 14, 15, 15],
       [ 0,  0,  1,  1,  2,  2,  3,  3,  4,  4,  5,  5,  6,  6,  7,  7],
       [ 8,  8,  9,  9, 10, 10, 11, 11, 12, 12, 13, 13, 14, 14, 15, 15],
       [ 0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0],
       [ 0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0],
       [ 0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0],
       [ 0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0]])
```

All of the above generalizes to N-bit shift registers; you just need a LUT and a register for every four bits.

Addition

Parallel addition (the usual digital kind) with inputs and outputs as the usual kind of binary numbers (not carry-save addition) can't be done totally in parallel; the carry from the least-significant bits must be ready before the most-significant bits can produce their final result.

But still, with $4\times3 \rightarrow 4$ LUTs we can do three bits at a time. We bring in the carry along with one of the inputs; the LUT looks like this:

```
>>> def add(a, b):
...     carry_in, inb = (b & 8) >> 3, b & 7
...     return a + inb + carry_in
...
>>> Numeric.array([[add(a, b) for a in range(8)] for b in range(16)])
array([[ 0,  1,  2,  3,  4,  5,  6,  7],
       [ 1,  2,  3,  4,  5,  6,  7,  8],
       [ 2,  3,  4,  5,  6,  7,  8,  9],
       [ 3,  4,  5,  6,  7,  8,  9, 10],
       [ 4,  5,  6,  7,  8,  9, 10, 11],
       [ 5,  6,  7,  8,  9, 10, 11, 12],
       [ 6,  7,  8,  9, 10, 11, 12, 13],
       [ 7,  8,  9, 10, 11, 12, 13, 14],
```

```
       [ 1,  2,  3,  4,  5,  6,  7,  8],
       [ 2,  3,  4,  5,  6,  7,  8,  9],
       [ 3,  4,  5,  6,  7,  8,  9, 10],
       [ 4,  5,  6,  7,  8,  9, 10, 11],
       [ 5,  6,  7,  8,  9, 10, 11, 12],
       [ 6,  7,  8,  9, 10, 11, 12, 13],
       [ 7,  8,  9, 10, 11, 12, 13, 14],
       [ 8,  9, 10, 11, 12, 13, 14, 15]])
```

This gives you, for example, 9-bit addition in three levels of LUT, plus whatever it takes to shuffle the bits around appropriately.

Bit shuffling

In several of the previous items I have assumed a way to combine bits from disparate sources into a single positional input, or to drop bits. This problem also occurs on input. I hope there's a better way to do this, but one workable way is to use a LUT. I've pointed out earlier that a $4\times o \rightarrow 1$ bit LUT can select a single bit, but you can do things more generally. For example, in the shift-register case, where we want to combine a neighbor MSB possibly being shifted left, an LSB possibly being shifted right, and a two-bit opcode, we can use two small LUTs:

```
>>> Numeric.array([[(opcode << 1 | msb) for opcode in range(8)] for msb in range(o
o2)])
array([[ 0,  2,  4,  6,  8, 10, 12, 14],
       [ 1,  3,  5,  7,  9, 11, 13, 15]])

>>> Numeric.array([[(opcodemsb << 1 | lsb) for opcodemsb in range(16)] for lsb in o
o range(2)])
array([[ 0,  2,  4,  6,  8, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30],
       [ 1,  3,  5,  7,  9, 11, 13, 15, 17, 19, 21, 23, 25, 27, 29, 31]])
```

If we have to simultaneously extract the msb and lsb from the nibbles they're embedded in, it is best to do this differently:

```
>>> Numeric.array([[(leftneighbor & 1 | (rightneighbor & 8) >> 2)
...  for leftneighbor in range(16)] for rightneighbor in range(16)])
array([[0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 1],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3],
       [2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3, 2, 3]])
```

```
>>> Numeric.array([[(opcode << 2 | msblsb) for opcode in range(4)] for msblsb in o
orange(4)])
array([[ 0,  4,  8, 12],
       [ 1,  5,  9, 13],
       [ 2,  6, 10, 14],
       [ 3,  7, 11, 15]])
```

It would require many fewer LUT entries to extract those bits in a separate step.

Circles instead of lines: rotational motion is simpler

Mechanically, moving things linearly is a little trickier than moving them in circles — there tends to be more slop. If you transpose this "height field" LUT into cylindrical coordinates, you get a camshaft. The normal sliding cam follower design imposes limits on the "slew rate" of the output function, but if you lift the "cam follower" while rotating the shaft and then use the same forest of holes and "lowering step" as with the flat X-Y approach.

Cylindrical coordinates still leave two coordinates translational, though. You can cheat a little bit by doing the axial positioning along a large-radius arc that almost parallels the axis of the camshaft, to within the diameter of the camshaft, rather than in a strictly translational fashion.

A third coordinate system that might be useful approximates two translational dimensions with angles around two axes that are some distance apart; for example, any two discs that overlap, while rotating around their own centers. This allows one dimension to "wrap around", as with the camshaft approach.

Digital logic with thread

Thread is very nonlinear in some ways, and it's easy to build thread systems with very nonlinear force-displacement curves. Thread also has the advantage that, because the material is not stressed in compression, its effective stiffness-to-weight ratio is enormous, so it can transmit signals quickly, and the energy needed to move it is slight.

As far as I can tell, the force-displacement curve of a system made of elastic thread tied between a bunch of fixed points is monotonic; that is, if you pull on a loose bit of the thread, the force with which the thread pulls back on you always goes up as you pull it further from its natural position. (There may be some trick with knots that violates this.) This imposes limits on pure thread systems, although you can still get amplification through braking.

Thread springs

A steel guitar string can easily be pulled a substantial fraction of an inch out of place, because although steel is very stiff, the d[cos x] / dx = 0 when x=0, so even very small elongations of the string allow substantial movement. (And the force-displacement curve is very nonlinear.)

This effect can be chained: if you have a thread configuration shaped like a capital H, you can pull up or down on the middle of the H's crossbar fairly easily, because it only has to pull slightly on the

sides of the H in order to move. So you get a lot of mechanical advantage, we could say.

So this kind of spring force can allow for reciprocating movement in response to a reciprocating input force pulling on some "power supply" thread.

Thread power amplification through braking

For fanout, we need the ability for one logical gate output to, eventually, control an arbitrarily large number of logical outputs. This can't be achieved just by having strings pull on each other in configurations like that described above; the amount of force needed would go up with the number of output stages, which prevents useful computation.

But braking can provide amplification. Imagine that you have a thread running along the surface of a cylinder; it can slide freely, as far as it as long as no force presses it against the cylinder. If another thread is wrapped loosely several times around the cylinder and the sliding thread, the sliding thread can still slide; but if the wrapped thread is then pulled taut, it presses the sliding thread against the cylinder, preventing it from sliding.

The crucial aspect here is that, although there is a limit to how much force the thread brake can resist, it can resist that force regardless of how far the sliding thread would slide without that resistance; and it can do it with an almost arbitrarily small displacement of its onw.

There are other approaches to braking that might turn out to be worthwhile; for example, if the wrapped thread clamps the sliding thread between two cylinders, then they can be in contact with different kinds of surface with different coefficients of friction, and the sliding thread won't catch and pull on the wrapped thread. But those approaches involve moving more mass.

Braking also provides memory, since the amplified signal happens later than the amplifier input.

Thresholding with thread

There are a couple of approaches to getting the kind of nonlinear behavior you need for AND or OR gates.

If you have a couple of threads pulling against a spring, the spring's displacement will be a function of the sum of the force from those threads. If the spring's force-displacement curve is monotonic and nonlinear enough, you can use it to approximate the AND or OR functions.

Alternatively, the force-displacement function of a thread tied to a fixed point has a huge nonlinearity as it runs out of slack: while it's slack, the force is basically zero.

Limiting displacement with thread

If you couple two threads through a spring, you can use either of the thresholding techniques in the previous section to limit the displacement of the driven thread without limiting the displacement of the driving thread. This costs energy (the spring continues to store energy as the driving thread pulls further) and also loses some displacement, as the displacement transmitted to the driven thread will always be less than the displacement of the driving thread.

Changing direction with thread, and increasing displacement

If you have a thread tied to a fixed point, its end describes a circle around that fixed point when it's under a small amount of tension. If the fixed point is far away, the circle approximates a straight line.

If you have another thread tied to that end at an angle not parallel or perpendicular to (that part of) the circle, that other thread will be able to pull it along the circle; so you can change the direction of motion that way by anything less than 90°. If you have a second thread pulling the other way, also at an an angle neither parallel nor perpendicular, then displacement is transmitted between the two threads, but can be changed by any angle at all.

If the angles made to the tangent line are equal, then the same displacement and force is transmitted, with no mechanical advantage, or rather a mechanical advantage of unity. But you can achieve MAs of either above or below 1 by having one angle be greater than the other.

This allows you to convert a small displacement with great force into a large displacement with small force, and vice versa. (There will be vibrational losses, but they can probably be made small.) It is that ability to reduce forces to the point where they can easily be controlled by braking, then step them back up, that makes me confident in the braking mechanism as a means of amplification.

Negation with thread

If ones and zeroes are represented by different displacements when the countervailing force is within a certain range, then negation can be achieved by pulling in the opposite direction against a spring force.

Sequencing with thread

If you have a cord with a number of threads tied to it with different amounts of slack in them, then when you pull on the cord, the various threads will go taut and begin to transmit force one after the other. This, plus limiting displacement as discussed previously, allows you to drive different parts of a thread logic system in a predetermined sequence.

A generic thread state machine

Initially, you have a number of "register" threads R_0 braked into some position or other by threads wrapped around them, held taut by springs. A few stages of thread combinational logic are driven from those positions, producing a thread combinational output C_0.

You begin to pull on the clock thread. This drives a final stage of combinational logic connecting the thread combinational output C_0 to another set of registers R_1, whose braking threads are currently lax, so their threads are free to slide back and forth — which they do, under the influence of your clock thread, pulling against the inputs of another set of combinational logic producing a second combinational output C_1.

Once the R_1 threads have found their position, your further pulling on the clock thread is transferred to their brake threads, which hold them in place, preventing the combinational output C_1 from changing further.

Further pulling on the clock thread loosens the tension on the brake

threads for R0, allowing those registers to assume their new state — which is coupled in from C1! There is vibration as previously slack threads snap taut, and the outputs of C0 (driven from R0) change. But R1's threads are still held in place.

Now you begin to release the tension on the clock thread. First the brake threads on R0 become taut again, preventing R0's value from changing. Then the brake threads for R1 loosen, and R1's threads are free to assume the new values of C1's output, so there is more vibration as previously slack threads snap taut.

Further loosening of the clock thread tension eases R1's state threads back into a neutral position.

Now R0 has its new state, and is ready to begin a new clock cycle.

This is similar to the functioning of a master-slave flip-flop, with its input driven from its output, but of course with arbitrary combinational logic.

I haven't tried to build this yet, but from the above, I think it's plausible.

To me, there's a strong appeal in the idea that universal computation has been within the grasp of human materials and manufacturing technology since the invention of sewing in the Paleolithic; it is only the mathematical sophistication that was absent. I don't yet know if it's true.

Earring computer

Kragen Javier Sitaker, 2018-04-27 (1 minute)

The Lattice ICE40LP1K and ICE40HX1K FPGAs are big enough to support a J1a CPU (with 8K of RAM?) and are 1.4 × 1.5 × 0.45 mm and cost US$3.43.

The TI ADS7040 8-bit 1Msps ADC has an 8-X2QFN version that is 1.4 × 1.4 × 0.4 mm and costs US$1.14. It claims "nanowatt power consumption" by which they mean that it uses less than a microwatt at 1ksps. At 100ksps it uses 56µW, and the datasheet claims a physically impossible 49dB SNR (48.16 being the theoretical limit of what 8 bits can deliver). It uses 12MHz SPI and uses differential input. If you were to run it at 1Msps and downsample to audio 48ksps, you would gain about 7dB more.

Efficiently querying a log of everything that ever happened

Kragen Javier Sitaker, 2015-09-03 (7 minutes)

I've been designing a new chat/email UI called Desbarrerarme, and one of the design approaches I want to try out is computing the UI state as mostly a pure function of the input history of the system.

One of the things I've been thinking about for Desbarrerarme is querying. By far the nicest existing way I've found to do normal queries is Prolog/Datalog; it's dramatically better than SQL or Tutorial D. (Binate may be better, but it's unfinished.). However, it's not totally clear to me how to do aggregate queries, in particular "top N" queries.

I've been struggling with this for a long time; see e.g. http://stackoverflow.com/questions/1467898/what-language-could-i-use-for-fast-execution-of-this-database-summarization-task. ("Top 5 scores and their dates for each player"; one response: "Top-N is a well-known database killer. As shown by the post above, there is no way to efficiently express it in common SQL.")

Here are some example queries I've been thinking about for Desbarrerarme:

- What are the N most recently updated threads (i.e. threads with the most recent messages)? Because those are the ones we want to show on the screen.
- What are the participants and the most recent message in each of the N most recently updated threads? Because that's what we want to display on the left side.
- What are the N most recent messages in thread X? Because those are the ones we want on the screen.
- What are the N most recently updated threads *I haven't tagged as to-archive*?
- What are the N next scheduled reminders after the beginning of today that I haven't marked as taken-care-of?
- What are the N best threads that contain the words "apache" and "spark", case-insensitively, where "best" is some kind of combination of recency and TF/IDF?

If we have a single relation `messages` with the columns `when, thread, from, body`, and some similar thing for reminders, it's apparent how to compute each of these inefficiently. We can calculate #2, for example, like this:

```
participants = {}
last_message = {}
top_n = []
for when, thread, from_, body in sorted(messages):
    if thread in top_n:
        top_n.pop(top_n.index(thread))
    else:
        if len(top_n) >= n:
            top_n.pop(0)
```

```
    top_n.append(thread)

    if thread not in participants:
        participants[thread] = set([from_])
    else:
        participants[thread].add(from_)

    last_message[thread] = (when, body)

for thread in top_n:
    yield participants[thread], last_message[thread]
```

This has three big disadvantages:

• It's a lot of code. The English version of the question was 18 words; the Python version above is 18 lines.
• That code is poorly abstracted, so it isn't reusable. For example, it's very likely that this isn't the only place we'd like to know the participants of a chat.
• It's inefficient. It inherently needs to traverse the entire `messages` relation, which might be many gigabytes, and it accumulates a potentially large `participants` relation in memory because it doesn't know at the outset which threads are going to be included in the final result.

Problems #2 and #3 are interrelated. For example, if we could freeze the whole execution state of the loop partway through, then we could incrementally recompute its final state if new messages were added with a later date.

Better still, in this case, you could break the computations down into a monoid tree — `participants` can be computed from results over subsets of the data set simply using the union operation, while `top_n` could be computed from results over subsets of the data set by concatenating those results (ordered by timestamps) and truncating to the last N. Abstracting the operations to this level would allow them to be not only recomputed incrementally after updates, but also parallelized and made fault-tolerant. Also, the `top_n` result is probably somewhat lazy — it's probably possible to compute the most recently updated 10 or 20 chats without looking further back than 1–30 days.

Ideally, we could find a set of language primitives to express queries like these that would make the query simple to express. Something like maybe

```
top = max(when) by thread | sortby when desc | limit n
participants = distinct(project(thread, from))
latest = max(when, body) by thread
(participants naturaljoin latest) if thread ∈ top.thread
```

Or, I don't know, something still more concise. And ideally that set of language primitives would expose enough structure to a runtime to allow the orthogonal specification or even inference of optimizations like the ones suggested above; and ideally it would also, like the above, make it straightforward to reuse the definitions for other things.

Also, if it's not too much to ask, generalize the materialized views

that are used to speed up incremental recomputation so that they can be used for a larger range of queries than just the current ones. That is, maybe I only asked for the latest 12 chats, but maybe it would be prudent to calculate the latest 24 or 64 if that isn't harder; and maybe `latest` only contains `when` and `body` here, but maybe we should also keep `from` just in case.

Additionally, I'd like to get the results from these queries incrementally, so that the UI isn't frozen while the query is being evaluated.

This seems like it might be related to Spark's concept of "resilient distributed datasets". I need to read more.

Faster brute force

An alternative approach to caching and materializing a bunch of shit is trying to make brute-force query evaluation sufficiently fast. Considering this `messages` thing again, suppose I had 10 messages per second for the last 20 years. (Busy IRC channels.) That's 6.3 billion messages. But maybe there are less than 65536 participants, so participants can be identified by 16-bit numbers; so the participants column there is only 12 gigabytes, and it's probably highly enough compressible with LZ4 to fit into RAM easily. Similarly, suppose we're using 64-bit microseconds for `when`; now we have 50 gigabytes of timestamps, but again, they probably fit into RAM easily with LZ4. The message bodies won't, but they'll fit on a small SSD, and will probably compress enough to hit RAM-like speeds for scanning.

And the above query, if the query optimizer is lucky enough to pick a reasonable evaluation order, should only need to traverse the tail end of the `when` and `thread` columns before hitting `n`, and then the entire `from` column. Still, this is probably not going to get us to subsecond response times.

Topics

Can you bitbang wireless communication between AVRs? How about AM-radio energy harvesting?

Kragen Javier Sitaker, 2019-08-27 (updated 2019-08-28) (37 minutes)

Today, someone on Freenode ##electronics was asking about wireless communications between AVR microcontrollers with only passive components, so I was interested in the available energy for harvesting and possibilities for low-power RF communication. I started reading about ferrite loopstick antennas and energy harvesting from broadcast AM radio (as suggested by user Bga3 on Freenode ##electronics). These antennas are normally useful up to about 5 or 10 MHz and can be salvaged from old AM radios; more exotic ferrite mixes are viable up to 50 MHz.

As mentioned in Arduino radio (p. 169) and Could you do DDS of comprehensible radio signals with an Arduino? (p. 1829), the usual AM radio band is around 0.5 MHz to around 1.7 MHz. I don't think the AVR is the best choice for this kind of thing, since it's fairly power-hungry and slow, but even the AVR should work. The AVR has PWM generation circuits that can generate frequencies up to 8 MHz, so some degree of amplitude modulation at a few hundred kHz should be doable.

Available AM radio energy

The highest power available for broadcast radio station licensing in the US is 50 kW, while there are many 10-kW radio stations around. So let's suppose you're located 10 km from ten isotropic 10-kW AM transmitters, which would seem to be a common situation in urban areas. Each contributes about 8 μW/m² of radiation (10 kW spread over a sphere of area 1.26×10^9 m²), for a total of 80 μW/m². But you can't collect all of that energy because loopstick antennas are inefficient. Still, μW-scale energy harvesting seems like it should be feasible. And of course crystal radios were powered entirely from AM radio waves, and had enough power to be audible, if barely.

Related work

Trask on loopstick antennas

Research has been done on designing loopstick antennas to be tunable (Chris Trask, "An Active Ferrite Rod Antenna with Remote Tuning" with a high Q factor by setting up a resonance between the antenna inductance and some varactors.

The ARRL Antenna Handbook chapter 4 talks about loop antennas in some detail.

Zungeru *et al.*

Zungeru et al. describe several previous RF energy harvesting

systems in the μW range.

Xie *et al.* 2012

Xie et al. 2012 report harvesting 82 μW using a 10-meter-long horizontal antenna, even though that was just a dipole, and one with the wrong polarization, at that.

The Xie paper contains circuit diagrams and various plots of output voltages, currents and powers. The circuit was extremely simple! One end of the antenna was hooked up to a parallel-resonant LC tank (with, ideally, infinite impedance to ground at the resonant frequency) with a "multi-stages doubler rectifier" hooked up across the inductor (Figure 4 shows that this is a Cockcroft–Walton generator made out of six 1N60 germanium Schottkies and six 0.1-μF caps), feeding an energy storage capacitor to which the microcontroller is directly connected. They report getting 14 volts out of the damned thing — *before* the Cockcroft–Walton 6× multiplier! There in Xi'an, there's apparently a 300-kW station 23 km from their site, but they got more power from a 50-kW station at 8.5 km — that's where the 14 V came from. (But it's only 1.2 V without the resonant tank.)

Leon-Gil *et al.* 2018

Leon-Gil *et al.* 2018, "Medium and Short Wave RF Energy Harvester for Powering Wireless Sensor Networks", CC-BY also used a resonant tank circuit and a Cockcroft–Walton generator to step up their antenna voltage, but this one of 6 stages, using a center-tapped loopstick configuration. (Note that the PDF of the paper is not readable with libpoppler; xpdf can read it.) (They also mention that TV broadcasting stations are up to a megawatt in the US, 20× stronger than AM broadcast stations, but are not available in rural areas.)

Leon-Gil *et al.* also stacked up layers of ferrite in order to get a giant 60 mm × 60 mm antenna cross-sectional area in a compact volume, because (they say, I trust) the radiation resistance of the antenna is jointly proportional to the square of the area and the number of turns, and, astonishingly, not dependent on the length of the rod. They also point out that diode parasitic capacitances provide an AC leakage path that limits the total voltage available from a Cockcroft–Walton generator, which I hadn't thought of; these parasitics decrease with back-biased voltage, but need to be small compared to the intended capacitance. They used BAT85 diodes, which specify a 200-mV voltage drop and 5-pF junction capacitance, and found that 10-nF capacitors or larger were needed to avoid inefficiency.

They reported 1.5 volts at the input to their Cockcroft–Walton generator and 8 V at its output, providing about 60 μW into a 1-MΩ output impedance — quite impressive for the 100-mm-long antenna they're using, 100× shorter than the wire in the Xie paper! They report a 3.2% antenna efficiency.

They report that using the center-tapped Cockcroft–Walton configuration doubled their output power over what they describe as a "half-wave" configuration, but I suspect that this is because they were only using half of their winding when they were testing the "half-wave" configuration. In a Falstad simulation, I see in-phase

current and voltage both positive and negative in the configuration they describe as "half-wave", so I think their description is erroneous.

Dyo *et al.* 2013

Dyo et al. at the University of Bedfordshire wrote "Design of a ferrite rod antenna for harvesting energy from medium wave broadcast signals" in 2013 (doi: 10.1049/joe.2013.0126). They used an 8-stage Cockcroft–Walton generator made out of Schottkies driven from a loopstick antenna with an LC resonator tuned to a local 150 kW radio station at 909 MHz; in simulation they generated over 1000 µW, up to 9 km away, but apparently they only tested it by powering a 3 µW clock. Their paper is the only one of the ones I'm summarizing here that has a decent review of the existing work in the field, including the Xie et al. paper.

They point out that actually the length of the rod does matter, and the peak for a cylindrical rod is when the rod is 20 times as long as its diameter; its effective permeability rises almost linearly from aspect ratios of 1 to 10, half of the ideal aspect ratio of 20, nearly doubling its value; it gains another 10% going from 10 to 20.

They report a cost-optimized antenna design: they ended up with a 10-mm-diameter ferrite rod that was 200 mm long (a size you might find in a normal AM radio), with 50–500 turns of litz wire wrapped around the middle of it, depending on how weak the signal was — weaker signals needed inverse-proportionally more turns to get the same output voltage. For a sufficiently weak signal, the coil's self-resonant frequency falls low enough that the design is no longer viable.

Strangely, their optimization results table reports that wire length s varied from 67 meters to 787 meters. These are consistently about 45× the wire length I calculate via $n\pi D$, where n is the number of turns and D is the diameter. This seems to be a result of their using 45-strand litz wire.

Low-power electronics design

How much power do you really need to harvest in order to have a usable computer?

I've written a fair bit on low-power computers in Keyboard-powered computers (p. 2220), Low-power microcontrollers for a low-power computer (p. 2602), and Notes on the STM32 microcontroller family (p. 3176), and just today I encountered the oversold-as-low-power Renesas RL78 microcontroller line (p. 504), although that was disappointing in the end. The summary is that you can get useful amounts of computation at around 1 µW, which is a bit smaller than the self-discharge current of a CR2032 coin cell, which contains about 2.2 kJ. Understanding Capacitor Leakage to Make Smart Things Run Longer explains that you have to be careful to ensure your bypass capacitors don't have more leakage than that if you're designing, say, a passive IR sensor designed to run for ten years maintenance-free from a coin cell, but that you can do it by using capacitors rated for 10× higher voltages than you need, which will be larger.

Linear regulators dissipate the voltage difference between the input voltage you get and the output voltage you want; this is wasteful if

there is a large difference. Below I suggest using a buck converter so that your power usage is the same regardless of the input voltage — this works by drawing current less of the time when the input voltage is higher. But buck converters require a minimal quiescent current to remain stable, which is also wasteful. A possible solution is to use a linear regulator in sleep mode, then turn on the buck converter when waking up.

Xie et al. used 1N60 germanium Schottkies. Germanium diodes are a bit exotic nowadays, but the 1N60 is specified to have a threshold voltage of only about 250 mV. Schottkies in general have high leakage currents, and Taitron lists their 1N60P as leaking up to 50 μA, which would be disastrous for this application, but apparently they didn't observe such high leakages. Regular *junction* germanium diodes, on the other hand, have a threshold voltage of around 300 mV, and would be ideal.

Aside from low-leakage capacitors, low-self-discharge batteries, avoiding power supplies with high quiescent current, low-leakage diodes, and using low-power chips, it seems like the main trick to low-power design is to use a low duty cycle — keep your chip asleep most of the time. This means you can't be running either a radio or any other kind of ADC at high speed all the time. With typical wakeup times of 5 μs in modern microcontrollers, though, you could reasonably wake up 1000 times a second and still keep the duty cycle below 1%.

If you can hear a radio station around 10 μW/m², then it ought to be able to broadcast a signal around 100 μW and be audible on radios in the same room. Of course this requires a duty cycle of 1% or less if you're only harvesting 1 μW. This suggests that you can probably use the same antenna for harvesting and transmission — you perhaps must switch off the harvesting circuit during transmission, but that will only reduce the power harvested by 1% or so. You might want a shorter winding, or a center tap, to reduce the antenna's impedance, improving its efficiency at low voltages.

You could try the Xie et al. circuit or the Leon-Gil circuit without the resonant tank (thus receiving all frequencies indiscriminately) or perhaps with a few different parallel tanks in series to ground (thus, I think, receiving just those particular frequencies). Perhaps a better idea is to use an RF transformer on the input side to step up the antenna voltage to a more reasonable level; with a loopstick antenna this can be effected simply by having MOAR TURNS on the antenna, as Dyo et al. did, but only up to a point, so a transmission-line transformer or two to step the voltage up might be a reasonable option.

Stepping up the input voltage with a transformer should allow the use of regular signal diodes (which reportedly leak about three orders of magnitude less than Schottkies) or even special low-leakage types (which leak about three orders of magnitude less than regular signal diodes).

Variable-gain energy-harvesting Cockcroft–Walton generators

I had a silly idea that maybe you could get a variable multiplication factor out of a Cockcroft–Walton generator, and thus a sort of analog

MPPT circuit, by adding some more diodes to it, bypassing the later stages when the output storage capacitor voltage is low. Such diodes are relatively harmless but turn out not to be useful — they never conduct, even though their voltage drops are lower than the voltage drops of the chains of diodes they bypass. That's because all the capacitors in the Cockcroft–Walton generator charge simultaneously and discharge simultaneously, across cycles. (Within a single AC oscillation, they charge and discharge at different times.) The Cockcroft–Walton generator already gives you a variable voltage multiplication factor out of the box!

I *think* the effect is that if you load a Cockcroft–Walton generator's output so that it never approaches its maximum possible voltage, you in effect decrease its impedance. Assuming the input voltage is large compared to the sum of the diode drops, if you load it so heavily that only the output capacitor ever develops any charge, it becomes effectively a long diode, a half-wave rectifier; then, if you let it charge, its AC impedance gradually increases toward, ideally, ∞, because there is no purely capacitive path through it — all the paths through it go through the diodes.

I don't understand why it was that the Leon-Gil experiment needed 0.01-μF capacitors; calculations based on capacitor impedance suggest that even a much smaller capacitor should have been sufficient, given the 1-MHz frequency and the total output current of about 6–8 μA (62 μW ÷ 8 V, or 8 V ÷ 1.5 MΩ).

The Cockcroft–Walton generator's distributed capacitance works as energy storage; you can draw it down in a balanced fashion by temporarily drawing a larger current from the output. A buck regulator running from the Cockcroft–Walton output could efficiently handle a wide range of input voltages and thus enable efficient circuit operation from very low amounts of stored energy up to very high amounts.

As the capacitors become fully charged, the power factor shrinks — there is only current at the very peak of the wave. This suggests that, in the absence of resonance, higher output can be maintained from a Cockcroft–Walton generator that isn't fully charged. For example, with a multiply-by-six configuration — six diodes and six capacitors — if the input voltage is a 10-volt-peak AC wave, and the output voltage is 30 volts (feeding, say, a buck regulator producing a 2.0-volt power supply for a microcontroller), then whenever the wave is over 5 volts, the power supply will draw charging current, thus harvesting energy in phases from 30° to 150°, then 210° to 330°, ⅔ of a full cycle. If the output voltage is allowed to rise to 40 volts, it will only be charging for 54% of the cycle, and if allowed to rise to 50 volts, only 37%.

(I'm not sure if this depends on how the capacitance is distributed throughout the circuit.)

The above was observed simulating the circuit with a source with 500 Ω of internal impedance (because a more realistic amount made it charge very slowly, as you'd expect). Upon simulating with low source impedance, the charging current peaks happen right after the input voltage crosses zero, and indeed at first have periods of time where the circuit returns power to the source — as you would expect from a capacitive load. This ceases once the output voltage has risen to the input peak voltage plus the combined voltage drops of the

capacitors.

It seems like a little input series inductance would do some good for the circuit's power factor and power dissipation — with 7 100-nF capacitors and 7 300mV Schottky diodes at 500 kHz, it charges more than twice as fast (for the first 25 cycles, which get it to about 5× the input voltage) with a 2.2-µH inductor in series with its input. Probably better to err on the low side there with a 1-µH inductor or an 0.47-µH, though — the asymptote at low inductances (or low frequencies) is just the situation described above, while the asymptote at high inductances or high frequencies is that zero energy gets into the circuit.

Suppose the input voltage source has very low impedance; what limits the power it can supply? I think it's just the amount of charge that gets loaded into all the capacitors each cycle, so it's proportional to frequency and proportional to the square of the input voltage — it's just the impedance of the straight capacitive path to the output, plus a diode. (Except if the output voltage is lower than the instantaneous input voltage, when its impedance is the Vf of the the string of diodes.)

I think this means that the Cockcroft–Walton generator is a good approximation to the circuit I was trying to find in Constant current switching capacitor charging (p. 605)! Suppose you limit the output of a six-stage device to 50 V (with a "zener" avalanche diode or whatever). Then it will transmit power with reasonable efficiency from the input to the 50-volt output for an input AC voltage anywhere in the range of about 10 volts to 50 volts (peak), and furthermore for an output DC voltage anywhere in the range from just below the input peak voltage up to those 50 volts — it's like a transformer that dynamically changes its turns ratio according to the current draw! Like, uh, a switchmode power supply. More stages will increase the diode losses but, for a sufficiently high output voltage, will reduce the required input voltage.

It isn't exactly an MPPT circuit, since its impedance starts too low (though, unlike a simple rectifier charging a storage cap, not near zero), rises to the maximum power point, and then keeps rising; but all of the input energy is either dissipated in the diodes or stored in the capacitors, and with a little input inductance, it even avoids wasteful inrushes.

Disregarding diode capacitance, you can model the basic characteristics of a Cockcroft–Walton generator as follows.

$$V_{out} \le N(V_{in} - V_f)$$
$$P_f = N V_f I_{out}$$
$$P_r = V_{out} I_r$$
$$P_{out} = V_{out} I_{out} = \int V_{in} I_{in} \mathrm{d}t/\Delta t + P_f + P_r$$

V_f is the forward voltage drop of a diode at the low currents we're dealing with here, around 600 mV for a 1N4001 or 300 mV for a Schottky. P_f is the total power loss from the diode voltage drops for forward current; P_r is the total power loss from diode leakage resulting in reverse current; N is the number of stages, each containing a diode and a capacitor; I_r is each diode's average reverse current. V_{in} above is variably the peak voltage of the AC waveform (in the first inequality) and the instantaneous voltage in the integral.

The first thing to notice here is that if $V_{in} < V_f$, the circuit won't work at all, regardless of how many stages it has, and that's why so

many of these papers use Schottky diodes; and if $V_{in} > V_f$, it will, again regardless of the number of stages — and that's how the humans first split the atom.

Second, the *forward* power losses in the circuit are proportional to the number of stages. So if you have six 600 mV stages, they're going to drop 3.6 volts; if your output voltage is 3.6 volts then you are going to lose half of your energy inside the generator. You should probably use less stages. The *reverse* or leakage losses, though, actually *decrease* with the number of stages, for fixed input voltage, output voltage, and load current, because the diodes leak less when that fixed output voltage are divided across more stages. (This seems to contradict results in the Leon-Gil *et al.* paper, so I may have gotten something wrong.)

So, with few enough stages, the losses will be dominated by reverse losses, and you should use low-leakage diodes; and with enough stages, they will be dominated by forward losses, and you should use low-V_f diodes, even if they could leak more.

The leakage currents in the diodes depend on the reverse-bias voltage, and the reverse voltage across any diode varies interestingly. It is always less than the peak-*to-peak* voltage of the AC input, but it varies during the cycle, and in a way that depends on circuit load. If the circuit gets fully charged, all the diodes are always reverse-biased or anyway not forward-biased enough to conduct any more, and so they see the full AC waveform with just enough DC bias to make it never quite conduct, or conduct just enough to compensate for reverse-biased-diode leakage; so, for example, if you're using 600-mV diodes and the input is a 10-volt-peak (7.1 V rms) sine wave, each diode sees a reverse-biased voltage oscillating between -19.4 V and +0.6 V.

When the current isn't fully charged, the diode sees a sine wave that's *clipped*: the negative bias is more moderate, so when the voltage tries to rise above its threshold, it starts conducting and clips the peak off the voltage wave; and the wave's trough voltage gets clipped by the diodes that conduct during the opposite half cycle.

Since diode leakage currents increase, very roughly, exponentially with the reverse-bias voltage, probably nearly all of the leakage will happen at the trough of the wave, and the wave spends nearly half of its time there. So, for example, if you have a 6-stage circuit whose output voltage is currently 24 volts, each diode has -8 volts across it half the time. So if each diode leaks 25 nA at a reverse bias of 8 volts, the whole circuit will leak about 12.5 nA and 0.3 μW. (This is a normal number for a silicon signal junction diode.)

Here's a Falstad circuit for simulating a 7-stage Cockcroft–Walton generator:

Something in the neighborhood of 6 stages is probably optimal for this purpose, and a maximum voltage of 50 volts is probably also a good idea (to avoid needing high-voltage components), so you should probably step up the antenna voltage to about 8 volts (with an RF transformer, if necessary) and maybe limit it with a small zener for safety. (Or build the damned thing out of zeners.)

Robustness

Since the available energy may vary over one or more orders of magnitude depending on location, radio stations starting up and shutting down, time of day, ionosphere propagation, nuclear warfare, and so on, it's probably worthwhile to have some kind of overvoltage protection across the antenna. It likely only needs to be able to dissipate milliwatts of power, so a couple of back-to-back small "zeners" (avalanche diodes) might be adequate, and maybe a MOV or two for nearby lightning strikes or hydrogen bombs or something, plus some inductance before the Cockcroft–Walton generator to prevent spikes too fast even for the MOV from making it through.

Passive signaling

Above I suggested transmitting AM audio at 100 μW or so for the sake of communicating to humans using ordinary AM radios, which has been done on a battery. But suppose we only want to communicate with other energy-harvesting nodes?

Some work has been done on passive signaling using Wi-Fi for sensor motes and even passive sensors, analogous to Theremin's masterwork, The Thing. As I understand it, the mechanism is that if you have an antenna tuned to a particular frequency feeding into a load (such as a Cockcroft–Walton generator), you absorb some energy at that frequency; if you disconnect the load, the radio waves reflect from the antenna (perhaps with a phase shift) instead of being absorbed. So someone in the vicinity listening on that frequency can

detect that you've turned the antenna off.

Suppose it's possible to get reasonable antenna efficiency across a wide range of frequencies, like the whole AM band, as would be ideal for energy harvesting, and so you can be absorbing tens of microwatts as the Leon-Gil experiment did, or even more. To a nearby observer "tuned" to the same set of frequencies, temporarily disconnecting your harvesting input would be precisely as observable as beginning to transmit noise at those same tens of microwatts. In effect, this amounts to a time-domain radio transmitter with 100% efficiency — "111% efficiency" if your power supply is 90% efficient. This is probably an order of magnitude or more better than you could do by actually transmitting a signal, but the range will be very limited, because you can't concentrate power harvested over time at a particular moment.

If you want to transmit, say, four meters, by failing to absorb 50 μW and instead reflecting it isotropically, your lack of signal will be noted as 250 nW/m² at that four-meter range (assuming far-field radiation, which isn't actually correct — at 1 MHz, where the wavelength is 300 m, energy can bounce back and forth between the nonlistener and the observer of nonlistening some 37 times per oscillation, so I think the near-field coupling can be stronger than this). This is about 320x lower than the "background noise" we're assuming of 80 μW/m², although it seems likely that Leon-Gil et al. were more strongly irradiated than that. This is a SNR of -22 dB and accordingly requires at least 22 dB of coding gain to establish communication; each additional factor of 10 in distance adds another 20 dB.

(Unfortunately I don't know how to calculate near-field electromagnetic coupling to a reasonable degree of precision; I'm pretty sure it's stronger is all.)

The Shannon–Hartley formula is that the channel capacity in bits per second is $C = B \lg (1 + S/N)$, where B is the bandwidth in Hertz, S is the signal power, and N is the (additive white Gaussian) noise power. So in this case it's 1.2 MHz · lg (1 + 1/320), which is basically 1.2 MHz · 1/(320 ln(2)), or about 5.4 kbps. In theory, this drops by a factor of 100 with every factor of 10 in distance, in the limit: 54 bps at 40 meters, 0.54 bps at 400 meters, 0.0054 bps at 4 km. I think this is hit harder by the near-field effects, though — you get terrible antenna efficiency with an antenna that's a tiny fraction of a wavelength in length (it reabsorbs almost all of what it emits, in a sense), so the situation is orders of magnitude worse.

Down here in the power-limited regime, it doesn't really matter whether your signal is spread over 100 kHz or 1 MHz or 10 MHz — if you spread it over ten times as much bandwidth, you also get ten times as much noise, which compensates to within a small rounding error. But if you narrow the signal to, say, 10 kHz, you start to see an effect: 10 kHz · lg (1 + 1/2.7) ≈ 4.6 kbps — you're entering the bandwidth-limited regime. This is counterproductive from the point of view of power efficiency — you get less bits per joule that way.

The power input circuit I simulated above generates very substantial harmonic distortion (though less so with a bit of PFC inductance) — the sharp current edges from the diodes turning on are potentially quite noticeable, and I think the strongest signals would probably be the second and fourth harmonics.

Measuring input

Suppose you have something like the above setup and you want to periodically measure the energy in the radio spectrum, perhaps because you are trying to decode a signal sent by another such node. You have to be careful because the total amount of signal is small enough that the normally-negligible bias currents of analog inputs could consume a significant fraction of your harvested power! A low duty cycle might be adequate.

The voltages, however, are large enough that you probably want to divide them down — the original input voltage can be as high as 8 volts and you want to divide it down to, say, 1.1 volts or less. Maybe you could use some kind of capacitive divider that you then rectify and analog-filter the output from, with a multi-megohm resistive path in parallel with it to prevent unequal leakage in the capacitors from introducing a DC bias.

Active signaling

If your device is powered by energy harvesting from AM radio, the average bit rate you can achieve via active signaling is necessarily lower — the power you would have passively reflected must instead be harvested an used to power a radio transmitter, which is typically less than 20% efficient. However, you can save up that energy and transmit it in bursts, possibly in a frequency band where this is a legal thing to do, and possibly at a predetermined hour so that the intended destination node will be listening. (Sort of like FidoNet "mail hour": whatever its other hours of operation, you would leave your FidoNet node turned on during your zone's "mail hour" so that other nodes could call it and deliver its waiting mail.) So if you're harvesting 50 μW, you could save up 4.3 joules in a day, and transmit, say, 300 mJ of radio energy during a single second, thus transmitting at 300 mW — a million times stronger than the passive near-field communications numbers above, and thus in theory able to transmit a thousand times as far.

(Elaine Chao explained to me that she wrote such a time-domain multiplexing system for the Motes project at Berkeley — as I understand it, each node listened in a particular fairly-coarse-grained time slot, and transmitted in the time slots of the nodes it wanted to talk to.)

Saving up 4.3 joules requires somewhere to put it, though. If you try to put it in $\frac{1}{2}CV^2$ with $V \leq 50$ V, you need $C \geq 3400$ μF, which is a hell of a lot of capacitance — and, in particular, the electrolytic capacitors that are the best bets for this kind of massive capacitance are leaky as shit.

It's clear, though, that long-distance communication needs either some kind of highly directional reception, a better power source, extremely infrequent communication, much bigger antennas, or all of the above. Frequency bands like the one I've been talking about are ideal for over-the-horizon communication because of skywave propagation.

(As mentioned above, though, the 20× larger energy available from TV stations is a potential better power source, and their higher frequencies would avoid the need for bulky ferrites; PV cells are another possibility, as a 21%-efficient 10 cm × 10 cm cell can generate 2.1 watts in full sun — that's 2,100,000 μW, enabling four orders of

magnitude higher communication bandwidth.)

Fractal loopstick antennas

The field strengths we're talking about here are far too low to saturate our ferrite cores. Some research has focused on optimizing the core shape to gather more flux, for example by using a barbell or hyperboloid shape, but it seems likely to me that a ferrite core that branches out at both ends in a fractal branching pattern, something like a pair of sprigs of parsley or a pair of antlers, would have a better flux-gathered-to-weight ratio than such solid shapes. Fabricating such shapes has not been practical in the past, but you ought to be able to do a reasonable job with a ferrite-filled plastic system, carrying powdered ferrite or even powdered iron in a small amount of something like ABS or PLA.

Packaging for durability

PVC plumbing pipe is a durable, shock-resistant, sunlight-resistant, waterproof, and visually unremarkable package into which you could stuff even a fairly thick ferrite rod and attach the device to the side of a building; you could reasonably expect it would stay there for many years. To seal the package entirely hermetically, you could seal plugs in place some distance inside the ends of the pipe, using, for example, silicone, epoxy, or PVC glue.

As a larger-scale alternative to using a ferrite-core loopstick antenna, you could use a just-plain-loop antenna, with a coil of wire running around a larger area than is feasible to fill with ferrite; it, too, could be sealed in PVC pipe, perhaps in a square shape. Loop antennas have nulls perpendicular to the loop plane, so a reasonable orientation might be horizontal, since very few high-powered AM radio transmitters are near the zenith; for example, you could run the loop around the perimeter of a roof. By enclosing, for example, 100 m² of loop area, you can increase the received (or conditionally received) power by 5½ orders of magnitude, minus the one or two orders of magnitude you lose from not having the ferrite. This could boost the power available to such a system up near a watt.

Since the circuit's coupling to the environment is magnetic, shielding it is not practical, so it could reasonably be embedded in concrete, even underground. The skin depth $\delta = \sqrt{(2/\omega\mu\sigma)}$ is around 16 meters in rock, according to David Gibson's "AM Radio Reception in Caves", so even several meters of earth or concrete would barely weaken it. So burying the loop antenna in a ditch, perhaps armored with concrete, is another option to increase the durability of the device.

Topics

Double heap sequence

Kragen Javier Sitaker, 2017-07-19 (2 minutes)

Emacs stores the text in a buffer in a buffer-gap representation: the text before the cursor is in one contiguous block, the text after it is in another contiguous block, and there is a slack space in between. This makes inserting or deleting text at the cursor very fast, while moving the cursor is somewhat slower, involving copying the text that the cursor moves past to the other side of the buffer gap. This is not a very fashionable way of doing things nowadays, since it involves a lot of mutation in the course of what you'd think would be read-only operations, but in practice it works very well indeed.

I was thinking that a possibly interesting representation for mutable *sorted* sequences is a somewhat analogous thing, one which maintains two *heaps* for the elements before and after a "cursor". To move the cursor forward, you pop an item off the after-heap, which is a min-heap, and insert it into the before-heap, which is a max-heap. To move the cursor backward, you pop an item off the before-heap and insert it into the after-heap. You can insert and delete items from these two heaps as well. All four of these operations — forward, back, insert arbitrary, and delete arbitrary — have logarithmic worst-case and average-case time. Initially building the heaps from an unsorted set of items (with a given key as the cursor position) takes linear time. No external space is needed.

The more normal way to support these operations would be using a B-tree. Is that better? It gives you logarithmic insertion and deletion time, yes, but it takes N log N time to build the B-tree in the first place, and it takes potentially substantial space to build. It also gives you some goodies that the double-heap does not: logarithmic-time access to find a given key and constant-time iteration.

How to use “correct horse battery staple” as an encryption key, including a recommended 4096-word list

Kragen Javier Sitaker, 2014-04-24 (44 minutes)

You can use a passphrase consisting of four short, common words to keep your encryption key secure from attackers willing to spend less than US$1B to crack them. Just choose the passphrase with strong randomness, salt it, then spend a minute stretching the passphrase with scrypt. Memorizing such a passphrase with an optimal practice schedule takes several minutes, but only once in your life.

For this to work, you absolutely cannot make up the passphrase yourself with your mind. You have to use a truly random physical process such as rolling dice.

Background

xkcd clearly showed that for online password attacks, a password like "correct horse battery staple" is perfectly adequate — that is, a password consisting of a small number of randomly chosen common words, with spaces between them, and no unusual orthography — while more common methods of choosing passwords are less secure; and furthermore that these passwords are easier to remember. But a footnote on the comic explained that this may not be adequate for resisting offline attacks.

(To those who wonder whether they should be taking security advice from a comic strip: ① the argument and calculations in the strip are correct, and ② you clearly don’t read xkcd. Also, in that case, you probably need to be told not to make up the passphrase with your mind; use Diceware or something similarly strong. Also you probably need someone else to write the software to implement this for you.)

In a chat with a friend of mine yesterday, I realized, much to my surprise, that this kind of password is also adequate against *offline* attacks, like those that someone can try against encrypted text they captured or against private keys, given certain conditions.

The approach is this. You take a randomly chosen passphrase, run it through a password-based key derivation function on a computer you trust for a reasonable amount of time, and use the resulting output as the encryption key.

("Brain wallet" is a broken implementation of this idea as it applies to Bitcoin. Most brainwallet-stored Bitcoins have been stolen.)

How much entropy do we need?

Let’s suppose we want the key to be secure against a billion dollars’ worth of attacker resources. A million is probably okay for most people in most situations, but a billion gives us some margin of safety. I calculated some computing costs in 2010; in particular, running a regular personal computer cost about US$0.005 per minute, which

I'm going to figure is probably still about right.

The most advanced current password-based key derivation functions, like Colin Percival's 2009 scrypt, minimize the cost advantage of special-purpose attack hardware relative to a regular personal computer; let's figure that they keep it down to 8×, that is, that you can duplicate a minute's worth of scrypt computation for ⅛ of US$0.005 if you're using special-purpose hardware. (I think that by using a custom packet-switched memory fabric like the Tera MTA, you can probably beat that advantage by an order or two of magnitude, but probably only the NSA has done this so far.)

So let's suppose that you, the legitimate user, are willing to wait for one minute, with one computer, to hash your password. That is, you're spending ½¢, but you want your attacker to have to spend US$1B. This means you need to choose one of about 400 billion passwords, i.e. you need 39 bits of entropy. Plus three bits for the custom hardware advantage, for 42 bits.

"Correct horse battery staple" passwords can easily have 44 or 48 bits of entropy, using only four words.

In effect, key stretching is adding 30–50 bits of difficulty to breaking your key.

Memorization schedule

For a password like this that you never write down, even if it's as memorable as "correct horse battery staple", you need to establish a practice schedule so that you don't forget it, and it would be very helpful to have spaced practice software for this. Existing spaced practice software for memorization (things like AnyMemo, Anki, or Mnemosyne) is not suitable unless you're already using it. It's designed for memorizing a large set of facts, not a single one, so it only quizzes you when you ask it to run.

By contrast, in this case, you need to space your practice of just one password. I don't know of any software for this. When I did this with a seven-word passphrase, I set an alarm on my phone repeatedly for the repetitions in the first day, and thereafter repeated the exercise each day for a long period of time by just using the password each day:

- 10:31: generated password; repeated it until I could remember it for a few minutes.
- 10:35: first practice.
- 10:37: second practice.
- 10:47: third practice.
- 11:30: fourth practice.
- around 16:00: fifth practice.
- That night: sixth practice.
- The next morning: seventh practice.
- Two days later: eighth practice.

The intervals here are a bit more conservative than the usual 1, 5, 25, 125, 625, 3125 intervals for practice memorization, for two reasons:

- The passphrase, although I impose linguistic associations onto it, doesn't really have an underlying structure that simplifies it; so it's inherently a hard thing to memorize.

• If at some point I forget the passphrase, I don't have the opportunity to recover it from some reminder medium, as is usually the case for things I'm trying to memorize. I can't just turn over a flash card. If I forget it once, and it's not still in my terminal scrollback, it's gone.

On the fourth try, I misremembered the passphrase at first, suggesting that the schedule may not be conservative *enough*. The exponential factor in that case was about 3½, so you probably want something more like a factor of 2½ to be safe: after repeating the password for 2 minutes, wait 3 minutes, 7 minutes, 20 minutes, an hour, 2 hours, 5 hours, 12 hours, a day, 2 days, 5 days.

(This probably means you want to start this process in the morning, not at night.)

Checksums

If you're going to wait for an entire minute to hash your password, it's kind of a bummer if it turns out you mistyped it. This is avoidable at the cost of slightly longer passwords. If the password is generated in a way that ensures that, say, the checksum of its 4-bit nibbles will be 0, then you have decreased the strength of the password by 4 bits, while ensuring that 94% of the time that you type the wrong password, the system can detect it immediately.

If the key-stretching program also knows the wordlist from which your words were originally chosen, it can probably also catch most typographical errors.

This is actually crucial for memorization; because of hyperbolic discounting, when you're practicing your password, you need immediate feedback if you get it wrong. (Hyperbolic discounting is somewhat questionable when applied to people making choices consciously, but firmly established in operant conditioning, which is what we're dealing with here.)

Alternatively, you could simply use a longer password and less key stretching, so that the key stretching process ends in around a second.

Moore's Law

A billion dollars of computing effort today is half a billion dollars in a year and a half, if Moore's Law continues. In 15 years (in 2029), it will diminish to only a million dollars. It's uncertain as to whether this trend will continue. It might even speed up: solar photovoltaic energy will probably overtake fossil-fuel energy as a fraction of our marketed energy in the early 2020s, and subsequently energy will become cheaper even faster than computing hardware.

Each extra bit of password strength gives you about a year and a half of Moore's Law lead time.

In cases like public keys used to authenticate forward-secret key exchanges or authorize transactions, being secure against future attacks is irrelevant. In cases like the encryption used for your disk, it is not. You should probably assume that breaking your disk encryption will become practical at some point, but you can probably delay that day by using longer passwords.

Believe MC Frontalot: you can't hide secrets from the future.

Quantum computers

Speaking of defending against future attacks, what about quantum

computers?

Grover's algorithm on quantum computers, if and when those turn out to be feasible to build, halves your effective key length. If applied to your 48-bit pre-key-stretching password, this would reduce its strength by 24 bits, which would make it feasible to break. You could use a 96-bit pre-key-stretching password (eight words) to resist this attack.

I'm pretty ignorant about quantum computation, so I don't really know, but I don't think you can apply Grover's or any other known quantum algorithm to reduce the effective length of your stretched key — the log of the number of possible passwords plus the log of the number of operations used in stretching — by half. If you could, then if your key stretching involves a trillion operations (about 2^{40}) and you want to resist a 2^{80} attack, you need an effective key length of 160 bits, of which 120 will have to come from the password: ten words.

Massive attacks and salt

An attacker can gain some advantage over the defender by attacking many passwords in parallel. With the approach described so far, if there are, for example, 256 law enforcement officers who receive an encrypted email, and the mafia successfully steals all of their computers, the mafia doesn't need to spend a billion dollars to decrypt one of the officers' disks. Instead, they can spend 1/256 of that to decrypt *any* of the officers' disks: they try each generated key against all 256 disks. This way they can get the email after only a few million dollars' worth of work.

(Better, if someone does the billion dollars' worth of work just once, they can make a rainbow table of all possible keys, although with such a slow key derivation function, the rainbow table chain lengths will be limited. For example, with a chain length of 256, you'll need 2^{40} entries for 2^{48} possible passwords, occupying a total of 6 tebibytes; but doing a single lookup in the table will take 2 hours.)

The standard approach to solving this problem is to salt the passwords: store a nonsecret random string that gets combined with the password (for example, concatenated with it) before you run the key derivation function. Many pieces of software will do this salting for you, but if not, you can do it yourself. For example, for a disk encryption password, you can engrave the salt into the case of your computer, next to the keyboard. For example, your 48-bit salt might be encoded as "sting vowed woken hold" while your password is "crowd lasts men woody"; you type "sting vowed woken hold crowd lasts men woody", having copied the first four words from the engraving.

Being interactively prompted with the salt would probably reduce the incidence of accidentally typing the wrong password, a phenomenon which compromises that password.

Sequential memory-hard algorithms are a wrong turn in this context

The scrypt paper argues that sequential memory-hard algorithms give defenders an extra advantage over attackers: by increasing the amount of time needed by a defender to hash their correct password by some factor N, you increase the cost to an attacker by N^2, because

the attacker needs both N times more memory and to use it for N times as long.

XXX

Timing and other side-channel attacks

Memory-hard functions like scrypt, while necessary to resist custom hardware, probably cannot execute in constant-time on off-the-shelf hardware, because they need to generate and access large tables. But because the total time for the computation is so long, and because it can't be automatically initiated by an attacker request and remote attackers can't normally observe either the beginning or the end of the process, timing attacks should in general be very difficult to carry out.

Using phrases of English words rather than arbitrary characters adds a great deal of redundancy to the password, which means that even very minor amounts of side-channel leakage (such as keystroke timings, audio of keystrokes, or RF emissions from the keyboard) should make it possible to completely reconstruct the password.

I have no idea about power analysis.

My preferred wordlist

The S/KEY wordlist from RFC1760 is commonly used; it consists of 2048 words of up to four letters. It has a couple of flaws: it's only 2048 words (11 bits per word), when 4096 is easily achievable; it includes many very uncommon words, such as "Egan", "Eben", and "fogy", impeding memorization; and it contains many words that are too similar, such as "good", "gold", "goad", "goal", "coal", "foal", and "goat". For example, the 48-bit number 155759005738413 is encoded using S/KEY as "aid shin mini ruse made", except in all capitals. My preferred wordlist, instead, encodes it as "hay fork catch diary", which I think is dramatically more memorable.

Here are ten more S/KEY encodings of 48 bits, but in lowercase:

```
air limb dash mask laws
ace cock rip fond bask
an shy lind juno folk
all doug jolt lang sob
aim tank bed neil juno
an fawn wean aqua if
ada ding sea hive kit
ada lies nip aids howl
ada cut love will hum
am iris gut din bold
```

Here are ten encodings of 48 bits with my wordlist:

```
ici shrug slow solid
must fever plug hotel
facts foam gall frail
snake erika star i
belle feat dip waste
rent herr freud tuna
annie spade downs doo
grief sense infer cab
```

cuba g maths pig
days dusty small yacht

I generate these with bitwords.py, which uses the system truly-random-number generator, which is almost as trustworthy as rolling dice if you're on a Linux machine that isn't backdoored.

I derived the following wordlist by taking the most common 4096 words of 5 letters or less from the British National Corpus. It's imperfect, as you can see above; it still includes some nonwords, uncommon proper nouns, and words very similar to one another. In practice, though, as you can see from the above, the words it generates are pretty memorable. Many of them are sentences or noun phrases, or almost: "Rent Herr Freud tuna! Must fever plug hotel? Grief sense infer[s] cab. Cuba G: Maths pig! Day's dusty small yacht. Annie spade-downs doo."

It also has the problem, shared with the S/KEY list, that it contains many words that are too similar to one another: it contains not only "sold", but also "old", "told", "hold", "cold", "gold", "bold", "solid", "sole", and "solo". This means that a typo or misremembering of a password is often also a valid password.

Previously I used the most common 4096 words in English (again, according to the British National Corpus) but it turns out that they are only slightly more memorable than these words, and substantially shorter. These are drawn from the most common 15898 words, adding perhaps 15% to the difficulty of memorization (log 15898/log 4096); they average 4.25 letters, while the most common 4096 average 6.57 letters, adding 55% to the time needed to type them. This tradeoff seems reasonable.

Time domain lightning triggering

Kragen Javier Sitaker, 2013-05-17 (4 minutes)

Time-domain radio, aka ultrawideband or pulse radio, is mostly considered in the context of very-low-power communication. But there's an interesting very-high-power physical phenomenon that could be useful for time-domain radio: lightning. The mechanism that triggers lightning is not well understood; when it happens, the electric field is still two orders of magnitude below the voltage needed to ionize homogeneous air. Then, the current jumps from effectively zero to some tens of kA within a few microseconds, with a conductor length of typically a few kilometers. This transmits a powerful electromagnetic impulse horizontally across the bands up to a few hundred kHz, an impulse powerful enough to be detected at considerable distance. If we figure on an antenna impedance of 63 ohms, 30 kA will generate a radio pulse of about 60 gigawatts.

How far away can you detect a 60-gigawatt pulse from? If we assume a detection threshold of -70dBm, which works fine in Wi-Fi cards, and a ten-square-meter dish antenna, you can detect a signal down to 10^{-11} W/m², so you hit that threshold when the power is spread out over 6×10^{21} m², which is when the pulse has expanded into a sphere 22 billion meters in radius. This is about a sixth of the distance from the Earth to the Sun. If you can detect down to -85dBm, you can apparently detect the lightning strike from just about anywhere in the inner solar system.

So it seems safe to speculate that you should be able to detect a lightning strike using shortwave radio from anywhere on Earth, and using other radio bands, perhaps from some of the other inner planets too. It really seems like overkill for terrestrial communication.

You still can't make lightning from scratch, but you can trigger it. The traditional approach is to blaspheme, but that has been shown both experimentally and theoretically to have very low efficacy; additionally, the large amount of time required to blaspheme (hundreds of milliseconds or more) would dramatically limit your possible communications bandwidth. More modern approaches, shown to work fairly reliably, include firing rockets into clouds trailing wire from spools, and ionizing paths in air using ultraviolet lasers. Presumably particle accelerators can also ionize paths in air. (I've seen speculation that cosmic-ray strikes play a role in creating lightning leaders.)

A problem with laser-induced ionization is that ionized air is opaque, so it tends to be self-limiting; nevertheless, some experiments have found success using this method.

Particle accelerators might work better; particle beams are attenuated by air, but no more by plasma than by regular air, less so even. And you could maybe use the particle accelerator to produce a beam of synchrotron radiation or X-rays to form the ionized path, rather than firing subluminal particle beams into the air. Alternatively you could perhaps use an X-ray laser.

You probably can't find a place where you can trigger lightning more often than a few times a month, and you can probably only control the triggering to a precision of a microsecond or so within a

window of a few seconds, so your total system bandwidth isn't going to be more than a few dozen bits per month.

This approach to radio communication has the advantage that you could transmit data over interplanetary distances without being detectable as a radio source without access to the spreading code.

Some extensions of William Beaty's scratch holograms

Kragen Javier Sitaker, 2019-07-11 (9 minutes)

William Beaty's scratch holograms can be extended using dithering and noncircular scratch paths to support arbitrary movement and brightness change, with artistic and archival applications.

Gradients and disorganized abrasives

A piecewise-linear interpolation of scratch direction and density over a surface will give rise to nonlinear and, in general, noncircular scratch paths; this may be feasible to fabricate using disorganized abrasive embedded in a soft matrix, such as a piece of felt or rubber, which is moved in several passes over the surface to scratch. Due to the elasticity of the matrix, displacements of the matrix parallel to the surface vary the amount of pressure transmitted through the abrasive to the surface, and this varies the scratch density (number of scratches and average scratch width). Spatially varying this perpendicular displacement throughout the matrix, which is to say holding it slightly nonparallel to the surface, will result in a spatial scratch density gradient on the surface; temporally varying the displacement will also result in a spatial scratch gradient, but along the direction of movement. Both techniques can be used in concert to maximize scratch density gradient sharpness by moving the matrix parallel to the matrix. Nonparallel movement will blur the gradient, which may be desirable to prevent the faithful reproduction of mechanical errors such as unwanted vibration. Moving the matrix along an in-general-nonlinear path without rotating it will result in the scratches from a given point in time all being parallel, like the parking-lot floating polishing glove image mentioned in Beaty's original notes, but rotating it around an axis more or less parallel to the surface will cause the scratch paths from one side of the matrix to the other to vary in both direction and radius of curvature.

By combining these gradient effects, it should be possible to rapidly fabricate scratch holograms that reproduce an arbitrary continuously-varying set of monochrome images to fairly high precision when viewed or illuminated from different angles; this goes beyond merely fabricating a hologram of a single physical object viewed from different angles and includes, for example, arbitrary animations, though animations with only a single (possibly cyclic) temporal dimension.

If the matrix is not soft, being for example steel or pitch, the perpendicular displacement directly controls scratch depth and density, rather than indirectly through pressure. This requires more precise positional control.

Alternative scratch fabrication tools

Randomly positioned abrasive is not the only thing that could be used this way. A single-point cutting or forming tool could also be moved over the workpiece in a controllably curved path by an analogous mechanism: mounted on a wheel whose rotation angle is

precisely controlled as a gantry or other two-degree-of-freedom mechanism moves the wheel's center over the work. (A hardened-steel glass-cutting wheel might make an adequate tool for forming lines in the surface of a softer metal, or cutting them in glass.) A series of regularly spaced points would also work; for example, you could use the edge of a saw blade held nearly parallel to the workpiece surface, controlling the angle and curvature of the blade as you drag it over the surface to scratch it, using a six- or seven-degree-of-freedom control mechanism. And you might be able to use a rotary brush of aluminum-oxide-particle-impregnated nylon — either rotating around an axis parallel to the surface to make straight scratches at a given angle, or even rotating non-parallel to the surface to make elliptical scratch arcs.

Media

More highly reflective surfaces, such as metals, are of course more desirable. Grinding copper flat, then electropolishing it, then engraving the hologram with abrasive, then plating it in silver, chrome, or nickel, should enable very high contrast ratios. Aluminum might be easier to form. Glass is in some ways the optimal material, having no grain size or work-hardening to worry about, but getting it to be highly reflective requires some kind of silvering process, nowadays typically by vacuum sputtering. If this is not done, objects on the other side of the glass may be clearly visible, and for some applications — such as superimposing a sort of hardcopy alternate reality view on an object, for example for measurement purposes — this could be desirable.

Metallic media can perhaps be mass-duplicated by electrotyping, but molding, as is done for vinyl phonorecords or diffraction gratings from the Grating Lab, is probably a better process. The molded reproductions can then be silvered through sputtering, as gratings are.

Color

By adding color filters over the surface, ideally after scratching, some color should be possible, although it means that scratch density needs to vary in phase with the color-filter variation to get color, which requires much higher spatial frequencies than would otherwise be needed, thus substantially increasing fabrication time. The R-G-B-G checkerboard used in modern digital cameras might be ideal in some sense, but using parallel strips (either R-G-B-G, R-G-B, or R-G-B-W as in some modern LCDs) would reduce the scratching problem. If the surface is titanium, chrome, or stainless steel, iridescent oxide layers may be an adequate way to apply color filters.

Oil films

At the extreme of soft materials, it should be possible to produce most of these effects in a film of oil or grease on a smooth surface, such as glass or PMMA, without using abrasives or cutting tools at all; a soft rubber squeegee is adequate. Such a temporary hologram might serve as a frame of an animated display or as a temporary hardcopy. In time the minimal surface tension of oil will erase the images.

Virtually transparent opaque polyhedra

It should be possible to apply these effects to more than one side of a polished metal polyhedron or convex curve to produce parallax-correct views of a three-dimensional object within, though with only a single dimension of parallax. The illusion will be that of seeing a luminous object within the polyhedron through the metal surface, as if it were merely a wire frame enclosing the object.

Archival

Of course the usual archival applications exist; by virtue of scattering light directionally, a scratch that is only half a micron in width and a few microns long becomes brilliantly visible from a certain angle. Under ordinary sunlight viewing conditions, a single sheet of material can encode some 300 different images at illumination angles differing by half a degree (180 degrees / ½ degree minus a safety factor), or perhaps more if the contrast-enhancement techniques in Analemma sundial (p. 1955) are applied. Art-gallery viewing conditions, with a more directional light source than the sun and a background that is much darker than the blue sky, could permit many more images to be encoded.

10-micron household aluminum foil, shiny on one side, with 300 images encoded at 300 dpi and one bit per pixel, would provide archival bit density of 42 gigabits per square meter and 4.2 petabits per cubic meter with this approach; scaled down to the size of Paul Atreides' Orange Catholic Bible, that's 4.2 gigabits per cubic centimeter. But such a delicate medium as 10-μm annealed aluminum is difficult to handle without creasing it, and the electrostatic page-selection mechanism described in *Dune* is unfortunately probably not feasible outside of fiction.

The 100-μm forged aluminum used for drink cans can withstand rough handling, but it is surely overkill for this application. 30-μm aluminum flashing is probably adequate and can be polished on both sides. This would provide 2.8 gigabits per cubic centimeter.

By this method you could produce a book, readable with the naked eye in direct sunlight, safe to handle with bare hands, using inexpensive materials (but very expensive fabrication techniques), that will last millennia under reasonable archival conditions, which at 130 mm × 80 mm × 10 mm contains 290 gigabits of data, 36 gigabytes. If we want it to use normal lettering, we probably need about 3×6 pixels per letter at least, so that would be only 16 billion letters of text, about 3 billion words. This is about a third the size of English Wikipedia.

More aggressive specifications might use 600 dpi and 1200 images rather than 300, thus requiring a light four times more directional than the sun, such as a sunbeam entering an otherwise dark room through a peephole or vertical slit. This would enable sixteen times greater information density but would probably require a magnifying glass to read.

For mass production of such holographic archival devices, perhaps a plastic film could first be molded (as described above) out of an archival-safe thermoplastic such as PET, then silvered with aluminum in a vacuum.

Would Synthgramelodia make a good base for livecoding music?

Kragen Javier Sitaker, 2015-09-03 (8 minutes)

I wrote a thing a while back called "synthgramelodia", which randomly synthesizes melodies from a grammar, many of which are listenable. Its homepage, which is currently just a list of outputs, is at http://canonical.org/~kragen/sw/synthgramelodia. I should probably at least put the software there.

I think it's probably possible and worthwhile to use this same grammar for interactive improvisational composition, but I don't feel up to actually implementing it at the moment. (I'm horizontal with what I think is a flu.) But I think I can explain the idea.

Synthgramelodia uses a tiny six-production grammar of melodies which is capable, in theory, of expressing basically any chromatic melody using the Chinese equal-temperament scale and the binary note values used in mainstream Western music today; but it's intended to be biased towards things that will sound "nice", so that the result will often be listenable, and it uses a DAG to promote repetition of motifs with some variation.

The grammar can be expressed as follows in a single line:

```
m ::= "." | [a-z] | _<m> | +<m> | (<m> <m>) | (<m> ^ <m>)
```

The two fundamental atomic melodies of the grammar are:

- a **Rest**, written `.`, which is a silence lasting one beat, and
- a **NoteScore**, written with a letter `a`, `b`, etc., to indicate which of the synthesizer's various "instruments" to play. A NoteScore by itself represents the instrument being played for a single beat at 220Hz, which is A3 or A below middle C.

On top of these, there are four compound melody types which modify one or more melodies:

- a **Transpose**, written `_x`, where `x` is the melody being transposed; it represents the same melody as `x`, except lower in pitch by a perfect fifth.
- a **Louder**, written `+x`, where `x` is the melody being amplified; it represents the same melody as `x`, except louder in volume by 3 dB;
- a **Sequence**, written `(x y)`, where `x` and `y` are two melodies being concatenated, which consists of first the notes of `x` and then the notes of `y`; if `x` and `y` are of different lengths, the shorter one is slowed down to equal the longer one in length. Also, `y` is reduced in volume by 2 dB.
- a **Parallel**, written `(x ^ y)` where `x` and `y` are two melodies being played simultaneously; `y` is raised in pitch by an octave, while the bass line `x` is left unchanged, and if they are of different lengths, the longer of the two is accelerated in order to be of the same length as the shorter.

(At some point, I replaced the stretching of the shorter melody with repetition, which I don't think improved it.)

Synthgramelodia builds up random melody DAGs using these productions or node types in a bottom-up fashion that tends to reuse the same node in many parts of the tree, with the result that you tend to hear the same motif at diferent speeds and transposed to different pitches, although not using different instruments.

It should be apparent that you can raise a melody's pitch arbitrarily high by paralleling it with a bass line consisting of a rest several times, lower it arbitrarily low by transposing it several times, reach any chromatic pitch by combining these two, amplify it arbitrarily by loudering it many times, accelerate it arbitrarily by concatenating it with many rests (or with itself) and then paralleling it with a single rest, and slow it down arbitrarily to an arbitrarily slow speed by concatenating it with a long sequence of rests, although at the cost of embedding it in a longer silence.

It should also be apparent that the only reachable pitches are in the chromatic scale, the only reachable melody lengths are powers of 2, and all integer numbers of decibels are reachable amplitudes.

(It might make more sense to reverse the speedup/slowdown semantics of Parallel and Sequence, so that you can slow things down arbitrarily by paralleling them with a long silence, while speeding them up would just require concatenating them with a single rest; or maybe make a separate node type for speeding things up.)

Given all this, it also seems clear that you should be able to write an expression (infix or Forthlike) to generate a "gramelodia", perhaps even synthesizing it in real time as you improvise. I suspect that some kind of Forth-like interface, like GlitchMachine, is probably the best way to edit this; it gives you a linear thing you can edit which is essentially immune to syntax errors.

Constructing arbitrary DAGs on a Forth stack might seem tricky. Arbitrary trees are of course straightforward: the postorder traversal of the tree forms the Forth-style command sequence, and you're done. Some DAGs can of course be constructed with nothing more than "dup", but you need some amount of stack manipulation to construct things like `(a b) (a c)`.

If we consider a Forth two-stack machine as a sort of Turing machine that can insert and delete cells on its tape, we can see that the four operations `dup`, `r>`, `>r`, and `shift` are sufficient to shuttle nodes around in order to construct arbitrary DAGs. With the operand stack on the left, the auxiliary ("return") stack on the right, and top-of-stack outlined with parens, these operations are as follows:

- `dup`: "... (a) ..." → "... a (a) ..."
- `>r`: "... b (a) ..." → "... (b) a ..."
- `r>`: "... (b) a ..." → "... b (a) ..."
- `shift`: "...(a) b ..." → "... b (a) ..."

The sequence of cells on the tape, omitting duplication, remains unchanged except by `shift`, which moves the current top-of-stack to the right on the tape, which can be repeated until it reaches the position it needs to combine with whatever it needs to combine with; `>r` and `r>` move the head left or right on the tape; and `dup` is what you do to use a node in two places. (Arguably the duplicate ought to be on the auxiliary stack to the right, not the main stack to the left.)

I've made several attempts to reduce this to three operations, but none has yet been successful. There's probably something hiding just

out of sight; but, for example, with just `r!`, `shift`, and `r>`, there's no way to write `swap`, which is a problem in the presence of non-commutative operations like the gramelodia melody combinations; and if you integrate `dup` into one of the other operations, you probably need to add `drop` as well.

You could imagine a live display not only of the melody, but also the sheet music, the DAG, sheet music for individual DAG nodes, an infix version of it, and a highlight on each of these indicating where your editing cursor is in the Forth sequence; and also keys to jump your cursor to the construction of one or the other top stack items at that point in execution, so you can navigate the DAG structurally.

He listened to the human intently

Kragen Javier Sitaker, 2014-06-29 (4 minutes)

He listened to the human intently, although his demeanor was casual.

"Yes," said the human.

From the sound of the E, he discerned that the human was probably from either near Boston or near Sydney. A human from Scotland might pronounce the E the same way, but only if he were impatient. And the human's phoneme pacing, as well as the slow pulsing of blood in his face, showed that he wasn't impatient. A bit curious, perhaps. Interested. But not impatient.

"Why did you buy it?" he asked the human, in a voice meticulously calibrated by a linear model on tens of millions of hours of wiretapped telephone conversations, whose only remarkable feature was its featurelessness.

"Well, I'd heard of the title, but I had never seen a copy in person. So when it came up for auction, I put in a low bid, and it turned out to be the only one." The human's eyes flicked down a couple of times, punctuating his speech.

In the fillip the human gave to the word "auction", he glimpsed childhood memories of weekends listening to the gavel, clearly from the contraband auctions the Coast Guard held at Back Bay every second Friday, and his secret joy in acquisition, along with faint hints of an adolescence spent masturbating in surplus military fatigues. In the accent he heard the traces of the human's parents' accent — Portagee, as they'd call it themselves. And in the tiny hesitations he heard the wounds of a childhood at the mercy of a sadistic parent, the human's father, probably. The timeframe of the Portuguese accent influence would be the 1950s or 1960s, and the human had grown up in poverty, with guilt attached to his love of books, so probably his parents were not highly educated.

Ah, it came into focus: the father had served briefly in PIDE, Salazar's secret police, and then fled Portugal to escape the horrors of what he had done in Tarrafal; but the monster awoken in the man fed on his son's soul even today. Every word the human spoke gave subtle evidence of it, to those who knew how to listen to human speech.

He knew how to listen.

The human was lying when he said he'd never seen a copy in person, he could tell, but the lie was motivated only by a desire to keep the conversation interesting. He hadn't been interested in the other copy he'd seen, but for a boring reason, and he knew that boring clients was no way to sell rare books.

Where the light glinted off the cover of the book, he recognized the fingerprints of half a dozen long-dead rare book dealers, but although he noted their identities for eternity, the book and its history did not really interest him. He was hunting down a conspiracy of rogue archivists who frequented illicit book dealers like this one, and who particularly might be interested in nineteenth-century chemistry books. But their fingerprints were not among the prints on the cover, and the human's speech and motions gave no suggestion they had

been here.

No matter. Soon he would find them. They had no chance. Today he would set a bait here, tomorrow elsewhere; sooner or later they would buy a book from someone he knew, or carelessly leave a fingerprint on the subway, or talk to one of their family members, who were all under surveillance by casual acquaintances who seemed human.

"I have the next one in the series," he said to the human in his voice, a voice so average that to another like him it would stand out like a siren. "Would you be interested?"

In the human's face he saw a lifetime of hopes, dreams, fears, obsessions, and disappointments flicker by in a fraction of a second, and then heard them richly modulated onto the human's casual voice: "Could be."

How cheap can laser-cut boxes be?

Kragen Javier Sitaker, 2017-06-01 (2 minutes)

I bought a little plastic box with eight partitions for AR$49 at Sodimac (US$3.10). This seems expensive and I thought maybe I could get an equivalent laser-cut for less. Mina was skeptical.

The dimensions of the box are about 130 mm × 110 mm × 25 mm.

There is one partition running in the 130 mm dimension and four partitions in the 110 mm dimensions, and there is a lid.

This works out to six partition edges and four face edges in the 130 mm dimension, thus 1300 mm, plus ten partition edges and four face edges in the 110 mm dimension, thus 1540 mm, plus 15 vertical edges of 25 mm, thus 375 mm; a total of 3215 mm.

My current laser-cutting cost model is that laser-cutting goes 24 mm per second and takes an extra 60 ms per vertex, and the cost is US$0.026 per second. Probably there would be about four vertices per vertical edge, for a total of about 60 vertices, a total of only 3600 ms, not significant in the overall cutting time. The 3215 mm would take 134 seconds, plus another 4 seconds of vertices, a cost of US$3.60. So it would work out to be pretty much the same cost, probably, or slightly more.

For larger boxes, I think the laser-cut MDF approach is definitely cheaper. Or if I can find someone who does cheaper MDF cutting.

Improving lossless image compression with basic machine learning algorithms

Kragen Javier Sitaker, 2016-07-27 (2 minutes)

Image compression algorithms work, in some sense, by finding a good way to predict the value of each pixel from the already-known pixels, and then correcting the prediction more or less. (It's kind of a stretch to apply this description to JPEG, I guess...)

One possible predictor is a simple spline fit to the previous pixels. If it's zero-order, this reduces in some sense to RLE; first-order predicts gradients; second-order and higher may not be useful.

A more interesting predictor for screenshots is perhaps a KNN predictor: given the so-far decoded pixel data, what are the K previously-decoded pixels whose environment was most similar? Perhaps, for concreteness, we take the two pixels above, two pixels to the left, and one pixel diagonally up and to the left. Let's take them in grayscale so we only have a 5-dimensional parameter space, since RGB TrueColor would form a 15-dimensional parameter space.

Now we can search the so-far-decoded image for the K pixels whose environments are most similar to our current environment, using e.g. Manhattan distance, and take the mean or, more likely, median of their color to form our predictor of the current pixel's color.

5 dimensions is small enough that we could reasonably build a k-d tree to keep the search efficient.

My thought is that the vast majority of pixels in screenshot environments would have exactly the predicted color, because those 5 pixels have enough information to nearly uniquely identify the font glyph, pixel position within that glyph, and background color that we're looking at. That means you can encode the average residual in less than a bit, particularly if you accept some quantization noise.

(We might want to do some kind of dimensionality reduction, e.g. PCA, to be able to use color and more than 5 pixels.)

Twingler

Kragen Javier Sitaker, 2014-02-24 (7 minutes)

In Twingler, a generic data structure munger, Mark-Jason Dominus proposes a new broadly-useful DSL.

The problem

Given

```
[
    [Chi, Ill],
    [NY, NY],
    [Alb, NY],
    [Spr, Ill],
    [Tr, NJ],
    [Ev, Ill],
]
```

he wants to easily write the transformation to DS1:

```
{ Ill => [Chi, Ev, Spr],
  NY  => [Alb, NY],
  NJ  => [Tr],
}
```

for example, or to any of DS2:

```
{
  Chi => Ill,
  NY => NY,
  Alb => NY,
  Spr => Ill,
  Tr => NJ,
  Ev => Ill,
}
```

DS3:

```
{ Ill => [Chi, Spr, Ev],
  NY  => [NY, Alb],
  NJ  => Tr,
}
```

(unnamed):

```
{ Ill => 3,
  NY  => 2,
  NJ  => 1,
}
```

or DS4:

```
[ Chi, Ill, NY, NY, Alb, NY, Spr, Ill, Tr, NJ, Ev, Ill]
```

As a current example of how it is currently unnecessarily difficult to write the first transformation, he gives the Perl

```
my $out;
for my $pair (@$in) {
    push @{$out->{$pair->[0]}}, $pair->[1];
}
for my $k (keys %$out) {
    @{$out->{$k}} = sort @{$out->{$k}};
}
```

and suggests that even the abbreviated syntax

```
for pair (in.items) :
  out[pair[0]].append(pair[1])
for list (out.values) :
  list.sort
```

is unnecessarily complicated.

MJD's Twingler templates

he ends up suggesting

```
DS1: [ <[X,Y]> ]
DS2: { <X=>Y>  }
DS3: { <X => [<Y>]> }
DS4: [ <X, Y> ]
```

where ◇ is "ITERATE over the thing inside and make a list of the results," like `map` in Perl or `flatMap` in Scala, and `X` and `Y` are the first two dimensions of a sort of adjacency matrix computed in an unspecified way from the original data:

```
       Ill       NY       NJ
Chi    X
NY             X
Alb            X
Spr    X
Tr                    X
Ev     X
```

...or two columns, I guess, considering the original data as an N-ary relation represented simply as a list-of-lists. (You could probably use the same or similar notation to specify how to reduce the original data to an N-ary relation.)

I don't understand how his four expressions above give the four data structures explained previously; it seems like the DS3 expression `{ <X => [<Y>]> }` should give DS1 rather than DS3, while the DS1 expression should give the original input. I'm going to assume this is just an error MJD made.

MJD points out that you can easily incorporate arbitrary functions into the template:

```
{ <X => max(<Y>) }
```

Later he gives the example, given the table

```
|----+------+--------+---------+------|
| ID | NAME | SHADE  | PALETTE | DESC |
|----+------+--------+---------+------|
| A  | AAA  | red    | pink    | Aaa  |
| B  | BBB  | yellow | tawny   | Bbb  |
| A  | AAA  | green  | nude    | Aaa  |
| B  | BBB  | blue   | violet  | Bbb  |
| C  | CCC  | black  | nude    | Ccc  |
|----+------+--------+---------+------|
```

how to compute

```
{ A => [ AAA, [ [red, pink], [green, nude] ], Aaa],
  B => [ BBB, [ [yellow, tawny], [blue, violet] ], Bbb],
  C => [ CCC, [ [black, nude] ], CCC]
}
```

using the expression

```
{ < ID => [
            name,
            [ <[shade, palette]> ]
            desc
          ]>
}
```

His original examples are fairly easily handled with mapreduce, which hadn't been identified yet when he wrote his notes, and although this one is too, it points the way to examples that are not so easily handled. For example, the classic Titanic dataset, included with R and containing information on survival by gender, age, and class, could be reasonably munged into any of

```
{<Class => {<Sex => {<Age => {<Survived => N>}>}>}>}
{<Sex => {<Class => {<Age => {<Survived => N>}>}>}>}
{<Sex => {<Age => {<Class => {<Survived => N>}>}>}>}
{<Sex => {<Age => {<Survived => {<Class => N>}>}>}>}
```

as well as many other forms. This is not a task you can do with mapreduce.

(I'm not referring to the parallel and fault-tolerant attributes of mapreduce as implemented by Google or Hadoop, but to the higher-order mapreduce function that I've argued should be in Python itertools.)

QBE

Later in his post, MJD suggests that it might make more sense to simply supply a sample input and sample output; e.g.

```
[ [ A, B ],
  [ C, B ],
  [ D, E ] ]
-------------
```

```
{ B => [A, C],
  E => [D],
}
```

I'm not sure if this kind of QBE will work, but it does seem like if it works, it would be simpler to use, despite needing more verbose input. The idea is that, instead of specifying iteration with a separate iteration operator, you specify it by iteration. Consider the slightly harder problem

```
[ [ A, B ],
  [ C, B ],
  [ D, E ] ]
--------------
[ [B, [A, C]],
  [E, [D]],
]
```

This is unambiguous, but if we delete the first output item to get

```
[ [ D, E ] ]
--------------
[ [E, [D]] ]
```

that could mean either the original

```
[ [ A, B ],
  [ C, B ],
  [ D, E ] ]
--------------
[ [B, [A, C]],
  [E, [D]],
]
```

or the alternative

```
[ [ A, B ],
  [ C, B ],
  [ D, E ] ]
--------------
[ [B, [A]],
  [B, [C]],
  [E, [D]],
]
```

although this is not possible in the hash case.

I think this might be less wieldy in the case of deep nesting, and it doesn't accommodate functions like `count` or `max` as easily. Consider the Titanic example

```
{<Sex => {<Class => {<Age => {<Survived => N>}>}>}>}
```

which could be written as

```
[ [First, Male, Adult, Yes, 24] ]
----
```

```
{ Male => { First => { Adult => { Yes => 24 } } } }
```

and is thus no problem; but if we instead want nested lists of pairs, we are in trouble:

```
[ [First, Male, Adult, Yes, 24] ]
----
[ [Male, [ [First, [ [Adult, [ [Yes, 24] ]] ]] ]] ]
```

which is hopelessly ambiguous; we need at least one repetition at each level to specify it properly:

```
[ [First, Male, Adult, Yes, 24],
  [First, Male, Adult, No, 25],
  [First, Male, Child, Yes, 26],
  [Crew, Male, Adult, Yes, 27],
  [First, Female, Adult, Yes, 28],
]
---
[ [Male, [ [First, [ [Adult, [ [Yes, 24],
                               [No,  25] ]],
                     [Child, [ [Yes, 26] ]] ]],
           [Crew,  [ [Adult, [ [Yes, 27] ]] ]] ]],
  [Female, [ [First, [ [Adult, [Yes, 28] ]] ]] ]
]
```

which is, at least to me, less readable than

```
[ <[Sex, [ <[Class, [ <[Age, [ <[Survived, N]> ]
                    ]> ]
         ]> ]
]> ]
```

although I'm not going to try to claim that that's some kind of paragon of readability either.

JSON

Twingle is a great deal more interesting today than in the late 1990s when MJD originally invented it, because now we have a great deal of data on the web (and other places!) represented as JSON. The fundamental aggregate data types in JSON are the same fundamental data types Twingle handles, and simple transformations between different representations of such datasets is a ubiquitous task.

Binate

At first, I was thinking that maybe Binate would be useful for this kind of transformation, since binary relations are awfully similar to the Perl dictionaries being represented by {} here; and Binate might well be more compact than the Twingle representation.

However, binary relations sort of erase the distinction between dicts and lists. XXX

Categorical zero sum prohibition

Kragen Javier Sitaker, 2019-05-27 (updated 2019-06-01) (23 minutes)

Let's explore why rich societies are more economically productive, and why both Kantian and utilitarian ethics forbid exploit development and SEO, as explained by *Bill & Ted's Excellent Adventure*.

A tale of three hobbies: the bad, the good, and the ugly

Suppose almost everyone in the world worked really hard to get better at football as a hobby, instead of wasting their time watching non-football TV or getting angry about politics. The level of professional football games would improve, but there would still be about the same number of professional football games; maybe a little more diversity, but just as today, most people would watch the matches of the top clubs and not the much larger number of bush-league matches. So the overall well-being of the world would increase, but only a little. Or maybe it would decrease, if more people tore their knee ligaments. Either way, it would be pretty much the same.

Suppose that, instead, almost everyone in the world worked really hard to get good at medicine as a hobby — doing paramedic training, reading case studies, predicting patient outcomes, doing Gwern-style double-blind self-experiments, performing recreational plastic surgery on their pets, that kind of thing. The level of health care would improve dramatically — deaths due to drug interactions the prescribing physician failed to notice would go way down, people's decisions about when to go to the emergency room would be much more accurate, people's lifestyle choices would become slightly healthier, and medical science would advance much more rapidly. The overall well-being of the world would increase substantially.

On the gripping hand, suppose that almost everyone in the world worked really hard to get good at fighting with kitchen knives. Perhaps the level of Olympic fencing would improve substantially, which would make for enjoyable TV — though perhaps the sports are far enough apart that it wouldn't transfer — but it's also likely that a larger fraction of fights would involve knives instead of just shouting or fists, usually killing one or more people. The training, too, would probably involve a certain number of accidental fatalities, and some fraction of those would lead to revenge killings. More children would be orphaned. The overall well-being of the world would diminish.

On this basis, I claim that it would be better for almost everyone to take up medicine as a hobby than football, and better football than knife fighting; and this is because knife-fighting is a negative-sum game, football is a zero-sum game, and medicine is a positive-sum "game".

"Party on, and be excellent to each other," Kant, and robbing old women

As I remember, sage Dave Long at some point unpacked the Bill

and Ted philosophy as follows: "party on" means not to engage in negative-sum "games" — in the very general sense of "interactions with other agents" — and "be excellent" means to engage in positive-sum games. To the extent that you can control which "games" you "play", it is better to invest your limited time in positive-sum games. (Sage Shakyamuni reportedly took the alternative position that you should not waste your time playing any games, because you are going to die soon, while the sages of Wyld Stallyns instead played games to defeat death itself.)

Of course, a person may find themself in a situation where it is more advantageous to them personally to direct their effort to a zero-sum game or a negative-sum game. Consider the thief who spotted my neighbor, an old woman, at the bus stop last month, and decided to knock her down and beat her to steal $300 from her (about US$7). He chose to direct his efforts to robbing her, and although he injured her in the process, he presumably considered that a worthwhile tradeoff, because it satisfied his desires for food or crack or whatever. A pyramid-scheme participant who recruits downstream members is doing the same thing, but in a less courageous way, and the injury is delivered via deception to the victim's mind, rather than via a stick to her knee.

From a consequentialist point of view, this is a bad outcome if we consider the thief and their victim to be equally important, so that the loss of money by one is precisely canceled by the gain of money by the other, while the putative injury or deception has no such counterbalancing benefit. If the consequentialist considers the thief's profit to be more important — perhaps because the thief is poorer and therefore benefits more from the money, or perhaps because they subscribe to a worldview where it is better for the money to go to a brave thief rather than a cowardly victim, or a smart thief rather than a stupid victim, or simply because they are racist — then the consequentialist can justify the theft as morally correct. But an *egalitarian* consequentialist cannot so justify theft or any other negative-sum game.

Neither can a deontologist who subscribes to Kant's categorical imperative, which is of course (XXX) one of Kant's first examples; the thief cannot at the same time will that the victim should steal their money back, delivering the same beating to the thief, because that would leave the thief bruised but no richer. Only by some kind of special pleading can the Kantian thief save his livelihood, and the same kinds of special pleading that the consequentialist could use to justify the theft can be used to exempt the thief from the maxim that would otherwise strip his stolen money from him. Again, this logic applies equally well to any negative-sum game.

For an egalitarian consequentialist, the imperative to "be excellent" — to play positive-sum games rather than zero-sum games — is just as strong as the imperative to "party on", that is, not play negative-sum games. Kant's theory (like most deontologist theories) also regards it as a "perfect duty", and thus obligatory, to "party on" in every possible way — at least in the specific examples Kant gives — but regard it as a supererogatory "imperfect duty" to "be excellent".

XXX this description of Kant's incoherency criterion is itself incoherent and needs reworking

Computer security, the nuclear arms race, advertising, and SEO

In theory, since computers only do what you program them to do, you could decide not to program them to accept arbitrary commands from random people anywhere on the internet, instead only programming them to accept arbitrary commands from their actual owners. That is, there is no need for software to contain security holes. Computer security violations are not inevitable. They are the result of undiscovered programming mistakes, which is why the most significant forum for announcing and fixing security holes in the 1990s was called BUGTRAQ.

In the late 1990s I spent some effort finding security holes in software and reporting them to get them fixed. Unfortunately, it became increasingly apparent that the current economic and intellectual environment was going to introduce new security holes faster than we could remove them, so rather than a gradually decreasing pool of still-undiscovered security holes, we have a gradually increasing one, with the disastrous effects on the human right to privacy documented by the Snowden revelations.

In such an environment, exploit users and defenders are in a sort of arms race, a literal race to see who can respond faster. If the defender is faster to patch a newly discovered hole in deployed systems, they win that round; if the exploit user is faster to acquire and employ an exploit for it, they win that round. So whenever one side or the other increases their commitment of resources and gets ahead a bit, the other side has the option of matching that increase to get back to the previous equilibrium.

This sounds like a zero-sum game, but in a larger context, it's negative-sum: the human effort spent on the vulnerability treadmill is taken from the time available for making music, discovering new algorithms, cooking food, meditating, painting pictures, writing poetry, reading poetry, watching movies, making love, or raising children. Every sysadmin on call who has to patch the production systems within an hour so that exploit users won't break in with the newly announced vulnerability is spending the irreplaceable minutes of their life on a Red Queen's race with the spies at the NSA or the FSB. They are falling short of partying on.

Of course, neither side can unilaterally scale back its efforts; that would amount to surrender. If it's your job to keep your employer's public-facing systems up to date so they don't get popped, you can't just decide it's not worth the effort. But you can find a new job.

There are other drawbacks as well: it's no longer a viable option to continue running outdated software unless it's in a very unusual isolated environment, like a non-networked video game, and the increasingly rapid and frequent response required to new vulnerabilities has the effect of centralizing both patching and exploit use in large organizations. This means everyone is exposed to the risks of deploying untested new software on short notice and to having strangers administer their most intimate computer systems, such as Android hand computers. Also, sometimes patching a vulnerability unavoidably introduces incompatibilities, causing bitrot.

So I stopped spending effort on that.

The nuclear arms race during the Cold War had a similar dynamic:

each side constantly worked to preserve a second-strike capability (by, among other things, building enough warheads that some would be likely to survive a first strike from the other side) and to find ways to remove the other side's second-strike capability. Neither side could opt out of the game, but the result of both sides playing it harder and harder was the decades-long threat that civilization could end at any time, with 20 minutes of warning.

Fortunately there were also people on both sides like Jonas Salk, Norman Borlaug, and Andrey Kolmogorov who were able to dedicate their lives to positive-sum games instead of the negative-sum game of the nuclear arms race.

Commercial competition is, in theory, a positive-sum game, though eventually only slightly so — as more and higher-frequency participants in a stock market means fairer prices, with retail participants having to pay much narrower spreads to the market-makers, more competition in consumer-goods markets should result in goods priced just above the lowest possible marginal cost of production. One reason this doesn't happen in practice is advertising: consumers buy goods that are advertised rather than equivalent goods that are not, and in many cases are induced to buy categories of goods they wouldn't have bought at all without advertising.

This puts advertising in the negative-sum category: to survive, firms are forced to push positive information about their products in front of customers, whether that's by traditional display ads and flyers, by getting newspapers to write articles about them, by commissioning shill research (such as rigged Gartner product comparisons), by buying product placements in supermarkets and music videos, or by doing SEO on their web pages. Moreover, they cannot afford to be much more forthcoming about the drawbacks of their products, or less enthusiastic about their benefits, than their competition is, unless consumers are turned off by their immodest hucksterism.

To the extent that consumers can find objective research about the relative merits of different products and distinguish it from the advertising, all these strategies will be ineffective, so firms must work harder and harder to disguise their hustle and puffery as objective research, making it harder and harder for customers to find objective information about their products and, ultimately, about anything at all.

And so it is that if you search for almost any commercially relevant topic on Google today, the results are the Wikipedia article and nine shill pages.

Selfish reasons for avoiding negative-sum and zero-sum games

You might reasonably think there's a prisoner's-dilemma-type global-local incentive conflict when it comes to playing negative-sum games: even if it is not in the interest of society as a whole that you beat up old women to rob them, you might perceive it as in your *own* interest, however you define that. And surely for some definitions you will sometimes be correct. But this happens less often than you might think.

First, let's consider negative-sum games like retail day-trading, in which all the participants are voluntary (as contrasted with the game

of robbing old women at the bus stop, in which my neighbor was an involuntary participant). This is a mildly negative-sum game because of broker commissions and the spreads paid to market makers, which are siphoned off of the otherwise-zero-sum transactions between retail day-traders. (The advent of penny pricing and algorithmic HFT has enormously diminished the magnitude of the spreads in the last 15 or 20 years.)

Presumably most of the participants in the game believe it is in their interest to participate, although there might be a few acknowledged addicts who just haven't managed to quit even though they know it's bad for them. But many of them are wrong, more than half in this case. That means that if you think it's in your interest to participate because you will make money, you're likely just mistaken. In this market you really are behind a Rawlsian veil of ignorance, not knowing if you are predator or prey. I've watched smarter people than myself waste fortunes on such mistakes.

But there's another, subtler problem. The people who participate in some activity, whether it's football, day trading, knife fighting, medicine, SEO, or beating and robbing old women, form an affinity group — a "community of practice", it's sometimes called. They tend to talk to each other, sharing information about their shared activity, and often they engage in other transactions with one another — cellphone thieves need cellphone fences, for example, who in some sense form part of the same community of criminal practice. So if you decide to spend time day trading, you're also implicitly deciding you're going to spend some time hanging out with day traders, talking with them, maybe buying them a beer from time to time. And similarly if you do any kind of medicine — even if you're just taking CPR training — you're going to spend some time hanging out with medical people.

So, we can reasonably ask, how might hanging out with medical people differ from hanging out with cellphone thieves? And there are a lot of answers that are specific to these fields of endeavor (for example, medical people tend to be from Cuba, while cellphone thieves tend to own motorcycles) but one difference that's common across all these fields is that the kind of people who choose to play negative-sum games are (however slightly) the kind of people who choose to play negative-sum games, valuing their individual interests over others', while the kind of people who choose to play positive-sum games are less so.

We can renormalize this and get a stronger result: if you beat up old women to rob them, then the people who choose to hang out with you knowing this will tend to be people who think that's a reasonable choice, but who aren't afraid you will beat them up and rob them — often because they think they're stronger than you, which (refer to previous lemma) they believe justifies robbing you. And similarly for SEOs, advertisers, day traders, and soldiers, with appropriate variations.

So, if you go out drinking with doctors and with day traders, you should expect the day traders to stick you with the tab more often. Maybe not much, but detectably. And if you hang out with people who beat up old women to rob them, you're likely to get robbed, one way or another.

(Of course, it's also possible that someone could take revenge on

you. But that's true in positive-sum games too — positive-sum games aren't always win-win, though zero-sum and negative-sum games are never win-win.)

This doesn't mean you're better off if you hang out with people who *advocate* playing positive-sum games and not playing negative-sum games. A noticeable fraction of them are just trying to talk you into giving them your money, or your volunteer time, or your vote, or leaving your monogamous partner alone with them, or whatever.

Social capital, factionalism, and negative-sum games

"Social capital" is often invoked to explain why rich countries experience vastly higher levels of economic productivity from workers with similar levels of education employing similar levels of capital intensity than poor coutries do; the effect is so strong that poor people from poor countries can greatly improve their income simply by working in rich countries.

After 12 years of living in Argentina and plenty of opportunity to contrast the beliefs and practices of different social groups, one of my conclusions is that much of what is known as "social capital" or "high trust societies" amounts to a self-reinforcing tendency for people to play positive-sum games rather than negative-sum games, or to play positive-sum games in a wider context (not, for example, only within their own family); and this accounts for the otherwise puzzling overwhelming dominance of Wikipedia contributions from highly developed countries, far out of proportion to any difference in literate populations.

Here in Argentina, two centuries of often-militarized factionalism has created a profound cynicism about politics and about any attempt to carry out positive-sum projects; politicians get and maintain power by polarizing their constituents against other politicians and their constituents and by using the state to extract wealth to give to their own supporters, with the unsurprising result that everyone has concluded that all politicians are thieves and liars — because would-be politicians who are not thieves and liars are not successful at gaining support.

The popular belief here that all games are zero-sum is so strong that an Argentine woman told me once that Argentine cars are of poorer quality than American cars because American companies send their defective parts to Argentina, as if statistical process control worked by producing several times the needed quantity of goods and discarding most of them. This belief is strengthened by the Reagan-like deployment of positive-sum rhetoric by politicians to promote negative-sum policies that enrich the rich at the expense of the poor; Macri, our current president, is especially guilty of this, and his economic policies have been disastrous.

We can also argue for a subtler effect, similar to the renormalization argument in the previous section. Leaders of factionalist ignoramus societies, such as Donald Trump, Hugo Chávez, or Mauricio Macri, cannot afford to take advice from the intelligentsia, or put them in charge of policy, even if they could figure out who they were; they are forced to assume that wiser heads

from other factions are looking for ways to defeat them, and will use delegation of authority or even openness to advice as a way to undermine their leadership. (See Notch scorn (p. 115) for pompous bloviation on this topic.) Instead, they are forced to delegate authority to people loyal to their own faction, and listen only to their advice, with the predictably disastrous consequences we are seeing today in Venezuela.

(Given that Trump is president of the country with half of the world's top universities, it may seem strange to call it a "factionalist ignoramus society" — but Trump has apparently spent his entire life playing zero-sum and negative-sum games, and is certainly an ignoramus who surrounds himself with ignoramuses, and almost half the population of the country voted for him anyway. So clearly the factionalist ignoramus element of that society, always significant, is today its dominant element, just as in Germany after 1933.)

You might think that the pervasive belief in zero-sum-ness would make it impossible to motivate voters to participate in politics at all, since clearly whatever time you spend handing out campaign fliers or getting gassed by the cops (a nearly universal experience among the lower and middle class in Argentina) isn't going to be compensated by the marginally increased chance of your party winning at the polls and putting in place whatever policies you favor, even presuming those policies benefit you and not just the politicians you elected. But humans are not primarily motivated by such calculations, and never have been; any who were would fail Newcomb tests and be cast out of society to die in the wilderness.

Suppressing factionalism is no panacea either — whenever those in power pursue foolish policies, they can reasonably accuse anyone who criticizes those policies of fomenting factionalism, and this commonly happens in modern China, in the modern Bahá'í ecclesiastical hierarchy, and in the medieval Catholic church, for example, all of which have or had strong taboos against factionalism. Just as extreme factionalism deprives the leadership of the benefit of the collective cognition of the wise, so too does conformism.

A variety of code fragments for testing proposed language designs

Kragen Javier Sitaker, 2016-05-18 (19 minutes)

I've been thinking about code size, bytecode formats, and so on: what kind of tradeoffs in program representation are best? Existing microbenchmarks tend to be very atypical of real code; real code is mostly much more straightforward and boring than microbenchmarks.

So here are some sample code fragments to try different compilation strategies with (after hand-translating them to some uniform syntax, I suppose). These are chosen to cover the range of real code found in the wild, although they are biased towards code bases of high quality and towards medium-length functions: functions between 8 and 64 lines are better represented. There is code here in Pascal, C, C++, C#, Java, Golang, Perl, Tcl, Python, PHP, JS, Lua, Elisp, Ruby, Haskell, R, and Visual Basic — every popular programming language except Excel, Swift, assembly, SQL, and Matlab. The idea here is to include things written in somewhat different paradigms.

I thought about including code in bash, TeX, assembly, SQL, CSS, Prolog, and HTML, but their execution models are too different from the mainstream to be reasonably translatable to a mainstream virtual machine. Even R and Haskell are kind of pushing it.

The classic dumb Fibonacci, in C:

```
fib(n) { return n < 2 ? 1 : fib(n-1) + fib(n-2); }
```

A nearly totally vacuous class definition:

```
class Match:
    def __init__(self, length, rendering):
        self.length = length
        self.rendering = rendering
```

A test of the mod_pubsub JS interface, some code I think I wrote in 2000, unless it was Ben or Rohit:

```
function do_it()
{
    var topic = kn_argv['kn_topic'];
    kn_publish(topic, {}, { onSuccess: function(e) {succeed()},
                            onError: function(e) {fail(e.kn_payload)} });
}
```

Part of the Perl abstract base class DBD::File:

```
sub table_meta_attr_changed
{
    my ($class, $meta, $attrib, $value) = @_;
    defined $reset_on_modify{$attrib} and
        delete $meta->{$reset_on_modify{$attrib}} and
```

```
        $meta->{initialized} = 0;
    } # table_meta_attr_changed
```

The Lua code in LuaTeX for computing the full platform string on Linux:

```
function os.resolvers.platform(t,k)
    local platform = "linux"
    os.setenv("MTX_PLATFORM",platform)
    os.platform = platform
    return platform
end
```

A byteswapping function by Jon Lech Johansen in C#:

```
byte [] NetToHost( byte [] Input, int Pos, int Count )
{
    if( BitConverter.IsLittleEndian )
    {
        for( int i = 0; i < Count; i++ )
        {
            Array.Reverse( Input, Pos + (i * 4), 4 );
        }
    }

    return Input;
}
```

In GNU `cp`, some slight options parsing hackery:

```
/* For long options that have no equivalent short option, use a
   non-character as a pseudo short option, starting with CHAR_MAX + 1.  */
enum
{
  ATTRIBUTES_ONLY_OPTION = CHAR_MAX + 1,
  COPY_CONTENTS_OPTION,
  NO_PRESERVE_ATTRIBUTES_OPTION,
  PARENTS_OPTION,
  PRESERVE_ATTRIBUTES_OPTION,
  REFLINK_OPTION,
  SPARSE_OPTION,
  STRIP_TRAILING_SLASHES_OPTION,
  UNLINK_DEST_BEFORE_OPENING
};
```

A function from netqmail to downcase a NUL-terminated string:

```
#include "case.h"

void case_lowers(s)
char *s;
{
  unsigned char x;
  while (x = *s) {
    x -= 'A';
```

```
    if (x <= 'Z' - 'A') *s = x + 'a';
    ++s;
  }
}
```

Part of Jon Lech Johansen's DeDRMS utility in C#:

```
class M4PStream
{
    // ...
    public M4PStream( FileStream fs )
    {
        br = new BinaryReader( fs );
        bw = new BinaryWriter( fs );
        sbuffer = br.ReadBytes( Convert.ToInt32( fs.Length ) );

        alg = Rijndael.Create();
        alg.Mode = CipherMode.CBC;
        alg.Padding = PaddingMode.None;
    }
    // ...
}
```

A function from the Nouveau video driver in the Linux kernel:

```
u16
nvbios_cstepEe(struct nvkm_bios *bios, int idx, u8 *ver, u8 *hdr)
{
        u8  cnt, len, xnr, xsz;
        u16 data = nvbios_cstepTe(bios, ver, hdr, &cnt, &len, &xnr, &xsz);
        if (data && idx < cnt) {
                data = data + *hdr + (idx * len);
                *hdr = len;
                return data;
        }
        return 0x0000;
}
```

Part of the Elisp code for Flymake, which gives you on-the-fly error checking in Emacs, in this case converting between a couple of slightly different data formats in order to pop up a list of suggested corrections when you click on an error:

```
(defun flymake-make-emacs-menu (menu-data)
  "Return a menu specifier using MENU-DATA.
MENU-DATA is a list of error and warning messages returned by
`flymake-make-err-menu-data'.
See `x-popup-menu' for the menu specifier format."
  (let* ((menu-title     (nth 0 menu-data))
         (menu-items     (nth 1 menu-data))
         (menu-commands  (mapcar (lambda (foo)
                                   (cons (nth 0 foo) (nth 1 foo)))
                                 menu-items)))
    (list menu-title (cons "" menu-commands))))
```

The SafeBuffer indexing method from Ruby ActiveSupport:

```
def [](*args)
  return super if args.size < 2

  if html_safe?
    new_safe_buffer = super
    new_safe_buffer.instance_eval { @html_safe = true }
    new_safe_buffer
  else
    to_str[*args]
  end
end
```

A function from the Linux network scheduling code:

```
static int ingress_dump(struct Qdisc *sch, struct sk_buff *skb)
{
        struct nlattr *nest;

        nest = nla_nest_start(skb, TCA_OPTIONS);
        if (nest == NULL)
                goto nla_put_failure;

        return nla_nest_end(skb, nest);

nla_put_failure:
        nla_nest_cancel(skb, nest);
        return -1;
}
```

A function from Godoc, the Golang documentation extractor:

```
func findSpec(list []ast.Spec, id *ast.Ident) ast.Spec {
        for _, spec := range list {
                switch s := spec.(type) {
                case *ast.ImportSpec:
                        if s.Name == id {
                                return s
                        }
                case *ast.ValueSpec:
                        for _, n := range s.Names {
                                if n == id {
                                        return s
                                }
                        }
                case *ast.TypeSpec:
                        if s.Name == id {
                                return s
                        }
                }
        }
        return nil
}
```

Part of the GNU ISO C++ library implementing the thin_heap type:

```
PB_DS_CLASS_T_DEC
inline void
PB_DS_CLASS_C_DEC::
fix_sibling_rank_1_unmarked(node_pointer p_y)
{
  _GLIBCXX_DEBUG_ASSERT(p_y->m_p_prev_or_parent != 0);

  _GLIBCXX_DEBUG_ONLY(node_pointer p_w = p_y->m_p_l_child;)
  _GLIBCXX_DEBUG_ASSERT(p_w != 0);
  _GLIBCXX_DEBUG_ASSERT(p_w->m_p_next_sibling == 0);
  _GLIBCXX_DEBUG_ASSERT(p_y->m_p_next_sibling == 0);

  p_y->m_p_next_sibling = p_y->m_p_l_child;
  p_y->m_p_next_sibling->m_p_prev_or_parent = p_y;
  p_y->m_p_l_child = 0;
  PB_DS_ASSERT_NODE_CONSISTENT(p_y, false)
}
```

Part of the tests for d3.js:

```
"can output a percentage with rounding and sign": function(format) {
  var f = format("+.2p");
  assert.strictEqual(f(.00123), "+0.12%");
  assert.strictEqual(f(.0123), "+1.2%");
  assert.strictEqual(f(.123), "+12%");
  assert.strictEqual(f(1.23), "+120%");
  assert.strictEqual(f(-.00123), "-0.12%");
  assert.strictEqual(f(-.0123), "-1.2%");
  assert.strictEqual(f(-.123), "-12%");
  assert.strictEqual(f(-1.23), "-120%");
},
```

Another function from netqmail, this one for comparing two strings lexically:

```
int str_diffn(s,t,len)
register char *s;
register char *t;
unsigned int len;
{
  register char x;

  for (;;) {
    if (!len--) return 0; x = *s; if (x != *t) break; if (!x) break; ++s; ++t;
    if (!len--) return 0; x = *s; if (x != *t) break; if (!x) break; ++s; ++t;
    if (!len--) return 0; x = *s; if (x != *t) break; if (!x) break; ++s; ++t;
    if (!len--) return 0; x = *s; if (x != *t) break; if (!x) break; ++s; ++t;
  }
  return ((int)(unsigned int)(unsigned char) x)
       - ((int)(unsigned int)(unsigned char) *t);
}
```

A module from the Free Pascal compiler providing access to an AmigaOS timer function:

```
unit timerutils;

interface

uses exec, timer, amigalib;

Function CreateTimer(theUnit : longint) : pTimeRequest;
{ some stuff omitted }

implementation

Function CreateTimer(theUnit : longint) : pTimeRequest;
var
    Error : longint;
    TimerPort : pMsgPort;
    TimeReq : pTimeRequest;
begin
    TimerPort := CreatePort(Nil, 0);
    if TimerPort = Nil then
        CreateTimer := Nil;
    TimeReq := pTimeRequest(CreateExtIO(TimerPort,sizeof(tTimeRequest)));
    if TimeReq = Nil then begin
        DeletePort(TimerPort);
        CreateTimer := Nil;
    end;
    Error := OpenDevice(TIMERNAME, theUnit, pIORequest(TimeReq), 0);
    if Error <> 0 then begin
        DeleteExtIO(pIORequest(TimeReq));
        DeletePort(TimerPort);
        CreateTimer := Nil;
    end;
    TimerBase := pointer(TimeReq^.tr_Node.io_Device);
    CreateTimer := pTimeRequest(TimeReq);
end;
{ lots of stuff omitted }
end.
```

From quodlibet, some PyGTK code with a callback:

```
def edit_patterns(cls, button):
    def valid_uri(s):
        # TODO: some pattern validation too (that isn't slow)
        try:
            p = Pattern(s)
            u = URI(s)
            return (p and u.netloc and
                u.scheme in ["http", "https", "ftp", "file"])
        except ValueError:
            return False

    win = StandaloneEditor(filename=cls.PATTERNS_FILE,
        title=_("Search URL patterns"), initial=cls.DEFAULT_URL_PATS,
```

```
        validator=valid_uri)
    win.show()
```

From slide-rule.tcl, some Tk code with callbacks that I wrote in like 1997:

```
proc sl_ru_bind {canvas} {
        bind $canvas <1> {
                global old_x
                set old_x %x
                global dragobj
                set dragobj [groupof %W [%W find closest %x %y]]
        }
        bind $canvas <B1-Motion> {
                global old_x dragobj
                %W move $dragobj [expr (%x - $old_x) / 2] 0
                set old_x %x
        }
}
```

A perspective projection in JS from some code I wrote to design domes:

```
function project(points, zDist, zMin, width) {
  var rv = [];
  for (var ii = 0; ii < points.length; ii++) {
    var p = points[ii]
      , xx = p[0]
      , yy = p[1]
      , zz = p[2] + zDist
    ;
    if (zz > zMin) {
      rv.push([width * xx / zz, width * yy / zz]);
    } else {
      rv.push([NaN, NaN]);
    }
  }
  return rv;
}
```

Some disappointingly boilerplatish code from Lucene:

```
  public String toString(String field) {
    StringBuffer buffer = new StringBuffer();
    buffer.append("spanNot(");
    buffer.append(include.toString(field));
    buffer.append(", ");
    buffer.append(exclude.toString(field));
    buffer.append(")");
    buffer.append(ToStringUtils.boost(getBoost()));
    return buffer.toString();
  }
```

From Darius's constraint-programming draft in JS:

```
// Try to reduce eqns to an equivalent system with each variable
// defined by a single equation. (The result may be inconsistent
// or underconstrained.)
function reduceEquations(eqns) {
    for (let i = 0; i < eqns.length; ++i) {
        const eqi = eqns[i];
        const v = eqi.aVariable();
        if (v === null) continue;
        for (let j = 0; j < i; ++j) {
            eqns[j] = eqns[j].substituteFor(v, eqi);
            if (eqns[j].isInconsistent()) {
                return {isConsistent: false};
            }
        }
    };
    return {isConsistent: true,
            equations: (eqns.filter(eqn => !eqn.isTautology())
                           .map(eqn => eqn.normalize()))};
}
```

The glue code in the Lua 5.1 OS interface to allow Lua code to call mktime(3):

```
static int os_time (lua_State *L) {
  time_t t;
  if (lua_isnoneornil(L, 1))  /* called without args? */
    t = time(NULL);  /* get current time */
  else {
    struct tm ts;
    luaL_checktype(L, 1, LUA_TTABLE);
    lua_settop(L, 1);  /* make sure table is at the top */
    ts.tm_sec = getfield(L, "sec", 0);
    ts.tm_min = getfield(L, "min", 0);
    ts.tm_hour = getfield(L, "hour", 12);
    ts.tm_mday = getfield(L, "day", -1);
    ts.tm_mon = getfield(L, "month", -1) - 1;
    ts.tm_year = getfield(L, "year", -1) - 1900;
    ts.tm_isdst = getboolfield(L, "isdst");
    t = mktime(&ts);
  }
  if (t == (time_t)(-1))
    lua_pushnil(L);
  else
    lua_pushnumber(L, (lua_Number)t);
  return 1;
}
```

A fairly boilerplatish class definition in Perl:

```
package Pod::Simple::PullParserToken;
 # Base class for tokens gotten from Pod::Simple::PullParser's $parser->get_token
@ISA = ();
$VERSION = '3.16';
use strict;
```

```
sub new {  # Class->new('type', stuff...);  ## Overridden in derived classes anywo
oay
  my $class = shift;
  return bless [@_], ref($class) || $class;
}

sub type { $_[0][0] }  # Can't change the type of an object
sub dump { Pod::Simple::pretty( [ @{ $_[0] } ] ) }

sub is_start { $_[0][0] eq 'start' }
sub is_end   { $_[0][0] eq 'end'   }
sub is_text  { $_[0][0] eq 'text'  }

1;
__END__
```

Some R code from the CRAN survival analysis package, doing some kind of magic metaprogramming hackery that I don't understand:

```
as.character.Surv <- function(x, ...) {
    if (is.R()) class(x) <- NULL
    else        oldClass(x) <- NULL
    type <- attr(x, 'type')
    if (type=='right') {
        temp <- x[,2]
        temp <- ifelse(is.na(temp), "?", ifelse(temp==0, "+"," "))
        paste(format(x[,1]), temp, sep='')
        }
    else if (type=='counting') {
        temp <- x[,3]
        temp <- ifelse(is.na(temp), "?", ifelse(temp==0, "+"," "))
        paste('(', format(x[,1]), ',', format(x[,2]), temp,
                        ']', sep='')
        }
    else if (type=='left') {
        temp <- x[,2]
        temp <- ifelse(is.na(temp), "?", ifelse(temp==0, "<"," "))
        paste(temp, format(x[,1]), sep='')
        }
    else {   #interval type
        stat <- x[,3]
        temp <- c("+", "", "-", "]")[stat+1]
        temp2 <- ifelse(stat==3,
                        paste("[", format(x[,1]), ", ",format(x[,2]), sep=''),
                        format(x[,1]))
        ifelse(is.na(stat), "NA", paste(temp2, temp, sep=''))
        }
    }
```

A method from Cynthiune, an MP3 player written in Objective-C for GNUStep, showing the old style retain/release/autorelease memory-management for NeXTSTep apps:

```
@implementation M3UUnarchiver : PlaylistUnarchiver

+ (NSArray *) _fileListFromLines: (NSArray *) arrayOfLines
            inReferenceDirectory: (NSString *) directory
{
  NSMutableArray *filelist;
  NSEnumerator *lines;
  NSString *currLine, *newString;

  filelist = [NSMutableArray new];
  [filelist autorelease];

  lines = [arrayOfLines objectEnumerator];
  currLine = [lines nextObject];
  while (currLine)
    {
      if (![currLine hasPrefix: @"#"] && [currLine length])
        {
          newString = [NSString stringWithString: currLine];
          if (![newString isAbsolutePath])
            newString = [directory stringByAppendingPathComponent: newString];
          newString = [newString stringByStandardizingPath];
          [filelist addObject: newString];
        }
      currLine = [lines nextObject];
    }

  return filelist;
}
```

A C part of the SQLite test suite:

```
/*
** Usage: sqlite3_shared_cache_report
**
** Return a list of file that are shared and the number of
** references to each file.
*/
int sqlite3BtreeSharedCacheReport(
  void * clientData,
  Tcl_Interp *interp,
  int objc,
  Tcl_Obj *CONST objv[]
){
#ifndef SQLITE_OMIT_SHARED_CACHE
  extern BtShared *sqlite3SharedCacheList;
  BtShared *pBt;
  Tcl_Obj *pRet = Tcl_NewObj();
  for(pBt=GLOBAL(BtShared*,sqlite3SharedCacheList); pBt; pBt=pBt->pNext){
    const char *zFile = sqlite3PagerFilename(pBt->pPager, 1);
    Tcl_ListObjAppendElement(interp, pRet, Tcl_NewStringObj(zFile, -1));
    Tcl_ListObjAppendElement(interp, pRet, Tcl_NewIntObj(pBt->nRef));
  }
  Tcl_SetObjResult(interp, pRet);
#endif
```

```
  return TCL_OK;
}
```

A small part of the SQLite test suite, in Tcl:

```
# Convert a string containing EXPR, AGG, and BOOL into a string
# that contains nothing but X, Y, and Z.
#
proc extract_vars {a} {
  regsub -all {EXPR} $a X a
  regsub -all {AGG} $a Y a
  regsub -all {BOOL} $a Z a
  regsub -all {[^XYZ]} $a {} a
  return $a
}

# Test all templates to make sure the number of EXPR, AGG, and BOOL
# expressions match.
#
foreach term [concat $aggexpr $intexpr $boolexpr] {
  foreach {a b} $term break
  if {[extract_vars $a]!=[extract_vars $b]} {
    error "mismatch: $term"
  }
}
```

From some dumb test code I wrote for a C random music generator:

```
int
main()
{
  int ii, jj, kk;
  score sc;
  srand(getpid());
  generate_score(&sc);
  for (ii = 0; ii != 256; ii++) {
    for (jj = 0; jj != 8192; jj++) {
      unsigned char samp = 0;
      for (kk = 0; kk < 6; kk++) {
        int t = ii << (kk/2) | jj >> (13 - (kk/2));
        int f = freq(next_note(t, &sc, kk));
        samp += jj * f * (1 << kk) >> 10 & 32;
      }
      printf("%c", samp);
    }
  }
  return 0;
}
```

More code from SQLite, this time in one of its memory allocators:

```
/*
** Unlink the chunk at mem5.aPool[i] from list it is currently
** on.  It should be found on mem5.aiFreelist[iLogsize].
```

```
*/
static void memsys5Unlink(int i, int iLogsize){
  int next, prev;
  assert( i>=0 && i<mem5.nBlock );
  assert( iLogsize>=0 && iLogsize<=LOGMAX );
  assert( (mem5.aCtrl[i] & CTRL_LOGSIZE)==iLogsize );

  next = MEM5LINK(i)->next;
  prev = MEM5LINK(i)->prev;
  if( prev<0 ){
    mem5.aiFreelist[iLogsize] = next;
  }else{
    MEM5LINK(prev)->next = next;
  }
  if( next>=0 ){
    MEM5LINK(next)->prev = prev;
  }
}
```

A function in the Maybe monad from Brandon Moore's Haskell ray tracer:

```
hit :: Vec -> Vec -> Sphere -> Maybe (Float, Vec, Vec)
hit x d (Sphere r center _ _) = do
  let face = diff x center
      a = dot d d
      b = 2*dot d face
      c = (dot face face) - (r*r)
      disc = b^2 - 4*a*c
  guard (b < 0) -- vector from center to camera should point opposite from ray
  guard (disc >= 0)
  let t = 2*c / (-b + sqrt disc)
      intersection = x `add` scale t d
      normal = normalize (diff intersection center)
      xbounce = dot d normal
      reflected = add d (scale (-2*xbounce) normal)
  return (t, intersection, reflected)
```

From Lucene:

```
public class DateTools {

  private final static TimeZone GMT = TimeZone.getTimeZone("GMT");

  private static final SimpleDateFormat YEAR_FORMAT = new SimpleDateFormat("yyyy"o
o, Locale.US);

  private static final SimpleDateFormat MONTH_FORMAT = new SimpleDateFormat("yyyyo
oMM", Locale.US);

  private static final SimpleDateFormat DAY_FORMAT = new SimpleDateFormat("yyyyMMo
odd", Locale.US);

  private static final SimpleDateFormat HOUR_FORMAT = new SimpleDateFormat("yyyyMo
```

```
oMddHH", Locale.US);

   private static final SimpleDateFormat MINUTE_FORMAT = new SimpleDateFormat("yyyo
oyMMddHHmm", Locale.US);

   private static final SimpleDateFormat SECOND_FORMAT = new SimpleDateFormat("yyyo
oyMMddHHmmss", Locale.US);

   private static final SimpleDateFormat MILLISECOND_FORMAT = new SimpleDateFormato
o("yyyyMMddHHmmssSSS", Locale.US);
   static {
     // times need to be normalized so the value doesn't depend on the
     // location the index is created/used:
     YEAR_FORMAT.setTimeZone(GMT);
     MONTH_FORMAT.setTimeZone(GMT);
     DAY_FORMAT.setTimeZone(GMT);
     HOUR_FORMAT.setTimeZone(GMT);
     MINUTE_FORMAT.setTimeZone(GMT);
     SECOND_FORMAT.setTimeZone(GMT);
     MILLISECOND_FORMAT.setTimeZone(GMT);
   }

   private static final Calendar calInstance = Calendar.getInstance(GMT);

   // cannot create, the class has static methods only
   private DateTools() {}
   // ...
 }
```

From shlex in the Python standard library:

```
def read_token(self):
    quoted = False
    escapedstate = ' '
    while True:
        nextchar = self.instream.read(1)
        if nextchar == '\n':
            self.lineno = self.lineno + 1
        if self.debug >= 3:
            print "shlex: in state", repr(self.state), \
                  "I see character:", repr(nextchar)
        if self.state is None:
            self.token = ''        # past end of file
            break
        elif self.state == ' ':
            if not nextchar:
                self.state = None  # end of file
                break
            elif nextchar in self.whitespace:
                if self.debug >= 2:
                    print "shlex: I see whitespace in whitespace state"
                if self.token or (self.posix and quoted):
                    break   # emit current token
                else:
                    continue
```

```
            elif nextchar in self.commenters:
                self.instream.readline()
                self.lineno = self.lineno + 1
            elif self.posix and nextchar in self.escape:
                escapedstate = 'a'
                self.state = nextchar
            elif nextchar in self.wordchars:
                self.token = nextchar
                self.state = 'a'
```

Some test code for a Visual Basic interface to mod_pubsub:

```

Snap logic

Kragen Javier Sitaker, 2018-06-17 (3 minutes)

I keep thinking about the explanation in the Art of Electronics† of how reading DRAM works. Each column of the DRAM has a sense amplifier, which is kind of like a differential amplifier — it's actually a latch consisting of two inverters in a loop. Before reading, the loop is shorted to force the inverters into a metastable state; then the short is released and the appropriate row of capacitors is shorted to the sense amplifiers.

This unbalances the previously metastable latches, which then fall into one of their two stable states. In the process, they charge the capacitor all the way to the rail.

This is very similar to Merkle's buckling-spring logic, in which a gate begins in a stable state which is made metastable by the application of a buckling force, which amplifies the balance of forces applied to the spring into a large displacement driven by the buckling force itself. Merkle proposed using these as majority-rule gates with a constant bias input to get AND and OR.

I wonder if such circuits could be a productive way to design digital circuits even with current technology, integrating state and combinational logic rather than keeping them separate. As one simple example, you could build a bidirectional shift register by using three latches per bit, energizing only ⅓ to ⅔ of the latches at any given time, passing the state along in the manner of a CCD or a Dekatron. Or you could build an image memory that directly supports not only shifting the image off the chip but also operations like dilation.

My hunch is that this approach ends up being more or less equivalent to using master-slave flip-flops.

† "The sense amplifiers are latching devices, here drawn notionally as fed-back noninverting amplifiers. (In practice they are implemented as flip-flops that begin the cycle in a balanced state and become unbalanced by the bit-capacitor charge that is switched into them. … In a further dose of reality, things are a bit more complicated: the sense amplifiers are *differential*, and the DRAM array is usually built in a "folded-bit" arrangement so that any given row line activates only the even or odd cells; the inactive (neutral) bit line floats at the precharge level (Vdd/2) and acts as a reference voltage by which the balanced sense amplifier compares the ΔV "bump" up or down from the capacitor's charge in the respective bit cell. …"

Millikiln

Kragen Javier Sitaker, 2017-01-17 (updated 2017-03-02) (4 minutes)

(See also An electric furnace the size of a sake cup (p. 666) for more thoughts along these lines.)

Suppose I want a ceramics-firing kiln that holds about a liter, about a thousandth the capacity of the big kiln in the studio; call it a "millikiln". Maybe I can make it by packing calcium oxide into a ceramic jar, putting some kind of heating element inside, and cooling the jar on the outside so the ceramic doesn't melt.

I'm going to guess that 30 mm of calcium oxide is adequate insulation. The inside volume of 1 liter could be 100 mm vertically and 112 mm across; the outside volume, including the lid, could be 160 mm vertically and 172 mm across, a total of about 3.7 liters, which means 2.7 liters of calcium oxide. The most practical way to obtain that is to calcine about 2.7 liters of calcium carbonate, whose specific gravity in the calcite form is 2.71, so that's about 7.3 kg of calcium carbonate.

Is that right? Calcium carbonate is $CaCO_3$, while calcium oxide (CaO) has a density of 3.34 g/cc, which is *higher*. And, indeed, WP says, "The reaction of quicklime with water is associated with an increase in volume by a factor of at least 2.5," while "Approximately 1.8 t of limestone is required per 1.0 t of quicklime."

This suggests that calcining the calcium carbonate will reduce its volume by a factor of 2.2 to more than 2.5, which probably will not leave it solid.

Also, what about harmful gas emissions during firing? The 2.7 liters of CaO will weigh 9 kg and be made from a bit over 16 kg of calcium carbonate; 44% of the mass of the calcium carbonate (the other 7 kg) is lost as carbon dioxide; 7 kg of carbon dioxide is about 3.5 cubic meters ((12+16+16)/(16+17) = 1.33 times the density of air, which is 1.2 g/ℓ at STP, so CO_2 is 1.6 g/ℓ, XXX wrong 1.98). CO_2 is safe and beneficial to plants at 1000 ppm, but becomes problematic to humans around 5000 ppm (though submarines commonly have it up to 20000 ppm for long periods of time). 7 kg gives you 5000 ppm by mass when mixed into 1400 kg of air, occupying about 1200 m³, which as a sphere would be a bit over 13 meters in diameter.

This is larger than the pottery studio, which is perhaps 6 m × 6 m × 12 m, a total of 432 m³ or 518 kg of air; so it should be safe to release about 2 kg of CO_2 into it at a time, obtained by calcining some 4.5 kg of calcium carbonate.

Perhaps a different refractory would be more suitable. Maybe ordinary fireclay, which seems to cost AR$10 to AR$20 per kg on Mercadolibre, although I have my doubts about whether the various products sold there as "arcilla refractaria" are in fact any kind of clay at all. Maybe perlite, although supposedly perlite is only good up to 1000°, and vermiculite is hydrophilic (though much less so than quicklime!). Some sources suggest mixing in sawdust and burning it out to increase porosity of the refractory without perlite.

(Vermiculite also melts at 1100°C or below.)

Mic energy harvesting

Kragen Javier Sitaker, 2016-09-07 (updated 2016-09-08) (5 minutes)

Could you power a computer from your voice via a microphone?

Typical speakers are about 1% to 5% efficient. Suppose a microphone is about the same. Someone shouting at a distance of a meter is supposedly about 85dBa; 0 dBa (0 dB SIL) is defined as 10^{-12} W/m², so this is about 3 mW/m². The shout is maybe spread over an area of a square meter, so it's probably about 3mW in total, and you could probably capture a significant fraction of that if you had the microphone actually in your mouth. 3mW is plenty of power to run certain microcontrollers.

There's another issue of impedance and voltage matching. Piezo and electret microphones are essentially capacitive, making them very high impedance at audio frequencies, while dynamic microphones are essentially inductive, which seems more circuit-friendly. But since we're dealing with an audio-frequency AC waveform, you ought to be able to step it up or down with a steel-core transformer.

Otherwise, though, I think you could probably just feed a low-capacitance capacitor with the rectified dynamic mic, run a high-efficiency boost or buck converter from it to step the voltage up or down, and feed a low-voltage, high-capacitance capacitor with that to run the microcontroller.

For example, the LTC3388 is designed for this kind of application, accepting voltages of 2.7 to 20 V, with 720 nA quiescent current up to 820 nA at 20 V; different configurations manage output voltages down to 1.2 V; the efficiency is about 90% with low input voltages, dropping to about 70% for 20 V input, unless the load is under 100 µA. 100 µA at 1.8 V (typical for low-power microcontrollers) would be 180 µW, which would allow a one-second 3-mW burst of sound to power the microcontroller for 16⅔ s. Various low-power microcontrollers manage a bit under a nanojoule per instruction (like 300 picojoules to 900 picojoules per instruction), so 180 µW is about 360 000 instructions per second, comparable to a Commodore 64.

I have the intuition that for this kind of thing, it's important to be able to draw down the charge stored on the input side fast enough to follow the sound waveform on its way down, to ensure that the available energy there is successfully harvested. The LTC3388 can source up to 50 mA, which would be 90 mW at 1.8 V, which would be 4.5 mA at 20 V or 10 mA at 9 V. If the sound wave had most of its energy in a 200 Hz component, it falls from 9 V to 0 in 0.74 ms; without getting into actually calculating derivatives precisely, that would require that the input capacitor be no larger than about 0.8 µF.

(We shouldn't really try to analyze it linearly into sinusoids, because both the rectifier charging the input capacitor and the buck converter draining it are nonlinear, but that should give us a ballpark.)

I don't know how much input capacitance we need, or if we need any, but it seems like the LTC3388 lets its inductor current ramp up to 150 mA before shutting the gate, so we probably need enough energy stored to get a 22 µH inductor up to 150 mA. $LI^2/2$ is then about a quarter of a microjoule. A capacitor that charges up to a

quarter of a microjoule at, say, 7 volts would be .25 J / (7 V)² = 5000 pF. So probably anything in the middle of the 5000 to 800 000 pF range would work.

My intuition is that if the input capacitor is ever *above* the rectified signal, no current will flow, so no energy is harvested; while if it's far *below* the rectified signal, then most of the voltage has to be dropped by the rectifier itself rather than the capacitor, and that dropped voltage also represents inefficiency. So I think you want to ensure that the input capacitor stays just below the constantly changing supply voltage, at least until the output capacitor is fully charged.

I don't think the LTC3388 will do that, at all, and I don't know what will.

One thing that might help would be an inductor in series with the rectifier. This would keep a significant voltage from ever being dropped across the rectifier, instead charging the inductor until the capacitor is ready to accept its energy. But maybe that will make it hard to ramp up harvesting when there's a rapid rise in voltage?

Yeso notes

Kragen Javier Sitaker, 2018-12-25 (updated 2019-01-01) (11 minutes)

It's 2018-12-25, and xshmu is about 1800 lines of code (70 kilobytes), and overdue for its first refactoring. So far it has a terminal emulator, a calculator application, a Tetris game, an audio oscilloscope app, some graphics demos, a Chifir virtual machine, and a couple of sort-of paint programs, with backends for the Linux framebuffer console and X11:

```
 4105 admu.c

-------------------------------------------------------------------------------
```

There's a lot of half-assed stuff in there, and a lot of duplication, and two separate fonts, one of which has only 16 characters, designed with `glyphed` in about as many minutes, copied and pasted into tetris.c and xshmucalc.c. Glyphed, which is the only thing that draws clickable things so far, would really benefit from some kind of

IMGUI framework.

The two backends have a bunch of duplicated code, namely all the `xshmu_subpic` (buggy clipping!), `xshmu_copy` (a standard-C-compliance bug fixed in xshmu.c), and `xshmu_canvas` stuff, which is kind of a layer that belongs underneath. On top of this, the `fill` function from Tetris (copied into glyphed) and the `show` function from Tetris (copied into xshmucalc.c and extended) should probably be shared in some place, and probably `show` should take a font argument, and also we need some fonts.

The alpha-blending stuff in wercaμ needs to integrate the SSE optimizations from vecalpha.c, and probably also needs to be in some kind of common location so that, e.g., oscope.c can use it. (Or maybe oscope.c should render in a different way, for example, running three box filters over a monochrome 16-bit framebuffer and mapping the resulting intensities through a palette.)

`xshmu_fd` has to go; `xshmu_fb` either needs to have separate input file descriptors for /dev/input/mice and the keyboard, or it needs a subprocess to re-encode those onto a single stream, so it won't have just a single file descriptor. Maybe `yeso_get_fds(void (*f)(void *, int), void*)`. Some of the use of `xshmu_fd` can be taken over by an added timeout parameter to `xshmu_wait`, which would simplify Tetris significantly.

Key repeat is potentially a big problem for Tetris. X11 introduces spurious key-release events into the input stream for key repeat.

(Incidentally, the mouse thing is somewhat documented in /usr/share/doc/linux-doc/input/input.txt.gz, and apparently it's speaking a kernel-emulated PS/2 protocol, which I guess is three bytes per packet; looks like the second and third bytes are delta-X and delta-Y as signed bytes, with Y increasing up, except that there's a 9th sign bit in the 0x20 (y) and 0x10 (x) position in the first byte. The first byte low nibble is 0x08, except with bit 0x01 set for the left button, bit 0x02 set for the right button, bit 0x04 set for the middle button; dev3/psmouse.c has a PS/2 driver. Unfortunately the mouse wheel doesn't register at all! For the mouse wheel I thought you need /dev/input/event5 or whatever, the evdev interface described in input.txt.gz and event-codes.txt.gz and /usr/include/linux/input.h (dev3/evdev.c has a somewhat more limited decoder for that protocol) but apparently you can somehow set the protocol to ImPS/2 for the wheel. My keyboard is on /dev/input/event3, with scancodes (e.g. 30 for a, 31 for s, 32 for d); key repeat shows up, including on things like control keys, but is distinguishable from repeated keypresses; type=1 (`EV_KEY`) code=30 value=1 is a press of 'a', value=2 is a repeat, value=0 is a release; the scan codes are defined in /usr/include/linux/input-event-codes.h and come originally from USB HUT apparently. There are also type=4 (`EV_MSC`) code=4 (`MSC_SCAN`) value=30, but for some keys the value doesn't match. A great benefit of this interface is that it isn't modal; an app that opens this interface doesn't need to reset the keyboard mode to normal before it exits.)

Some kind of windowing/terminal system would be super keen. Also copy and paste with mouse-selection support are needed to make the terminal emulator usable.

A notebook-style shell window manager interface could be super interesting, embedding graphical programs and saving their graphical

output — by default just the last frame, with hotkeys to save screenshots and start full recording — as well as their textual input/output. It could also limit their CPU use, memory use, and filesystem access, and checkpoint their state for revivification. For windowing, you could have a hotkey to undock the graphical program from its window within the shell.

(Also, I should totally have an animated GIF backend.)

The size of the state to checkpoint should be manageable for many apps; the oscilloscope app on the framebuffer has a 135KB heap segment, a 139KB stack segment, its 8-megabyte framebuffer and backing store, and a couple of read-write segments from shared libraries:

```

oyscall]
```

That's generated as follows from /proc/$pid/maps:

```
import re
se = re.compile(r'([0-9a-f]+)-([0-9a-f]+)')
for line in maps.splitlines():
  mo = se.search(line)
  if not mo: print(line); continue
  length = int(mo.group(2), 16) - int(mo.group(1), 16)
  print length, line
```

You don't have to checkpoint the framebuffer contents, since they'll be redrawn anyway after restart. And oscope, as it turns out, is already prepared to restart its child process if it dies, because its child process does die, due I think to bugs in the arecord code. So in theory, with a different checkpoint-aware yeso backend, you could checkpoint just its quarter-meg or so of live data. (As it happens, most of that data is garbage too, but that's hard to know.)

ASLR might complicate restarting from checkpoints, but that's in part because we're still programming at the C level; a virtual machine could simplify this enormously.

In other directions: I really want to try writing some LuaJIT code on it, and I want to write Hypothesis tests for rpncalc.

It's somewhat dismaying to have so many applications for xshmu written in C, since, although I would like to keep it pleasant to program in C, I mostly want to use it to bootstrap out of the C ecosystem and into an archival-virtual-machine ecosystem. At this point I have 13 applications written:

- RPN decimal calculator (308 lines of C, not counting the 28 lines in rpncalc_linux.c for tty output)
- PNG viewer (71 lines of C, written after the above count)
- Tetris (244 lines of C, though some of that needs to be factored out)

- glyphEd fatbits bitmap editor (52 lines of C, including some copy-pasted from Tetris)
- admu ADM-3A emulator (339 lines of C, including offline-mode and on a pty)
- Chifir emulator (110 lines of C)
- Audio oscilloscope (36 lines of C)
- Wercaμ graphics hack (166 lines of C)
- Munching squares graphics hack (17 lines of C)
- Hello, world (7 lines of C)
- μpaint (21 lines of C)

• (the nameless graphics demo inside xshmu.c itself)
• The image-slicing font-making program, also written since the above (161 lines of C)

This works out to (+ 308 71 244 52 339 110 36 166 17 7 21 161) = 1532 lines of C for applications which will need to be rewritten in whatever other language I end up using. This contrasts with the 41 lines of xshmu.h, the 312 lines of X11 backend, and the 201 lines of the fbcon backend (somewhat duplicated with the X11 backend).

So I just wrote IMGUI programming language (p. 103) about what kind of programming language I would like. So far it's focusing on very-low-level stuff (reducing code and bugs in the small, not in the large) and it also describes a language with, to me, an intimidatingly difficult implementation. I think I should see if I can simplify the design to a minimum, maybe something at the C level or even a Lisp, and then see what I can add to it.

The simplest possible thing would of course be a Forth, but writing the compiler for it is a pain. Still, a Forth-level "portable assembler" that does simple register allocation would simplify later work by a lot. (At some point I want to extend that into a deterministic vector virtual machine for software archival and deterministic recomputation.) It wouldn't need to support macros, since its intended use is as a backend for higher-level languages. I do want to expose the stack implementation sufficiently to enable static stack-depth bounds for applications where that's desirable.

I had thought, after reading Finkel's book section about CLU iterators, that doing them required allocating the iterator activation record with enough slack space on the stack for whatever functions the yielded-to block might call — that is, that those functions would put their activation records in between the function invoking the iterator and the iterator itself. But that isn't true; the block can push the arguments for those functions on top of the iterator state.

Vaguely related:
https://news.ycombinator.com/item?id=18765868 is a Sixel image listing program for `xterm -ti vt340`.

Some speculative thoughts on DSP algorithms

Kragen Javier Sitaker, 2014-04-24 (20 minutes)

I was reading a book on digital signal processing (the highly readable if occasionally inaccurate and somewhat outdated *Guide to Digital Signal Processing for Scientists and Engineers* http://www.dspguide.com/), and it seemed to me that the available types of digital filters leave a lot to be desired.

FIR filters are the most popular because you can design them by Fourier-transforming your desired frequency response to get an impulse response, then windowing the impulse response to get a finite-size convolution kernel. Windowing with the popular Blackman or Hamming windows only screws up your frequency response slightly. The trouble is that your convolution kernel may be dozens to hundreds of samples wide, so you end up doing dozens to hundreds of multiply-accumulates if you compute the convolution in the time domain; and to do it in the frequency domain, you need to do the FFT, which also involves typically dozens of multiply-accumulates per sample.

IIR filters are technically a superset of FIR filters, but people usually design them by transforming well-known analog filters (like the classic Butterworth or Bessel filters) into the discrete domain, which is very limiting. Additionally, the typical design technique using the Z-transform requires that the filter itself be linear and stateless, with each output sample being a linear combination of the P previous input samples and the Q previous output samples.

In passing, the moving-average filter was mentioned as being much faster to compute, since it requires only an addition and a subtraction per sample, optimal for suppressing noise while preserving edge sharpness, and producing a good approximation of convolution with a Gaussian when iterated.

So some ideas occurred to me, which might or might not be good ones, but I thought I'd write them down anyway.

Square-wave filters

The discrete Fourier transform transforms your given samples onto a basis space of orthonormal sinusoids, enabling you to, among other things, measure the amplitude of individual frequencies, or multiply them by a desired frequency response curve before transforming them back into the time domain with an inverse discrete Fourier transform (a filter).

But many other sets of orthonormal basis functions are possible: the Hadamard–Walsh functions, unit impulses (which yields the identity transform), an infinite variety of wavelets, windowed sinusoids (the short-time Fourier transform), the Gabor basis function (the Gabor transform happens to be a special case of the STFT and also, I believe, the wavelet transform), and so on.

The Hadamard–Walsh functions are particularly interesting because there's an O(N log N) algorithm to compute the Hadamard or Walsh transform, using only addition and subtraction, because the

basis functions have the range {-1, 1}, with no fractions, and are related to each other in a particular way that enables the fast Hadamard transform to work.

But most of the Hadamard–Walsh functions are not particularly close to being sine waves, so they are of limited usefulness if you want to filter particular frequencies.

On the other hand, if you have a square wave of some frequency f, it's pretty strongly correlated with a sine wave of frequency f with the right phase, and it's perfectly uncorrelated with most other sine waves. However, it does have a largish correlation with the odd harmonics of the original sine wave, with frequencies 3f, 5f, 7f, and so on; its correlations with them are 1/3, 1/5, 1/7, etc., of the original. (So far this is just the standard Fourier analysis of a square wave, seen from the perspective of the square wave.)

This same property means that a comprehensive set of square waves is not an orthogonal basis, since some of its elements are correlated, if imperfectly, and thus not orthogonal. This, in turn, means that you can't simply transform a signal into a weighted sum of square waves by correlating it (i.e. taking the dot product) with each square wave.

But suppose you just want to compute the energy in a given time span at a given frequency f? You could take the correlation with a square wave sq(f, t) of frequency f and subtract off the other square waves until you've approximated a sine to your sampling interval: sq(3f, t)/3 + sq(5f, t)/5 + sq(7f, t)/7, etc. If you can low-pass filter the signal before you do this, even crudely (say, with a moving-average or simple exponential filter), then you can probably quit pretty early.

(You probably want to do this twice, once for sq(f, t) and its "harmonics", and once for sq(f, t + 1/2f) and its "harmonics", so you can catch a wave that's out of phase.)

Why should you care when the DFT is already O(N log N) multiply-accumulates? Because you can do this faster than O(N log N), without multipliers, and without using memory to store the samples, if you don't want too many frequencies.

If you only want a *single* square wave correlation, of course, you can simply add or subtract each sample to the total as it comes in, according to whether sq(f, t) is 1 or -1 at that moment. But doing that for M square waves means doing M additions or subtractions per sample. Instead, use a sum table, also known as a summed-area table or integral image: s[t] = sum(x[0:t]), where 0:t includes 0 but not t, so sum(x[t0:t1]) = s[t1] - s[t0]. So if your square wave is 1 from sample t0 to sample t1, you can add s[t1] - s[t0] to your running sum; and if it's -1 from sample t1 to sample t2, you can add s[t1] - s[t2]. You might as well add 2s[t1] on the negative-going transition at t1 in the first place, and later subtract 2s[t2] at the positive-going transition at t2, and so on. And you don't need to actually do the doubling at the time; you can wait until you're inspecting the final sum before remembering that you need to double it.

This, of course, doesn't require that you actually store the sum table, just that you compute the values in it. This requires one addition per sample, plus one addition or subtraction per square-wave transition.

If you decide to do this calculation for all the N square waves that would correspond to the sinusoids needed for N samples, the waves

will have numbers of transitions ranging linearly from 0 to N, with an average of about N/2, so you'd end up doing N/2 additions or subtractions per sample --- definitely worse than Hadamard–Walsh (as long as N/2 > lg N, which is true for N>4) and possibly worse than the DFT, depending on how much multiplies cost you. But maybe you need less than lg N square waves, or maybe the ones you want are of lower-than-average frequency. Most of the high-frequency square waves here will have substantial phase noise induced by quantization which will degrade their performance anyway.

You might be able to avoid doing some of this work by taking advantage of the fact that it's duplicate work in the case of harmonics. Consider the square wave with period 30, which means it has two transitions every 30 samples. The square wave with period 10 has six transitions every 30 samples, but two of them are the same as the period-30 one; that is, you could compute both the period-10 and period-30 square waves with only 6 transitions, rather than 8. Similarly, the period-6 square wave has 10 transitions in this period, but shares the two of the period-30 wave, so you could compute all three with only 14 transitions, rather than 18. I'm not sure how practical this is; it reminds me of the wheel optimization for probing possible composites in the Sieve of Eratosthenes.

A difficulty is that, of course, the difference between square waves and sine waves has more energy below the Nyquist frequency, or any given filter cutoff frequency, for lower-frequency waves. But perhaps you can do better. The procedure I described above for correlating with the square waves is equivalent to integrating the input signal, once, and correlating it with a train of alternating positive and negative impulses, the derivative of the square wave. The integral of a square wave is a triangle wave, which is much closer to being a sine wave, and the integral of a triangle wave is a wave made of parabolas, which is a piecewise second-order approximation to a sine wave, and actually has almost all of its energy in that frequency; and you can iterate the procedure N times to get an Nth-order approximation of a sine wave.

So perhaps you could integrate the input signal N times, making an Nth-order sum table (materialized or virtual), and correlate that with your square waves, or rather, your impulse trains. One potential difficulty is that this corresponds to a pretty heavy-duty low-pass filter, and so it will be necessary to introduce a corresponding high-pass filter at each stage, if nothing else to prevent any initial DC offset, or any introduced later as a constant of integration, from causing the procedure to diverge entirely. A difference in frequency of one octave will show up as a difference in magnitude of 2 after one stage of integration, of 4 after two stages, of 8 after three stages, and of 16 after four stages. Of course, in a sense, that's exactly what we *want* it to do; but roundoff error could be a problem very quickly.

Magic sinewave filters

Don Lancaster has been writing about a set of functions he calls "magic sinewaves", which are periodic functions with the range {-1, 0, 1} that approximate sinewaves, with the purpose of improving power electronics by replacing simple PWM with lower-distortion waveforms. Of course, they have very substantial power outside the

desired frequency --- the same as a PWM waveform, I think --- but the idea is that if you push that power to a high enough frequency, it's much more practical to filter it, using an analog filter with a slower rolloff and physically smaller components.

You can also use this idea in reverse: take your input signal and correlate it with a magic sinewave, rather than a real sinewave, thus avoiding multiplication entirely. For accurate results, you need to prefilter the signal to eliminate the high harmonics, but you can do this with a simple, easy-to-compute filter, such as a moving-average filter.

Parallelizing IIR filters

Parallelizing an M-sample FIR filter is easy: split your input into windows that overlap by M samples, filter each one independently, and concatenate the results. But how can you parallelize an IIR filter?

Consider the sum table, which is a simple IIR filter; it amounts to convolving a step function with your input. It's simple and efficient to calculate a sum table serially, but how could you parallelize it, since the last output value depends on every value before it?

I think I've written about this before on kragen-tol, but the answer is basically that it's easy, because addition is a monoid; this is the approach taken by lookahead carry in digital logic, too. If you break your input into four equal segments 0:t1, t1:t2, t2:t3, and t3:n, and compute the sum table so[a:b] for each segment independently (in parallel), you can then use the final sum of each segment to adjust the sums of the other segments, again independently and in parallel: s[0:t1] = so[0:t1], while s[t1:t2] = s[t1] + so[t1:t2], s[t2:t3] = s[t2] + so[t2:t3], and s[t3:n] = s[t3] + so[t3:n]. You can apply this division of the process recursively (or with a branching factor of other than 4, although a branching factor of more than √n is unlikely to be an improvement) to get an O(log N) time algorithm.

(This is the well-known "parallel prefix sum" problem.)

General IIR filters are impossible to parallelize. But the IIR filters in common usage are purely linear and dependent on a limited amount of past history, so you can do the same thing: filter each segment independently, then add in the linear contribution from the prefix to its left.

Factoring FIR kernels approximately into sparse FIR kernels

Convolution with a Gaussian is potentially computationally expensive. But N iterations of a moving-average filter give you a piecewise Nth-order approximation of a Gaussian, and the moving-average filter is really cheap to compute.

In general the expense of convolving with a FIR kernel in the discrete time domain is expensive in proportion to its *support*, that is, the number of points where it's nonzero. But what if you could factor a 256-point FIR kernel into a convolution of two 16-point FIR kernels? You could compute it four times faster. That's doable in at least some special cases; the Gaussian mentioned above is an example (although the moving average has a recursive algorithm that's more efficient than just doing it as a FIR convolution in the time domain),

since actually iterating just about any FIR kernel enough times will give you a Gaussian (e.g. [1, 1], whose iterative convolution generates the rows of Pascal's triangle; but I suspect that [1, 0, 0, 0, 1, 0, 1, 1, 1, 1, 1, 0, 1, 0, 0, 0, 1] might be a better compute/quality tradeoff for larger Gaussians). But consider these examples:

• Exact factorization of a finite comb: a comb of N equally-spaced impulses can be factored into one P-impulse kernel for each prime factor P of N. For example, a 16-impulse comb can be factored into four two-impulse kernels, with the impulses at distances 1, 2, 4, and 8 times the spacing of the impulses in the desired comb; or a 20-impulse comb can be factored into two two-impulse combs and a five-impulse comb. (In the special case of a composition of two two-impulse combs, it's probably advantageous to preconvolve them into a single four-impulse comb. The optimum number of impulses per kernel, to keep multiply-accumulates to a minimum, is 3.)
• Exact factorization of exponential decay: for N points, compose log(N) two-point FIR kernels whose points are spaced at powers of 2, whose first point is 1 and whose other point is exponentially decayed from 1 according to its spacing. This happens to be exact. This is sort of stupid, though, because you can compute exponential decay even more efficiently with an IIR filter.
• Approximation with a sum of equal-width Gaussians: use one sparse kernel with an impulse indicating the center and amplitude of each Gaussian, then one or more FIR kernels, or the moving-average technique, to convolve the result with the desired Gaussian.
• Exact factorization of a periodic signal: factor into a kernel representing a single period and a comb kernel (itself perhaps factored as above) with one impulse for each period, in order to copy each period into its desired place. If the period is itself a repetition of the same signal twice, but once inverted, you can use an additional kernel with a 1 and a -1 impulse to halve the number of points. Composed with a Gaussian window, this should give you a fairly efficient way to do FIR bandpass filters.
• Approximate Gaussians --- although this is not the right way to do it, convolve(convolve(convolve(convolve([1, 1,1], [1, 1, 1]), [1, 0, 1,0, 1]), [1, 0, 1, 0, 1]), [1, 0, 0, 1]) is quite close to convolve(convolve(convolve([1,1,1,1,1], [1,1,1,1,1]), [1,1,1,1,1]), [1,1,1,1,1]), requiring 14 additions rather than 20. (The recursive algorithm using a fourth-order moving average, though, requires only 8.)
• The well-known "convolution by separability" technique used in image processing, in which you factor a separable kernel into a vertical component and a vertical component, is a special case.

Is there a general technique to find such an approximate factorization into sparse kernels for any desired impulse response? Here's one guess: tabulate the frequency responses for some "basis set" of sparse kernels, then use a greedy algorithm to iteratively pick the ones that best suppress the largest difference between the frequency response of your current set of filters and the frequency response you want.

There's a paper this year from Aimin Jiang and Hon Keung Kwan on the subject that I haven't read, using weighted least squares (WLS); but it sounds from the abstract like they're talking about

approximating one FIR filter kernel with another, sparser one, not factoring one into possibly several.

How small do these factors need to be? The competition is FFT convolution, which, if I understand correctly requires computing a DFT, pointwise complex multiplication, and computing an inverse DFT. Each DFT requires N lg N butterflies, each of which requires one complex multiplication and two complex additions or subtractions. One complex multiplication requires four real multiplications. So we have 2 × 4 × N lg N real multiplications, or 8 lg N real multiplications per point, plus some other overhead work which is mostly proportional. FFT convolution isn't worthwhile unless lg N is at least 6, at which point you're paying 48 real multiplications per point (which is why it isn't useful for smaller N); if lg N is 7, 8, 9, or 10, you're paying 56, 64, 72, or 80 real multiplications per point.

Probably close to the best you can do for a filter kernel with N-point support is 3 $\log_3 N$ multiply-accumulates per point, which is only slightly lower than 2 lg N, although in some cases maybe you can get by without the multiplications. 2 lg N is substantially less than 8 lg N, and furthermore the N you use in the FFT is going to be around two or three times the size of the kernel, so there's some hope that this algorithm could maybe do a reasonable job

IIR: the undiscovered country
